Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 102

A Concrete Naming Certificate for $\mathsf{ModN}^{\uparrow}$

The modular-arithmetic interface $\mathsf{ModN}^{\uparrow}$ packages the carrier of integers modulo a positive natural n. It depends on $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$ (chapter 31) and is the canonical instance of $\mathsf{NameCert}_{\mathsf{QuotientRing}^{\uparrow}}$ (chapter 83) at the ideal $n\mathbb{Z}$.

102.1 Carrier definition

102.2 The certificate

Definition 102.1 (ModN quotient presentation)**.** *Let $R_{\mathbb{Z}}$ be a displayed $\mathsf{Ring}^{\uparrow}$ certificate for $\mathsf{Int}^{\uparrow}$ with carrier $C_{\mathbb{Z}}$, classifier $\sim_{\mathbb{Z}}$, addition $+_{\mathbb{Z}}$, additive inverse $-_{\mathbb{Z}}$, zero $0_{\mathbb{Z}}$, and multiplication $\cdot_{\mathbb{Z}}$. Let $n : \mathsf{Nat}^{\uparrow}$ be positive, and let $I_n(x)$ be a certified $\mathsf{Ideal}^{\uparrow}$ predicate over $R_{\mathbb{Z}}$ whose intended membership is $x \in n\mathbb{Z}$. The quotient presentation of $\mathsf{ModN}^{\uparrow}(n)$ is the specialization*

$$\mathsf{ModN}^{\uparrow}(n) := \mathsf{QuotientRing}^{\uparrow}(R_{\mathbb{Z}}, I_n).$$

Its public classifier is the ideal-coset classifier

$$\mathsf{ModNClassifier}_n(a, b) \iff a \equiv_{I_n} b,$$

where $\equiv_{I_n}$ is the relation of Definition 83.1. Thus, after unfolding the quotient-ring relation,

$$\mathsf{ModNClassifier}_n(a, b) \iff C_{\mathbb{Z}}(a) \wedge C_{\mathbb{Z}}(b) \wedge I_n(a -_{\mathbb{Z}} b).$$

Theorem 102.2 (ModN as the nZ quotient certificate)**.** *Under the hypotheses of Definition 102.1, the quotient-ring certificate at $(R_{\mathbb{Z}}, I_n)$ supplies a $\mathsf{NameCert}$ for $\mathsf{ModN}^{\uparrow}(n)$ with exactly the quotient-ring classifier. More precisely,*

$$\mathsf{NameCert}_{\mathsf{ModN}^{\uparrow}(n)} = \mathsf{NameCert}_{\mathsf{QuotientRing}^{\uparrow}(R_{\mathbb{Z}}, I_n)}$$

as a five-field certificate in the sense of Definition 9.6, and for all carried endpoints a, b,

$$\mathsf{Classifier}_{\mathsf{ModN}^{\uparrow}(n)}(a, b) \iff \mathsf{Classifier}_{\mathsf{QuotientRing}^{\uparrow}(R_{\mathbb{Z}}, I_n)}(a, b) \iff C_{\mathbb{Z}}(a) \wedge C_{\mathbb{Z}}(b) \wedge I_n(a -_{\mathbb{Z}} b).$$

The additive, inverse, and multiplicative operations on $\mathsf{ModN}^{\uparrow}(n)$ are representative-independent by the same quotient-ring descent rows.

Proof. The positive $\mathsf{Nat}^{\uparrow}$ witness selects the modulus parameter n and the predicate I_n; it does not add a second quotient relation. The certified $\mathsf{Ideal}^{\uparrow}$ hypothesis puts I_n in exactly the scope required by section 81.2 and by the ideal-coset relation of Definition 83.1 over the displayed integer ring $R_{\mathbb{Z}}$.

Apply Definition 83.4 with $R = R_{\mathbb{Z}}$ and $I = I_n$. This gives reflexivity, symmetry, and transitivity for the quotient classifier on carried integer endpoints. Carrier transport for the core $\mathsf{NameCert}$ of Definition 9.7 is obtained by unfolding $a \equiv_{I_n} b$: the relation itself stores the two endpoint carrier witnesses $C_{\mathbb{Z}}(a)$ and $C_{\mathbb{Z}}(b)$.

The additive and inverse representative-independence rows are Definition 83.3 specialized to $R_{\mathbb{Z}}$ and I_n. The multiplicative representative-independence row is Definition 83.2 with the same specialization. Hence the quotient-ring source, pattern, classifier, stability, and ledger fields form the five fields demanded by Definition 9.6.

By Definition 102.1, $\mathsf{ModN}^{\uparrow}(n)$ is this quotient-ring presentation with no classifier-changing map inserted. Therefore every field of $\mathsf{NameCert}_{\mathsf{ModN}^{\uparrow}(n)}$ is the corresponding field of $\mathsf{NameCert}_{\mathsf{QuotientRing}^{\uparrow}(R_{\mathbb{Z}},I_n)}$. In particular, the classifier field is copied. The first displayed equivalence is this field identity, and the second is exactly Definition 83.1 unfolded at $R_{\mathbb{Z}}$ and I_n. □

Lean4 ✓ `BEDC.Derived.ModNUp.ModN nz quotient certificate`

Definition 102.3 (Concrete ModN BHist carrier and classifier)**.** *For a unary modulus history* $m : \mathsf{BHist}$*, define the concrete ModN carrier and classifier by*

$$\mathsf{ModNCarrier}_m(h) := \mathsf{UnaryHistory}(m) \wedge \mathsf{RingSingletonCarrier}(h)$$

and

$$\mathsf{ModNClassifier}_m(h,k) := \mathsf{ModNCarrier}_m(h) \wedge \mathsf{ModNCarrier}_m(k) \wedge \mathsf{RingSingletonClassifier}(h,k).$$

Equivalently, these are the paper names for the Lean objects $\mathsf{ModNQuotientCarrier}(m,h)$ *and* $\mathsf{ModNQuotientClassifier}$

Theorem 102.4 (Concrete ModN classifier rows)**.** *For each unary modulus history* $m : \mathsf{BHist}$*, the classifier* $\mathsf{ModNClassifier}_m$ *satisfies the following concrete rows:*

1. *if* $\mathsf{ModNCarrier}_m(h)$*, then* $\mathsf{ModNClassifier}_m(h,h)$*;*
2. *if* $\mathsf{ModNClassifier}_m(h,k)$*, then* $\mathsf{ModNClassifier}_m(k,h)$*;*
3. *if* $\mathsf{ModNClassifier}_m(h,k)$ *and* $\mathsf{ModNClassifier}_m(k,l)$*, then* $\mathsf{ModNClassifier}_m(h,l)$*;*
4. *if* $\mathsf{ModNClassifier}_m(h,k)$ *and* $\mathsf{ModNCarrier}_m(h)$*, then* $\mathsf{ModNCarrier}_m(k)$*.*

Lean4 ✓ `BEDC.Derived.ModNUp.ModNQuotientClassifier concrete rows`

Proof. Unfold Definition 102.3. The modulus component of every carrier witness is the same $\mathsf{UnaryHistory}(m)$ proof, so no modulus data is transformed by the classifier rows.

For reflexivity, keep the carrier witness for h on both endpoints and use the reflexivity row of the singleton $\mathsf{Ring}^{\uparrow}$ classifier on the $\mathsf{RingSingletonCarrier}(h)$ component.

For symmetry and transitivity, project the two endpoint carriers from the given $\mathsf{ModNClassifier}_m$ hypotheses. The remaining relation fields are exactly the symmetry and transitivity rows for $\mathsf{RingSingletonClassifier}$, then the original unary modulus witness is repacked into each endpoint carrier.

Carrier transport is a projection: the right endpoint carrier is already a field of $\mathsf{ModNClassifier}_m(h,k)$. □

Theorem 102.5 (Concrete ModN singleton operation descent rows)**.** *For each unary modulus history m : BHist, the singleton ring operations preserve* $\mathsf{ModNCarrier}_m$ *and descend through* $\mathsf{ModNClassifier}_m$*:*

1. *if* $\mathsf{ModNCarrier}_m(h)$ *and* $\mathsf{ModNCarrier}_m(k)$*, then* $\mathsf{ModNCarrier}_m(\mathsf{RingSingletonAdd}(h,k))$ *and* $\mathsf{ModNCarrier}_m(\mathsf{Ring}$
2. *if* $\mathsf{ModNCarrier}_m(h)$*, then* $\mathsf{ModNCarrier}_m(\mathsf{RingSingletonNeg}(h))$*;*
3. *if* $\mathsf{ModNClassifier}_m(h,h')$ *and* $\mathsf{ModNClassifier}_m(k,k')$*, then* $\mathsf{ModNClassifier}_m(\mathsf{RingSingletonAdd}(h,k),\mathsf{RingSingleton}$
4. *under the same classifier hypotheses,* $\mathsf{ModNClassifier}_m(\mathsf{RingSingletonMul}(h,k),\mathsf{RingSingletonMul}(h',k'))$*;*
5. *if* $\mathsf{ModNClassifier}_m(h,h')$*, then* $\mathsf{ModNClassifier}_m(\mathsf{RingSingletonNeg}(h),\mathsf{RingSingletonNeg}(h'))$*.*

Lean4 ✓ `BEDC.Derived.ModNUp.ModNQuotientCarrier singleton operation descent rows`
Lean4 ✓ `BEDC.Derived.ModNUp.ModNQuotient singleton operation descent rows`
↪variant `BEDC.Derived.ModNUp.ModNQuotientSingleton operation descent rows`

Proof. Unfold the ModN carrier. Preservation of the modulus component is immediate: each output carrier keeps the same $\mathsf{UnaryHistory}(m)$ witness carried by the input endpoints.

The $\mathsf{Ring}^{\uparrow}$ singleton operation laws supply the history component. Addition, negation, and multiplication all return the singleton ring endpoint, so the RingSingletonCarrier field is obtained from the singleton closure rows of Definition 43.6.

For descent, project the RingSingletonClassifier fields from the two ModN classifier hypotheses. The singleton $\mathsf{Ring}^{\uparrow}$ congruence rows identify the add, multiply, and negated outputs under RingSingletonClassifier.

Finally, pair those singleton classifier witnesses with the output carriers just constructed. This repacks the result in the definition of $\mathsf{ModNClassifier}_m$. □

Theorem 102.6 (Concrete ModN NameCert scope)**.** *For every unary modulus history m : BHist, the carrier* $\mathsf{ModNCarrier}_m$*, classifier* $\mathsf{ModNClassifier}_m$*, and singleton ring operations* RingSingletonAdd*,* RingSingletonNeg*, and* RingSingletonMul *form the concrete* BHist *scope consumed by Definition 102.2. In that scope the quotient certificate reads exactly the carrier rows of Definition 102.4 and the operation rows of Definition 102.5.*

Proof. Begin with a unary modulus witness for m and unfold Definition 102.3. The source, pattern, and ledger carriers are all the same predicate $\mathsf{ModNCarrier}_m$, so the core certificate fields are supplied by Definition 102.4.

Next use Definition 102.5 to fix the additive, inverse, and multiplicative output obligations. These rows ensure that operations remain inside the concrete carrier and that replacing classified representatives does not change the classified output.

Only after those rows are in place, apply Definition 102.2. The checked quotient certificate then packages the already fixed carrier, classifier, stability, and ledger fields as the displayed NameCert scope for $\mathsf{ModN}^{\uparrow}(m)$. □

Lean4 ✓ `BEDC.Derived.ModNUp.ModNQuotient concrete namecert scope`

Closure status for $\mathsf{NameCert}_{\mathsf{ModN}^{\uparrow}}$**.**

Constructive story: A residue modulo N is presented here by a unary modulus history m together with the singleton $\mathsf{Ring}^{\uparrow}$ endpoint: a history is admitted exactly when m is unary and the history lies in the singleton ring carrier, so all non-singleton ring data and all non-unary moduli stay outside this concrete carrier. The classifier keeps both endpoint carrier witnesses and then uses the singleton ring classifier, which means this BEDC scope models the quotient-ring descent rows without forming a host quotient set or changing representatives by an external congruence. The source is the concrete $\mathsf{ModNCarrier}_m$, the pattern records the copied quotient-ring presentation at the ideal $n\mathbb{Z}$ together with

singleton addition, negation, and multiplication closure, and the ledger keeps the displayed modulus witness, endpoint carrier fields, and operation-descent rows visible. The five name-certificate obligations are exactly the checked classifier rows: the singleton endpoint gives nonemptiness, reflexivity, symmetry, and transitivity come from the singleton classifier, and carrier transport is already stored in the two endpoint fields of $\mathsf{ModNClassifier}_m$. A history h lies in the signature gap of a $\mathsf{ModN}^{\uparrow}$ token p when the source-domain accepts the unary modulus and singleton endpoint, the signature relation pairs that endpoint with an answer endpoint and operation ledger, and the token-introduction relation names the answer as p; unfolded, h is the singleton representative in the modulus scope encoded by p. The chapter registers this displayed unary-modulus quotient scope under the name $\mathsf{ModN}^{\uparrow}$; it introduces no standard bridge, no full integer modulo arithmetic, and no quotient primitive beyond the checked BHist quotient certificate.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModN}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 102.6 exports the public unary-modulus ModN quotient scope over $\mathsf{ModNCarrier}_m$, $\mathsf{ModNClassifier}_m$, the singleton $\mathsf{Ring}^{\uparrow}$ operations, quotient-ring descent rows, and the displayed BHist and hsame boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModN}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ModNUp.ModNQuotient\_concrete\_namecert\_scope`

Bridge status: none

Not claimed: This chapter does not close a standard bridge, full integer modulo arithmetic, or quotient primitives beyond the displayed BHist quotient certificate.

Upgrade path: The next grade requires a public bridge from this BHist quotient scope to the standard $\mathbb{Z}/n\mathbb{Z}$ interface.

Theorem 102.7 (Concrete ModN singleton inverse sum classifies as empty)**.** *For each unary modulus history* $m : \mathsf{BHist}$ *and each history* $h : \mathsf{BHist}$*, if* $\mathsf{ModNCarrier}_m(h)$*, then*

$$\mathsf{ModNClassifier}_m\big(\mathsf{RingSingletonAdd}(h, \mathsf{RingSingletonNeg}(h)), \mathsf{e}\big).$$

Proof. Unfold Definition 102.3 in the given carrier witness. It supplies the unary modulus witness $\mathsf{UnaryHistory}(m)$ and the singleton ring carrier witness for h.

The singleton inverse row of Definition 102.5 keeps $\mathsf{RingSingletonNeg}(h)$ inside $\mathsf{ModNCarrier}_m$. Applying the singleton addition carrier row in the same theorem to h and $\mathsf{RingSingletonNeg}(h)$ keeps $\mathsf{RingSingletonAdd}(h, \mathsf{RingSingletonNeg}(h))$ inside $\mathsf{ModNCarrier}_m$. The empty endpoint is also in $\mathsf{ModNCarrier}_m$: the modulus component is the same $\mathsf{UnaryHistory}(m)$ witness, and the singleton ring carrier of e is the carrier-inhabited row of Definition 43.6.

The additive inverse law in the singleton empty-history ring of Definition 43.6 gives the singleton classifier comparison

$$\mathsf{RingSingletonClassifier}\big(\mathsf{RingSingletonAdd}(h, \mathsf{RingSingletonNeg}(h)), \mathsf{e}\big).$$

Together with the two $\mathsf{ModNCarrier}_m$ endpoint witnesses just constructed, this is exactly the definition of $\mathsf{ModNClassifier}_m$ in Definition 102.3. □

Lean4 ✓ `BEDC.Derived.ModNUp.ModNQuotient singleton add neg empty classifier`

Chapter 103

A Concrete Naming Certificate for $\mathsf{LFunction}^{\uparrow}$

The L-function interface $\mathsf{LFunction}^{\uparrow}$ packages a Dirichlet series whose coefficients arise from a fixed character or Galois representation, together with the analytic continuation and functional-equation witnesses. It depends on $\mathsf{NameCert}_{\mathsf{Dirichlet}^{\uparrow}}$ (chapter 70) and is the abstract pattern instantiated by the Riemann zeta certificate $\mathsf{NameCert}_{\mathsf{ZetaBasic}^{\uparrow}}$ (chapter 71).

103.1 Carrier definition

Theorem 103.1 (L-function Dirichlet partial-sum successor index is positive)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, a closed witness* $\mathsf{DirichletPartSum}(term, s, n, S)$ *makes the successor history* $\mathsf{BHist.e1}(n)$ *a Dirichlet positive index.*

Proof. Induct on the closed partial-sum witness. The zero constructor gives unary e, and the step constructor preserves unaryness through the successor constructor. Thus the exposed index n is unary, and n itself is the tail witness showing that $\mathsf{BHist.e1}(n)$ is positive. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum successor positive index`

Theorem 103.2 (L-function Dirichlet partial-sum successor previous uniqueness)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, a closed witness* $\mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e}$ *exposes a previous partial sum P such that* $\mathsf{DirichletPartSum}(term, s, n, P)$, $\mathsf{Cont}(P, term(n, s), S)$, *and every other closed partial sum at index n is* hsame *to P.*

Proof. Invert the successor partial-sum witness. Its predecessor gives the previous partial sum and continuation into S. Positivity of the successor index recovers unaryness of n, and unary-index determinacy identifies every other predecessor partial sum with the exposed one. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum successor previous unique`

Theorem 103.3 (L-function Dirichlet partial-sum successor determinacy)**.** *For any Dirichlet term operation term, parameter s, index n, and sum histories S, T, two closed witnesses at the same successor index determine the same result:*

$$\mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e1}(n), S) \wedge \mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e1}(n), T) \Longrightarrow S \mathsf{hsame} T.$$

Proof. Invert one successor partial-sum witness. Positivity of the exposed successor recovers unaryness of n, hence unaryness of $\mathsf{BHist.e1}(n)$. The Dirichlet unary-index determinacy theorem then compares the reconstructed left successor witness with the second witness. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum successor deterministic`

Theorem 103.4 (L-function Dirichlet zero-term successor stability)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, if* $\mathsf{DirichletPartSum}(term, s, n, S)$ *holds and the next term $term(n, s)$ is* hsame *to* e*, then the same displayed sum S is also a closed partial sum at successor index* $\mathsf{BHist.e1}(n)$*:*

$$\mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e1}(n), S).$$

Proof. Compare the canonical right-unit continuation out of S with the term history $term(n, s)$ using the assumed hsame identification with e. This supplies the successor-step continuation from S through the zero term back to S, and the `DirichletPartSum.step` constructor closes the successor partial-sum witness. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum zero term successor stable`

Theorem 103.5 (L-function Dirichlet successor zero term recovers previous result)**.** *For any Dirichlet term operation term, parameter s, index n, and result history T, if* $\mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e1}(n), T$ *holds and the step term $term(n, s)$ is* hsame *to* e*, then the successor witness exposes a predecessor P such that*

$$\mathsf{DirichletPartSum}(term, s, n, P) \wedge P\mathsf{hsame}T.$$

Proof. Invert the successor partial-sum witness to expose the predecessor P and the continuation from P through $term(n, s)$ into T. Compare this continuation with the canonical right-unit continuation from P through e, transporting the term endpoint by $term(n, s)\mathsf{hsamee}$. Continuation determinacy then identifies T with P under hsame. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum successor zero term previous result same`

Theorem 103.6 (L-function Dirichlet successor zero-term result iff)**.** *For any Dirichlet term operation term, parameter s, index n, and result history T, if $term(n, s)\mathsf{hsamee}$, then*

$$\mathsf{DirichletPartSum}(term, s, \mathsf{BHist.e1}(n), T) \iff \exists P : \mathsf{BHist},\ \mathsf{DirichletPartSum}(term, s, n, P) \wedge P\mathsf{hsame}T.$$

Proof. The forward direction is the predecessor readback for a successor whose step term is empty. Conversely, a predecessor P with $P\mathsf{hsame}T$ supplies the successor continuation by transporting the right-unit continuation $\mathsf{Cont}(P, \mathsf{e}, P)$ along $term(n, s)\mathsf{hsamee}$ and $P\mathsf{hsame}T$, after which the `DirichletPartSum.step` constructor closes the successor witness. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum successor zero term result iff`

Theorem 103.7 (L-function Dirichlet zero-terms result is empty)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, suppose every unary index m has zero term $term(m, s)\mathsf{hsamee}$. Then every closed partial-sum witness* $\mathsf{DirichletPartSum}(term, s, n, S)$ *has empty result $S\mathsf{hsamee}$.*

Proof. Induct on the closed partial-sum witness. The zero constructor gives $S = \mathsf{e}$. In the step case, the predecessor index is unary by the partial-sum index theorem, so the zero-term hypothesis identifies the next term with e. Comparing the displayed continuation with the right-unit continuation at e gives the empty successor result. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum zero terms result empty`

Theorem 103.8 (L-function positive Dirichlet partial-sum index exposes predecessor)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, if*

$$\mathsf{DirichletPartSum}(term, s, n, S)$$

holds and n is a Dirichlet positive index, then there are histories m and P such that

$$n = \mathsf{BHist.e1}(m) \wedge \mathsf{DirichletPartSum}(term, s, m, P) \wedge \mathsf{Cont}(P, term(m, s), S).$$

Proof. Apply the Dirichlet partial-sum index case split. The zero-index branch is incompatible with positive-index shape, since e cannot be identified with a visible $\mathsf{BHist.e1}$ constructor. The successor branch already exposes the displayed predecessor index, predecessor partial sum, and final continuation into S. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum positive index previous exists`

Theorem 103.9 (L-function positive Dirichlet partial-sum predecessor uniqueness)**.** *For any Dirichlet term operation term, parameter s, index n, and sum history S, if*

$$\mathsf{DirichletPartSum}(term, s, n, S)$$

holds and n is a Dirichlet positive index, then there are histories m and P such that

$$n = \mathsf{BHist.e1}(m) \wedge \mathsf{DirichletPartSum}(term, s, m, P) \wedge \mathsf{Cont}(P, term(m, s), S),$$

and every other closed partial sum at the predecessor index m is hsame *to P.*

Proof. The predecessor-existence theorem exposes the visible predecessor index m, the displayed predecessor partial sum P, and the continuation into S. The predecessor partial-sum witness makes m unary. Dirichlet unary-index determinacy then identifies any other closed partial sum at m with the exposed predecessor result P. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum positive index previous unique`

Theorem 103.10 (L-function visible Dirichlet predecessor decomposition is deterministic)**.** *For any Dirichlet term operation term, parameter s, visible index n, and sum history S, suppose S admits two displayed predecessor decompositions*

$$n = \mathsf{BHist.e1}(m) \wedge \mathsf{DirichletPartSum}(term, s, m, P) \wedge \mathsf{Cont}(P, term(m, s), S)$$

and

$$n = \mathsf{BHist.e1}(m') \wedge \mathsf{DirichletPartSum}(term, s, m', P') \wedge \mathsf{Cont}(P', term(m', s), S).$$

Then $m = m'$ and $P \mathsf{hsame} P'$.

Proof. Invert both visible successor equalities. The constructor equality identifies the predecessor indices. The exposed predecessor partial-sum witness makes the index unary, and Dirichlet unary-index determinacy identifies the two displayed predecessor results. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum visible previous decomposition deterministic`

Theorem 103.11 (L-function zero-term positive partial-sum predecessor readback)**.** *For any Dirichlet term operation term, parameter s, positive index n, and sum history S, suppose every unary index m has zero term $term(m, s)$*hsame*e. If*

$$\mathsf{DirichletPartSum}(term, s, n, S)$$

holds and n is a Dirichlet positive index, then there are histories m and P such that

$$n = \mathsf{BHist.e1}(m) \wedge \mathsf{DirichletPartSum}(term, s, m, P) \wedge P\mathsf{hsame}S,$$

and every other closed partial sum at index m is hsame *to P.*

Proof. Use positive-index predecessor inversion to write n as $\mathsf{BHist.e1}(m)$ and expose the predecessor partial sum P together with the continuation through $term(m, s)$ into S. The predecessor partial-sum witness makes m unary, so the zero-term hypothesis identifies $term(m, s)$ with e. Comparing the displayed continuation with the canonical right-unit continuation from P gives $P\mathsf{hsame}S$, and unary-index determinacy gives the stated uniqueness of predecessor readback. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum zero terms positive previous readback`

103.2 The certificate

Theorem 103.12 (L-function Dirichlet partial-sum result hsame transport)**.** *For any Dirichlet term operation term, parameter s, index n, and histories S and S', result history-sameness transports closed partial-sum witnesses:*

$$S\mathsf{hsame}S' \Longrightarrow (\mathsf{DirichletPartSum}(term, s, n, S) \Longleftrightarrow \mathsf{DirichletPartSum}(term, s, n, S')).$$

In particular, no separate unary-index hypothesis is required.

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum result hsame transport`

Proof. It is enough to prove the forward implication; applying that implication to the symmetric result identification gives the reverse direction by Definition 3.8. Fix $S\mathsf{hsame}S'$ and a closed witness of $\mathsf{DirichletPartSum}(term, s, n, S)$, and induct on that witness. In the zero case, closed generation gives $n = \mathsf{e}$ and $S = \mathsf{e}$. The result hypothesis therefore reduces to $\mathsf{ehsame}S'$. By symmetry from Definition 3.8 it also gives $S'\mathsf{hsame}$e; the empty case of the constructor characterization in Definition 3.4 makes S' literally e. After this literal replacement, the zero constructor of Definition 70.9 gives $\mathsf{DirichletPartSum}(term, s, \mathsf{e}, S')$.

In the step case, the witness has index $\mathsf{E1}(m)$ and consists of a predecessor witness $\mathsf{DirichletPartSum}(term, s, m, P$ together with the final continuation $\mathsf{Cont}(P, term(m, s), S)$. By Definition 4.40, this continuation transports along $S\mathsf{hsame}S'$ to $\mathsf{Cont}(P, term(m, s), S')$. The step constructor of Definition 70.9 then gives $\mathsf{DirichletPartSum}(term, s, \mathsf{E1}(m), S')$. □

Definition 103.13 (L-function Dirichlet finite zero tail)**.** *For a Dirichlet term operation term, parameter s, base index n, and unary tail length k, the predicate*

$$\mathsf{DirichletFiniteZeroTail}(term, s, n, k)$$

is the closed finite-interval predicate generated by:

1. $\mathsf{DirichletFiniteZeroTail}(term, s, n, \mathsf{e})$*;*
2. *if* $\mathsf{DirichletFiniteZeroTail}(term, s, n, k)$ *and* $term(\mathsf{append}(n, k), s)\mathsf{hsamee}$*, then* $\mathsf{DirichletFiniteZeroTail}(term, s, n, \mathsf{E}$

Thus it records that all displayed terms in the BEDC interval $[n, n+k)$ are history-same to e*, with $n+k$ represented by* $\mathsf{append}(n, k)$*.*

Lean4 (definition) `BEDC.Derived.LFunctionUp.DirichletFiniteZeroTail`
Lean4 (definition) `BEDC.Derived.LFunctionUp.LFunctionDirichletFiniteZeroTail`

Theorem 103.14 (L-function Dirichlet finite zero-tail stability)**.** *For any Dirichlet term operation term, parameter s, base index n, tail length k, and sum history S, if*

$$\mathsf{DirichletPartSum}(term, s, n, S) \quad \textit{and} \quad \mathsf{DirichletFiniteZeroTail}(term, s, n, k),$$

then

$$\mathsf{DirichletPartSum}(term, s, \mathsf{append}(n, k), S).$$

Lean4 ✓ `BEDC.Derived.LFunctionUp.DirichletFiniteZeroTail stability`

Proof. Induct on the closed finite zero-tail witness. In the empty-tail branch, the right-unit law for history append from Definition 4.38 identifies $\mathsf{append}(n, \mathsf{e})$ with n, so the displayed partial-sum witness is already the required partial sum at the target index.

For the successor-tail branch, write the tail as $\mathsf{E1}(k_0)$. The induction hypothesis applied to the predecessor tail gives

$$\mathsf{DirichletPartSum}(term, s, \mathsf{append}(n, k_0), S).$$

The final zero-tail field gives

$$term(\mathsf{append}(n, k_0), s)\mathsf{hsamee}.$$

Apply the one-step zero-term stability theorem Definition 103.4 at the index $\mathsf{append}(n, k_0)$. It yields

$$\mathsf{DirichletPartSum}(term, s, \mathsf{E1}(\mathsf{append}(n, k_0)), S).$$

By the recursive definition of history append, $\mathsf{append}(n, \mathsf{E1}(k_0))$ is the successor history $\mathsf{E1}(\mathsf{append}(n, k_0))$. This is exactly the target partial-sum witness for the successor tail. □

Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletPartSum finite zero tail stability`
Lean4 ✓ `BEDC.Derived.LFunctionUp.LFunctionDirichletFiniteZeroTail stability`

Closure status for $\mathsf{NameCert}_{\mathsf{LFunction}^{\uparrow}}$**.**

Constructive story: An $\mathsf{LFunction}^{\uparrow}$ certificate is generated from closed Dirichlet partial-sum witnesses, unary index rows, term histories, zero-tail ledgers, continuation endpoints, and hsame transport. The BHist carrier does not store analytic continuation as an ambient theorem; it builds finite Dirichlet evidence by induction over displayed partial sums and finite zero tails. Each successor read exposes the predecessor sum and the Cont row adding the next term, while hsame transports result histories without changing the closed witness. The chapter therefore certifies the finite Dirichlet-series substrate used by the L-function interface.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LFunction}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds L-function Dirichlet partial-sum predecessor, determinacy, zero-tail, transport, and finite stability theorems.

Formal verification: FormalStatus(NameCert$_{\mathsf{LFunction}\uparrow}$, unformalized)
Bridge status: none
Origin: human
Not claimed: It does not claim analytic continuation, a functional equation, Euler product convergence, meromorphic extension, or host complex analysis.
Upgrade path: To reach obligationClosure, package the checked finite Dirichlet partial-sum and zero-tail theorems as an explicit NameCert carrier surface.

Chapter 104

A Concrete Naming Certificate for $\mathsf{Automorphic}^{\uparrow}$

The automorphic-form interface $\mathsf{Automorphic}^{\uparrow}$ packages a function on $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$ (chapter 101) invariant under a discrete subgroup action and satisfying the constructive growth conditions. It supplies the substrate connecting representations of the adelic group to L-functions in the Langlands programme.

104.1 Carrier definition

Theorem 104.1 (Automorphic adele graph continuation is non-empty)**.** *For adelic domain and value histories, any continuation graph produced by* Cont *is not* hsame*-equal to* e*.*

Proof. Transport the continuation result to e. Empty-result inversion forces the domain endpoint to be e, contradicting the non-empty property of the $\mathsf{Adele}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph cont nonempty`

Theorem 104.2 (Automorphic adele graph visible-context core is non-empty)**.** *For adelic domain and value histories, if a visible two-sided context displays* $\mathsf{Cont}(p \cdot d, v \cdot q, (p \cdot c) \cdot q)$*, then the exposed core* c *is not* hsame*-equal to* e*.*

Proof. Suffix cancellation removes the visible right context q, yielding $\mathsf{Cont}(p \cdot d, v, p \cdot c)$. Prefix cancellation removes the visible left context p, yielding $\mathsf{Cont}(d, v, c)$. The core non-emptiness theorem for automorphic adele graphs then rules out $c\mathsf{hsame}\mathsf{e}$. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context core nonempty`

Theorem 104.3 (Automorphic adele graph visible-context core determinacy)**.** *For adelic domain and value histories, if the same visible left and right contexts display two central continuation cores* c *and* c'*, then* $c\mathsf{hsame}c'$*. Both displayed cores are also not* hsame*-equal to* e*.*

Proof. Peel the common right context by suffix cancellation and the common left context by prefix cancellation. This recovers two central ledgers $\mathsf{Cont}(d, v, c)$ and $\mathsf{Cont}(d, v, c')$. Continuation determinacy compares the two recovered cores, and automorphic adele graph non-emptiness rules out emptiness for each core. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context core deterministic nonempty`

Theorem 104.4 (Automorphic adele graph visible-context value determinacy)**.** *For adelic domain and value histories, if the same visible left context and result display $v \cdot q$ and $v' \cdot q$ as the value side of the graph, then v*hsame*v'. The exposed graph is also not* hsame*-equal to* e*.*

Proof. Peel the common right context by suffix cancellation from both displayed continuations. The remaining ledgers share the same source and result, so continuation left cancellation compares the two value histories. Prefix cancellation recovers the central graph ledger, and automorphic adele graph non-emptiness rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context value deterministic`

Theorem 104.5 (Automorphic adele graph visible-context domain determinacy)**.** *For adelic domain and value histories, if the same visible value context and result display $p \cdot d$ and $p \cdot d'$ as the domain side of the graph, then d*hsame*d'. The exposed graph is also not* hsame*-equal to* e*.*

Proof. Peel the common right context by suffix cancellation from both displayed continuations. The remaining ledgers share the same value and result, so continuation right cancellation compares the prefixed domain histories. Left prefix cancellation removes p. The recovered central graph ledger supplies automorphic adele graph non-emptiness. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context domain deterministic`

Theorem 104.6 (Automorphic adele graph visible-context non-empty)**.** *For adelic domain and value histories, a displayed graph inside a visible left and right continuation context cannot be* hsame*-equal to* e*.*

Proof. Peel the right visible context and then the left visible context using continuation cancellation. The recovered central graph continuation is non-empty by the automorphic adele graph continuation theorem. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context nonempty`

Theorem 104.7 (Automorphic adele graph visible-context value readback)**.** *For adelic domain and value histories, if a visible two-sided context displays* $\mathsf{Cont}(p \cdot d, v \cdot q, (p \cdot graph) \cdot q)$ *and the same central graph is displayed by* $\mathsf{Cont}(d, v', graph)$*, then the visible value reads back to v*hsame*v'. The recovered graph is also not* hsame*-equal to* e*.*

Proof. Suffix cancellation removes the visible right context, and prefix cancellation removes the visible left context, recovering $\mathsf{Cont}(d, v, graph)$. Continuation left cancellation compares this recovered ledger with $\mathsf{Cont}(d, v', graph)$, while automorphic adele graph non-emptiness rules out an empty recovered graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context value readback`

Theorem 104.8 (Automorphic adele graph visible-context domain readback)**.** *For adelic domain and value histories, if a visible two-sided context displays* $\mathsf{Cont}(p \cdot d, v \cdot q, (p \cdot graph) \cdot q)$ *and the same central graph is displayed by* $\mathsf{Cont}(d', v, graph)$*, then the visible domain reads back to d*hsame*d'. The recovered graph is also not* hsame*-equal to* e*.*

Proof. Suffix cancellation removes the visible right context, and prefix cancellation removes the visible left context, recovering $\mathsf{Cont}(d, v, graph)$. Continuation right cancellation compares this recovered ledger with $\mathsf{Cont}(d', v, graph)$, while automorphic adele graph non-emptiness rules out an empty recovered graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context domain readback`

Theorem 104.9 (Automorphic adele graph visible-context displayed graph readback)**.** *For adelic domain and value histories, if a visible two-sided context displays* $\mathsf{Cont}(p{\cdot}d, v{\cdot}q, (p{\cdot}graph){\cdot}q)$ *and another central display gives* $\mathsf{Cont}(d, v, graph')$*, then the visible graph reads back to graph*hsame*graph′. The displayed graph is also not* hsame*-equal to* e*.*

Proof. Suffix cancellation removes the visible right context, and prefix cancellation removes the visible left context, recovering $\mathsf{Cont}(d, v, graph)$. Continuation determinacy compares this recovered ledger with $\mathsf{Cont}(d, v, graph')$. The displayed graph is non-empty by the automorphic adele graph continuation theorem. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context displayed graph readback`

Theorem 104.10 (Automorphic adele graph visible-context result is non-empty)**.** *For adelic domain and value histories, the whole visible-context result* $(p \cdot graph) \cdot q$ *of a displayed automorphic adele graph cannot be* hsame*-equal to* e*.*

Proof. If the visible result were empty, append-empty inversion first forces the right context q and the prefix $p \cdot graph$ to be empty, and then forces *graph* itself to be empty. The visible-context graph non-emptiness theorem gives the contradiction. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context result nonempty`

Theorem 104.11 (Automorphic adele graph visible result is non-empty)**.** *For adelic domain and value histories, any continuation result from a visible left-context domain* $p \cdot d$ *to a visible right-context value* $v \cdot q$ *cannot be* hsame*-equal to* e*.*

Proof. Transport the visible continuation result to e. Empty-result inversion then forces the source endpoint $p{\cdot}d$ to be empty. Append-empty inversion exposes $d\mathsf{hsame}\mathsf{e}$, contradicting the non-empty property of the $\mathsf{Adele}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible result nonempty`

Theorem 104.12 (Automorphic adele graph visible-context result hsame transport)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph graph, and graph*hsame*graph′, then the same visible context displays graph′. The transported graph is also not* hsame*-equal to* e*.*

Proof. Apply hsame congruence to the nested result $(p \cdot graph) \cdot q$, transport the displayed continuation ledger along that result comparison, and then apply visible-context graph non-emptiness to the transported display. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context result hsame transport`

Theorem 104.13 (Automorphic adele graph visible-context value hsame transport)**.** *For adelic domain and transported value histories, if a visible two-sided context displays an automorphic graph using value, and value*hsame*value′, then the same visible result displays the graph using value′. The graph remains not* hsame*-equal to* e*.*

Proof. Append congruence carries $value\mathsf{hsame}value'$ to the visible value leg $value \cdot q\mathsf{hsame}value' \cdot q$. Continuation hsame-transport rebuilds the visible ledger with $value'$, and visible-context non-emptiness applied to the transported ledger rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context value hsame transport`

Theorem 104.14 (Automorphic adele graph visible-context domain hsame transport)**.** *For adelic transported domain and value histories, if a visible two-sided context displays an automorphic graph using domain, and* $domain\mathsf{hsame}domain'$*, then the same visible result displays the graph using* $domain'$*. The graph remains not* hsame*-equal to* e*.*

Proof. Append congruence carries $domain\mathsf{hsame}domain'$ to the visible domain leg $p \cdot domain\mathsf{hsame}p \cdot domain'$. Continuation hsame-transport rebuilds the visible ledger with $domain'$, and visible-context non-emptiness applied to the transported ledger rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context domain hsame transport`

Theorem 104.15 (Automorphic adele graph visible-context endpoint hsame transport)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph using domain and value, and* $domain\mathsf{hsame}domain'$ *and* $value\mathsf{hsame}value'$*, then the same visible result displays the graph using the transported endpoints. The graph remains not* hsame*-equal to* e*.*

Proof. Append congruence carries the two endpoint classifiers to $p \cdot domain\mathsf{hsame}p \cdot domain'$ and $value \cdot q\mathsf{hsame}value' \cdot q$. Continuation hsame-transport rebuilds the displayed ledger with both endpoints transported. The original visible-context non-emptiness theorem rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context endpoint hsame transport`

Theorem 104.16 (Automorphic adele graph visible-context left hsame transport)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph using left context* p*, and* $p\mathsf{hsame}p'$*, then replacing the visible left context by* p' *preserves the continuation display. The graph remains not* hsame*-equal to* e*.*

Proof. Append congruence carries $p\mathsf{hsame}p'$ to both the visible source endpoint $p \cdot domain\mathsf{hsame}p' \cdot domain$ and the visible result endpoint $(p \cdot graph) \cdot q\mathsf{hsame}(p' \cdot graph) \cdot q$. Continuation hsame-transport rebuilds the visible ledger with left context p', and visible-context non-emptiness applied to that ledger rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context left hsame transport`

Theorem 104.17 (Automorphic adele graph visible-context right hsame transport)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph using right context* q*, and* $q\mathsf{hsame}q'$*, then replacing the visible right context by* q' *preserves the continuation display. The graph remains not* hsame*-equal to* e*.*

Proof. Append congruence carries $q\mathsf{hsame}q'$ to the visible value endpoint $value \cdot q\mathsf{hsame}value \cdot q'$ and to the visible result endpoint $(p \cdot graph) \cdot q\mathsf{hsame}(p \cdot graph) \cdot q'$. Continuation hsame-transport rebuilds the visible ledger with right context q', and visible-context non-emptiness applied to that ledger rules out an empty graph. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context right hsame transport`

Theorem 104.18 (Automorphic adele graph visible-context core readback)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph and that whole visible result is* hsame*-equal to the same context around a core, then the graph reads back to the core. The exposed core is also not* hsame*-equal to* e*.*

Proof. Reassociate both displayed visible results, then cancel the common left and right append contexts to recover $graph\mathsf{hsame}core$. Transport the displayed continuation ledger from the graph result to the core result and apply the visible-context core non-emptiness theorem. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context core readback`

Theorem 104.19 (Automorphic adele graph visible-context core continuation readback)**.** *For adelic domain and value histories, if a visible two-sided context displays an automorphic graph and the visible result is* hsame*-equal to the same context around a core, then the core itself is displayed by* $\mathsf{Cont}(domain, value, core)$*. Moreover* $graph\mathsf{hsame}core$*, and the core is not* hsame*-equal to* e*.*

Proof. Transport the visible continuation ledger from the graph endpoint to the core endpoint. Peel the right suffix and then the left prefix to recover $\mathsf{Cont}(domain, value, core)$. The existing core readback theorem supplies $graph\mathsf{hsame}core$ and core non-emptiness. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible context core cont readback`

Theorem 104.20 (Automorphic adele graph visible-result context factorization)**.** *For adelic domain and value histories, if a visible result is* hsame*-equal to* $(p \cdot graph) \cdot q$*, then the exposed graph is displayed by* $\mathsf{Cont}(domain, value, graph)$ *and is not* hsame*-equal to* e*.*

Proof. Transport the visible continuation ledger along the displayed result hsame. Peel the right suffix and then the left prefix to recover the central continuation, and apply adelic graph non-emptiness to that central ledger. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph visible result context factorizes`

104.2 The certificate

Definition 104.21 (Automorphic adele graph carrier)**.** *For a history* g*, the predicate* AutomorphicAdeleGraphCarrier *holds exactly when there are histories* $domain, value : \mathsf{BHist}$ *such that*

$$\mathsf{AdeleHistoryCarrier}(domain) \wedge \mathsf{AdeleHistoryCarrier}(value) \wedge \mathsf{Cont}(domain, value, g).$$

Lean4 (definition) `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraphCarrier`

Theorem 104.22 (Automorphic adele graph carrier hsame transport)**.** *If* $\mathsf{AutomorphicAdeleGraphCarrier}(g)$ *and* $g\mathsf{hsame}g'$*, then* $\mathsf{AutomorphicAdeleGraphCarrier}(g')$*.*

Proof. Unpack the graph-carrier witness for g into histories $domain, value : \mathsf{BHist}$, adele endpoint witnesses for both histories, and a continuation witness $\mathsf{Cont}(domain, value, g)$.

Apply continuation-result hsame transport along $g\mathsf{hsame}g'$. This keeps the hidden domain and value histories fixed and yields a transported continuation witness $\mathsf{Cont}(domain, value, g')$.

Repack the same adele endpoint witnesses together with the transported continuation ledger. The resulting witness is exactly $\mathsf{AutomorphicAdeleGraphCarrier}(g')$. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraphCarrier hsame transport`

1. Traditional target: automorphic graph carrier transport.
2. BEDC source: $\mathsf{Adele}^{\uparrow}$ together with Cont over histories.
3. Carrier: $\mathsf{AutomorphicAdeleGraphCarrier}$.
4. Classifier: hsame on BHist.
5. Stability obligation: Definition 104.22.
6. Ledger: the hidden domain, value, and continuation witnesses.
7. Core theorem: Definition 104.22.
8. Exactness: continuation-result transport.
9. Standard bridge: adelic graph presentation.
10. Status: $\mathsf{ProofTarget}$.

Theorem 104.23 (Automorphic adele graph semantic name certificate)**.** *The automorphic adele graph carrier, used as source predicate, pattern predicate, and ledger policy, forms a* $\mathsf{SemanticNameCert}$ *with classifier* hsame.

Proof. Apply Definition 101.31 to obtain an inhabited adele history carrier. Use the same adele endpoint as the domain and value endpoint, and apply the BEDC continuation constructor to obtain a graph endpoint.

The classifier laws are the reflexivity, symmetry, and transitivity laws for hsame. Since the source, pattern, and ledger policies are the same graph carrier predicate, their inclusion obligations are identity maps on the same witness package.

For carrier transport, apply Definition 104.22. The theorem supplies the reusable movement of a graph-carrier witness across hsame, so the certificate uses it as its shared source, pattern, and ledger transport. □

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph semanticNameCert`

Theorem 104.24 (Automorphic public certificate export)**.** *The adele-domain row, adele-value row, displayed graph carrier, context readbacks,* hsame *transports, and semantic certificate repack into the public* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *export for downstream consumers. The export keeps the* $\mathsf{Adele}^{\uparrow}$ *domain endpoint, the* $\mathsf{Adele}^{\uparrow}$ *value endpoint, the displayed graph history, and the* Cont *witness visible, and it exposes only the classifier, stability, ledger, and exactness rows already present in the automorphic adele graph certificate.*

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph public certificate export`

Proof. Apply the visible-context core readback Definition 104.18. It recovers the carried graph core from any displayed visible context.

Next apply the endpoint transport rows Definition 104.15 and the graph carrier hsame transport Definition 104.22. These rows keep the adele-domain endpoint, adele-value endpoint, and graph carrier stable under the declared classifier.

Finally apply Definition 104.23. Its semantic certificate supplies the shared source, pattern, and ledger policies. Repacking these visible rows gives the public $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ export without adding a Langlands bridge, spectral decomposition, or analytic continuation claim. □

Theorem 104.25 (Automorphic standard adelic graph bridge boundary)**.** *Any standard adelic-graph bridge for* $\mathsf{Automorphic}^{\uparrow}$ *may read only the* $\mathsf{Adele}^{\uparrow}$ *domain endpoint,* $\mathsf{Adele}^{\uparrow}$ *value endpoint, displayed graph history,* Cont *witness, visible-context readbacks,* hsame *transports, semantic certificate rows, and* Pkg *provenance from Definition 104.24. It does not supply Langlands correspondence, automorphic representation theory, spectral decomposition, analytic continuation, or an* L*-function bridge.*

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicUp StdBridge`

Proof. Project the public certificate export through Definition 104.24. Its visible rows are the two $\mathsf{Adele}^{\uparrow}$ endpoints, the displayed graph history, the continuation witness, classifier transports, semantic certificate rows, and package provenance.

Use the visible-context core readback of Definition 104.18 together with the endpoint transport rows of Definition 104.15. These rows keep the domain, value, and graph endpoint determined only through the declared hsame classifier.

Finally repack the same rows as the standard adelic graph boundary. Since the public export contains no row for Langlands correspondence, representation theory, spectral decomposition, analytic continuation, or L-function data, none of those claims is supplied by the bridge boundary. □

Theorem 104.26 (Automorphic mature adelic graph consumer coverage)**.** *Every downstream consumer of the standard adelic graph boundary receives exactly the* $\mathsf{Automorphic}^{\uparrow}$ *carrier, visible-context core, domain, and value readbacks, result factorization,* hsame *transport rows, semantic* NameCert *export, and standard adelic graph bridge boundary of Definition 104.25.*

The consumer boundary receives no Langlands bridge, L-function analytic continuation, spectral decomposition, or representation-theoretic structure.

Lean4 ✓ `BEDC.Derived.AutomorphicUp.AutomorphicTasteGate single carrier alignment`

Proof. Begin with the carrier and displayed visible context. Apply Definition 104.18 to recover the carried graph core, and use Definition 104.15 to keep the adele-domain and adele-value endpoints fixed up to the declared hsame classifier.

Next apply Definition 104.20 together with Definition 104.22. These rows ensure that any consumer of the boundary reads the same carrier, endpoint, context, continuation, factorization, and transport data already present in the graph packet.

Apply Definition 104.23. The semantic certificate supplies the shared source, pattern, ledger, exactness, and transport rows exported by the public NameCert surface.

Finally use Definition 104.25. The standard boundary repacks exactly those carrier, readback, factorization, transport, certificate, and package rows. Since none of the cited rows carries Langlands correspondence, L-function analytic continuation, spectral decomposition, or representation-theoretic structure, no downstream consumer receives such data. □

1. Traditional target: automorphic graph names.
2. BEDC source: $\mathsf{Adele}^{\uparrow}$ together with Cont over histories.
3. Carrier: the predicate $\mathsf{AutomorphicAdeleGraphCarrier}(g)$ displayed above.
4. Classifier: hsame on BHist.
5. Stability: the hsame equivalence laws and continuation-result transport for graph endpoints.
6. Ledger: the hidden domain and value adele endpoints together with the continuation witness.

7. Core theorem: Definition 104.23.
8. Exactness: graph endpoint generation by Cont from carried adele domain and value endpoints.
9. Standard bridge: adelic graph presentation.
10. Status: ProofTarget.

Closure status for $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$.

Constructive story: An automorphic graph starts with two admitted Adele$^{\uparrow}$ histories, one serving as the domain endpoint and one as the value endpoint, and the kernel continuation displays their graph history; without both adele carriers and the continuation witness, the history is outside the carrier. The classifier is ordinary history-sameness on these carried graph endpoints, with transport theorems peeling or replacing visible left and right contexts so that the underlying domain, value, and graph core remain determined. The source, pattern, and ledger are the same graph-carrier predicate: the source accepts exactly these adele-domain, adele-value, and continuation packages, the pattern records non-emptiness, context determinacy, endpoint readback, and result factorization, and the ledger keeps the hidden domain, value, continuation, and context witnesses available. Since the adele carrier is inhabited and nonempty, a displayed adele endpoint can be used on both sides to inhabit the graph carrier, while hsame supplies reflexivity, symmetry, and transitivity and continuation-result transport closes the carrier under classified graph endpoints. A history h lies in the signature gap of an Automorphic$^{\uparrow}$ token p when the source-domain accepts h as such an adele graph, the signature relation pairs it with an answer graph and evidence ledger, and token introduction names that answer as p; concretely, the central graph exposed after cancelling any visible contexts has the domain and value encoded by p. The visible-context rows give the constructive content usually hidden behind invariance language: they prove that adding contexts does not change the recovered core, domain, or value except through the declared classifier. The chapter registers this adele-continuation graph construction under the name Automorphic$^{\uparrow}$; it introduces no Langlands bridge, automorphic representation theory, spectral decomposition, or analytic continuation of L-functions.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$, maturePackageClosed)

Scope closed: The named carrier, visible-context determinism and readback, hsame transport, result factorization, carrier transport, semantic certificate blocks, standard adelic graph bridge boundary of Definition 104.25, and mature consumer coverage of Definition 104.26 fix the carrier, classifier, stability, ledger, exactness, bridge-boundary, and consumer-boundary obligations over Adele$^{\uparrow}$ and Cont.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.AutomorphicUp.AutomorphicAdeleGraph\_semanticNameCert`

Bridge status: bridgeChecked

Not claimed: No Langlands bridge, automorphic representation theory, L-function analytic continuation, spectral decomposition, or machine-checked standard bridge is claimed.

Upgrade path: No further upgrade remains on the formal bridge axis for the recorded standard bridge surface.

Chapter 105

A Concrete Naming Certificate for $\mathsf{CatLimit}^{\uparrow}$

The categorical-limit interface $\mathsf{CatLimit}^{\uparrow}$ packages a cone over a diagram in a $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) certified universal among all such cones. It depends on $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62) and is dual to $\mathsf{NameCert}_{\mathsf{CatColimit}^{\uparrow}}$ (chapter 106).

105.1 Carrier definition

105.2 The certificate

Definition 105.1 (Fixed-diagram cone comparison data)**.** *Fix a* $\mathsf{Cat}^{\uparrow}$ *certificate* $\mathcal{C}$*, an indexing category* $\mathcal{J}$*, and a certified* $\mathsf{Functor}^{\uparrow}$ *diagram* $D : \mathcal{J} \to \mathcal{C}$*. Write* $\mathrm{Mor}_{\mathcal{C}}(A, B; f)$ *for the certified assertion that* f *is a morphism* $A \to B$*,* $\mathrm{MorEq}_{\mathcal{C}}(A, B; f, g)$ *for the morphism classifier between parallel morphisms* $f, g : A \to B$*, and* $\mathrm{Comp}_{\mathcal{C}}(A, B, C; f, g, h)$ *for the certified composition witness saying that* $h : A \to C$ *classifies the composite of* $f : A \to B$ *followed by* $g : B \to C$*.*

For D*-cones* λ *and* μ *with apexes* L *and* M*, the predicate*

$$\mathrm{ConeMor}_D(\lambda, \mu; f)$$

means that $\mathrm{Mor}_{\mathcal{C}}(L, M; f)$ *holds and, for every object* j *of* $\mathcal{J}$*, there is a component composite* $c_j : L \to D(j)$ *such that*

$$\mathrm{Comp}_{\mathcal{C}}(L, M, D(j); f, \mu_j, c_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(L, D(j); c_j, \lambda_j).$$

A certified limiting cone is written

$$\mathrm{LimCone}_D(L, \lambda).$$

It consists of a D*-cone* λ *with apex* L *and the universal field that every* D*-cone* χ *with apex* X *admits a morphism* $m : X \to L$ *satisfying* $\mathrm{ConeMor}_D(\chi, \lambda; m)$*, with any two such morphisms classified by* $\mathrm{MorEq}_{\mathcal{C}}(X, L; -, -)$*.*

Lean4 (definition) `BEDC.Derived.CatLimitUp.CatLimitConeMor`

Lemma 105.2 (Composition closure for cone morphisms)**.** *Let λ, μ, ν be D-cones with apexes L, M, N. Suppose*

$$\mathrm{ConeMor}_D(\lambda, \mu; f)$$

for $f : L \to M$, and

$$\mathrm{ConeMor}_D(\mu, \nu; g)$$

for $g : M \to N$. If

$$\mathrm{Comp}_{\mathcal{C}}(L, M, N; f, g, h),$$

then

$$\mathrm{ConeMor}_D(\lambda, \nu; h).$$

Proof. The composition field of the $\mathsf{Cat}^{\uparrow}$ certificate gives $\mathrm{Mor}_{\mathcal{C}}(L, N; h)$ from the displayed composition witness and the morphism fields of f and g.

Fix an object j of $\mathcal{J}$. From $\mathrm{ConeMor}_D(\mu, \nu; g)$, obtain a composite $d_j : M \to D(j)$ with

$$\mathrm{Comp}_{\mathcal{C}}(M, N, D(j); g, \nu_j, d_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(M, D(j); d_j, \mu_j).$$

From $\mathrm{ConeMor}_D(\lambda, \mu; f)$, obtain a composite $e_j : L \to D(j)$ with

$$\mathrm{Comp}_{\mathcal{C}}(L, M, D(j); f, \mu_j, e_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(L, D(j); e_j, \lambda_j).$$

The associativity field of the $\mathsf{Cat}^{\uparrow}$ certificate applies to

$$L \xrightarrow{f} M \xrightarrow{g} N \xrightarrow{\nu_j} D(j).$$

Together with the witnesses for $h = g \circ f$ and $d_j = \nu_j \circ g$, it supplies a composite $r_j : L \to D(j)$ with

$$\mathrm{Comp}_{\mathcal{C}}(L, N, D(j); h, \nu_j, r_j)$$

and a classifier comparison between r_j and the composite of f followed by d_j. The morphism-classifier congruence field transports

$$\mathrm{MorEq}_{\mathcal{C}}(M, D(j); d_j, \mu_j)$$

across right composition by f, giving a classifier comparison between the composite of f followed by d_j and the composite e_j of f followed by μ_j. Transitivity of $\mathrm{MorEq}_{\mathcal{C}}$ then yields

$$\mathrm{MorEq}_{\mathcal{C}}(L, D(j); r_j, \lambda_j).$$

Since the object j was arbitrary, the component witnesses r_j assemble the component ledger for $\mathrm{ConeMor}_D(\lambda, \nu; h)$. □

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor comp closed`

Lemma 105.3 (Identity cone morphism)**.** *If λ is a D-cone with apex L, then*

$$\mathrm{ConeMor}_D(\lambda, \lambda; 1_L).$$

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor empty identity`

Proof. The identity field of the $\mathsf{Cat}^{\uparrow}$ certificate gives $\mathrm{Mor}_{\mathcal{C}}(L, L; 1_L)$. Fix an object j of $\mathcal{J}$. The unit field for the component $\lambda_j : L \to D(j)$ supplies a composite $c_j : L \to D(j)$ with

$$\mathrm{Comp}_{\mathcal{C}}(L, L, D(j); 1_L, \lambda_j, c_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(L, D(j); c_j, \lambda_j).$$

These witnesses, indexed by the objects of $\mathcal{J}$, give the cone-morphism ledger for $\mathrm{ConeMor}_D(\lambda, \lambda; 1_L)$. □

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor identity`
Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor identity comparison`

Theorem 105.4 (Fixed-diagram cone-morphism category package)**.** *For a fixed certified diagram $D : \mathcal{J} \to \mathcal{C}$ in a $\mathsf{Cat}^{\uparrow}$ certificate, the data whose objects are D-cones and whose arrows from λ to μ are witnesses of*

$$\mathrm{ConeMor}_D(\lambda, \mu; f)$$

has the certified category surface induced by $\mathcal{C}$. The identity arrow at a cone λ is supplied by

$$\mathrm{ConeMor}_D(\lambda, \lambda; 1_L),$$

and a composable pair

$$\mathrm{ConeMor}_D(\lambda, \mu; f), \qquad \mathrm{ConeMor}_D(\mu, \nu; g)$$

together with

$$\mathrm{Comp}_{\mathcal{C}}(L, M, N; f, g, h)$$

supplies the composite arrow

$$\mathrm{ConeMor}_D(\lambda, \nu; h).$$

Moreover, composition of cone morphisms is stable under the morphism classifier inherited from $\mathrm{MorEq}_{\mathcal{C}}$*: replacing any displayed arrow or component composite by a parallel* $\mathrm{MorEq}_{\mathcal{C}}$*-classified representative gives a classified representative of the same cone-morphism composite.*

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor comp classifier transport`

Proof. The identity row is exactly Definition 105.3. For every D-cone λ with apex L, that lemma supplies the certified morphism $1_L : L \to L$ and the component ledger proving $\mathrm{ConeMor}_D(\lambda, \lambda; 1_L)$.

For composition, take cone morphisms $\lambda \to \mu$ and $\mu \to \nu$ represented by f and g, and take a certified composite witness $\mathrm{Comp}_{\mathcal{C}}(L, M, N; f, g, h)$. Applying Definition 105.2 gives the required cone-morphism ledger $\mathrm{ConeMor}_D(\lambda, \nu; h)$.

It remains to record stability under the inherited classifier. The proof of Definition 105.2 uses the associativity field of $\mathsf{Cat}^{\uparrow}$ to compare the two component-composite parenthesizations and the classifier-congruence field to transport $\mathrm{MorEq}_{\mathcal{C}}$ across right composition. Those same fields show that replacing f, g, h, or any component composite by a parallel $\mathrm{MorEq}_{\mathcal{C}}$ representative preserves the displayed cone-morphism composite up to the same classifier. □

Proposition 105.5 (Limiting-cone endomorphism rigidity)**.** *If*

$$\mathrm{LimCone}_D(L, \lambda)$$

and

$$\mathrm{ConeMor}_D(\lambda, \lambda; a),$$

then

$$\mathrm{MorEq}_{\mathcal{C}}(L, L; a, 1_L).$$

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitLimCone endomorphism rigidity`

Proof. By Definition 105.3, the identity morphism satisfies

$$\mathrm{ConeMor}_D(\lambda, \lambda; 1_L).$$

The universal uniqueness field of $\mathrm{LimCone}_D(L, \lambda)$ applies to the source cone λ and to the two cone morphisms $a, 1_L : L \to L$. It gives

$$\mathrm{MorEq}_{\mathcal{C}}(L, L; a, 1_L).$$

□

Theorem 105.6 (CatLimit apex uniqueness from universal cones)**.** *Let $D : \mathcal{J} \to \mathcal{C}$ be a fixed certified* $\mathsf{Functor}^{\uparrow}$ *diagram in a* $\mathsf{Cat}^{\uparrow}$ *certificate $\mathcal{C}$. If*

$$\mathrm{LimCone}_D(L, \lambda)$$

and

$$\mathrm{LimCone}_D(L', \lambda')$$

are two certified limiting cones over D, then there exist comparison morphisms

$$u : L \to L'$$

and

$$v : L' \to L$$

such that

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u)$$

and

$$\mathrm{ConeMor}_D(\lambda', \lambda; v).$$

Moreover, there are composite results $c_L : L \to L$ and $c_{L'} : L' \to L'$ satisfying

$$\mathrm{Comp}_{\mathcal{C}}(L, L', L; u, v, c_L)$$

and

$$\mathrm{Comp}_{\mathcal{C}}(L', L, L'; v, u, c_{L'})$$

with

$$\mathrm{MorEq}_{\mathcal{C}}(L, L; c_L, 1_L)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(L', L'; c_{L'}, 1_{L'}).$$

Lean4 ✓ BEDC.Derived.CatLimitUp.CatLimitLimCone comparison identities

Proof. Apply the universal existence field of $\mathrm{LimCone}_D(L', \lambda')$ to the D-cone λ with apex L. This supplies a morphism $u : L \to L'$ and a cone-morphism ledger

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u).$$

Apply the universal existence field of $\mathrm{LimCone}_D(L, \lambda)$ to the D-cone λ' with apex L'. This supplies a morphism $v : L' \to L$ and a cone-morphism ledger

$$\mathrm{ConeMor}_D(\lambda', \lambda; v).$$

The composition field of $\mathcal{C}$ supplies a composite result $c_L : L \to L$ with

$$\mathrm{Comp}_{\mathcal{C}}(L, L', L; u, v, c_L).$$

Using Definition 105.2 with the two cone morphisms

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u)$$

and

$$\mathrm{ConeMor}_D(\lambda', \lambda; v),$$

one obtains

$$\mathrm{ConeMor}_D(\lambda, \lambda; c_L).$$

Now Definition 105.5, applied to $\mathrm{LimCone}_D(L, \lambda)$ and this cone endomorphism, gives

$$\mathrm{MorEq}_{\mathcal{C}}(L, L; c_L, 1_L).$$

The composition field of $\mathcal{C}$ also supplies a composite result $c_{L'} : L' \to L'$ with

$$\mathrm{Comp}_{\mathcal{C}}(L', L, L'; v, u, c_{L'}).$$

Using Definition 105.2 with the two cone morphisms

$$\mathrm{ConeMor}_D(\lambda', \lambda; v)$$

and

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u),$$

one obtains

$$\mathrm{ConeMor}_D(\lambda', \lambda'; c_{L'}).$$

Now Definition 105.5, applied to $\mathrm{LimCone}_D(L', \lambda')$ and this cone endomorphism, gives

$$\mathrm{MorEq}_{\mathcal{C}}(L', L'; c_{L'}, 1_{L'}).$$

□

Corollary 105.7 (Comparison-fiber collapse)**.** *Under the hypotheses of Definition 105.6, if* $u_1, u_2 : L \to L'$ *both satisfy*

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u_1)$$

and

$$\mathrm{ConeMor}_D(\lambda, \lambda'; u_2),$$

then

$$\mathrm{MorEq}_{\mathcal{C}}(L, L'; u_1, u_2).$$

If $v_1, v_2 : L' \to L$ *both satisfy*

$$\mathrm{ConeMor}_D(\lambda', \lambda; v_1)$$

and

$$\mathrm{ConeMor}_D(\lambda', \lambda; v_2),$$

then

$$\mathrm{MorEq}_{\mathcal{C}}(L', L; v_1, v_2).$$

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitLimCone comparison fiber collapse`

Proof. The two morphisms $u_1, u_2 : L \to L'$ are cone morphisms from the same source cone λ to the same limiting cone λ'. The universal uniqueness field of $\mathrm{LimCone}_D(L', \lambda')$ applied to the source cone λ gives

$$\mathrm{MorEq}_{\mathcal{C}}(L, L'; u_1, u_2).$$

The two morphisms $v_1, v_2 : L' \to L$ are cone morphisms from the same source cone λ' to the same limiting cone λ. The universal uniqueness field of $\mathrm{LimCone}_D(L, \lambda)$ applied to the source cone λ' gives

$$\mathrm{MorEq}_{\mathcal{C}}(L', L; v_1, v_2).$$

□

Proposition 105.8 (Field dependency of the comparison construction)**.** *The construction in Definition 105.6 is obtained from the following fields:*

1. *the universal existence field of each limiting cone, applied once to the other cone;*
2. *the* $\mathsf{Cat}^{\uparrow}$ *composition field, applied once to* u *followed by* v *and once to* v *followed by* u*;*
3. *the associativity and morphism-classifier congruence fields used in Definition 105.2;*
4. *the identity and unit fields used in Definition 105.3;*
5. *the universal uniqueness field of each limiting cone, applied to its own cone endomorphism.*

No object equality, quotient carrier, host-level function extensionality, or external isomorphism principle enters the construction.

Proof. The first universal existence application is made to $\mathrm{LimCone}_D(L', \lambda')$ with source cone λ, and it produces the morphism $u : L \to L'$ together with $\mathrm{ConeMor}_D(\lambda, \lambda'; u)$. The second universal existence application is made to $\mathrm{LimCone}_D(L, \lambda)$ with source cone λ', and it produces the morphism $v : L' \to L$ together with $\mathrm{ConeMor}_D(\lambda', \lambda; v)$.

The $\mathsf{Cat}^{\uparrow}$ composition field produces c_L from u followed by v, and it produces $c_{L'}$ from v followed by u. The passage from these raw composites to cone endomorphisms is exactly Definition 105.2; its proof uses associativity to compare $\nu_j \circ (g \circ f)$ with $(\nu_j \circ g) \circ f$, morphism-classifier congruence

to replace $\nu_j \circ g$ by the corresponding cone component, and transitivity to reach the original source component.

The classification of an arbitrary cone endomorphism with the identity is exactly Definition 105.5. That proposition first uses Definition 105.3, whose proof uses only the identity and unit fields of the $\mathsf{Cat}^{\uparrow}$ certificate, and then applies the universal uniqueness field of the limiting cone to the pair consisting of the given cone endomorphism and the identity cone morphism.

Combining these field projections gives precisely the two comparison morphisms, the two composite witnesses, and the two identity classifications stated in Definition 105.6. Each displayed equality is an instance of $\mathrm{MorEq}_{\mathcal{C}}$, and every object-level comparison used in the construction is one of the fields listed above. □

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitLimCone comparison field dependency`

Definition 105.9 (Pointwise certified diagram equivalence)**.** *Fix* $\mathsf{Cat}^{\uparrow}$ *certificates* $\mathcal{J}$ *and* $\mathcal{C}$*, and certified* $\mathsf{Functor}^{\uparrow}$ *diagrams* $D, E : \mathcal{J} \to \mathcal{C}$*. A pointwise certified diagram equivalence between* D *and* E *is a pair of certified* $\mathsf{NatTrans}^{\uparrow}$ *carriers*

$$\alpha : D \Rightarrow E, \qquad \beta : E \Rightarrow D,$$

such that, for every object j *of* $\mathcal{J}$*, the component composites are classified as identities in* $\mathcal{C}$*. Thus there are composites* $d_j : D(j) \to D(j)$ *and* $e_j : E(j) \to E(j)$ *with*

$$\mathrm{Comp}_{\mathcal{C}}(D(j), E(j), D(j); \alpha_j, \beta_j, d_j) \quad \textit{and} \quad \mathrm{MorEq}_{\mathcal{C}}(D(j), D(j); d_j, 1_{D(j)}),$$

and

$$\mathrm{Comp}_{\mathcal{C}}(E(j), D(j), E(j); \beta_j, \alpha_j, e_j) \quad \textit{and} \quad \mathrm{MorEq}_{\mathcal{C}}(E(j), E(j); e_j, 1_{E(j)}).$$

The naturality, component-carrier, and component-classifier rows are exactly the rows required by the $\mathsf{NatTrans}^{\uparrow}$ *carrier and certificate obligations.*

Lean4 (definition) `BEDC.Derived.CatLimitUp.CatLimitPointwiseDiagramEquivalence`

Theorem 105.10 (CatLimit transport along pointwise certified diagram equivalence)**.** *Let* $\mathcal{J}$ *and* $\mathcal{C}$ *satisfy the* $\mathsf{Cat}^{\uparrow}$ *certificate obligations, and let* $D, E : \mathcal{J} \to \mathcal{C}$ *be certified* $\mathsf{Functor}^{\uparrow}$ *diagrams. Suppose* (α, β) *is a pointwise certified diagram equivalence between* D *and* E *in the sense of Definition 105.9. If*

$$\mathrm{LimCone}_D(L, \lambda)$$

holds, and if λ^E *is the component family obtained by certified composition*

$$\mathrm{Comp}_{\mathcal{C}}(L, D(j), E(j); \lambda_j, \alpha_j, \lambda^E_j)$$

for every object j *of* $\mathcal{J}$*, then*

$$\mathrm{LimCone}_E(L, \lambda^E).$$

Proof. First verify the E-cone ledger for λ^E. For a displayed morphism $u : j \to k$ in $\mathcal{J}$, the D-cone law for λ classifies the composite of λ_j followed by $D(u)$ with λ_k. Naturality of α classifies α_j followed by $E(u)$ with $D(u)$ followed by α_k. Associativity and composition congruence from Definition 61.201 paste these two classifier comparisons and identify the composite of λ^E_j followed by $E(u)$ with λ^E_k. Thus λ^E is an E-cone with apex L.

Let χ be any E-cone with apex X. Form a D-component family χ^D by composing each component with β_j:

$$\mathrm{Comp}_{\mathcal{C}}(X, E(j), D(j); \chi_j, \beta_j, \chi^D_j).$$

The E-cone law for χ, naturality of β, and the same associativity and congruence fields show that χ^D is a D-cone. The universal existence field of $\mathrm{LimCone}_D(L, \lambda)$ therefore supplies a morphism $m : X \to L$ with

$$\mathrm{ConeMor}_D(\chi^D, \lambda; m).$$

For each j, the component comparison of this cone morphism classifies m followed by λ_j with χ_j followed by β_j. Composing that comparison on the right with α_j, using associativity, and then using the $E(j)$-identity row β_j followed by α_j classified with $1_{E(j)}$, gives a classifier comparison between m followed by λ^E_j and χ_j. The right identity law in $\mathcal{C}$ supplies the final comparison with χ_j. Hence

$$\mathrm{ConeMor}_E(\chi, \lambda^E; m),$$

which is the universal existence field for λ^E.

It remains to verify universal uniqueness. Let $m, n : X \to L$ both satisfy

$$\mathrm{ConeMor}_E(\chi, \lambda^E; m) \quad \text{and} \quad \mathrm{ConeMor}_E(\chi, \lambda^E; n).$$

For m, compose the component comparison $m; \lambda^E_j$ classified with χ_j on the right by β_j. Since λ^E_j is the composite of λ_j followed by α_j, associativity rewrites the left side as $m; \lambda_j; \alpha_j; \beta_j$. The $D(j)$-identity row classifies α_j followed by β_j with $1_{D(j)}$, and the right identity law reduces this to $m; \lambda_j$. The right side is the defining component χ^D_j. Thus

$$\mathrm{ConeMor}_D(\chi^D, \lambda; m).$$

The same argument gives

$$\mathrm{ConeMor}_D(\chi^D, \lambda; n).$$

The universal uniqueness field of $\mathrm{LimCone}_D(L, \lambda)$ applies to these two D-cone morphisms and yields

$$\mathrm{MorEq}_{\mathcal{C}}(X, L; m, n).$$

This is exactly the uniqueness field required for $\mathrm{LimCone}_E(L, \lambda^E)$. □

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitLimCone transport pointwise equiv`

Theorem 105.11 (Cone morphism classifier descent through natural-transformation whiskering)**.** *Let $\mathcal{J}$ and $\mathcal{C}$ satisfy the $\mathsf{Cat}^{\uparrow}$ certificate obligations. Let $D, E : \mathcal{J} \to \mathcal{C}$ be certified $\mathsf{Functor}^{\uparrow}$ diagrams, and let $\alpha : D \Rightarrow E$ be a certified $\mathsf{NatTrans}^{\uparrow}$ carrier with components $\alpha_j : D(j) \to E(j)$. Let λ and μ be D-cones with apexes L and M, and let λ^α and μ^α be the corresponding E-cones obtained by composing each cone leg with the component of α:*

$$\mathrm{Comp}_{\mathcal{C}}(L, D(j), E(j); \lambda_j, \alpha_j, \lambda^\alpha_j) \qquad \textit{and} \qquad \mathrm{Comp}_{\mathcal{C}}(M, D(j), E(j); \mu_j, \alpha_j, \mu^\alpha_j)$$

for every object j of $\mathcal{J}$, with image endpoints read through the certified endpoint-transport fields. If

$$\mathrm{ConeMor}_D(\lambda, \mu; f),$$

then

$$\mathrm{ConeMor}_E(\lambda^\alpha, \mu^\alpha; f).$$

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitConeMor nattrans whiskering descent`

Proof. By Definition 63.1, each α_j is a displayed morphism $D(j) \to E(j)$ in $\mathcal{C}$, and the naturality row is the cone-whiskering ledger that makes the displayed component families λ^α and μ^α into E-cones. If any object image is represented by a classified endpoint rather than by a literal endpoint, the source-target replacement row of Definition 62.78 and the endpoint-indexed transport fields of Definition 61.201 reindex the component morphisms before the following composition ledgers are formed.

Unpack $\mathrm{ConeMor}_D(\lambda, \mu; f)$ using Definition 105.1. It gives the apex morphism field $\mathrm{Mor}_{\mathcal{C}}(L, M; f)$ and, for each object j of $\mathcal{J}$, a displayed composite $d_j : L \to D(j)$ such that

$$\mathrm{Comp}_{\mathcal{C}}(L, M, D(j); f, \mu_j, d_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(L, D(j); d_j, \lambda_j).$$

The same apex morphism field is the apex morphism required for $\mathrm{ConeMor}_E(\lambda^\alpha, \mu^\alpha; f)$.

Fix j. The postwhiskered target leg is displayed by

$$\mathrm{Comp}_{\mathcal{C}}(M, D(j), E(j); \mu_j, \alpha_j, \mu_j^\alpha).$$

Composition closure in Definition 61.201 supplies a composite $s_j : L \to E(j)$ of f followed by μ_j^α:

$$\mathrm{Comp}_{\mathcal{C}}(L, M, E(j); f, \mu_j^\alpha, s_j).$$

It also supplies a composite $t_j : L \to E(j)$ of d_j followed by α_j:

$$\mathrm{Comp}_{\mathcal{C}}(L, D(j), E(j); d_j, \alpha_j, t_j).$$

Associativity in the same category certificate, applied to

$$L \xrightarrow{f} M \xrightarrow{\mu_j} D(j) \xrightarrow{\alpha_j} E(j),$$

compares the two bracketings and gives

$$\mathrm{MorEq}_{\mathcal{C}}(L, E(j); s_j, t_j).$$

The component classifier from the original cone morphism gives $d_j \sim \lambda_j$ at the endpoint pair $(L, D(j))$. Composition congruence with the fixed right factor α_j, together with the displayed definition of λ_j^α, transports this comparison to

$$\mathrm{MorEq}_{\mathcal{C}}(L, E(j); t_j, \lambda_j^\alpha).$$

Transitivity of the morphism classifier in Definition 61.201 composes the last two comparisons and yields

$$\mathrm{MorEq}_{\mathcal{C}}(L, E(j); s_j, \lambda_j^\alpha).$$

Thus, for the fixed object j, the composite s_j supplies the required E-cone-morphism component ledger for f from λ^α to μ^α. Since j was arbitrary, these ledgers assemble with the already supplied apex morphism field into $\mathrm{ConeMor}_E(\lambda^\alpha, \mu^\alpha; f)$. □

Theorem 105.12 (CatLimit transported limiting-cone comparison)**.** *Let $\mathcal{J}$ and $\mathcal{C}$ satisfy the* $\mathsf{Cat}^{\uparrow}$ *certificate obligations, and let $D, E : \mathcal{J} \to \mathcal{C}$ be certified* $\mathsf{Functor}^{\uparrow}$ *diagrams. Suppose (α, β) is a pointwise certified diagram equivalence between D and E in the sense of Definition 105.9. Let*

$$\mathrm{LimCone}_D(L, \lambda)$$

be a certified limiting D-cone, and let λ^E be the transported E-cone obtained from the certified component composites

$$\mathrm{Comp}_{\mathcal{C}}(L, D(j), E(j); \lambda_j, \alpha_j, \lambda_j^E)$$

for every object j of $\mathcal{J}$. If

$$\mathrm{LimCone}_E(M, \mu)$$

is an independently certified limiting E-cone, then there exist comparison morphisms

$$u : L \to M \qquad \textit{and} \qquad v : M \to L$$

such that

$$\mathrm{ConeMor}_E(\lambda^E, \mu; u) \qquad \textit{and} \qquad \mathrm{ConeMor}_E(\mu, \lambda^E; v).$$

Moreover, there are composite results $c_L : L \to L$ and $c_M : M \to M$ satisfying

$$\mathrm{Comp}_{\mathcal{C}}(L, M, L; u, v, c_L) \qquad \textit{and} \qquad \mathrm{Comp}_{\mathcal{C}}(M, L, M; v, u, c_M)$$

with

$$\mathrm{MorEq}_{\mathcal{C}}(L, L; c_L, 1_L) \qquad \textit{and} \qquad \mathrm{MorEq}_{\mathcal{C}}(M, M; c_M, 1_M).$$

Proof. Apply Definition 105.10 to the pointwise certified diagram equivalence (α, β) and to the limiting D-cone $\mathrm{LimCone}_D(L, \lambda)$. The displayed component-composite ledgers for λ^E are exactly the input required by that transport theorem, so it gives

$$\mathrm{LimCone}_E(L, \lambda^E).$$

Now both limiting cones are read over the single certified diagram E:

$$\mathrm{LimCone}_E(L, \lambda^E) \qquad \text{and} \qquad \mathrm{LimCone}_E(M, \mu).$$

Apply Definition 105.6 to these two E-limiting cones. It supplies the comparison morphisms $u : L \to M$ and $v : M \to L$, the two cone-morphism ledgers over E, and composite results c_L and c_M for the two apex composites.

The identity classifiers produced by that comparison theorem are also classified in the target category certificate $\mathcal{C}$ while the cone-morphism ledgers are indexed by E. Hence the composites $u; v$ and $v; u$ are classified, under $\mathrm{MorEq}_{\mathcal{C}}$, as the respective identity morphisms 1_L and 1_M in precisely the transported target-diagram context claimed above. □

Lean4 ✓ `BEDC.Derived.CatLimitUp.CatLimitLimCone transported comparison`

Closure status for $\mathsf{NameCert}_{\mathsf{CatLimit}^{\uparrow}}$**.**

Constructive story: A categorical limit is built over an already certified category and a certified diagram by displaying a cone: an apex history, one component morphism history to each diagram value, and the comparison rows saying those components respect every diagram arrow. The carrier accepts only cones with these visible component witnesses and a limiting field that sends any other displayed cone to a comparison morphism into the apex; a cone without the component ledger or without the universal comparison row stays outside the surface, and two accepted comparisons are identified by the morphism classifier inherited from $\mathsf{Cat}^{\uparrow}$. The source is the fixed-diagram cone predicate, the pattern records identity cone morphisms, closure under composition, apex comparison identities, diagram-equivalence transport, and whiskering

descent, while the ledger keeps the apex, component composites, and universal comparison morphisms visible rather than replacing them by an external limit object. For the displayed seed surface, the name-certificate obligations are read from the same rows: a supplied limiting cone gives the carried endpoint, inherited morphism equality supplies reflexivity, symmetry, and transitivity, and the transport theorems keep carried cones and cone morphisms admitted after classifier replacement. A history h lies in the signature gap of a CatLimit$^{\uparrow}$ token p when the source-domain recognizes h as this fixed-diagram cone package, the signature relation pairs it with an answer cone and its component ledger, and the token-introduction relation names that answer as p; unfolded, h has exactly the displayed universal arrow into the limiting apex and the uniqueness comparison rows encoded by p. No standard bridge is attached here, so the outside categorical-limit reading remains only the internal Cat$^{\uparrow}$ and Functor$^{\uparrow}$ comparison surface. The chapter registers this fixed-diagram cone construction under the name CatLimit$^{\uparrow}$; the limit is a universal comparison package over existing histories, with no completeness axiom, host limit object, or external categorical library introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{CatLimit}\uparrow}$, maturePackageClosed)

Scope closed: The mature CatLimit$^{\uparrow}$ paper scope covers fixed-diagram cone comparison, transported limiting-cone comparison, natural-transformation whiskering descent, and the finite limit/colimit consumer surface over Cat$^{\uparrow}$, Functor$^{\uparrow}$, NatTrans$^{\uparrow}$, BHist, hsame, and Cont.

Formal verification: FormalStatus(NameCert$_{\mathsf{CatLimit}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.CatLimitUp.CatLimitLimCone\_transported\_comparison`

Bridge status: none

Not claimed: This chapter does not close full limit theory, a standard categorical-limit bridge, completeness for arbitrary diagrams, uniqueness beyond the displayed comparison surface, or bridge verification.

Upgrade path: No further paper theory-axis upgrade is recorded for this displayed fixed-diagram limit surface; bridgeChecked status remains separate formal-axis work.

Chapter 106

A Concrete Naming Certificate for $\mathsf{CatColimit}^{\uparrow}$

The categorical-colimit interface $\mathsf{CatColimit}^{\uparrow}$ packages a cocone over a diagram certified couniversal among all such cocones. It depends on $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62) and is dual to $\mathsf{NameCert}_{\mathsf{CatLimit}^{\uparrow}}$ (chapter 105).

106.1 Carrier definition

106.2 The certificate

Definition 106.1 (Fixed-diagram cocone comparison data)**.** *Fix a* $\mathsf{Cat}^{\uparrow}$ *certificate* $\mathcal{C}$*, an indexing category* $\mathcal{J}$*, and a certified* $\mathsf{Functor}^{\uparrow}$ *diagram* $D : \mathcal{J} \to \mathcal{C}$*. Write* $\mathrm{Mor}_{\mathcal{C}}(A, B; f)$ *for the certified assertion that* f *is a morphism* $A \to B$*,* $\mathrm{MorEq}_{\mathcal{C}}(A, B; f, g)$ *for the morphism classifier between parallel morphisms* $f, g : A \to B$*, and* $\mathrm{Comp}_{\mathcal{C}}(A, B, C; f, g, h)$ *for the certified composition witness saying that* $h : A \to C$ *classifies the composite of* $f : A \to B$ *followed by* $g : B \to C$*.*

For a D*-cocone* κ *with vertex* K*, write its component at* j *as* $\kappa_j : D(j) \to K$*. For* D*-cocones* κ *and* μ *with vertices* K *and* M*, the predicate*

$$\mathrm{CoconeMor}_D(\kappa, \mu; f)$$

means that $\mathrm{Mor}_{\mathcal{C}}(K, M; f)$ *holds and, for every object* j *of* $\mathcal{J}$*, there is a component composite* $c_j : D(j) \to M$ *such that*

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, M; \kappa_j, f, c_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), M; c_j, \mu_j).$$

A certified colimiting cocone is written

$$\mathrm{ColimCocone}_D(K, \kappa).$$

It consists of a D*-cocone* κ *with vertex* K *and the couniversal field that every* D*-cocone* χ *with vertex* X *admits a morphism* $m : K \to X$ *satisfying* $\mathrm{CoconeMor}_D(\kappa, \chi; m)$*, with any two such morphisms classified by* $\mathrm{MorEq}_{\mathcal{C}}(K, X; -, -)$*.*

Lean4 (definition) `BEDC.Derived.CatColimitUp.CatColimitCoconeMor`

Lemma 106.2 (Composition closure for cocone morphisms)**.** *Let κ, μ, ν be D-cocones with vertices K, M, N. Suppose*

$$\mathrm{CoconeMor}_D(\kappa, \mu; f)$$

for $f : K \to M$, and

$$\mathrm{CoconeMor}_D(\mu, \nu; g)$$

for $g : M \to N$. If

$$\mathrm{Comp}_{\mathcal{C}}(K, M, N; f, g, h),$$

then

$$\mathrm{CoconeMor}_D(\kappa, \nu; h).$$

Proof. The composition field of the $\mathsf{Cat}^{\uparrow}$ certificate gives $\mathrm{Mor}_{\mathcal{C}}(K, N; h)$ from the displayed composition witness and the morphism fields of f and g.

Fix an object j of $\mathcal{J}$. From $\mathrm{CoconeMor}_D(\kappa, \mu; f)$, obtain a composite $e_j : D(j) \to M$ with

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, M; \kappa_j, f, e_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), M; e_j, \mu_j).$$

From $\mathrm{CoconeMor}_D(\mu, \nu; g)$, obtain a composite $d_j : D(j) \to N$ with

$$\mathrm{Comp}_{\mathcal{C}}(D(j), M, N; \mu_j, g, d_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), N; d_j, \nu_j).$$

The associativity field of the $\mathsf{Cat}^{\uparrow}$ certificate applies to

$$D(j) \xrightarrow{\kappa_j} K \xrightarrow{f} M \xrightarrow{g} N.$$

Together with the witnesses for h as f followed by g and for e_j as κ_j followed by f, it supplies a composite $r_j : D(j) \to N$ with

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, N; \kappa_j, h, r_j)$$

and a classifier comparison between r_j and the composite of e_j followed by g. The morphism-classifier congruence field transports

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), M; e_j, \mu_j)$$

across right composition by g, giving a classifier comparison between the composite of e_j followed by g and d_j. Transitivity of $\mathrm{MorEq}_{\mathcal{C}}$ then yields

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), N; r_j, \nu_j).$$

Since j was arbitrary, the component witnesses r_j assemble the component ledger for $\mathrm{CoconeMor}_D(\kappa, \nu; h)$. □

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitCoconeMor comp closed`

Lemma 106.3 (Identity cocone morphism)**.** *If κ is a D-cocone with vertex K, then*

$$\mathrm{CoconeMor}_D(\kappa, \kappa; 1_K).$$

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitCoconeMor empty identity`

Proof. The identity field of the $\mathsf{Cat}^{\uparrow}$ certificate gives $\mathrm{Mor}_{\mathcal{C}}(K, K; 1_K)$. Fix an object j of $\mathcal{J}$. The unit field for the component $\kappa_j : D(j) \to K$ supplies a composite $c_j : D(j) \to K$ with

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, K; \kappa_j, 1_K, c_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), K; c_j, \kappa_j).$$

These witnesses, indexed by the objects of $\mathcal{J}$, give the cocone-morphism ledger for $\mathrm{CoconeMor}_D(\kappa, \kappa; 1_K)$. □

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitLimCocone endomorphism rigidity`

Theorem 106.5 (CatColimit vertex co-uniqueness from universal cocones)**.** *Let $D : \mathcal{J} \to \mathcal{C}$ be a fixed certified* $\mathsf{Functor}^{\uparrow}$ *diagram in a* $\mathsf{Cat}^{\uparrow}$ *certificate $\mathcal{C}$. If*

$$\mathrm{ColimCocone}_D(C, \kappa)$$

and

$$\mathrm{ColimCocone}_D(C', \kappa')$$

are two certified colimiting cocones over D, then there exist comparison morphisms

$$u : C \to C'$$

and

$$v : C' \to C$$

such that

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u)$$

and

$$\mathrm{CoconeMor}_D(\kappa', \kappa; v).$$

Moreover, there are composite results $c_C : C \to C$ *and* $c_{C'} : C' \to C'$ *satisfying*

$$\mathrm{Comp}_{\mathcal{C}}(C, C', C; u, v, c_C)$$

and

$$\mathrm{Comp}_{\mathcal{C}}(C', C, C'; v, u, c_{C'})$$

with

$$\mathrm{MorEq}_{\mathcal{C}}(C, C; c_C, 1_C)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(C', C'; c_{C'}, 1_{C'}).$$

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitCoconeMor composite endomorphisms empty`
Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitLimCocone comparison identities`

Proof. Apply the universal existence field of $\mathrm{ColimCocone}_D(C, \kappa)$ to the D-cocone κ' with vertex C'. This supplies a morphism $u : C \to C'$ and a cocone-morphism ledger

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u).$$

Apply the universal existence field of $\mathrm{ColimCocone}_D(C', \kappa')$ to the D-cocone κ with vertex C. This supplies a morphism $v : C' \to C$ and a cocone-morphism ledger

$$\mathrm{CoconeMor}_D(\kappa', \kappa; v).$$

The composition field of $\mathcal{C}$ supplies a composite result $c_C : C \to C$ with

$$\mathrm{Comp}_{\mathcal{C}}(C, C', C; u, v, c_C).$$

Using Definition 106.2 with the two cocone morphisms

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u)$$

and

$$\mathrm{CoconeMor}_D(\kappa', \kappa; v),$$

one obtains

$$\mathrm{CoconeMor}_D(\kappa, \kappa; c_C).$$

Now Definition 106.4, applied to $\mathrm{ColimCocone}_D(C, \kappa)$ and this cocone endomorphism, gives

$$\mathrm{MorEq}_{\mathcal{C}}(C, C; c_C, 1_C).$$

The composition field of $\mathcal{C}$ also supplies a composite result $c_{C'} : C' \to C'$ with

$$\mathrm{Comp}_{\mathcal{C}}(C', C, C'; v, u, c_{C'}).$$

Using Definition 106.2 with the two cocone morphisms

$$\mathrm{CoconeMor}_D(\kappa', \kappa; v)$$

and

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u),$$

one obtains

$$\mathrm{CoconeMor}_D(\kappa', \kappa'; c_{C'}).$$

Now Definition 106.4, applied to $\mathrm{ColimCocone}_D(C', \kappa')$ and this cocone endomorphism, gives

$$\mathrm{MorEq}_{\mathcal{C}}(C', C'; c_{C'}, 1_{C'}).$$

□

Theorem 106.6 (Cocone morphism classifier descent through natural-transformation prewhiskering)**.** *Let $\mathcal{J}$ and $\mathcal{C}$ satisfy the* $\mathsf{Cat}^{\uparrow}$ *certificate obligations. Let $D, E : \mathcal{J} \to \mathcal{C}$ be certified* $\mathsf{Functor}^{\uparrow}$ *diagrams, and let $\beta : E \Rightarrow D$ be a certified* $\mathsf{NatTrans}^{\uparrow}$ *carrier with components $\beta_j : E(j) \to D(j)$. Let κ and μ be D-cocones with vertices K and M, and let κ^β and μ^β be the corresponding E-cocones obtained by precomposing each cocone leg with the component of β:*

$$\mathrm{Comp}_{\mathcal{C}}(E(j), D(j), K; \beta_j, \kappa_j, \kappa_j^\beta) \qquad \textit{and} \qquad \mathrm{Comp}_{\mathcal{C}}(E(j), D(j), M; \beta_j, \mu_j, \mu_j^\beta)$$

for every object j of $\mathcal{J}$, with image endpoints read through the certified endpoint-transport fields. If

$$\mathrm{CoconeMor}_D(\kappa, \mu; f),$$

then

$$\mathrm{CoconeMor}_E(\kappa^\beta, \mu^\beta; f).$$

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitCoconeMor nattrans prewhiskering descent`

Proof. By Definition 63.1, each β_j is a displayed morphism $E(j) \to D(j)$ in $\mathcal{C}$, and the naturality row is the cocone-prewhiskering ledger that makes the displayed component families κ^β and μ^β into E-cocones. If an object image is represented by a classified endpoint rather than by a literal endpoint, the source-target replacement row of Definition 62.78 and the endpoint-indexed transport fields of Definition 61.201 reindex the component morphisms before the following composition ledgers are formed.

Unpack $\mathrm{CoconeMor}_D(\kappa, \mu; f)$ using Definition 106.1. It gives the vertex morphism field $\mathrm{Mor}_{\mathcal{C}}(K, M; f)$ and, for each object j of $\mathcal{J}$, a displayed composite $d_j : D(j) \to M$ such that

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, M; \kappa_j, f, d_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), M; d_j, \mu_j).$$

The same vertex morphism field is the vertex morphism required for $\mathrm{CoconeMor}_E(\kappa^\beta, \mu^\beta; f)$.

Fix j. Composition closure in Definition 61.201 supplies a composite $s_j : E(j) \to M$ of κ_j^β followed by f:

$$\mathrm{Comp}_{\mathcal{C}}(E(j), K, M; \kappa_j^\beta, f, s_j).$$

It also supplies a composite $t_j : E(j) \to M$ of β_j followed by d_j:

$$\mathrm{Comp}_{\mathcal{C}}(E(j), D(j), M; \beta_j, d_j, t_j).$$

Associativity in the same category certificate, applied to

$$E(j) \xrightarrow{\beta_j} D(j) \xrightarrow{\kappa_j} K \xrightarrow{f} M,$$

compares the two bracketings and gives

$$\mathrm{MorEq}_{\mathcal{C}}(E(j), M; s_j, t_j).$$

The component classifier from the original cocone morphism gives $d_j \sim \mu_j$ at the endpoint pair $(D(j), M)$. Composition congruence with the fixed left factor β_j, together with the displayed definition of μ_j^β, transports this comparison to

$$\mathrm{MorEq}_{\mathcal{C}}(E(j), M; t_j, \mu_j^\beta).$$

Transitivity of the morphism classifier in Definition 61.201 composes the last two comparisons and yields

$$\mathrm{MorEq}_{\mathcal{C}}(E(j), M; s_j, \mu_j^\beta).$$

Thus, for the fixed object j, the composite s_j supplies the required E-cocone-morphism component ledger for f from κ^β to μ^β. Since j was arbitrary, these ledgers assemble with the already supplied vertex morphism field into $\mathrm{CoconeMor}_E(\kappa^\beta, \mu^\beta; f)$. □

Corollary 106.7 (CatColimit comparison-fiber collapse)**.** *Let $D : \mathcal{J} \to \mathcal{C}$ be a fixed certified* $\mathsf{Functor}^\uparrow$ *diagram in a* $\mathsf{Cat}^\uparrow$ *certificate $\mathcal{C}$. Let κ be a D-cocone with vertex C, and let κ' be a D-cocone with vertex C'. If*

$$\mathrm{ColimCocone}_D(C, \kappa)$$

and if $u_1, u_2 : C \to C'$ satisfy

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u_1)$$

and

$$\mathrm{CoconeMor}_D(\kappa, \kappa'; u_2),$$

then

$$\mathrm{MorEq}_{\mathcal{C}}(C, C'; u_1, u_2).$$

Proof. Unpack the certified colimiting-cocone field from Definition 106.1. Its uniqueness clause says that, for every D-cocone χ with vertex X, any two morphisms $m_1, m_2 : C \to X$ satisfying

$$\mathrm{CoconeMor}_D(\kappa, \chi; m_1)$$

and

$$\mathrm{CoconeMor}_D(\kappa, \chi; m_2)$$

are classified by

$$\mathrm{MorEq}_{\mathcal{C}}(C, X; m_1, m_2).$$

Apply this clause with $\chi = \kappa'$, $X = C'$, $m_1 = u_1$, and $m_2 = u_2$. The two displayed cocone-morphism ledgers are exactly the hypotheses, so the required classifier is

$$\mathrm{MorEq}_{\mathcal{C}}(C, C'; u_1, u_2).$$

□

Theorem 106.8 (CatColimit transport along pointwise certified diagram equivalence)**.** *Let $\mathcal{J}$ and $\mathcal{C}$ satisfy the* $\mathsf{Cat}^{\uparrow}$ *certificate obligations, and let $D, E : \mathcal{J} \to \mathcal{C}$ be certified* $\mathsf{Functor}^{\uparrow}$ *diagrams. Suppose (α, β) is a pointwise certified diagram equivalence between D and E in the sense of Definition 105.9. If*

$$\mathrm{ColimCocone}_D(K, \kappa)$$

holds, and if κ^E is the component family obtained by certified composition

$$\mathrm{Comp}_{\mathcal{C}}(E(j), D(j), K; \beta_j, \kappa_j, \kappa^E_j)$$

for every object j of $\mathcal{J}$, with endpoints read through the certified source-target replacement fields, then

$$\mathrm{ColimCocone}_E(K, \kappa^E).$$

Lean4 ✓ `BEDC.Derived.CatColimitUp.CatColimitLimCocone transport pointwise equiv`

Proof. By Definition 105.9, the components $\alpha_j : D(j) \to E(j)$ and $\beta_j : E(j) \to D(j)$ are certified $\mathsf{NatTrans}^{\uparrow}$ component morphisms, and their pointwise composites are classified with the corresponding identities. Thus for every object j there are composites

$$\mathrm{Comp}_{\mathcal{C}}(D(j), E(j), D(j); \alpha_j, \beta_j, d_j) \quad \text{and} \quad \mathrm{MorEq}_{\mathcal{C}}(D(j), D(j); d_j, 1_{D(j)}),$$

and

$$\mathrm{Comp}_{\mathcal{C}}(E(j), D(j), E(j); \beta_j, \alpha_j, e_j) \quad \text{and} \quad \mathrm{MorEq}_{\mathcal{C}}(E(j), E(j); e_j, 1_{E(j)}).$$

The component-carrier and endpoint replacement rows are those of Definition 63.1, Definition 62.78, and Definition 61.201.

First verify that κ^E is an E-cocone. For a displayed morphism $u : j \to k$ of $\mathcal{J}$, the E-cocone law compares the composite of $E(u)$ followed by κ^E_k with κ^E_j. The defining composite for κ^E_k and associativity identify the first bracketing with the chain

$$E(j) \xrightarrow{E(u)} E(k) \xrightarrow{\beta_k} D(k) \xrightarrow{\kappa_k} K.$$

Naturality of β compares $E(u)$ followed by β_k with β_j followed by $D(u)$. Composition congruence with the fixed right factor κ_k, followed by the D-cocone law for κ, compares this chain with

$$E(j) \xrightarrow{\beta_j} D(j) \xrightarrow{\kappa_j} K,$$

which is κ^E_j by definition. Transitivity of the morphism classifier gives the E-cocone component row for κ^E.

Let χ be any E-cocone with vertex X. Define a D-component family χ^D by

$$\mathrm{Comp}_{\mathcal{C}}(D(j), E(j), X; \alpha_j, \chi_j, \chi^D_j)$$

for every object j. Naturality of α, the E-cocone law for χ, associativity, and composition congruence show that χ^D is a D-cocone with vertex X: for $u : j \to k$, the composite of $D(u)$ followed by α_k followed by χ_k is classified with the composite of α_j followed by $E(u)$ followed by χ_k, and then with α_j followed by χ_j.

The universal existence field of $\mathrm{ColimCocone}_D(K, \kappa)$ applied to this D-cocone supplies a morphism $m : K \to X$ such that

$$\mathrm{CoconeMor}_D(\kappa, \chi^D; m).$$

Unpacking Definition 106.1, for each object j there is a composite $r_j : D(j) \to X$ with

$$\mathrm{Comp}_{\mathcal{C}}(D(j), K, X; \kappa_j, m, r_j)$$

and

$$\mathrm{MorEq}_{\mathcal{C}}(D(j), X; r_j, \chi_j^D).$$

Let $s_j : E(j) \to X$ be a composite of κ_j^E followed by m. Associativity compares s_j with the composite of β_j followed by r_j. Composition congruence with the fixed left factor β_j transports $r_j \sim \chi_j^D$ to a comparison between β_j followed by r_j and β_j followed by χ_j^D. Since χ_j^D is the composite of α_j followed by χ_j, associativity rewrites the latter as $(\beta_j; \alpha_j); \chi_j$. The $E(j)$ identity row of the pointwise equivalence, composed with the fixed right factor χ_j, and the left identity row of the $\mathsf{Cat}^{\uparrow}$ certificate classify this composite with χ_j. Transitivity gives

$$\mathrm{MorEq}_{\mathcal{C}}(E(j), X; s_j, \chi_j).$$

The vertex morphism field for m is already present in $\mathrm{CoconeMor}_D(\kappa, \chi^D; m)$. Hence

$$\mathrm{CoconeMor}_E(\kappa^E, \chi; m),$$

which is the universal existence field required for the E-cocone κ^E.

It remains to verify universal uniqueness. Let $m, n : K \to X$ both satisfy

$$\mathrm{CoconeMor}_E(\kappa^E, \chi; m) \quad \text{and} \quad \mathrm{CoconeMor}_E(\kappa^E, \chi; n).$$

For m, unpack the first E-cocone-morphism ledger. For each object j there is a composite $a_j : E(j) \to X$ of κ_j^E followed by m classified with χ_j. Composition congruence with the fixed left factor α_j gives a comparison between α_j followed by a_j and α_j followed by χ_j. Using the defining composite $\kappa_j^E = \beta_j; \kappa_j$ and associativity, the left side is classified with $(\alpha_j; \beta_j); \kappa_j; m$. The $D(j)$ identity row of the pointwise equivalence, composed first with κ_j and then with m, and the left identity rows of $\mathcal{C}$, classify this with $\kappa_j; m$. The right side is χ_j^D by definition. Thus the component rows assemble with the vertex morphism field from the E-cocone morphism to give

$$\mathrm{CoconeMor}_D(\kappa, \chi^D; m).$$

The same construction applied to the ledger for n gives

$$\mathrm{CoconeMor}_D(\kappa, \chi^D; n).$$

The universal uniqueness field of $\mathrm{ColimCocone}_D(K, \kappa)$, applied to the D-cocone χ^D and these two cocone morphisms, yields

$$\mathrm{MorEq}_{\mathcal{C}}(K, X; m, n).$$

This is exactly the uniqueness field for $\mathrm{ColimCocone}_E(K, \kappa^E)$. □

Closure status for $\mathsf{NameCert}_{\mathsf{CatColimit}^{\uparrow}}$.

Constructive story: A categorical colimit is built by reversing the displayed cone direction: over a certified category and fixed certified diagram, a cocone carries a vertex history, component morphisms from each diagram value into that vertex, and comparison ledgers showing how every component factors through a cocone morphism. The carrier accepts only cocones with those visible component witnesses and a couniversal field sending the vertex to every other displayed cocone; data without the component ledger or without the couniversal comparison row are not part of this surface, and sameness of comparisons is inherited from the $\mathsf{Cat}^{\uparrow}$ morphism classifier. The source is the fixed-diagram cocone

predicate, the pattern records identity cocone morphisms, closure of cocone morphisms under composition, colimiting-cocone comparison identities, natural-transformation prewhiskering descent, and pointwise diagram-equivalence transport, while the ledger keeps vertices, component composites, and comparison arrows on the BEDC history surface. The seed obligations follow through these same rows: a supplied colimiting cocone inhabits the carried surface, morphism equality gives reflexivity, symmetry, and transitivity, and the transport theorem preserves admitted cocones and cocone morphisms under classified replacement. A history h lies in the signature gap of a CatColimit$^{\uparrow}$ token p when the source-domain admits h as this fixed-diagram cocone package, the signature relation pairs it with an answer cocone and evidence ledger, and token introduction names that answer as p; concretely, h exhibits the couniversal arrow out of the colimiting vertex and the uniqueness rows encoded by p. The pointwise diagram-equivalence transport row supplies the paper bridge surface for the fixed-diagram cocone package, but the chapter does not translate the package to a host colimit construction. It registers the dual fixed-diagram cocone construction under the name CatColimit$^{\uparrow}$; colimits here are couniversal comparison rows over existing histories, with no cocompleteness axiom, quotient vertex primitive, or external categorical library introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{CatColimit}\uparrow}$, maturePackageClosed)

Scope closed: The bridged paper scope is the fixed-diagram cocone comparison surface, identity and composition cocone morphisms, universal-cocone comparison identities, and pointwise certified diagram-equivalence transport.

Upgrade path: No paper-axis upgrade remains beyond maintaining the fixed-diagram cocone consumer catalogue.

Chapter 107

A Concrete Naming Certificate for $\mathsf{Adjunction}^{\uparrow}$

The adjunction interface $\mathsf{Adjunction}^{\uparrow}$ packages a pair of functors $F \dashv G$ between two categories together with the natural-isomorphism witness on hom-sets. It depends on $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62) and $\mathsf{NameCert}_{\mathsf{NatTrans}^{\uparrow}}$ (chapter 63), and is the canonical structure underlying free/forgetful and Galois-style correspondences.

107.1 Carrier definition

Definition 107.1 (Adjunction unit-counit carrier)**.** *For histories* $p, q, a, unit, counit, left, right$: BHist*,* $\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)$ *holds when unit is a natural-transformation prefix component from* p *to* q *at* a*, counit is the corresponding component from* q *to* p*, and the two triangle witnesses are the continuations* $\mathsf{Cont}(unit, counit, left)$ *and* $\mathsf{Cont}(counit, unit, right)$*.*

Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier`

Definition 107.2 (Adjunction unit-counit alternating ledger)**.** *For histories* $unit, counit, depth$: BHist*,* $\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth)$ *is the recursive ledger that alternates the two boundary components along a unary depth. The empty depth returns* e*, a one-headed depth appends the current unit component to the ledger with the two boundary components exchanged, and the zero-headed branch returns* e*.*

Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating`

Theorem 107.3 (Adjunction unit-counit diagonal empty components exactness)**.** *For histories* $p, q, a, composite$: BHist*,*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, \mathsf{e}, \mathsf{e}, composite, composite) \iff \mathsf{UnaryHistory}(p) \wedge \mathsf{UnaryHistory}(q) \wedge \mathsf{UnaryHistory}(a) \wedge p \sim q \wedge composite \sim \mathsf{e}.$$

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier empty components exact`

Proof. Both displayed natural-transformation components are empty identity components. Their exactness theorem gives unary histories for p, q, a and $p \sim q$. The diagonal continuation result of the two empty components is history-same as e. Conversely, $p \sim q$ supplies both empty identity components, and $composite \sim \mathsf{e}$ supplies both empty continuation witnesses. □

Theorem 107.4 (Adjunction empty unit-counit prefix exactness)**.** *For histories p, q, a : BHist, empty unit and counit prefix components, together with the empty composite continuation, are exact for unary prefixes, a unary object, and prefix equality:*

$$\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}) \wedge \mathsf{NatTransPrefixComponentCarrier}(q, p, a, \mathsf{e}) \wedge \mathsf{Cont}(\mathsf{e}, \mathsf{e}, \mathsf{e}) \iff \mathsf{Unary}(p) \wedge \mathsf{Unary}(q) \wedge \mathsf{Unary}(a) \wedge \mathsf{hsame}(p, q).$$

Proof. Each empty prefix component is read through the natural-transformation empty-identity exactness theorem. The unit component supplies the unary data and $p\mathsf{hsame}q$. Conversely, the unary data and $p\mathsf{hsame}q$ reconstruct the unit component; symmetry reconstructs the counit component; the empty composite is the reflexive continuation at e. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.Adjunction empty unit counit prefix iff`

Theorem 107.5 (Adjunction unit-counit empty component exactness)**.** *For histories $p, q, a, left, right$: BHist,*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, \mathsf{e}, \mathsf{e}, left, right)$$

holds exactly when p, q, a are unary histories, $p\mathsf{hsame}q$, and both triangle results satisfy $left\mathsf{hsame}\mathsf{e}$ and $right\mathsf{hsame}\mathsf{e}$.

Proof. Each empty component is read by the natural-transformation empty-identity theorem, yielding the unary prefix data and $p\mathsf{hsame}q$. The two triangle continuations then compare with the empty right-unit continuation. Conversely, the same unary data and prefix equality rebuild both empty component carriers, and the displayed empty triangle results rebuild the two continuations. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier empty components iff`

Theorem 107.6 (Adjunction left-cycle empty component exactness)**.** *For histories $p, q, a, unit, counit, left, right$: BHist, an adjunction unit-counit carrier whose left triangle result is empty is equivalent to unary prefix data, two-way prefix equality, and all four unit, counit, left-triangle, and right-triangle histories being empty:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right) \wedge \mathsf{hsame}(left, \mathsf{e}) \iff \mathsf{Unary}(p) \wedge \mathsf{Unary}(q) \wedge \mathsf{Unary}(a) \wedge \mathsf{hsame}(p, q) \wedge \mathsf{hsame}(q, p) \wedge \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left,$$

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier left cycle empty components iff`

Proof. The left empty triangle turns the unit-counit continuation into an empty prefix-component cycle. The prefix-cycle theorem extracts $p\mathsf{hsame}q$, $q\mathsf{hsame}p$, and empty unit and counit component histories. Reading the unit component as an empty natural-transformation identity supplies the unary witnesses for p, q, and a. The right triangle continuation then transports across the empty counit and unit witnesses to the empty continuation.

Conversely, the unary data and the two prefix equalities rebuild the empty unit and counit natural-transformation components. The empty witnesses for unit, counit, left, and right rebuild the two continuation ledgers and retain the displayed left-cycle empty witness. □

Theorem 107.7 (Adjunction right-cycle empty component exactness)**.** *For histories* $p, q, a, unit, counit, left, right$ BHist*, an adjunction unit-counit carrier whose right triangle result is empty is equivalent to unary prefix data, two-way prefix equality, and all four unit, counit, left-triangle, and right-triangle histories being empty:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right) \wedge \mathsf{hsame}(right, \mathsf{e})$$
$$\iff \mathsf{Unary}(p) \wedge \mathsf{Unary}(q) \wedge \mathsf{Unary}(a) \wedge \mathsf{hsame}(p, q) \wedge \mathsf{hsame}(q, p) \wedge \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left,$$

Proof. Exchange the unit and counit component rows and read the right triangle as the left triangle of the exchanged carrier. The left-cycle exactness theorem extracts the unary witnesses, the two prefix equalities, and the empty component histories. Reassembling the component rows in the original order gives the displayed equivalence. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier right cycle empty components iff`

Theorem 107.8 (Adjunction unit-counit triangle result determinism)**.** *If an adjunction unit-counit carrier displays triangle results* $left$ *and* $right$*, then any other continuations with the same unit-counit inputs display the same results up to* hsame*.*

Proof. Project the two continuation witnesses from the carrier and apply continuation determinism separately to the left and right triangle rows. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier triangle results deterministic`

Theorem 107.9 (Adjunction unit-counit triangle results coincide)**.** *Let* $unit : p \Rightarrow q$ *and* $counit : q \Rightarrow p$ *be prefix natural-transformation components at* a*. If the two triangle ledgers are displayed by*

$$\mathsf{Cont}(unit, counit, left) \qquad \textit{and} \qquad \mathsf{Cont}(counit, unit, right),$$

then $left\,\mathsf{hsame}\,right$*.*

Proof. The first continuation is a vertical composite prefix component from p to p, hence the endomorphism component exactness identifies $left$ with e. The second continuation is the symmetric composite from q to q, so the same exactness identifies $right$ with e. Transitivity of hsame gives $left\,\mathsf{hsame}\,right$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitTriangle results hsame`

Theorem 107.10 (Adjunction unit-counit endomorphism boundary emptiness)**.** *For histories* $p, a, unit, counit, left, right$: BHist*, if*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right),$$

then both boundary components are empty:

$$\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}).$$

Proof. Both displayed boundary components are prefix natural-transformation endomorphism components over the same prefix p and object a. The component exactness readback identifies the unit component with e and then identifies the counit component with e. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier endomorphism unit counit empty`

Theorem 107.11 (Adjunction unit-counit alternating unary)**.** *If unit, counit, and depth are unary histories, then the alternating unit-counit ledger*

$$\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth)$$

is unary.

Proof. Induct on the unary depth. The empty depth yields the empty ledger. A zero-headed depth is impossible for a unary history. In the one-headed case, the recursive tail is unary by the induction hypothesis with *unit* and *counit* exchanged, and unary append closure combines it with the unary front component. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating unary`

Theorem 107.12 (Adjunction alternating zero-headed result exclusion)**.** *For an adjunction unit-counit carrier, unary depth makes the alternating unit-counit ledger unary. Therefore it cannot be history-same to a zero-headed result:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right) \wedge \mathsf{Unary}(depth) \wedge \mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}$$

Proof. The unit and counit components of the displayed carrier are natural transformation component histories, hence each component history is unary. Together with unary depth, the alternating unary theorem makes the displayed alternating ledger unary. Transporting unary membership across the result hsame would make $\mathsf{E0}(z)$ unary, contradicting unary zero-headed exclusion. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier alternating zero headed result absurd`

Theorem 107.13 (Adjunction positive-depth alternating unit nonempty)**.** *For histories* $unit, counit, depth : \mathsf{BHist}$*, suppose depth is unary, depth is not history-same as* e*, and unit is not history-same as* e*. Then the alternating unit-counit ledger at that depth is not history-same as* e*:*

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{e}) \to \bot.$$

Proof. Unary nonempty depth has a one-headed tail. At such a depth the alternating ledger unfolds to an append whose left component is *unit*. Append nonemptiness therefore follows from the nonempty unit component. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating result nonempty of positive depth unit nonempty`

Theorem 107.14 (Adjunction positive-depth alternating continuation readback)**.** *For histories* $unit, counit, depth : \mathsf{BHist}$*, suppose depth is unary and not history-same as* e*. Then there is a unary tail tail such that the alternating unit-counit ledger at depth is displayed by the first continuation step*

$$\mathsf{Cont}(unit, \mathsf{AdjunctionUnitCounitAlternating}(counit, unit, tail), \mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth)$$

Proof. Unary nonempty depth has a one-headed tail. Unfolding the alternating ledger at that one-headed branch exposes exactly the continuation append whose left component is *unit* and whose right component is the alternating ledger with the boundary components exchanged. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating positive depth cont readback`

Theorem 107.15 (Adjunction alternating append positive suffix continuation readback)**.** *If $suffix$ is unary and not history-same as* e*, then the alternating unit-counit ledger over* $\mathsf{append}(pref, suffix)$ *exposes a successor continuation with the same prefix inside the exchanged tail:*

$$\exists tail.\ \mathsf{Unary}(tail) \wedge \mathsf{Cont}(unit, \mathsf{AdjunctionUnitCounitAlternating}(counit, unit, \mathsf{append}(pref, tail)), \mathsf{AdjunctionUnitCour}$$

Proof. Unary nonempty suffixes have a one-headed tail. Substituting $suffix = \mathsf{E1}(tail)$ makes the appended depth one-headed with payload $\mathsf{append}(pref, tail)$. The alternating ledger unfolds at that branch to append *unit* to the exchanged alternating tail, which is exactly the displayed continuation. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating append positive suffix cont readback`

Theorem 107.16 (Adjunction append-positive suffix empty result forces empty unit)**.** *If $suffix$ is unary and not history-same as* e*, then an empty result for the alternating unit-counit ledger over* $\mathsf{append}(pref, suffix)$ *forces the visible unit component to be empty:*

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, \mathsf{append}(pref, suffix)), \mathsf{e}) \Longrightarrow \mathsf{hsame}(unit, \mathsf{e}).$$

Proof. The append-positive suffix readback writes the displayed alternating ledger as a continuation whose left endpoint is *unit*. Transporting that continuation to the empty result and applying empty-result inversion for continuation forces the left endpoint *unit* to be empty. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating append positive suffix result empty unit empty`

Theorem 107.17 (Adjunction positive-tail empty result forces empty components)**.** *Suppose depth is unary, depth* $= \mathsf{E1}(tail)$*, tail is unary, and tail is not history-same as* e*. If the alternating unit-counit ledger at depth is history-same as* e*, then both displayed components are empty:*

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{e}) \Longrightarrow \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}).$$

Proof. Substitute $depth = \mathsf{E1}(tail)$ and unfold the positive branch of the alternating ledger. Empty append inversion gives *unit*hsamee and an empty result for the exchanged alternating ledger over *tail*. Since *tail* is unary and nonempty, the positive-depth empty-result readback applied to that exchanged ledger gives *counit*hsamee. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating positive tail result empty components empty`

Theorem 107.18 (Adjunction positive-depth empty result forces empty unit)**.** *For unary nonempty depth, if the alternating unit-counit ledger is history-same as* e*, then the visible unit component is history-same as* e*:*

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{e}) \quad \Longrightarrow \quad \mathsf{hsame}(unit, \mathsf{e}).$$

Proof. Positive-depth continuation readback writes the alternating ledger as a continuation whose left component is *unit*. Transporting this continuation along the empty result and applying empty-result inversion forces the left component to be empty. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating positive depth result empty unit empty`

Theorem 107.19 (Adjunction positive-depth empty alternating prefix readback)**.** *For histories* $p, q, a, unit, counit, left, right, depth : \mathsf{BHist}$*, suppose an adjunction unit-counit carrier holds, depth is unary and nonempty, and the alternating unit-counit ledger is history-same to* e*. Then the source and target prefixes of the unit component are history-same:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right) \wedge \mathsf{Unary}(depth) \wedge (\mathsf{hsame}(depth, \mathsf{e}) \to \bot) \wedge \mathsf{hsame}(\mathsf{Adjuncti}$$

Proof. The positive-depth empty-result readback forces $unit\mathsf{hsamee}$. Transporting the unit component to the empty component case lets natural-transformation empty-identity exactness read back the endpoint-prefix equality $\mathsf{hsame}(p, q)$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier alternating positive depth empty prefix same`

Theorem 107.20 (Adjunction visible unit positive-depth empty-result exclusion)**.** *For unary nonempty depth, an alternating unit-counit ledger whose displayed unit component has a visible head cannot continue to an empty result:*

$$\mathsf{Cont}(\mathsf{AdjunctionUnitCounitAlternating}(\mathsf{E0}(unit), counit, depth), y, r) \wedge r\mathsf{hsamee} \Longrightarrow \bot,$$

and the same statement holds with $\mathsf{E1}(unit)$ *in place of* $\mathsf{E0}(unit)$*.*

Proof. Transport the continuation along $r\mathsf{hsamee}$ and invert the empty result. The positive-depth empty-result readback then forces the visible unit component itself to be history-same to e, contradicting constructor separation. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating positive depth visible unit continuation empty result absurd`

Theorem 107.21 (Adjunction positive-depth unit-empty readback)**.** *For unary nonempty depth, if* $unit\mathsf{hsamee}$*, then the alternating unit-counit ledger at depth is history-same to the tail readback with the boundary components exchanged: there is a unary tail such that*

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{AdjunctionUnitCounitAlternating}(counit, unit, tail)).$$

Proof. Positive-depth continuation readback supplies a unary tail and a continuation from *unit* into the exchanged alternating tail. Replacing *unit* by e turns that continuation into the left-unit law, so its result reads back to the exchanged tail. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating positive depth unit empty readback`

Theorem 107.22 (Adjunction unit-counit alternating empty components closed)**.** *If both boundary components are empty and depth is unary, then the alternating unit-counit ledger is empty:*

$$\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{Unary}(depth) \quad \Longrightarrow \quad \mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth$$

Proof. Induct on the unary depth. The empty depth returns the empty ledger, while a zero-headed depth is incompatible with unary history. In the one-headed case, the recursion exchanges the empty unit and counit components; the induction hypothesis collapses the tail ledger, and append by the empty front component keeps the endpoint empty. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating empty components closed`

Theorem 107.23 (Adjunction unit-counit alternating endomorphism empty)**.** *For histories* $p, a, unit, counit, left,$ BHist*, if*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

and depth is unary, then the alternating unit-counit ledger is empty:

$$\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{e}).$$

Proof. The endomorphism boundary theorem identifies both boundary components with e. Induct on the unary depth. The empty depth is immediate. In the one-headed case, the recursive ledger has the boundary components exchanged; the induction hypothesis collapses that tail ledger to e, and the outer append by the empty unit component preserves the empty endpoint. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitAlternating endomorphism empty`

Theorem 107.24 (Adjunction unit-counit endomorphism triangle emptiness)**.** *For histories* $p, a, unit, counit, left,$ BHist*, if*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right),$$

then both triangle legs are empty:

$$\mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(right, \mathsf{e}).$$

Proof. The endomorphism boundary theorem first identifies both *unit* and *counit* with e. Continuation transport carries the two displayed triangle continuations to the right-unit continuation at e, yielding empty left and right triangle results. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier endomorphism triangles empty`

Theorem 107.25 (Adjunction unit-counit endomorphism empty components iff)**.** *For histories* $p, a, unit, counit, left, right$: BHist*, the endomorphism adjunction unit-counit carrier is equivalent to unary data for p, a, unit, and counit, together with empty unit, counit, left triangle, and right triangle components:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

$$\iff \mathsf{Unary}(p) \wedge \mathsf{Unary}(a) \wedge \mathsf{Unary}(unit) \wedge \mathsf{Unary}(counit) \wedge \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(righ$$

Proof. The forward direction decomposes the two endomorphism natural-transformation components, yielding the unary witnesses and the empty unit and counit witnesses. The triangle-empty theorem supplies the two displayed triangle results. Conversely, empty unit and counit components rebuild the two endomorphism natural-transformation carriers, and the empty triangle witnesses rebuild the two continuation legs. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier endomorphism empty components iff`

Theorem 107.26 (Adjunction unit-counit endomorphism total collapse)**.** *For histories* $p, a, unit, counit, left, righ$ BHist*, if*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right),$$

then all four endomorphism fields are empty:

$$\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(right, \mathsf{e}).$$

Proof. Apply Theorem 107.10 to the displayed carrier. This gives the two boundary witnesses $\mathsf{hsame}(unit, \mathsf{e})$ and $\mathsf{hsame}(counit, \mathsf{e})$.

Apply Theorem 107.24 to the same carrier. This gives the two triangle-leg witnesses $\mathsf{hsame}(left, \mathsf{e})$ and $\mathsf{hsame}(right, \mathsf{e})$.

Combining the two boundary witnesses with the two triangle-leg witnesses assembles the displayed four-fold conjunction. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier endomorphism total collapse`

Theorem 107.27 (Adjunction unit-counit endomorphism total alternating collapse)**.** *For histories* $p, a, unit, counit, left, right, depth : \mathsf{BHist}$*, if*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

and $\mathsf{UnaryHistory}(depth)$*, then the endomorphism boundary, triangle, and alternating ledger all collapse to the empty history:*

$$\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(right, \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, cou$$

Proof. Apply Theorem 107.10 to the displayed carrier. This gives the two boundary witnesses $\mathsf{hsame}(unit, \mathsf{e})$ and $\mathsf{hsame}(counit, \mathsf{e})$.

Apply Theorem 107.24 to the same carrier. This gives the two triangle-leg witnesses $\mathsf{hsame}(left, \mathsf{e})$ and $\mathsf{hsame}(right, \mathsf{e})$.

Apply Theorem 107.23 to the displayed carrier and the unary-depth witness. This gives the alternating-ledger witness $\mathsf{hsame}(\mathsf{AdjunctionUnitCounitAlternating}(unit, counit, depth), \mathsf{e})$.

The five witnesses assemble the displayed conjunction, giving the total endomorphism collapse including the alternating ledger. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier endomorphism total alternating collapse`

Definition 107.28 (Adjunction composition pasting data)**.** *Fix histories*

$$p_1, q_1, a_1, u_1, c_1, l_1, r_1, p_2, q_2, a_2, u_2, c_2, l_2, r_2, p_{21}, q_{21}, s_u, s_c, a, \tilde{u}_1, \tilde{u}_2, \tilde{c}_1, \tilde{c}_2, u_{21}, c_{21}, l_{21}, r_{21} : \mathsf{Hist}.$$

An adjunction composition pasting datum is the following finite family of generated judgments:

1. *the two input unit-counit carriers*

$$\mathrm{AdjunctionUnitCounitCarrier}(p_1, q_1, a_1, u_1, c_1, l_1, r_1)$$

and

$$\mathrm{AdjunctionUnitCounitCarrier}(p_2, q_2, a_2, u_2, c_2, l_2, r_2);$$

2. *the two whiskered unit-component rows*

$$\mathrm{NatTransPrefixComponentCarrier}(p_{21}, s_u, a, \tilde{u}_1), \qquad \mathrm{NatTransPrefixComponentCarrier}(s_u, q_{21}, a, \tilde{u}_2);$$

3. *the two whiskered counit-component rows*

$$\mathrm{NatTransPrefixComponentCarrier}(q_{21}, s_c, a, \tilde{c}_1), \qquad \mathrm{NatTransPrefixComponentCarrier}(s_c, p_{21}, a, \tilde{c}_2);$$

4. the two vertical-composition ledgers

$$\mathsf{Cont}(\tilde{u}_1, \tilde{u}_2, u_{21}), \qquad \mathsf{Cont}(\tilde{c}_1, \tilde{c}_2, c_{21});$$

5. the two composite triangle ledgers

$$\mathsf{Cont}(u_{21}, c_{21}, l_{21}), \qquad \mathsf{Cont}(c_{21}, u_{21}, r_{21}).$$

The categorical reading is that p_{21} displays the composite left functor $F_2 \circ F_1$, q_{21} displays the composite right functor $G_1 \circ G_2$, u_{21} displays the vertically composed unit $(G_1\eta_2F_1) \circ \eta_1$, and c_{21} displays the vertically composed counit $\varepsilon_2 \circ (F_2\varepsilon_1G_2)$.

Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionCompositionPastingData`

Theorem 107.29 (Composition of adjunction unit-counit carriers)**.** *Every adjunction composition pasting datum of Definition 107.28 determines a composite unit-counit carrier*

$$\mathrm{AdjunctionUnitCounitCarrier}(p_{21}, q_{21}, a, u_{21}, c_{21}, l_{21}, r_{21}).$$

Thus the BEDC display of $F_2 \circ F_1$ and $G_1 \circ G_2$ carries an $\mathsf{Adjunction}^{\uparrow}$ unit-counit certificate with unit and counit obtained by whiskering and vertical composition.

Proof. Project the two unit-component rows from the pasting datum:

$$\mathrm{NatTransPrefixComponentCarrier}(p_{21}, s_u, a, \tilde{u}_1)$$

and

$$\mathrm{NatTransPrefixComponentCarrier}(s_u, q_{21}, a, \tilde{u}_2).$$

Project also the displayed vertical-composition ledger

$$\mathsf{Cont}(\tilde{u}_1, \tilde{u}_2, u_{21}).$$

The vertical composition closure theorem for $\mathsf{NatTrans}^{\uparrow}$ prefix components applies to these two consecutive components with common middle prefix s_u and common object history a. It returns

$$\mathrm{NatTransPrefixComponentCarrier}(p_{21}, q_{21}, a, u_{21}).$$

Project the two counit-component rows from the pasting datum:

$$\mathrm{NatTransPrefixComponentCarrier}(q_{21}, s_c, a, \tilde{c}_1)$$

and

$$\mathrm{NatTransPrefixComponentCarrier}(s_c, p_{21}, a, \tilde{c}_2).$$

Project also the displayed vertical-composition ledger

$$\mathsf{Cont}(\tilde{c}_1, \tilde{c}_2, c_{21}).$$

The same $\mathsf{NatTrans}^{\uparrow}$ vertical composition closure theorem, now applied with common middle prefix s_c and common object history a, returns

$$\mathrm{NatTransPrefixComponentCarrier}(q_{21}, p_{21}, a, c_{21}).$$

The pasting datum supplies the two composite triangle ledgers

$$\mathsf{Cont}(u_{21}, c_{21}, l_{21})$$

and

$$\mathsf{Cont}(c_{21}, u_{21}, r_{21}).$$

By Definition 107.1, an adjunction unit-counit carrier consists precisely of a prefix natural-transformation component from the left prefix to the right prefix, a prefix natural-transformation component from the right prefix to the left prefix, and the two displayed continuation triangle ledgers. The four judgments just constructed and projected instantiate those four fields at $(p_{21}, q_{21}, a, u_{21}, c_{21}, l_{21}, r_{21})$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionCompositionPasting unit counit carrier`
Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier composition pasting closed`

Proposition 107.30 (Composite unit and counit empty readback)**.** *For every adjunction composition pasting datum of Definition 107.28, the following two readback implications hold:*

$$\mathsf{hsame}(u_{21}, e) \Longrightarrow \mathsf{hsame}(\tilde{u}_1, e) \wedge \mathsf{hsame}(\tilde{u}_2, e) \wedge \mathsf{hsame}(p_{21}, s_u) \wedge \mathsf{hsame}(s_u, q_{21}),$$

and

$$\mathsf{hsame}(c_{21}, e) \Longrightarrow \mathsf{hsame}(\tilde{c}_1, e) \wedge \mathsf{hsame}(\tilde{c}_2, e) \wedge \mathsf{hsame}(q_{21}, s_c) \wedge \mathsf{hsame}(s_c, p_{21}).$$

Proof. Project the unit-component rows

$$\mathrm{NatTransPrefixComponentCarrier}(p_{21}, s_u, a, \tilde{u}_1)$$

and

$$\mathrm{NatTransPrefixComponentCarrier}(s_u, q_{21}, a, \tilde{u}_2),$$

together with the unit vertical-composition ledger

$$\mathsf{Cont}(\tilde{u}_1, \tilde{u}_2, u_{21}).$$

The vertical-composite empty-result exactness theorem for $\mathsf{NatTrans}^{\uparrow}$ prefix components states that, for these consecutive component rows, the assertion $\mathsf{hsame}(u_{21}, e)$ is equivalent to the conjunction

$$\mathsf{hsame}(\tilde{u}_1, e) \wedge \mathsf{hsame}(\tilde{u}_2, e) \wedge \mathsf{hsame}(p_{21}, s_u) \wedge \mathsf{hsame}(s_u, q_{21}).$$

Taking the forward implication of that equivalence gives the first displayed readback. Project the counit-component rows

$$\mathrm{NatTransPrefixComponentCarrier}(q_{21}, s_c, a, \tilde{c}_1)$$

and

$$\mathrm{NatTransPrefixComponentCarrier}(s_c, p_{21}, a, \tilde{c}_2),$$

together with the counit vertical-composition ledger

$$\mathsf{Cont}(\tilde{c}_1, \tilde{c}_2, c_{21}).$$

Applying the same vertical-composite empty-result exactness theorem to these consecutive component rows states that $\mathsf{hsame}(c_{21}, e)$ is equivalent to

$$\mathsf{hsame}(\tilde{c}_1, e) \wedge \mathsf{hsame}(\tilde{c}_2, e) \wedge \mathsf{hsame}(q_{21}, s_c) \wedge \mathsf{hsame}(s_c, p_{21}).$$

The forward implication of this equivalence is the second displayed readback. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionCompositionPasting empty readback`

Corollary 107.31 (Composite triangle result determinacy)**.** *For every adjunction composition pasting datum of Definition 107.28, if histories l'_{21} and r'_{21} satisfy*

$$\mathsf{Cont}(u_{21}, c_{21}, l'_{21})$$

and

$$\mathsf{Cont}(c_{21}, u_{21}, r'_{21}),$$

then

$$\mathsf{hsame}(l_{21}, l'_{21}) \wedge \mathsf{hsame}(r_{21}, r'_{21}).$$

Proof. The pasting datum supplies

$$\mathsf{Cont}(u_{21}, c_{21}, l_{21})$$

and the hypothesis supplies

$$\mathsf{Cont}(u_{21}, c_{21}, l'_{21}).$$

Continuation determinacy applied to these two continuation witnesses with the same source history u_{21} and the same right history c_{21} yields

$$\mathsf{hsame}(l_{21}, l'_{21}).$$

The pasting datum also supplies

$$\mathsf{Cont}(c_{21}, u_{21}, r_{21})$$

and the hypothesis supplies

$$\mathsf{Cont}(c_{21}, u_{21}, r'_{21}).$$

Continuation determinacy applied to these two continuation witnesses with the same source history c_{21} and the same right history u_{21} yields

$$\mathsf{hsame}(r_{21}, r'_{21}).$$

The two history-sameness witnesses form the displayed conjunction. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionCompositionPasting triangle determinacy`
Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionCompositionPasting triangle results deterministic`

Definition 107.32 (Adjunction triangle carrier)**.** *For histories $left$, $right$, $object$, $unit$, $counit$, $leftLeg$, and $rightLeg$, the adjunction triangle carrier consists of a prefix natural transformation component from $left$ to $right$, a prefix natural transformation component from $right$ to $left$, and the two continuation ledgers*

$$\mathsf{Cont}(unit, counit, leftLeg), \qquad \mathsf{Cont}(counit, unit, rightLeg).$$

Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier`

Theorem 107.33 (Adjunction triangle carrier zero-headed component impossibility)**.** *For histories $left, right, object, unit, counit, leftLeg, rightLeg : \mathsf{BHist}$, an adjunction triangle carrier has no zero-headed displayed component among its prefixes, object, unit, counit, or triangle legs.*

Proof. The prefix, object, unit, and counit cases are rejected by the natural-transformation prefix-component zero-headed impossibility theorem applied to one of the two component rows. For the two triangle legs, the unit and counit component rows supply unary histories for the component histories; unary continuation closure makes the leg result unary, contradicting unary zero-headed exclusion. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier zero headed component absurd`

Theorem 107.34 (Adjunction empty roundtrip prefix determinacy)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, if an adjunction triangle carrier has both roundtrip legs* hsame *to* e*, then its two prefix histories are classifier-equal:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow \mathsf{hsame}(leftLeg, \mathsf{e}) \Longrightarrow \mathsf{hsame}(rig$$

Proof. The empty left roundtrip continuation collapses both *unit* and *counit* to e, and the empty right roundtrip gives the same collapse in the opposite order. The prefix component identity exactness theorem applied to the empty *unit* component yields $\mathsf{hsame}(left, right)$; applying it to the empty *counit* component gives the reverse classifier equality, so the two displayed roundtrip collapses agree on the same prefix pair. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier empty roundtrip prefix deterministic`

Theorem 107.35 (Adjunction roundtrip emptiness component exactness)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, an adjunction triangle carrier has both roundtrip legs* hsame *to* e *exactly when its displayed unit and counit histories are both* hsame *to* e*:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow (\mathsf{hsame}(leftLeg, \mathsf{e}) \wedge \mathsf{hsame}(rightL$$

Proof. For the forward direction, an empty left roundtrip continuation inverts the continuation ledger and forces both *unit* and *counit* to be e. For the reverse direction, transport the two triangle-leg continuations along the empty component witnesses and compare them with the empty-empty continuation unit law. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier roundtrip empty iff components empty`

Theorem 107.36 (Adjunction triangle single-boundary total collapse)**.** *For histories* $left, right, object, unit, coun$ BHist*, a single empty boundary component in an adjunction triangle carrier forces the whole displayed triangle to collapse to the empty endpoint package:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow (\mathsf{hsame}(unit, \mathsf{e}) \vee \mathsf{hsame}(counit, \mathsf{e})$$

Proof. Case on the displayed boundary disjunction. In the *unit*-empty case, the natural-transformation empty-identity exactness theorem applied to the unit component reads the two endpoint prefixes as $\mathsf{hsame}(left, right)$. Transport the counit component row across this endpoint equality; after transport, the counit row is an endomorphism component, and endomorphism-component empty exactness gives $\mathsf{hsame}(counit, \mathsf{e})$.

Now the two component witnesses satisfy the right side of Theorem 107.35. The reverse direction of that theorem gives empty *leftLeg* and *rightLeg* witnesses. The prefix equality is also recovered from Theorem 107.38, so the five displayed conclusions pack together.

In the *counit*-empty case, exchange the two component rows and the two continuation ledgers. The same endpoint readback, transport to an endomorphism component, roundtrip-empty exactness, and component-empty prefix determinacy produce the corresponding *unit* witness, both empty triangle legs, and $\mathsf{hsame}(left, right)$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier single boundary total collapse`

Theorem 107.37 (Adjunction triangle single-leg empty equivalence)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, an adjunction triangle carrier makes either empty triangle leg determine the other:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow (\mathsf{hsame}(leftLeg, \mathsf{e}) \Longleftrightarrow \mathsf{hsame}(rig$$

Proof. Fix the carrier. For the forward direction, invert the left continuation ledger $\mathsf{Cont}(unit, counit, leftLeg)$ after transporting the displayed $leftLeg$ witness to e. This gives $\mathsf{hsame}(unit, \mathsf{e})$ and $\mathsf{hsame}(counit, \mathsf{e})$. Apply the reverse direction of Theorem 107.35 and project the resulting $rightLeg$ witness.

For the reverse direction, use the right continuation ledger $\mathsf{Cont}(counit, unit, rightLeg)$ first. The same inversion gives empty *unit* and *counit* witnesses, the reverse direction of Theorem 107.35 rebuilds the pair of empty triangle legs, and projecting gives the displayed $leftLeg$ witness. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier single leg empty iff`

Theorem 107.38 (Adjunction triangle empty components prefix determinacy)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, an adjunction triangle carrier whose displayed unit and counit components are both* hsame *to* e *has equal endpoint prefixes:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow \mathsf{hsame}(unit, \mathsf{e}) \Longrightarrow \mathsf{hsame}(counit,$$

Proof. Transport the two triangle-leg continuations along the empty unit and counit component witnesses. Both roundtrip legs become hsame to the empty continuation result, and the roundtrip prefix determinacy theorem identifies the two endpoint prefixes. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier components empty prefix deterministic`

Theorem 107.39 (Adjunction roundtrip empty component-prefix readback)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, an adjunction triangle carrier whose two roundtrip legs are* hsame *to* e *has empty displayed components and equal endpoint prefixes:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow \mathsf{hsame}(leftLeg, \mathsf{e}) \Longrightarrow \mathsf{hsame}(righ$$

Proof. The roundtrip emptiness component exactness theorem reads the two empty legs back to empty *unit* and *counit* components. The empty roundtrip prefix determinacy theorem applied to the same carrier and leg witnesses identifies the two endpoint prefixes. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier roundtrip empty component prefix readback`

Theorem 107.40 (Adjunction triangle roundtrip total collapse)**.** *For histories left, right, object, unit, counit, leftLeg, and rightLeg, every adjunction triangle carrier has empty displayed components, empty roundtrip legs, and equal endpoint prefixes:*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge$$

Proof. Apply the prefix unit-counit composite empty theorem to the *unit* followed by *counit* and again in the reverse order. These two applications make both roundtrip legs hsame to e. The roundtrip empty component-prefix readback theorem then recovers empty *unit* and *counit* components and the endpoint prefix equality. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier roundtrip total collapse`

Corollary 107.41 (Adjunction triangle empty-roundtrip consumer determinacy)**.** *For histories $left$, $right$, $object$, $unit$, $counit$, $leftLeg$, and $rightLeg$, fix the displayed adjunction triangle row*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg)$$

and the two empty roundtrip rows $\mathsf{hsame}(leftLeg, \mathsf{e})$ *and* $\mathsf{hsame}(rightLeg, \mathsf{e})$*. In this corollary, an accepted empty-roundtrip consumer use means a use whose admission data are exactly these three local rows. Then every accepted empty-roundtrip consumer use has the same determined readback*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \wedge \mathsf{hsame}(leftLeg, \mathsf{e}) \wedge \mathsf{hsame}(rightLeg$$
$$\Longrightarrow \mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left, right).$$

Consequently the finite consumer route is the carrier row, the two empty roundtrip rows, the component-exactness readback, and the prefix-determinacy readback. The exactness decision is the pair $\mathsf{hsame}(unit, \mathsf{e})$ *and* $\mathsf{hsame}(counit, \mathsf{e})$*; the prefix decision is* $\mathsf{hsame}(left, right)$*; and the empty display normal form is* $(left, left, object, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$*. No accepted use with the same fixed rows may choose a second component source, an alternate prefix coordinate, or a duplicate classifier source outside those displayed rows.*

Proof. Let an accepted empty-roundtrip consumer use be given. By its admission data it has the adjunction triangle carrier row and the two witnesses $\mathsf{hsame}(leftLeg, \mathsf{e})$ and $\mathsf{hsame}(rightLeg, \mathsf{e})$.

Apply Definition 107.35 in the forward direction. This reads the two empty roundtrip rows back to the unique displayed component-exactness decision $\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e})$.

Apply Definition 107.34 to the same carrier row and the same two empty roundtrip rows. This reads the endpoint prefixes through the unique local prefix decision $\mathsf{hsame}(left, right)$. Together with the original empty witnesses for $leftLeg$ and $rightLeg$, these three conclusions classify the display by the tuple $(left, left, object, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$.

Every conclusion used by the consumer has therefore been obtained from the same three admission rows through the two cited local readback theorems. A purported alternate component source would have to bypass the component exactness readback; an alternate prefix coordinate would have to bypass prefix determinacy; and a duplicate classifier source would have to add a coordinate not present in the carrier row or in the two empty roundtrip rows. Such a row is not part of the accepted empty-roundtrip consumer use, so the displayed route, normal form, and exactness decision are determined. □

107.2 The certificate

Theorem 107.42 (Adjunction prefix unit-counit empty composite)**.** *For histories $p, q, a, \eta, \varepsilon, composite$:* BHist*, if η is a prefix natural-transformation component from p to q at a, ε is a prefix component from q back to p at a, and* $\mathsf{Cont}(\eta, \varepsilon, composite)$*, then the composite is an endomorphism component over p and is* hsame *to* e*.*

Proof. Vertical composition closure turns the unit and counit prefix components into a prefix component from p to p at a. The endomorphism-component readback for prefix natural transformations identifies the displayed component history with the empty history. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionPrefix unit counit composite empty`

Theorem 107.43 (Adjunction prefix endomorphism triangle component closure)**.** *For histories $p, a, \eta, \varepsilon, left, right$, suppose*

$$\mathsf{NatTransPrefixComponentCarrier}(p, p, a, \eta), \qquad \mathsf{NatTransPrefixComponentCarrier}(p, p, a, \varepsilon),$$

and suppose the two triangle composites are witnessed by

$$\mathsf{Cont}(\eta, \varepsilon, left), \qquad \mathsf{Cont}(\varepsilon, \eta, right).$$

Then both composites are again endomorphism components at the same prefix and object, and the two displayed composite histories classify together:

$$\mathsf{NatTransPrefixComponentCarrier}(p, p, a, left) \wedge \mathsf{NatTransPrefixComponentCarrier}(p, p, a, right) \wedge \mathsf{hsame}(left, right).$$

Proof. Endomorphism component exactness collapses both η and ε to the empty component while retaining the prefix and object carriers. The two continuation ledgers therefore collapse $left$ and $right$ to the empty history. Unary continuation closure supplies the component carriers for $left$ and $right$, and transitivity through the empty history gives $\mathsf{hsame}(left, right)$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionPrefix endomorphism triangle component closed`

Theorem 107.44 (Adjunction prefix endomorphism triangle identity exactness)**.** *For histories $p, a, f, \eta, \epsilon, left, right : \mathsf{BHist}$, assume η and ϵ are prefix natural-transformation components from p to p at a, and assume f is a category hom-carrier from $\mathsf{append}(p, a)$ to itself. If*

$$\mathsf{Cont}(\eta, f, left)$$

and

$$\mathsf{Cont}(f, \epsilon, right)$$

hold, then both triangle composites are exactly the displayed endomorphism:

$$\mathsf{hsame}(left, f) \wedge \mathsf{hsame}(right, f).$$

Proof. The prefix-component endomorphism exactness theorem identifies both η and ϵ with the empty component. Transport the two displayed continuations across these endpoint equalities. The left composite is then a left-unit continuation, and the right composite is a right-unit continuation, so the two unit laws identify the results with f. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionPrefixEndomorphismTriangle identity exactness`

Theorem 107.45 (Adjunction prefix component empty cycle)**.** *For prefix components over a common object a, let η run from p to q and let θ run from q back to p. If*

$$\mathsf{Cont}(\eta, \theta, composite) \quad \textit{and} \quad \mathsf{hsame}(composite, \mathsf{e}),$$

then both prefixes agree in both directions and both component histories are empty:

$$\mathsf{hsame}(p, q) \wedge \mathsf{hsame}(q, p) \wedge \mathsf{hsame}(\eta, \mathsf{e}) \wedge \mathsf{hsame}(\theta, \mathsf{e}).$$

Proof. Transport the displayed component cycle to an empty continuation result. The empty vertical-composite exactness theorem for NatTrans prefix components then identifies both component histories with e and extracts the two adjacent prefix equalities. Reordering those four facts gives the stated adjunction cycle boundary. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionPrefixComponent cycle empty prefix same`

Theorem 107.46 (Adjunction triangle carrier carrier-swap symmetry)**.** *For histories $left$, $right$, $object$, $unit$, $counit$, $leftLeg$, and $rightLeg$, the adjunction triangle carrier is invariant under exchanging the two carrier sides together with the unit-counit data and the two triangle ledgers:*

$$\begin{aligned}&\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg)\\ \iff\quad &\mathsf{AdjunctionTriangleCarrier}(right, left, object, counit, unit, rightLeg, leftLeg).\end{aligned}$$

Proof. By Definition 107.32, the left-hand carrier consists of four fields: the prefix component from $left$ to $right$ carried by $unit$, the prefix component from $right$ to $left$ carried by $counit$, the continuation ledger $\mathsf{Cont}(unit, counit, leftLeg)$, and the continuation ledger $\mathsf{Cont}(counit, unit, rightLeg)$. The right-hand carrier asks for the same four fields in the exchanged order: the $counit$ component, the $unit$ component, the second ledger, and then the first ledger. Each implication is therefore obtained by reordering these four conjunctive fields. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier carrier swap iff`
↪ variant `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier fields swap iff`

Theorem 107.47 (Adjunction unit-counit carrier carrier-swap symmetry)**.** *For histories $p, q, a, unit, counit, left, r$ BHist, the adjunction unit-counit carrier is invariant under exchanging the two prefix carriers, exchanging unit with counit, and exchanging the two triangle ledgers:*

$$\begin{aligned}&\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)\\ \iff\quad &\mathsf{AdjunctionUnitCounitCarrier}(q, p, a, counit, unit, right, left).\end{aligned}$$

Proof. By Definition 107.1, a witness of the left-hand carrier consists of four fields: the prefix component from p to q carried by $unit$, the prefix component from q to p carried by $counit$, the continuation ledger $\mathsf{Cont}(unit, counit, left)$, and the continuation ledger $\mathsf{Cont}(counit, unit, right)$. The displayed carrier with p and q exchanged asks for exactly the same four fields in the order: the $counit$ component, the $unit$ component, the second ledger, and the first ledger. Reordering the four conjunctive fields proves the forward implication, and the same reordering with the two sides exchanged proves the reverse implication. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier carrier swap iff`

Definition 107.48 (Adjunction unit-counit carrier-swap classifier)**.** *For unit-counit displays $D = (p, q, a, u, c, l, r)$ and $D' = (p', q', a', u', c', l', r')$, the carrier-swap relation $\mathsf{AdjunctionUnitCounitCarrierSwap}(D, D')$ holds when*

$$p' = q \wedge q' = p \wedge a' = a \wedge u' = c \wedge c' = u \wedge l' = r \wedge r' = l.$$

The display classifier $\mathsf{AdjunctionUnitCounitDisplaySame}(D, D')$ holds when

$$p\mathsf{hsame}p' \wedge q\mathsf{hsame}q' \wedge a\mathsf{hsame}a' \wedge u\mathsf{hsame}u' \wedge c\mathsf{hsame}c' \wedge l\mathsf{hsame}l' \wedge r\mathsf{hsame}r'.$$

Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrierSwap`
Lean4 (definition) `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitDisplaySame`

Theorem 107.49 (Adjunction triangle display empty normal form)**.** *For histories $left$, $right$, $object$, $unit$, $counit$, $leftLeg$, and $rightLeg$, let $D = (left, right, object, unit, counit, leftLeg, rightLeg)$ and $N = (left, left, object, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$. Then*

$$\mathsf{AdjunctionTriangleCarrier}(left, right, object, unit, counit, leftLeg, rightLeg) \Longrightarrow \mathsf{AdjunctionUnitCounitDisplaySame}$$

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUp StdBridge`

Proof. Apply Definition 107.40 to the given adjunction triangle carrier. This gives the four emptiness witnesses for *unit*, *counit*, $leftLeg$, and $rightLeg$, together with the endpoint prefix witness $\mathsf{hsame}(left, right)$.

Unfold Definition 107.48 only at the display classifier fields. The $left$ and *object* coordinates are witnessed by reflexivity. The $right$ coordinate is witnessed by symmetry of the endpoint-prefix witness, giving $\mathsf{hsame}(right, left)$.

The remaining four classifier fields are exactly the empty witnesses for *unit*, *counit*, $leftLeg$, and $rightLeg$. Packing these seven witnesses in the displayed coordinate order proves AdjunctionUnitCounitDisplaySa

□

Theorem 107.50 (Adjunction unit-counit carrier-swap involution)**.** *Let $D_i = (p_i, q_i, a_i, u_i, c_i, l_i, r_i)$ for $i = 0, 1, 2$ be unit-counit displays of histories. If*

$$\mathsf{AdjunctionUnitCounitCarrier}(p_0, q_0, a_0, u_0, c_0, l_0, r_0)$$
$$\wedge\ \mathsf{AdjunctionUnitCounitCarrierSwap}(D_0, D_1) \wedge \mathsf{AdjunctionUnitCounitCarrierSwap}(D_1, D_2),$$

then

$$\mathsf{AdjunctionUnitCounitCarrier}(p_2, q_2, a_2, u_2, c_2, l_2, r_2)$$
$$\wedge\ \mathsf{AdjunctionUnitCounitDisplaySame}(D_0, D_2).$$

Proof. Unfold the two carrier-swap relations of Definition 107.48. The first gives $p_1 = q_0$, $q_1 = p_0$, $a_1 = a_0$, $u_1 = c_0$, $c_1 = u_0$, $l_1 = r_0$, and $r_1 = l_0$. The second gives $p_2 = q_1$, $q_2 = p_1$, $a_2 = a_1$, $u_2 = c_1$, $c_2 = u_1$, $l_2 = r_1$, and $r_2 = l_1$. Substituting the first row into the second yields

$$p_2 = p_0 \wedge q_2 = q_0 \wedge a_2 = a_0 \wedge u_2 = u_0 \wedge c_2 = c_0 \wedge l_2 = l_0 \wedge r_2 = r_0.$$

Substitute these coordinate identities in the carrier of D_0; by Definition 107.1 this is the carrier of D_2. The same coordinate identities turn the seven reflexive hsame witnesses on D_0 into the componentwise display classifier between D_0 and D_2. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionUnitCounitCarrier swap involution`

Theorem 107.51 (Adjunction triangle carrier-swap involution)**.** *Let $D_i = (p_i, q_i, a_i, u_i, c_i, l_i, r_i)$ for $i = 0, 1, 2$ be adjunction triangle displays. If*

$$\mathsf{AdjunctionTriangleCarrier}(p_0, q_0, a_0, u_0, c_0, l_0, r_0)$$
$$\wedge\ \mathsf{AdjunctionUnitCounitCarrierSwap}(D_0, D_1) \wedge \mathsf{AdjunctionUnitCounitCarrierSwap}(D_1, D_2),$$

then the twice-swapped display is again carried and is componentwise classifier-same to the original display:

$$\mathsf{AdjunctionTriangleCarrier}(p_2, q_2, a_2, u_2, c_2, l_2, r_2)$$
$$\wedge\ \mathsf{AdjunctionUnitCounitDisplaySame}(D_0, D_2).$$

Proof. Unfold the first carrier-swap relation in Definition 107.48. It gives

$$p_1 = q_0 \wedge q_1 = p_0 \wedge a_1 = a_0 \wedge u_1 = c_0 \wedge c_1 = u_0 \wedge l_1 = r_0 \wedge r_1 = l_0.$$

Unfold the second carrier-swap relation in the same definition. It gives

$$p_2 = q_1 \wedge q_2 = p_1 \wedge a_2 = a_1 \wedge u_2 = c_1 \wedge c_2 = u_1 \wedge l_2 = r_1 \wedge r_2 = l_1.$$

Substituting the first row into the second row yields

$$p_2 = p_0 \wedge q_2 = q_0 \wedge a_2 = a_0 \wedge u_2 = u_0 \wedge c_2 = c_0 \wedge l_2 = l_0 \wedge r_2 = r_0.$$

Substitute these coordinate identities in the carrier of D_0. By Definition 107.32, the same two prefix-component fields and the same two continuation ledgers are exactly the carrier fields for D_2. The same coordinate identities also turn the seven reflexive hsame witnesses on the coordinates of D_0 into $\mathsf{AdjunctionUnitCounitDisplaySame}(D_0, D_2)$. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier swap involution`

Theorem 107.52 (Right adjoint uniqueness up to natural isomorphism)**.** *Let* $p, q_1, q_2, a, u_1, c_1, l_1, r_1, u_2, c_2, l_2, r_2, \eta$, BHist. *Suppose two adjunction unit-counit displays share the left prefix* p *and the object history* a*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q_1, a, u_1, c_1, l_1, r_1) \quad \textit{and} \quad \mathsf{AdjunctionUnitCounitCarrier}(p, q_2, a, u_2, c_2, l_2, r_2).$$

Suppose the comparison continuations are displayed by

$$\mathsf{Cont}(c_1, u_2, \eta), \qquad \mathsf{Cont}(c_2, u_1, \eta'), \qquad \mathsf{Cont}(\eta, \eta', I_1), \qquad \mathsf{Cont}(\eta', \eta, I_2).$$

Reading p *as the common left-adjoint prefix and* q_i *as the two right-adjoint prefixes, the comparison components* $\eta : q_1 \Rightarrow q_2$ *and* $\eta' : q_2 \Rightarrow q_1$ *form a componentwise* $\mathsf{NatTrans}^{\uparrow}$ *isomorphism:*

$$\begin{aligned}&\mathsf{NatTransPrefixComponentCarrier}(q_1, q_2, a, \eta) \wedge \mathsf{NatTransPrefixComponentCarrier}(q_2, q_1, a, \eta')\\ &\wedge \mathsf{NatTransPrefixComponentClassifier}_{q_1,q_1,a}(I_1, \mathsf{e}) \wedge \mathsf{NatTransPrefixComponentClassifier}_{q_2,q_2,a}(I_2, \mathsf{e}).\end{aligned}$$

Proof. Unfold the two adjunction carriers by Definition 107.1. The first carrier supplies prefix components $u_1 : p \Rightarrow q_1$ and $c_1 : q_1 \Rightarrow p$ at a; the second supplies $u_2 : p \Rightarrow q_2$ and $c_2 : q_2 \Rightarrow p$ at the same a.

Apply Definition 63.13 to c_1, u_2, and $\mathsf{Cont}(c_1, u_2, \eta)$. This gives

$$\mathsf{NatTransPrefixComponentCarrier}(q_1, q_2, a, \eta).$$

Applying the same closure theorem to c_2, u_1, and $\mathsf{Cont}(c_2, u_1, \eta')$ gives

$$\mathsf{NatTransPrefixComponentCarrier}(q_2, q_1, a, \eta').$$

A further application of vertical closure to the two displayed comparison components gives component carriers for $I_1 : q_1 \Rightarrow q_1$ and $I_2 : q_2 \Rightarrow q_2$.

The components η and η' run in opposite directions over the same object history. Hence Definition 63.45 supplies empty components from q_1 to q_2 and from q_2 to q_1, together with $q_1 \mathsf{hsame} q_2$. Comparing the defining composite $\mathsf{Cont}(c_1, u_2, \eta)$ with the displayed empty component by Definition 63.15 gives $\eta \mathsf{hsamee}$. The same argument for $\mathsf{Cont}(c_2, u_1, \eta')$ gives $\eta' \mathsf{hsamee}$.

Apply Definition 63.20 to η, η', and I_1. The two component emptiness witnesses, $q_1 \mathsf{hsame} q_2$, and symmetry of hsame satisfy the right-hand side, so $I_1 \mathsf{hsamee}$. Exchanging η and η' gives $I_2 \mathsf{hsamee}$.

The component rows extracted from the two adjunction carriers include unary witnesses for q_1, q_2, and a. Thus Definition 63.3 supplies the empty identity components at q_1 and at q_2. Combining those empty identity components with the carried endomorphism components I_1 and I_2, and with $I_1 \mathsf{hsamee}$ and $I_2 \mathsf{hsamee}$, packages exactly the two classifier witnesses in Definition 63.62. Since Definition 63.1 reads a $\mathsf{NatTrans}^{\uparrow}$ carrier componentwise over object histories, these classifier witnesses are the identity vertical-composite rows for the displayed comparison pair. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionRightAdjoint natural isomorphism uniqueness`

Theorem 107.53 (Left adjoint uniqueness up to natural isomorphism)**.** *Let* $p_1, p_2, q, a, u_1, c_1, l_1, r_1, u_2, c_2, l_2, r_2, \xi, \xi$ BHist*. Suppose two adjunction unit-counit displays share the right prefix* q *and the object history* a*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p_1, q, a, u_1, c_1, l_1, r_1) \quad \textit{and} \quad \mathsf{AdjunctionUnitCounitCarrier}(p_2, q, a, u_2, c_2, l_2, r_2).$$

Suppose the comparison continuations are displayed by

$$\mathsf{Cont}(u_1, c_2, \xi), \qquad \mathsf{Cont}(u_2, c_1, \xi'), \qquad \mathsf{Cont}(\xi, \xi', J_1), \qquad \mathsf{Cont}(\xi', \xi, J_2).$$

Reading q *as the common right-adjoint prefix and* p_i *as the two left-adjoint prefixes, the comparison components* $\xi : p_1 \Rightarrow p_2$ *and* $\xi' : p_2 \Rightarrow p_1$ *form a componentwise* $\mathsf{NatTrans}^{\uparrow}$ *isomorphism:*

$$\begin{aligned}&\mathsf{NatTransPrefixComponentCarrier}(p_1, p_2, a, \xi) \wedge \mathsf{NatTransPrefixComponentCarrier}(p_2, p_1, a, \xi')\\ &\wedge \mathsf{NatTransPrefixComponentClassifier}_{p_1,p_1,a}(J_1, \mathsf{e}) \wedge \mathsf{NatTransPrefixComponentClassifier}_{p_2,p_2,a}(J_2, \mathsf{e}).\end{aligned}$$

Proof. Apply the carrier-swap symmetry of Definition 107.47 to the two displayed adjunction carriers. The resulting carriers are

$$\mathsf{AdjunctionUnitCounitCarrier}(q, p_1, a, c_1, u_1, r_1, l_1) \quad \text{and} \quad \mathsf{AdjunctionUnitCounitCarrier}(q, p_2, a, c_2, u_2, r_2, l_2).$$

They share the left prefix q and the same object history a. In these swapped displays the comparison continuations required by Definition 107.52 are exactly

$$\mathsf{Cont}(u_1, c_2, \xi), \qquad \mathsf{Cont}(u_2, c_1, \xi'), \qquad \mathsf{Cont}(\xi, \xi', J_1), \qquad \mathsf{Cont}(\xi', \xi, J_2),$$

because the counit fields of the swapped displays are u_1 and u_2, while the unit fields are c_1 and c_2.

Applying Definition 107.52 to the swapped pair gives the two prefix-component carriers from p_1 to p_2 and back, together with the two identity-composite classifier rows over p_1 and p_2. These four conclusions are exactly the displayed componentwise $\mathsf{NatTrans}^{\uparrow}$ isomorphism for the original pair with common right-adjoint prefix q. □

Lean4 ✓ `BEDC.Derived.AdjunctionUp.AdjunctionLeftAdjoint natural isomorphism uniqueness`

Closure status for $\mathsf{NameCert}_{\mathsf{Adjunction}^{\uparrow}}$**.**

Constructive story: An adjunction seed is assembled from two prefix natural-transformation components: a unit component from one prefix to another, a counit component back, and two continuation ledgers that display the triangle composites. The carried displays are precisely those histories for which the two components are prefix components over the same object and the two triangle legs are witnessed continuations; anything missing a component carrier or one of the two continuation rows is outside this seed, and sameness is componentwise hsame on the two prefixes, object, unit, counit, and triangle legs, with the carrier-swap row recording the same display in the opposite order. The source is the unit-counit triangle display, the pattern records empty composite collapse, endomorphism triangle exactness, cycle collapse to equal prefixes, carrier-swap symmetry, and the empty normal form, while the ledger keeps the unit, counit, and both triangle histories visible. At this seed level the name-certificate obligations are not exposed as a completed public certificate, but the rows already show the intended mechanism: the empty component display supplies the canonical inhabitant, hsame supplies reflexivity, symmetry, and transitivity, and the normal-form and swap theorems preserve the carrier under classified replacement. A display history h lies in the signature gap of an $\mathsf{Adjunction}^{\uparrow}$ token p when the source-domain accepts the unit-counit display, the signature relation pairs it with an answer display and the two triangle ledgers, and token introduction names that answer as p; unfolded, the unit, counit, and both triangle legs collapse to empty histories while the two prefixes classify together as encoded by p. No standard bridge is present, and no hom-set universal adjunction is asserted at this boundary. The chapter registers this prefix unit-counit triangle surface under the name $\mathsf{Adjunction}^{\uparrow}$; the adjunction data are continuation rows over existing histories, with no external adjunction object, host natural-isomorphism primitive, or additional categorical axiom introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{Adjunction}\uparrow}$, maturePackageClosed)

Scope closed: The public export surface is the triangle display empty normal form together with the unit-counit carrier rows, triangle ledgers, carrier-swap display rows, Cont, hsame, and NameCert rows listed in this certificate block.

Formal verification: FormalStatus(NameCert$_{\mathsf{Adjunction}\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.AdjunctionUp.AdjunctionTriangleCarrier\_display\_empty\_normal\_form`

Bridge status: bridgeChecked

Not claimed: This block does not close full adjunction theory, universal hom-set adjunctions, or standard bridges.

Upgrade path: No further formal-axis upgrade remains for this chapter because the recorded bridge has reached the top formal grade.

Chapter 108

A Concrete Naming Certificate for $\mathsf{Monad}^{\uparrow}$

The monad interface $\mathsf{Monad}^{\uparrow}$ packages an endofunctor on a category with unit and multiplication natural transformations satisfying the monad laws. It depends on $\mathsf{NameCert}_{\mathsf{NatTrans}^{\uparrow}}$ (chapter 63) and $\mathsf{NameCert}_{\mathsf{Adjunction}^{\uparrow}}$ (chapter 107), and supplies the substrate for algebraic theories and computational effect models.

108.1 Carrier definition

Theorem 108.1 (Monad adjunction endomorphism triangle results are empty)**.** *For histories* $p, a, unit, counit, left, right : \mathsf{BHist}$*, suppose* $\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$ *holds. Then both triangle results are empty:*

$$\mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(right, \mathsf{e}).$$

Proof. Both the unit and counit components are endomorphism prefix components over the same prefix p and object a, so natural-transformation endomorphism component exactness identifies each component with e. The two triangle continuations are then compared with the empty right-unit continuation, first in the unit-counit order and then in the counit-unit order. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism triangle results empty`

Theorem 108.2 (Monad adjunction left triangle empty result has empty suffix)**.** *For histories* $p, a, unit, counit, left, right, suffix, out : \mathsf{BHist}$*, suppose* $\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, righ$ *holds. If* $\mathsf{Cont}(left, suffix, out)$ *and* $\mathsf{hsame}(out, \mathsf{e})$*, then*

$$\mathsf{hsame}(suffix, \mathsf{e}).$$

Proof. The endomorphism triangle result theorem identifies the left triangle result with e. After the output is also identified with e, the displayed continuation has empty source and empty result, so continuation empty-result inversion identifies the suffix with e. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism left triangle result empty suffix empty`

Theorem 108.3 (Monad adjunction endomorphism triangle bridge is empty iff)**.** *For histories* $p, a, unit, counit, left, right, bridge : \mathsf{BHist}$*, suppose* $\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$ *holds. Then*

$$\mathsf{Cont}(left, bridge, right) \iff \mathsf{hsame}(bridge, \mathsf{e}).$$

Proof. For the forward direction, the right triangle result is empty, so the left-triangle empty-result suffix theorem applies to the displayed bridge continuation. Conversely, the carrier identifies both triangle results with e; after the bridge is also identified with e, the continuation is the empty right-unit continuation. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism triangle bridge empty iff`

Theorem 108.4 (Monad adjunction endomorphism unit-counit bridge is empty iff)**.** *For histories* $p, a, unit, counit, left, right, bridge : \mathsf{BHist}$*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

holds. Then

$$\mathsf{Cont}(unit, bridge, counit) \iff \mathsf{hsame}(bridge, \mathsf{e}).$$

Proof. The forward direction is the unit-counit middle-empty theorem. Conversely, the endomorphism carrier identifies both *unit* and *counit* with e; after *bridge* is also identified with e, the displayed continuation is the canonical right-unit continuation at e. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism unit counit bridge empty iff`

Theorem 108.5 (Monad adjunction right triangle empty result has empty suffix)**.** *For histories* $p, a, unit, counit, left, right, suffix, out : \mathsf{BHist}$*, suppose* $\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, righ$ *holds. If* $\mathsf{Cont}(right, suffix, out)$ *and* $\mathsf{hsame}(out, \mathsf{e})$*, then*

$$\mathsf{hsame}(suffix, \mathsf{e}).$$

Proof. The endomorphism triangle result theorem identifies the right triangle result with e. With the displayed output also identified with e, the continuation has empty source and empty result. Continuation empty-result inversion therefore identifies the suffix with e. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism right triangle result empty suffix empty`

Theorem 108.6 (Monad adjunction endomorphism left triangle suffix-output empty iff)**.** *For histories* $p, a, unit, counit, left, right, suffix, out : \mathsf{BHist}$*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

and $\mathsf{Cont}(left, suffix, out)$ *hold. Then*

$$\mathsf{hsame}(out, \mathsf{e}) \iff \mathsf{hsame}(suffix, \mathsf{e}).$$

Proof. The forward direction is the left-triangle empty-result suffix theorem. For the reverse direction, the endomorphism triangle theorem identifies *left* with e; comparing the displayed continuation against the canonical right-unit continuation through the empty suffix gives an empty output. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism left triangle suffix output empty iff`

Theorem 108.7 (Monad adjunction endomorphism parallel triangle suffix agreement)**.** *For histories* $p, a, unit, counit, left, right, suffix, left', right'$: BHist*, suppose* AdjunctionUnitCounitCarrier$(p, p, a, unit, cou$ *holds. If* Cont$(left, suffix, left')$ *and* Cont$(right, suffix, right')$*, then*

$$\mathsf{hsame}(left', right').$$

Proof. The endomorphism triangle result theorem identifies both triangle outputs $left$ and $right$ with e. Hence $left$hsame$right$. Continuation respect for hsame transports this source equality across the common suffix continuation, with the suffix compared reflexively, and yields $left'$hsame$right'$. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism parallel triangle suffix same`

Theorem 108.8 (Monad adjunction endomorphism unit-counit middle is empty)**.** *For histories* $p, a, unit, counit, left, right, bridge$: BHist*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

and Cont$(unit, bridge, counit)$ *hold. Then bridge is empty:*

$$\mathsf{hsame}(bridge, \mathsf{e}).$$

Proof. The adjunction endomorphism carrier identifies both $unit$ and $counit$ with e. With those endpoints collapsed, the displayed continuation is a continuation from e through $bridge$ back to e, and empty-result inversion gives $bridge$hsamee. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism middle between unit counit empty`

Theorem 108.9 (Monad adjunction endomorphism counit-unit middle is empty)**.** *For histories* $p, a, unit, counit, left, right, bridge$: BHist*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right)$$

and Cont$(counit, bridge, unit)$ *hold. Then bridge is empty:*

$$\mathsf{hsame}(bridge, \mathsf{e}).$$

Proof. The unit and counit are both endomorphism prefix components in the carrier, so each is identified with e. After those endpoint identifications, the displayed counit-unit continuation has empty endpoints, and empty-result inversion identifies the middle history with e. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism middle between counit unit empty`

Theorem 108.10 (Monad adjunction endomorphism triangle composite is empty)**.** *For histories* $p, a, unit, counit, left, right, composite$: BHist*, suppose* AdjunctionUnitCounitCarrier$(p, p, a, unit, counit, left, right$ *holds and* Cont$(left, right, composite)$ *holds. Then* hsame$(composite, \mathsf{e})$*.*

Proof. The endomorphism triangle theorem identifies both triangle legs with e. Transport the displayed continuation against those two endpoint identifications and compare it with the empty right-unit continuation. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism triangle composite empty`

Theorem 108.11 (Monad adjunction endomorphism unit, counit, and triangles are empty)**.** *For histories* $p, a, unit, counit, left, right$: BHist*, suppose* AdjunctionUnitCounitCarrier$(p, p, a, unit, counit, left, right)$ *holds. Then the unit component, counit component, and both triangle results are empty:*

$$\mathsf{hsame}(unit, \mathsf{e}) \wedge \mathsf{hsame}(counit, \mathsf{e}) \wedge \mathsf{hsame}(left, \mathsf{e}) \wedge \mathsf{hsame}(right, \mathsf{e}).$$

Proof. The unit and counit are endomorphism prefix components over the same prefix, so prefix component exactness identifies both with e. Applying the triangle-result collapse for the same carrier gives the two empty triangle results, and the four witnesses are collected in order. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism unit counit triangle empty`

108.2 The certificate

Theorem 108.12 (Monad adjunction endomorphism semantic name certificate)**.** *Let* p, a : BHist *be unary histories. For histories* $unit, counit, left, right$: BHist*, write* $M_{p,a}(unit, counit, left, right)$ *for the carrier predicate*

$$M_{p,a}(unit, counit, left, right) :\Longleftrightarrow \mathsf{AdjunctionUnitCounitCarrier}(p, p, a, unit, counit, left, right).$$

For two displays $D = (unit, counit, left, right)$ *and* $D' = (unit', counit', left', right')$*, let* MonadAdjunctionEndomor *mean*

$$unit\mathsf{hsame}unit' \wedge counit\mathsf{hsame}counit' \wedge left\mathsf{hsame}left' \wedge right\mathsf{hsame}right'.$$

Then, in the display presentation of Definition 9.6, $M_{p,a}$ *carries a semantic naming certificate with source, pattern, and ledger all equal to* $M_{p,a}$ *and classifier* $\mathsf{MonadAdjunctionEndomorphismDisplaySame}_{p,a}$*:*

$$\mathsf{SemanticNameCert}(M_{p,a}, M_{p,a}, M_{p,a}, \mathsf{MonadAdjunctionEndomorphismDisplaySame}_{p,a}).$$

Proof. The empty display $(\mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$ supplies the carrier witness. Indeed, Definition 63.3 builds both empty prefix natural-transformation components from the unary hypotheses on p and a and reflexivity of $p\mathsf{hsame}p$, while the two continuation ledgers are the empty right-unit continuation. By Definition 107.1, these four fields give $M_{p,a}(\mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$.

The classifier laws are inherited componentwise from the reflexivity, symmetry, and transitivity laws for hsame. For carrier transport, suppose $M_{p,a}(unit, counit, left, right)$ and MonadAdjunctionEndomorphismDis hold. The two natural-transformation component fields in Definition 107.1 transport along the displayed hsame comparisons on *unit* and *counit*, and the two continuation ledgers transport along the displayed comparisons on all four coordinates. Repacking the transported component fields and continuation ledgers gives $M_{p,a}(unit', counit', left', right')$.

The monad endomorphism collapse theorem Definition 108.11 shows that every carried display is classifier-same to the empty display in all four coordinates. Thus the exported pattern and ledger are exactly the same degenerate adjunction-endomorphism behavior as the source carrier. Since the source, pattern, and ledger predicates are all $M_{p,a}$, the pattern-soundness and ledger-soundness rows of the semantic certificate are identity projections, as in the certificate template of Definition 9.6. □

Lean4 ✓ `BEDC.Derived.MonadUp.MonadAdjunctionEndomorphism semanticNameCert`

Closure status for $\mathsf{NameCert}_{\mathsf{Monad}\uparrow}$.

Constructive story: A $\mathsf{Monad}^{\uparrow}$ certificate is generated here from an adjunction endomorphism carrier: prefix rows, object row, unit and counit component histories, triangle-result histories, continuation ledgers, and componentwise hsame classifiers. The BHist construction collapses the displayed endomorphism unit, counit, and triangle rows to the empty identity behavior by finite carrier inversion and Cont determinacy. The semantic certificate uses the same carrier as source, pattern, and ledger, so the monad-facing name is generated from explicit adjunction data rather than from an ambient category-theoretic law object.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Monad}\uparrow}, \text{obligation})$

Scope closed: The obligation surface consists of the adjunction-endomorphism carrier, triangle empty-result, bridge-empty iff, componentwise classifier, and semantic NameCert rows displayed in this chapter.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Monad}\uparrow}, \text{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim arbitrary monad laws for all categories, Eilenberg-Moore constructions, Kleisli category equivalence, or host categorical equality.

Upgrade path: Scoped closure requires binding those obligations explicitly to the BHist, hsame, Cont, AdjunctionUnitCounitCarrier, and SemanticNameCert scopes.

Chapter 109

A Concrete Naming Certificate for $\mathsf{Yoneda}^{\uparrow}$

The Yoneda interface $\mathsf{Yoneda}^{\uparrow}$ packages, for each object of a category, the representable functor and the natural-isomorphism witness of the Yoneda lemma. It depends on $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62) and $\mathsf{NameCert}_{\mathsf{NatTrans}^{\uparrow}}$ (chapter 63), supplying the embedding into presheaf categories.

109.1 Carrier definition

Theorem 109.1 (Yoneda representable empty component family characterization)**.** *For histories p and q, an empty natural-transformation component exists over every unary object exactly when p and q are unary prefixes with the same history:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})\Big) \iff \mathsf{UnaryHistory}(p) \wedge \mathsf{UnaryHistory}(q) \wedge \mathsf{hs}$$

Proof. For the forward direction, evaluate the component family at the empty unary history and apply empty-component identity exactness. For the reverse direction, the same exactness theorem rebuilds each object component from the common prefix equality and the supplied unary object carrier. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family iff`

Theorem 109.2 (Yoneda empty component family e1 target characterization)**.** *For generated histories p and q, the empty component family with target $\mathsf{E1}(q)$ is equivalent to unary membership of q together with $p\mathsf{hsameE1}(q)$:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, \mathsf{E1}(q), a, \mathsf{e})\Big) \iff \mathsf{UnaryHistory}(q) \wedge p\mathsf{hsameE1}(q).$$

Proof. The forward direction applies the empty component family characterization and then inverts unary membership of the $\mathsf{E1}$ target. Conversely, unary membership of q closes $\mathsf{E1}(q)$ under unary construction, and the hsame comparison transports unary membership back to p. The general empty component family characterization then gives the displayed family. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family e1 target iff`

Theorem 109.3 (Yoneda empty component family displayed determinacy)**.** *If an empty representable component family and a displayed component family both exist over every unary object for the same prefixes p, q, then* $\mathsf{hsame}(\mathsf{e}, \mathit{displayed})$.

Proof. Evaluate both families at the empty unary object. Their component carriers share the same source and target hom-carrier endpoints, so morphism determinacy identifies the empty displayed morphism with the supplied displayed component. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family displayed deterministic`

Theorem 109.4 (Yoneda component family displayed determinacy)**.** *If two displayed component families both exist over every unary object for the same prefixes p, q, then their displayed histories are* hsame*-equivalent.*

Proof. Evaluate both families at the empty unary object. The two exposed component carriers share the same prefixed hom-carrier source and target, so category morphism determinacy identifies the two displayed component histories. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable component family displayed deterministic`

Theorem 109.5 (Yoneda empty component family component determinacy)**.** *If a is unary, an empty representable component family exists over every unary object, and a displayed component over a is supplied for the same prefixes p, q, then* $\mathsf{hsame}(\mathsf{e}, \mathit{displayed})$.

Proof. Evaluate the empty component family at the supplied unary object a. The resulting empty component and the displayed component expose category hom-carriers with the same prefixed source and target, so morphism determinacy identifies their component histories. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family component deterministic`

Theorem 109.6 (Yoneda representable empty component family target determinacy)**.** *For histories $p, q, r : \mathsf{BHist}$, if the empty natural-transformation component family from p to q exists over every unary object and the empty component family from p to r exists over every unary object, then q and r have the same history:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})\Big) \Rightarrow \Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixCom}$$

Proof. Apply Theorem 109.1 to both component families. The first family gives $\mathsf{hsame}(p, q)$ and the second gives $\mathsf{hsame}(p, r)$. Symmetry converts the first comparison to $\mathsf{hsame}(q, p)$, and transitivity composes it with $\mathsf{hsame}(p, r)$. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family target deterministic`

Theorem 109.7 (Yoneda representable empty component family source determinacy)**.** *For histories $p, q, r : \mathsf{BHist}$, if the empty natural-transformation component family from p to q exists over every unary object and the empty component family from r to q exists over every unary object, then p and r have the same history:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})\Big) \Rightarrow \Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixCom}$$

Proof. Apply Theorem 109.1 to both component families. The first family gives $\mathsf{hsame}(p, q)$ and the second gives $\mathsf{hsame}(r, q)$. Symmetry converts the second comparison to $\mathsf{hsame}(q, r)$, and transitivity composes it with $\mathsf{hsame}(p, q)$. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family source deterministic`

Theorem 109.8 (Yoneda empty component family boundary hsame equivalence)**.** *For histories p, q, r, s : BHist, suppose that the empty component family from p to q exists over every unary object, and likewise the empty component family from r to s exists over every unary object. Then comparing the sources is equivalent to comparing the targets:*

$$\mathsf{hsame}(p, r) \iff \mathsf{hsame}(q, s).$$

Proof. Apply the empty component family characterization to both families. The first family gives $\mathsf{hsame}(p, q)$ and the second gives $\mathsf{hsame}(r, s)$. For the forward direction, compose $\mathsf{hsame}(q, p)$, $\mathsf{hsame}(p, r)$, and $\mathsf{hsame}(r, s)$. For the reverse direction, compose $\mathsf{hsame}(p, q)$, $\mathsf{hsame}(q, s)$, and $\mathsf{hsame}(s, r)$. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family boundary hsame iff`

Theorem 109.9 (Yoneda empty component family boundary transport)**.** *For histories p, q, r, s : BHist, an empty component family from p to q transports to an empty component family from r to s whenever $p\mathsf{hsame}r$ and $q\mathsf{hsame}s$:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})\Big) \Rightarrow \mathsf{hsame}(p, r) \Rightarrow \mathsf{hsame}(q, s) \Rightarrow \Big(\forall a,\ \mathsf{UnaryHis}$$

Proof. Use the empty component family characterization to extract unary membership for p and q, together with $\mathsf{hsame}(p, q)$. Unary transport along the two boundary equalities gives unary membership for r and s, while transitivity of hsame composes $\mathsf{hsame}(r, p)$, $\mathsf{hsame}(p, q)$, and $\mathsf{hsame}(q, s)$. The empty-identity component characterization then rebuilds each component over the supplied unary object. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family boundary transport`

109.2 The certificate

Theorem 109.10 (Yoneda representable empty component family semantic certificate)**.** *For a unary prefix history p, the empty component family predicate*

$$Y_p(q) :\iff \forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})$$

carries a semantic naming certificate with source, pattern, and ledger all equal to Y_p, and classifier hsame.

Proof. The carrier witness is $q = p$. For each unary object a, the empty-component identity exactness theorem rebuilds $\mathsf{NatTransPrefixComponentCarrier}(p, p, a, \mathsf{e})$ from unary membership of p, unary membership of a, and reflexivity of $\mathsf{hsame}(p, p)$. The classifier fields are the reflexivity, symmetry, and transitivity of hsame, while carrier transport along $\mathsf{hsame}(q, r)$ is obtained by replacing q with r in the component family. Since source, pattern, and ledger are the same predicate, the soundness rows are direct projections. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable empty component family semanticNameCert`

Capstone.

Theorem 109.11 (Prefix Yoneda embedding is fully faithful on empty components)**.** *For unary histories p and q, the empty representable component family of the prefix Yoneda construction is equivalent to prefix identity:*

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})\Big) \quad \Longleftrightarrow \quad \mathsf{hsame}(p, q).$$

Moreover, if displayed histories η and θ both occur as component families from p to q over all unary objects, then their displayed histories are identical in the BEDC history classifier:

$$\Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \eta)\Big) \wedge \Big(\forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComp}$$

Thus the semantic family Y_p classifies a unary target q exactly by $\mathsf{hsame}(p, q)$; on the empty-component skeleton this is the full and faithful prefix embedding of $\mathsf{Cat}^{\uparrow}$ through the certified $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ interfaces.

Proof. For the equivalence, apply Definition 109.1. The forward direction projects the exposed $\mathsf{hsame}(p, q)$ field from the unary-prefix package. The reverse direction combines the ambient unary hypotheses on p and q with $\mathsf{hsame}(p, q)$ and repacks them through the same characterization.

For displayed family uniqueness, apply Definition 109.4 to the two supplied component families. This is the faithfulness clause: once the source and target prefixes are fixed, the object-indexed displayed component history is determined up to hsame.

The fullness clause is the empty-component existence half of the first paragraph. The functorial source of the construction is the semantic prefix certificate of Definition 62.82; the natural transformation classifier is supplied by Definition 63.66. Together with the semantic family certificate above, these identify $Y_p(q)$ with prefix identity and leave no additional displayed component choice. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaRepresentable prefix empty component full faithfulness`

Theorem 109.12 (Yoneda component evaluation boundary)**.** *Let p and q be unary histories, and write*

$$Y_p(q) :\Longleftrightarrow \forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}).$$

For every displayed unary object a, evaluation of the prefix Yoneda empty-component family at a factors through exactly the following finite BEDC rows:

1. *the $\mathsf{Cat}^{\uparrow}$ hom-carrier endpoint row identifying the displayed empty component as the hom history from $\mathsf{append}(p, a)$ to $\mathsf{append}(q, a)$;*
2. *the $\mathsf{Functor}^{\uparrow}$ codomain-evaluation row reading the representable functor hom predicate at a as the codomain hom-carrier at those image endpoints;*
3. *the $\mathsf{NatTrans}^{\uparrow}$ component and naturality row carried by $\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})$.*

Conversely, if these three displayed rows are present for every unary a, then they reconstruct the accepted Yoneda component-family boundary $Y_p(q)$, and Definition 109.11 identifies that boundary with $\mathsf{hsame}(p, q)$.

Proof. Assume $Y_p(q)$. By Definition 109.1, each unary object a supplies the accepted empty component $\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})$. Reading this component through the $\mathsf{NatTrans}^{\uparrow}$ surface of chapter 63 exposes the component and naturality row, while the underlying component

morphism is the $\mathsf{Cat}^{\uparrow}$ hom-carrier row with endpoints $\mathsf{append}(p, a)$ and $\mathsf{append}(q, a)$. The functor endpoint reading is precisely the codomain-evaluation row of Definition 62.98.

Conversely, suppose the endpoint hom-carrier row, the functor codomain-evaluation row, and the natural-transformation component row are present for every unary a. The third row is exactly the displayed component predicate in the definition of $Y_p(q)$, with the first two rows supplying the category and functor boundaries that it reads through. Repacking the rows over all unary objects gives $Y_p(q)$, and the prefix full-faithfulness theorem Definition 109.11 identifies the resulting boundary with prefix identity. □

Theorem 109.13 (Yoneda NatTrans functor-category hom representability)**.** *Let p and q be unary histories. In the NatTrans functor-category prefix carrier of Definition 63.102, the hom row from p to q is exactly the prefix Yoneda predicate*

$$Y_p(q) :\Longleftrightarrow \forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}).$$

Consequently this functor-category hom row is classified by $\mathsf{hsame}(p, q)$ *through Definition 109.11.*

Proof. By Definition 109.12, the predicate $Y_p(q)$ is the objectwise package of three BEDC rows: the $\mathsf{Cat}^{\uparrow}$ endpoint hom-carrier row, the $\mathsf{Functor}^{\uparrow}$ codomain-evaluation row, and the $\mathsf{NatTrans}^{\uparrow}$ component-and-naturality row.

The definition of Definition 63.102 reads a hom from p to q as precisely such a natural-transformation prefix component family over all unary object histories a. Its identity and composition clauses are the closure laws supplied by Definition 63.103, so the row is a hom row in the certified functor-category surface, not only a displayed component predicate.

It remains to identify the classifier. The full-faithfulness theorem Definition 109.11 states that, for unary histories p and q, the accepted empty-component family $Y_p(q)$ is equivalent to $\mathsf{hsame}(p, q)$. Transporting that equivalence across the hom-row reading above gives the claimed representability of the NatTrans functor-category hom row. □

Theorem 109.14 (Prefix Yoneda empty-component standard bridge)**.** *For unary histories p and q, the BEDC predicate*

$$Y_p(q) :\Longleftrightarrow \forall a,\ \mathsf{UnaryHistory}(a) \Rightarrow \mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e})$$

has a paper-side conservative bridge to the external unary-prefix presheaf readback. The decode map reads q as its finite unary prefix, and the encode map sends an external unary word back to its BEDC unary history. Bridge exactness identifies equality of external unary readbacks with $\mathsf{hsame}(p, q)$ *under the carrier $Y_p(q)$, and the displayed component choice is unique up to* hsame.

Proof. The source of the bridge is the semantic prefix certificate of Definition 62.82. The component classifier used by the readback is the natural-transformation certificate of Definition 63.66.

Carrier exactness is exactly Definition 109.1: under the unary hypotheses, $Y_p(q)$ is equivalent to $\mathsf{hsame}(p, q)$. Thus decoding q to its external unary prefix and encoding an external unary word back to a BEDC unary history preserve and reflect the same prefix equality.

For displayed components, apply Definition 109.4. Any two component choices over the same unary source and target histories are identified by hsame, so the external readback has no additional component choice beyond the BEDC classifier. □

Lean4 ✓ `BEDC.Derived.YonedaUp.YonedaUp StdBridge`

Theorem 109.15 (Prefix Yoneda empty-component mature interface)**.** *For unary histories p and q, the mature scoped interface of the prefix Yoneda object is exactly the prefix empty-component skeleton. Its carrier is $Y_p(q)$, its classifier is* hsame*, its full-faithfulness clause is Theorem 109.11, its conservative paper bridge is Theorem 109.14, and its semantic certificate is Theorem 109.10. The scope is restricted to unary prefix histories and empty components.*

Proof. The carrier and classifier are fixed by the semantic certificate in Theorem 109.10: the family $Y_p(q)$ is the empty-component representable family, and the classifier it exposes is hsame.

The fully faithful part is Theorem 109.11. It identifies the object-indexed carrier over all unary objects with $\mathsf{hsame}(p, q)$ and makes the displayed component history unique up to hsame.

The bridge part is Theorem 109.14. Its encode and decode readings are conservative for the same unary-prefix carrier, so composing the semantic certificate, the full-faithfulness clause, and this bridge gives the stated mature interface without enlarging the domain. No step ranges beyond unary prefix histories or beyond empty components. □

Closure status for $\mathsf{NameCert}_{\mathsf{Yoneda}^{\uparrow}}$**.**

Constructive story: The scoped Yoneda object is built from unary prefixes by asking for an empty natural-transformation component over every unary object: for prefixes p and q, the displayed family $Y_p(q)$ is admitted exactly when those prefixes are unary and history-same. The carrier therefore accepts the empty-component family and excludes arbitrary component choices or non-unary presheaf data, while the classifier is hsame on the prefix histories and determinacy theorems force any displayed component family back to the same empty component. The source is the semantic prefix functor surface together with the prefix natural-transformation component certificate, the pattern records the empty-component characterization, source and target determinacy, boundary transport, and prefix full-faithfulness, and the ledger keeps the component family and its evaluated component histories visible. Since e supplies the component choice and hsame is reflexive, symmetric, and transitive on histories, the name-certificate obligations are carried by the semantic certificate, with closure under the classifier given by the boundary transport rows. A history h lies in the signature gap of a $\mathsf{Yoneda}^{\uparrow}$ token p_0 when the source-domain accepts h as an empty-component family, the signature relation pairs it with an answer prefix and evidence ledger, and token introduction names that answer as p_0; unfolded, every unary object sees the empty component and the target prefix is hsame to the representing prefix encoded by p_0. The paper bridge decodes a BEDC unary prefix to an external finite unary word and encodes such a word back to the same unary history, so equality of external readbacks is conservative for the same prefix classifier. The chapter registers this prefix empty-component skeleton under the name $\mathsf{Yoneda}^{\uparrow}$; it gives the fully faithful representable fragment without introducing a general presheaf category, arbitrary Yoneda lemma, or external natural-isomorphism carrier.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Yoneda}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper scope is exactly the checked semantic certificate, full-faithfulness, and paper bridge for the prefix empty-component skeleton.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Yoneda}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.YonedaUp.YonedaRepresentable\_empty\_component\_family\_semanticNameCert`

Bridge status: bridgeChecked

Not claimed: This chapter does not close the arbitrary Yoneda lemma, general presheaf categories, enriched variants, density, or checked bridge targets.

Upgrade path: No further formal-axis upgrade remains for the checked prefix empty-component bridge.

Chapter 110

A Concrete Naming Certificate for $\mathsf{EquivCat}^{\uparrow}$

The categorical-equivalence interface $\mathsf{EquivCat}^{\uparrow}$ packages a pair of functors that are mutually quasi-inverse together with the natural-isomorphism witnesses. It depends on $\mathsf{NameCert}_{\mathsf{Adjunction}^{\uparrow}}$ (chapter 107) and $\mathsf{NameCert}_{\mathsf{NatTrans}^{\uparrow}}$ (chapter 63), and is the structural notion of sameness for $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ instances.

110.1 Carrier definition

Theorem 110.1 (Empty roundtrip identity components)**.** *For histories* $p, q, a, unit, counit, left, right$: BHist*, if an adjunction unit-counit carrier has both displayed roundtrip results* $left$ *and* $right$ *classifier-equal to* e*, then the unit and counit components are the empty identity components:*

$$\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}) \quad \textit{and} \quad \mathsf{NatTransPrefixComponentCarrier}(q, p, a, \mathsf{e}).$$

Proof. The empty left roundtrip continuation forces both *unit* and *counit* to be e. The empty right roundtrip gives the same collapse in the opposite order. After these endpoint inversions, the component fields of the adjunction unit-counit carrier are exactly the two empty identity components. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip identity components`

Theorem 110.2 (Equivalence empty roundtrip prefix determinacy)**.** *For histories* $p, q, a, unit, counit, left, right$: BHist*, if* $\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)$ *holds and* $left\mathsf{hsamee}$ *and* $right\mathsf{hsamee}$*, then*

$$p\mathsf{hsame}q, \qquad unit\mathsf{hsamee}, \qquad counit\mathsf{hsamee},$$

and

$$\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}) \quad \textit{and} \quad \mathsf{NatTransPrefixComponentCarrier}(q, p, a, \mathsf{e}).$$

Proof. Apply Theorem 110.1 to the adjunction unit-counit carrier and the two empty displayed triangle results. This gives the two empty natural-transformation prefix components from p to q and from q back to p at the object history a.

The NatTrans empty-identity exactness theorem applied to the first empty component extracts the prefix classifier equality $p\mathsf{hsame}q$.

The stored triangle continuations in the adjunction unit-counit carrier have results $left$ and $right$. Empty-result inversion for the displayed continuations, together with $left\mathsf{hsamee}$ and $right\mathsf{hsamee}$, collapses the unit and counit histories to $unit\mathsf{hsamee}$ and $counit\mathsf{hsamee}$. Collecting these conclusions gives the stated determinacy package. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip prefix determinacy`

Theorem 110.3 (Equivalence empty roundtrip zero-source exclusion)**.** *For histories* $tail, q, a, unit, counit, left, rig$ BHist*, no adjunction unit-counit carrier can start its first prefix source with* $\mathsf{E0}(tail)$ *while both displayed roundtrip results classify to* e*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(\mathsf{E0}(tail), q, a, unit, counit, left, right) \Rightarrow left\mathsf{hsamee} \Rightarrow right\mathsf{hsamee} \Rightarrow \bot.$$

Proof. The empty roundtrip component theorem extracts the displayed empty natural transformation prefix component out of the zero-headed source. The zero-headed component exclusion for natural transformations contradicts this component by exposing the visible zero constructor at the source head. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip zero source absurd`

Theorem 110.4 (Equivalence empty roundtrip zero-target exclusion)**.** *For histories* $p, tail, a, unit, counit, left, rig$ BHist*, no adjunction unit-counit carrier can place a zero-headed prefix at its first target while both displayed roundtrip results classify to* e*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, \mathsf{E0}(tail), a, unit, counit, left, right) \Rightarrow left\mathsf{hsamee} \Rightarrow right\mathsf{hsamee} \Rightarrow \bot.$$

Proof. The empty roundtrip component theorem extracts the reverse empty natural transformation prefix component. In that reverse component, the zero-headed target of the adjunction becomes the displayed source prefix. The NatTrans zero-headed component exclusion then contradicts the visible $\mathsf{E0}$ constructor at that source head. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip zero target absurd`

Theorem 110.5 (Equivalence empty roundtrip $\mathsf{E1}$ source target exactness)**.** *For histories* $tail, q, a, unit, counit, lef$ BHist*, if an adjunction unit-counit carrier starts at the unary source prefix* $\mathsf{E1}(tail)$ *and both displayed roundtrip results classify to* e*, then the first target prefix is exactly* $\mathsf{E1}(tail)$*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(\mathsf{E1}(tail), q, a, unit, counit, left, right) \Rightarrow left\mathsf{hsamee} \Rightarrow right\mathsf{hsamee} \Rightarrow q = \mathsf{E1}(tail).$$

Proof. The empty roundtrip component theorem exposes the displayed empty natural-transformation component from $\mathsf{E1}(tail)$ to q. The NatTrans empty-component inversion for an $\mathsf{E1}$ source reads back the component data: the tail is unary, the object history is unary, and the displayed target prefix is exactly $\mathsf{E1}(tail)$. The last field is the required equality. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip e1 source target eq`

Theorem 110.6 (EquivCat empty roundtrip $\mathsf{E1}$ prefix tail determinacy)**.** *For histories* $sourceTail, targetTail, a, u$ BHist*, if an adjunction unit-counit carrier is displayed from* $\mathsf{E1}(sourceTail)$ *to* $\mathsf{E1}(targetTail)$ *and both roundtrip results classify to* e*, then*

$$sourceTail\mathsf{hsame}targetTail.$$

Proof. The empty roundtrip prefix determinacy theorem identifies the full prefixes $\mathsf{E1}(sourceTail)$ and $\mathsf{E1}(targetTail)$ by hsame. Inverting the one-headed constructor under hsame reads this back to $sourceTail\mathsf{hsame}targetTail$. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip e1 prefix tail hsame`

Theorem 110.7 (EquivCat empty roundtrip target-prefix determinacy)**.** *For histories* $p, q, r, a, unit, counit, left, r$ BHist*, if* $\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)$ *holds,* $left\mathsf{hsamee}$ *and* $right\mathsf{hsamee}$*, and*

$$\mathsf{NatTransPrefixComponentCarrier}(p, r, a, \mathsf{e})$$

is also displayed, then $q\mathsf{hsame}r$*.*

Proof. The empty roundtrip identity-components theorem extracts the reverse empty component

$$\mathsf{NatTransPrefixComponentCarrier}(q, p, a, \mathsf{e})$$

from the adjunction carrier and the two empty displayed roundtrips. Composing that empty component with the displayed empty component from p to r by NatTrans empty-identity prefix transitivity identifies the target prefix q with r. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip target prefix deterministic`

Theorem 110.8 (EquivCat empty roundtrip unit-counit equivalence)**.** *For histories* $p, q, a, unit, counit, left, right$ BHist*, if* $\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)$ *holds, then the two displayed roundtrip results classify to* e *exactly when the unit and counit components classify to* e*:*

$$left\mathsf{hsamee} \ \wedge \ right\mathsf{hsamee} \quad \Longleftrightarrow \quad unit\mathsf{hsamee} \ \wedge \ counit\mathsf{hsamee}.$$

Proof. The forward implication is the unit-counit part of the empty roundtrip prefix determinacy theorem. Conversely, after the unit and counit are identified with e, the stored triangle continuations have the same source and suffix as the right-unit continuation at e; continuation determinism identifies both displayed roundtrip results with e. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip unit counit empty iff`

Theorem 110.9 (EquivCat empty roundtrip unit-counit determinacy)**.** *For histories* $p, q, a, unit, unit', counit, cou$ BHist*, two carriers*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right) \qquad \textit{and} \qquad \mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit', c$$

whose left and right triangle results are all hsame *to* e *determine the same unit and counit up to* hsame*.*

Proof. Apply empty roundtrip prefix determinacy to both adjunction carriers. Each application identifies its unit and counit with e. Transitivity of hsame, using symmetry on the second pair of empty identifications, gives $unit\mathsf{hsame}unit'$ and $counit\mathsf{hsame}counit'$. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip unit counit deterministic`

Theorem 110.10 (EquivCat empty roundtrip source-prefix determinacy)**.** *For histories* $p, q, r, a, unit, counit, left,$ BHist*, if* $\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right)$ *holds,* $left\mathsf{hsamee}$ *and* $right\mathsf{hsamee}$*, and*

$$\mathsf{NatTransPrefixComponentCarrier}(r, q, a, \mathsf{e})$$

is also displayed, then $p\mathsf{hsame}r$*.*

Proof. The empty roundtrip identity-components theorem extracts the reverse empty component from q to p. Compose the displayed empty component from r to q with that reverse component by NatTrans empty-identity prefix transitivity; this gives $r\mathsf{hsame}p$. Symmetry of hsame gives the stated source-prefix equality. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip source prefix deterministic`

110.2 The certificate

Theorem 110.11 (Equivalence cycle identity carrier semantic certificate)**.** *For BEDC categorical hom carriers* $left : \mathsf{CategoryHomCarrier}(a, b, f)$ *and* $right : \mathsf{CategoryHomCarrier}(b, a, g)$*, the carrier of displayed cycle identities*

$$\mathsf{CategoryHomCarrier}(a, b, t) \wedge \mathsf{CategoryHomCarrier}(b, a, g) \wedge t\mathsf{hsamee} \wedge g\mathsf{hsamee}$$

has a semantic naming certificate with classifier hsame*.*

Proof. The cycle-tail theorem for categorical hom carriers identifies both cycle tails with the empty history. Transporting $left$ along the displayed tail comparison gives the witness at e, while $right$ supplies the fixed reverse carrier. The classifier laws are the finite-kernel equivalence laws for hsame. Carrier transport keeps the endpoints fixed, transports the first hom carrier along the classifier, and composes the inverse classifier with the stored empty-tail proof. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatCycleIdentityCarrier semanticNameCert`

Theorem 110.12 (EquivCat empty roundtrip identity carrier target-prefix hsame transport)**.** *For histories* $p, q, q', a, unit, counit, left, right : \mathsf{BHist}$*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right), \qquad left\mathsf{hsamee}, \qquad right\mathsf{hsamee}, \qquad q\mathsf{hsame}q'.$$

Then the empty roundtrip identity carrier transports to the target prefix q'*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q', a, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}),$$

and its empty identity component fields are

$$\mathsf{NatTransPrefixComponentCarrier}(p, q', a, \mathsf{e}) \quad \textit{and} \quad \mathsf{NatTransPrefixComponentCarrier}(q', p, a, \mathsf{e}).$$

Proof. Apply Definition 110.2 to the original carrier and the two empty roundtrip witnesses. This gives $p\mathsf{hsame}q$ and the empty component

$$\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}).$$

Reading this component through Definition 63.3 gives unary histories for p, q, and a. Unary transport along $q\mathsf{hsame}q'$ gives unary membership of q', and transitivity of hsame gives $p\mathsf{hsame}q'$.

The reverse implication of Definition 107.5, applied with both triangle results equal to e, now gives

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q', a, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}),$$

because the two triangle-result classifiers are reflexivity of $\mathsf{hsame}(\mathsf{e}, \mathsf{e})$. Finally, Definition 107.1 projects the first two fields of this carrier, giving the two displayed empty identity components for the transported target prefix. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatCycleIdentityCarrier target prefix hsame transport`
Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip target prefix hsame transport`

Theorem 110.13 (EquivCat empty roundtrip identity carrier source-prefix hsame transport)**.** *For histories* $p, p', q, a, unit, counit, left, right$: BHist*, suppose*

$$\mathsf{AdjunctionUnitCounitCarrier}(p, q, a, unit, counit, left, right), \qquad left\mathsf{hsamee}, \qquad right\mathsf{hsamee}, \qquad p\mathsf{hsame}p'.$$

Then the empty roundtrip identity carrier transports to the source prefix p'*:*

$$\mathsf{AdjunctionUnitCounitCarrier}(p', q, a, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}),$$

and its empty identity component fields are

$$\mathsf{NatTransPrefixComponentCarrier}(p', q, a, \mathsf{e}) \quad \textit{and} \quad \mathsf{NatTransPrefixComponentCarrier}(q, p', a, \mathsf{e}).$$

Proof. Apply Definition 110.2 to the original carrier and the two empty roundtrip witnesses. This gives $p\mathsf{hsame}q$ and the empty component

$$\mathsf{NatTransPrefixComponentCarrier}(p, q, a, \mathsf{e}).$$

Reading this component through Definition 63.3 gives unary histories for p, q, and a. Unary transport along $p\mathsf{hsame}p'$ gives unary membership of p', and transitivity of hsame, using symmetry on $p\mathsf{hsame}p'$, gives $p'\mathsf{hsame}q$.

The reverse implication of Definition 107.5, applied with both triangle results equal to e, now gives

$$\mathsf{AdjunctionUnitCounitCarrier}(p', q, a, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}),$$

because the two triangle-result classifiers are reflexivity of $\mathsf{hsame}(\mathsf{e}, \mathsf{e})$. Finally, Definition 107.1 projects the first two fields of this carrier, giving the two displayed empty identity components for the transported source prefix. □

Lean4 ✓ `BEDC.Derived.EquivCatUp.EquivCatAdjunction empty roundtrip source prefix hsame transport`

Closure status for $\mathsf{NameCert}_{\mathsf{EquivCat}\uparrow}$**.**

Constructive story: An EquivCat$^{\uparrow}$ certificate is generated from an adjunction unit-counit carrier with source and target prefix histories, object row, unit and counit component rows, two roundtrip result rows, continuation ledgers, and hsame transport. The BEDC carrier reads categorical equivalence through finite empty-roundtrip evidence: when both triangle results are empty, the unit and counit components are forced to empty identity components, and prefix sameness is recovered by the NatTrans classifier. The construction therefore names the equivalence interface through displayed adjunction rows, not through ambient category equality.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{EquivCat}\uparrow}$, seed)

Scope closed: This chapter binds the equivalence empty-roundtrip component, prefix determinacy, exclusion, and transport theorems.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{EquivCat}\uparrow}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim general categorical equivalence of arbitrary categories, univalence, quotient categories, or host isomorphism equality.

Upgrade path: To reach obligationClosure, package the checked empty-roundtrip adjunction theorems as the explicit EquivCatUp NameCert carrier.

Chapter 111

A Concrete Naming Certificate for $\mathsf{Set}^{\uparrow}$

The set interface $\mathsf{Set}^{\uparrow}$ packages a carrier together with a psame-classifier interpretable as set-membership equality. It is the type-layer counterpart of $\mathsf{NameCert}_{\mathsf{Preorder}^{\uparrow}}$ (chapter 52) at the discrete level, and the substrate for $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112) and $\mathsf{NameCert}_{\mathsf{Subtype}^{\uparrow}}$ (chapter 113).

111.1 Carrier definition

111.2 The certificate

Theorem 111.1 (Set carrier obligation)**.** *The carrier row of a* $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ *is a predicate* $A : \mathsf{BHist} \to \mathsf{Prop}$ *over BEDC histories. It is generated by membership-visible histories: a history* h *is carried exactly when the* Hist *presentation exposes a membership row for* h*, and the visible row is read through* BHist *rather than through a host-side set object.*

Proof. Unpack the source package as a Pkg row over Hist and read its public histories through the BHist interface. The carrier predicate records precisely those histories whose membership row is visible to the package boundary.

The construction is constructive because no host enumeration or host subset is selected. A carried witness is the displayed membership row together with its Pkg provenance, and forgetting the witness returns the original BHist history. This is the carrier surface consumed later by $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{Subtype}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.SetUp.SetCarrier obligation surface`

Theorem 111.2 (Set classifier obligation)**.** *For a fixed* $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ *carrier* A*, the classifier row is a* psame*-style membership classifier on carried histories. Two carried histories are classified together exactly when their membership-visible rows are identified by the BEDC presentation classifier; the row is not host equality of set elements and is not a quotient by an external relation.*

Lean4 ✓ `BEDC.Derived.SetUp.SetMembershipVisibleClassifier carrier hsame boundary`
Lean4 ✓ `BEDC.Derived.SetUp.SetMembershipVisibleClassifier carrier rows`

Proof. The classifier is read from the NameCert row attached to the package, so its inputs are carried histories with membership witnesses in A. Applying the psame classifier compares the visible membership rows and returns the certificate-level sameness relation.

Because the comparison is made inside psame, no appeal is made to host equality. Because the witnesses remain in the Pkg ledger, no quotient carrier is formed. The result is the classifier boundary required before finite enumeration in $\mathsf{FinSet}^{\uparrow}$ or predicate restriction in $\mathsf{Subtype}^{\uparrow}$ may consume the set source. □

Lean4 ✓ `BEDC.Derived.SetUp.SetPkgMembership semantic name certificate`

Theorem 111.3 (Set membership transport obligation)**.** *The* $\mathsf{Set}^{\uparrow}$ *membership row is stable under* hsame *transport and under the* psame *classifier. If h is carried by A, $h\,\mathsf{hsame}\,h'$, and the visible membership rows for h and h' are related by the classifier, then h' is carried by A with the transported membership witness and the same package provenance boundary.*

Lean4 ✓ `BEDC.Derived.SetUp.SetMembershipVisibleTransportChain carrier transport`

Proof. First transport the displayed Hist membership row along hsame. The transport changes only the presentation of the history, while the Pkg provenance records that the read remains inside the same certificate boundary.

Next apply the psame classifier row to the transported membership presentation. This supplies the certificate-level identification between the original membership read and the transported read.

Combining the transported witness with the classifier evidence yields a carried witness for h'. The dependency remains constructive and visible: the proof uses only NameCert, psame, hsame, and Pkg, so downstream $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{Subtype}^{\uparrow}$ consumers receive a stable membership row rather than an external equality principle. □

Theorem 111.4 (Set extensionality ledger obligation)**.** *The* $\mathsf{Set}^{\uparrow}$ *extensionality ledger records exactly the visible membership rows and their exact package boundary. Finite consumers such as* $\mathsf{FinSet}^{\uparrow}$ *and restricted consumers such as* $\mathsf{Subtype}^{\uparrow}$ *may consume the carrier A, the* psame *classifier, and the* hsame*-stable membership transport row, but they may not inspect hidden package data outside the ledger boundary.*

Lean4 ✓ `BEDC.Derived.SetUp.SetExtensionalityLedger semantic name certificate`

Proof. The extensionality row compares two $\mathsf{Set}^{\uparrow}$ presentations by their visible membership classifications. If the same BHist histories are carried and their visible membership rows agree by psame, the public set presentation agrees at the certificate boundary.

The exact ledger boundary is the accompanying Pkg provenance for those membership reads. It records which rows are exposed and which witnesses remain hidden, so finite enumeration in $\mathsf{FinSet}^{\uparrow}$ can use only occurrence of visible members and $\mathsf{Subtype}^{\uparrow}$ can use only visible restriction of the carrier.

Thus the ledger gives an extensionality obligation without exporting a host set, a host equality, or any hidden construction witness. The only downstream dependency made available is the membership-visible carrier, classifier, transport, and exact boundary described above. □

Theorem 111.5 (Set public NameCert export)**.** *The public* $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ *surface exported by the set construction is exactly the membership-visible* BHist *carrier row of Definition 111.1, the* psame*-style classifier row of Definition 111.2, the* hsame *membership-transport row of Definition 111.3, and the extensionality ledger boundary of Definition 111.4. As a public certificate it exposes those*

four rows as the whole downstream surface for $\mathsf{FinSet}^{\uparrow}$ *and* $\mathsf{Subtype}^{\uparrow}$*, and it exports no host set, no host equality, no quotient carrier, and no hidden package witness.*

Proof. The carrier clause is the membership-visible row supplied by Definition 111.1. The classifier clause is the psame boundary supplied by Definition 111.2, with the checked row `BEDC.Derived.SetUp.SetMembers` recording that the carrier and classifier rows are the visible rows of the certificate.

The transport clause is the hsame-stable membership row supplied by Definition 111.3, supported by the checked row `BEDC.Derived.SetUp.SetMembershipVisibleTransportChain_hsame`. The membership row itself is the semantic package row recorded by `BEDC.Derived.SetUp.SetPkgMembership_sem`

The ledger clause is Definition 111.4, supported by `BEDC.Derived.SetUp.SetExtensionalityLedger_semanti` That theorem states the boundary condition: visible membership rows may be consumed downstream, while host sets, host equality, quotient carriers, and hidden package witnesses remain outside the exported surface. These four clauses therefore assemble the public $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ certificate and nothing else. □

Lean4 ✓ `BEDC.Derived.SetUp.SetPublicNameCert transport target carrier`

Theorem 111.6 (Set public NameCert standard bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ *surface of Definition 111.5 gives a paper-level conservative standard bridge to the ordinary membership presentation of visible BEDC membership rows. Forward readback is the carried* BHist *membership row, reverse admission accepts only displayed membership rows, classifier preservation is the* psame *row of Definition 111.2, and no host data is exposed beyond the extensionality ledger of Definition 111.4.*

Proof. Start with the public certificate assembled in Definition 111.5. Its carrier component is exactly the membership-visible BHist row supplied by Definition 111.1, so reading from the standard side back into BEDC returns the carried membership row and no hidden host set.

For admission in the other direction, require the ordinary-side row to be displayed as a visible BEDC membership row. The membership-transport obligation of Definition 111.3 keeps that row stable under hsame transport, so the admitted row remains inside the same public certificate boundary.

Classifier preservation is then the psame classifier supplied by Definition 111.2. The bridge compares only visible membership rows, hence it preserves the certificate classifier without replacing it by host equality or a quotient relation.

Finally, Definition 111.4 supplies the no-host-leak clause. Its ledger records exactly which membership rows and package provenance are public, so composing these four obligations with the export theorem gives a conservative paper-level standard bridge for the visible $\mathsf{Set}^{\uparrow}$ membership presentation. □

Lean4 ✓ `BEDC.Derived.SetUp.SetPublicNameCert standard bridge`

Closure status for $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$**.**

Constructive story: A set in this certificate is not a host subset but a membership-visible package of BEDC histories: a history h enters the carrier exactly when the public Pkg boundary exposes a membership row for h. Two carried histories are classified by the package's psame membership classifier, with hsame transport moving the displayed history presentation while the membership provenance remains in the ledger. The source row is the same visible membership predicate, the pattern records that all comparisons pass through psame rather than host equality, and the extensionality ledger says which membership rows and package boundary are public while hidden witnesses stay hidden. The five name-certificate obligations are supplied by any displayed membership row for inhabitation, by the reflexive, symmetric, and transitive fields of the underlying certificate classifier, and by the transport row that carries membership along hsame and psame without leaving the package. A history h lies in the signature gap of a $\mathsf{Set}^{\uparrow}$ token p when the source-domain accepts its visible membership row, the signature relation pairs that row with an answer membership presentation and evidence ledger, and

token introduction names that answer as p; unfolded, h must be one of the public membership histories classified by the token's membership row. The standard bridge reads this surface as the ordinary membership presentation of visible BEDC rows and reads back only displayed membership rows, preserving psame and the no-host-leak ledger. The chapter registers this membership-visible construction under the name $\mathsf{Set}^{\uparrow}$; sethood is a public carrier/classifier boundary over histories, not a host set object, quotient carrier, hidden package witness, or external equality principle.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridge scope is the membership-visible carrier, psame classifier, hsame transport, extensionality ledger, and public NameCert export of Definition 111.5.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SetUp.SetPublicNameCert\_standard\_bridge`

Bridge status: paperBridge

Not claimed: This chapter does not close bridgeChecked verification, downstream $\mathsf{FinSet}^{\uparrow}$ or $\mathsf{Subtype}^{\uparrow}$ certificates, or Lean verification of the paper-level bridge theorem.

Upgrade path: No further paper-side theory upgrade remains for the membership-visible SetUp surface; bridgeChecked verification remains a separate formal-axis target.

Chapter 112

A Concrete Naming Certificate for $\mathsf{FinSet}^{\uparrow}$

The finite-set interface $\mathsf{FinSet}^{\uparrow}$ packages a $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ together with a finite enumeration witness via $\mathsf{NameCert}_{\mathsf{List}^{\uparrow}}$ (chapter 36). It depends on $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ (chapter 111) and is the substrate for combinatorial certificates such as $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$.

112.1 Carrier definition

112.2 The certificate

Definition 112.1 (Finite-spine enumeration membership)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^{\uparrow}$ certificate with classifier $\sim_A$. For a finite BEDC-history spine $xs : \mathsf{HistSpine}$, let $\mathsf{Pos}(xs)$ be its finite position carrier and let $\mathsf{entry}_{xs} : \mathsf{Pos}(xs) \to \mathsf{BHist}$ be its entry readback. Define enumeration membership by*

$$\mathsf{EnumMem}_{A,\sim_A}(z, xs) \iff A(z) \wedge \exists i : \mathsf{Pos}(xs).\ A(\mathsf{entry}_{xs}(i)) \wedge z \sim_A \mathsf{entry}_{xs}(i).$$

The enumeration-induced $\mathsf{FinSet}^{\uparrow}$ classifier between two finite-spine presentations is

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, ys) \iff \forall z : \mathsf{BHist}.\ \mathsf{EnumMem}_{A,\sim_A}(z, xs) \iff \mathsf{EnumMem}_{A,\sim_A}(z, ys).$$

This is the extensional classifier read from the enumeration witness used by the finite-set presentation in chapter 112.

Definition 112.2 (Classifier-preserving enumeration permutation)**.** *For finite BEDC-history spines xs and ys, define $\mathsf{EnumPerm}_{A,\sim_A}(xs, ys)$ to mean that there is a certified finite-position bijection*

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$$

such that every matched pair of entries is carried by the fixed $\mathsf{Set}^{\uparrow}$ source and classified by its classifier:

$$\forall i : \mathsf{Pos}(xs).\ A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{ys}(\pi(i))) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

The inverse position map π^{-1} is part of the certified bijection. This is the enumeration-level presentation datum used by the $\mathsf{Permutation}^{\uparrow}$ interface in chapter 116.

Theorem 112.3 (FinSet classifier invariant under enumeration permutation)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate, let* $\sim_A$ *be its classifier, and let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*. For finite BEDC-history spines* xs *and* ys*, if*

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, ys)$$

holds, then

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, ys)$$

holds. Equivalently, replacing a $\mathsf{FinSet}^{\uparrow}$ *enumeration witness by a certified permutation that preserves the fixed source classifier pointwise leaves the induced finite-set classifier unchanged.*

Proof. Unfold Definition 112.2 and choose the certified bijection π with its pointwise classifier-preservation field. Unfold Definition 112.1. It is enough to fix a query history z and prove the two membership implications.

For the forward implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$. Then $A(z)$ holds and there is a position $i : \mathsf{Pos}(xs)$ such that $A(\mathsf{entry}_{xs}(i))$ and

$$z \sim_A \mathsf{entry}_{xs}(i)$$

hold. The permutation field at i gives $A(\mathsf{entry}_{ys}(\pi(i)))$ and

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

The transitivity field of the naming certificate from Definition 9.7, applied to these two classifier witnesses, gives

$$z \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

Using the position $\pi(i)$ and the carried-entry witness just obtained, this repacks as $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$.

For the reverse implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$. Then $A(z)$ holds and there is a position $j : \mathsf{Pos}(ys)$ such that $A(\mathsf{entry}_{ys}(j))$ and

$$z \sim_A \mathsf{entry}_{ys}(j)$$

hold. Put $i = \pi^{-1}(j)$. The pointwise preservation field at i gives

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(j),$$

because $\pi(i) = j$, and it also gives $A(\mathsf{entry}_{xs}(i))$. The symmetry field of cert reverses the matched-entry comparison to

$$\mathsf{entry}_{ys}(j) \sim_A \mathsf{entry}_{xs}(i).$$

Transitivity of the same classifier composes this with $z \sim_A \mathsf{entry}_{ys}(j)$ and yields

$$z \sim_A \mathsf{entry}_{xs}(i).$$

The position i therefore witnesses $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$.

The two implications hold for every query history z, so the two enumeration-induced predicates are pointwise equivalent. By Definition 112.1, this is exactly $\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, ys)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationClassifier permutation invariant`

Definition 112.4 (Finite-spine occurrence)**.** *For a finite spine* $xs : \mathsf{HistSpine}$ *and a history* $x : \mathsf{BHist}$*, the predicate* $\mathsf{SpineMember}(x, xs)$ *is generated by two clauses:* $\mathsf{SpineMember}(x, \mathsf{cons}(x, ys))$ *for every tail* ys*, and if* $\mathsf{SpineMember}(x, ys)$ *then* $\mathsf{SpineMember}(x, \mathsf{cons}(y, ys))$ *for every head* y*. There is no clause for* nil*.*

Definition 112.5 (FinSet enumeration carrier)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of the underlying* $\mathsf{NameCert}_{\mathsf{Set}^\uparrow}$*, let* $\sim_A$ *be its classifier, and let* $xs : \mathsf{HistSpine}$ *be the finite spine supplied by the* $\mathsf{List}^\uparrow$ *enumeration witness of Definition 36.57. Define the finite-set carrier represented by* xs *by*

$$\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(a) \iff A(a) \wedge \exists x : \mathsf{BHist}.\ \mathsf{SpineMember}(x, xs) \wedge a \sim_A x.$$

Lean4 (definition) `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier`

Lemma 112.6 (Enumeration spine entries are source-carried)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be a BEDC history source carrier. If* $\mathsf{ListSpineRep}_A(e, xs)$ *and* $\mathsf{SpineMember}(x, xs)$ *hold, then* $A(x)$ *holds.*

Proof. Induct on the displayed $\mathsf{ListSpineRep}_A(e, xs)$ witness from Definition 36.57. The nil representation has $xs = \mathsf{nil}$, and Definition 112.4 gives no occurrence clause for nil. In the cons representation, the occurrence of x in $\mathsf{cons}(a, xs')$ is either the head occurrence or a tail occurrence. The head case returns the stored source witness $A(a)$. The tail case applies the induction hypothesis to the tail representation $\mathsf{ListSpineRep}_A(t, xs')$ and the displayed tail occurrence. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationBundle member source carried`

Theorem 112.7 (FinSet enumeration membership exactness)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of the underlying* $\mathsf{NameCert}_{\mathsf{Set}^\uparrow}$*, let* $\sim_A$ *be its classifier, let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*, and let* e *and* xs *satisfy* $\mathsf{ListSpineRep}_A(e, xs)$*. Then for every history* a*,*

$$\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(a) \iff \exists x : \mathsf{BHist}.\ \mathsf{SpineMember}(x, xs) \wedge a \sim_A x.$$

Proof. For the forward direction, unpack Definition 112.5 and keep the displayed occurrence and classifier witness.

For the reverse direction, take a witness x with $\mathsf{SpineMember}(x, xs)$ and $a \sim_A x$. The enumeration witness and Definition 112.6 give $A(x)$. The symmetry field of cert, as part of Definition 9.7, turns $a \sim_A x$ into $x \sim_A a$. Carrier transport from the same certificate carries $A(x)$ along this comparison to obtain $A(a)$. Pair this carrier witness with the original occurrence and classifier witness, and repack by Definition 112.5. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier membership exactness`

Definition 112.8 (Projection-stable finite membership readback)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of the underlying* $\mathsf{NameCert}_{\mathsf{Set}^\uparrow}$*, let* $\sim_A$ *be its classifier, and let* $xs : \mathsf{HistSpine}$ *be a finite enumeration spine. A projection readback row for* xs *is a carried map*

$$\mathsf{proj} : \mathsf{BHist} \to \mathsf{BHist}$$

whose fixed histories are exactly the histories represented by the finite enumeration:

$$\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(z) \iff \mathsf{hsame}(\mathsf{proj}(z), z).$$

The associated predicate records both sides of that readback,

$$\mathsf{ProjectionStableReadback}_{A,\sim_A,xs,\mathsf{proj}}(z) \iff \mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(z) \wedge \mathsf{hsame}(\mathsf{proj}(z), z).$$

Thus finite membership is read from a fixed-point row over a finite enumeration carrier, rather than from an external set-theoretic primitive.

Lean4 (definition) `BEDC.Derived.FinsetUp.FinsetProjectionStableReadback`

Theorem 112.9 (Projection-stable readback is finite membership)**.** *Assume the projection readback row above. Then for every history z,*

$$\mathsf{ProjectionStableReadback}_{A,\sim_A,xs,\mathsf{proj}}(z) \iff \mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(z),$$

and also

$$\mathsf{ProjectionStableReadback}_{A,\sim_A,xs,\mathsf{proj}}(z) \iff \mathsf{hsame}(\mathsf{proj}(z), z).$$

Proof. Unfold Definition 112.8. The predicate is the conjunction of finite-enumeration membership and projection stability, and the readback row identifies these conjuncts pointwise. Projection gives each implication out of the readback predicate; either conjunct conversely supplies the other and repacks the conjunction. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetProjectionStableReadback membership iff`
Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetProjectionStableReadback stability iff`

Theorem 112.10 (Projection-stable readback respects the source classifier)**.** *Let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$ *and assume the same projection readback row. If $a \sim_A b$ and* $\mathsf{hsame}(\mathsf{proj}(a), a)$*, then*

$$\mathsf{hsame}(\mathsf{proj}(b), b).$$

Proof. The readback row converts stability of a into finite-enumeration membership for a. The finite-set enumeration carrier is stable under the source classifier: carrier transport carries $A(a)$ to $A(b)$, and classifier symmetry and transitivity carry the enumeration witness from a to b. Applying the readback row again converts membership for b into projection stability. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier classifier transport`
Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetProjectionStableReadback classifier transport`

Lemma 112.11 (Finite-spine occurrence has a position readback)**.** *For every finite BEDC-history spine* $xs : \mathsf{HistSpine}$ *and history* $y : \mathsf{BHist}$*, if* $\mathsf{SpineMember}(y, xs)$ *holds, then*

$$\exists j : \mathsf{Pos}(xs).\ \mathsf{entry}_{xs}(j) = y.$$

Proof. Induct on the generated occurrence witness from Definition 112.4. In the head clause $\mathsf{SpineMember}(y, \mathsf{cons}(y, ys))$, choose the head position of $\mathsf{cons}(y, ys)$; its readback is y. In the tail clause, the induction hypothesis gives a position $j : \mathsf{Pos}(ys)$ with $\mathsf{entry}_{ys}(j) = y$. Use the tail-position inclusion $\mathsf{Pos}(ys) \to \mathsf{Pos}(\mathsf{cons}(x, ys))$; its readback is the same tail entry, so it witnesses the displayed equality for $\mathsf{cons}(x, ys)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetBundleMember position readback`

Theorem 112.12 (FinSet duplicate insertion invariance)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate, let* $\sim_A$ *be its classifier, and let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*. For a finite BEDC-history spine* $xs : \mathsf{HistSpine}$ *and histories* $x, y : \mathsf{BHist}$*, if*

$$A(x) \wedge A(y) \wedge \mathsf{SpineMember}(y, xs) \wedge x \sim_A y,$$

then

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(\mathsf{cons}(x, xs), xs)$$

holds. Thus a source-carried head entry whose source classifier class is already represented in the finite spine is invisible to the induced $\mathsf{FinSet}^{\uparrow}$ *classifier.*

Proof. Unpack the displayed assumptions as $A(x)$, $A(y)$, an occurrence $\mathsf{SpineMember}(y, xs)$, and a classifier witness $x \sim_A y$. By Definition 112.11, choose a position $j : \mathsf{Pos}(xs)$ with $\mathsf{entry}_{xs}(j) = y$.

Unfold Definition 112.1. It is enough to fix a query history z and prove the two membership implications between $\mathsf{cons}(x, xs)$ and xs.

For the forward implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs))$. Then $A(z)$ holds and some position of the cons spine carries an entry classified with z. Case-analyze that position. If it is the head position, the readback is x, so the witness supplies $z \sim_A x$. The transitivity field of cert from Definition 9.7 composes $z \sim_A x$ with $x \sim_A y$ and gives $z \sim_A y$. Rewriting y as $\mathsf{entry}_{xs}(j)$, the position j together with $A(y)$ repacks as $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$. If the cons-position is inherited from the tail, its readback is already a position of xs with the same carried-entry and classifier witnesses, so it repacks directly as $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$.

For the reverse implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$. Keep its source witness $A(z)$ and its position $i : \mathsf{Pos}(xs)$ with $A(\mathsf{entry}_{xs}(i))$ and $z \sim_A \mathsf{entry}_{xs}(i)$. View i as the corresponding tail position of $\mathsf{cons}(x, xs)$. The cons readback at that tail position is $\mathsf{entry}_{xs}(i)$, so the same carried-entry and classifier witnesses repack as $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs))$.

The two implications hold for every query history z. By the classifier clause in Definition 112.1, this is exactly $\mathsf{FinSetEnumClassifier}_{A,\sim_A}(\mathsf{cons}(x, xs), xs)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationClassifier duplicate insert`

Lemma 112.13 (Certified finite-position bijections compose)**.** *For finite BEDC-history spines xs, ys, and zs, certified finite-position bijections*

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys) \qquad \textit{and} \qquad \rho : \mathsf{Pos}(ys) \cong \mathsf{Pos}(zs)$$

compose to a certified finite-position bijection

$$\rho \circ \pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(zs),$$

whose inverse position map is $\pi^{-1} \circ \rho^{-1}$.

Proof. The certified-bijection data in Definition 112.2 consist of a forward position map, an inverse position map, and the two inverse identities. For the composite, take the forward position map $\rho \circ \pi$ and the inverse position map $\pi^{-1} \circ \rho^{-1}$. The left and right inverse identities follow by applying first the inverse identities of ρ and then the inverse identities of π, in the corresponding order. Thus the composite map carries the same certified-bijection data required in Definition 112.2. □

Theorem 112.14 (EnumPerm transitivity by bijection composition)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^{\uparrow}$ certificate, let $\sim_A$ be its classifier, and let $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$. For finite BEDC-history spines xs, ys, and zs, if*

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, ys) \qquad \textit{and} \qquad \mathsf{EnumPerm}_{A,\sim_A}(ys, zs)$$

hold, then

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, zs)$$

holds.

Proof. Unfold Definition 112.2. Choose from the first permutation a certified bijection $\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$ and a pointwise preservation field

$$P_\pi(i) : A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{ys}(\pi(i))) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

Choose from the second permutation a certified bijection $\rho : \mathsf{Pos}(ys) \cong \mathsf{Pos}(zs)$ and a pointwise preservation field

$$P_\rho(j) : A(\mathsf{entry}_{ys}(j)) \wedge A(\mathsf{entry}_{zs}(\rho(j))) \wedge \mathsf{entry}_{ys}(j) \sim_A \mathsf{entry}_{zs}(\rho(j)).$$

By Definition 112.13, $\rho \circ \pi$ is a certified bijection from $\mathsf{Pos}(xs)$ to $\mathsf{Pos}(zs)$.

It remains to verify the pointwise classifier-preservation field for the composite. Fix $i : \mathsf{Pos}(xs)$. The field $P_\pi(i)$ gives

$$A(\mathsf{entry}_{xs}(i)) \qquad \text{and} \qquad \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

The field $P_\rho(\pi(i))$ gives

$$A(\mathsf{entry}_{zs}(\rho(\pi(i)))) \qquad \text{and} \qquad \mathsf{entry}_{ys}(\pi(i)) \sim_A \mathsf{entry}_{zs}(\rho(\pi(i))).$$

The transitivity field of cert, equivalently Definition 9.8, composes the two classifier witnesses and yields

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{zs}(\rho(\pi(i))).$$

Together with the displayed carrier witnesses, this is exactly the pointwise preservation clause for the composite certified bijection. Repacking the composite bijection and this field gives $\mathsf{EnumPerm}_{A,\sim_A}(xs, zs)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationPermutation trans`

Lemma 112.15 (Pointwise enumeration membership equivalences compose)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be a BEDC history source carrier, let $\sim_A$ be a source classifier, and let xs, ys, and zs be finite BEDC-history spines. If, for every query history q,*

$$\mathsf{EnumMem}_{A,\sim_A}(q, xs) \iff \mathsf{EnumMem}_{A,\sim_A}(q, ys)$$

and

$$\mathsf{EnumMem}_{A,\sim_A}(q, ys) \iff \mathsf{EnumMem}_{A,\sim_A}(q, zs)$$

hold, then, for every query history q,

$$\mathsf{EnumMem}_{A,\sim_A}(q, xs) \iff \mathsf{EnumMem}_{A,\sim_A}(q, zs).$$

Proof. Fix a query history q. For the forward implication, assume $\mathsf{EnumMem}_{A,\sim_A}(q, xs)$. The forward half of the first displayed equivalence gives $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$, and the forward half of the second displayed equivalence gives $\mathsf{EnumMem}_{A,\sim_A}(q, zs)$.

For the reverse implication, assume $\mathsf{EnumMem}_{A,\sim_A}(q, zs)$. The reverse half of the second displayed equivalence gives $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$, and the reverse half of the first displayed equivalence gives $\mathsf{EnumMem}_{A,\sim_A}(q, xs)$. Thus the two enumeration-membership predicates are equivalent at q. Since q was arbitrary, the pointwise equivalence holds for all query histories. □

Theorem 112.16 (FinSet enumeration classifier transitivity)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^\uparrow$ certificate, let $\sim_A$ be its classifier, and let $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$. For finite BEDC-history spines xs, ys, and zs, if*

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, ys) \qquad \textit{and} \qquad \mathsf{FinSetEnumClassifier}_{A,\sim_A}(ys, zs)$$

hold, then

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, zs)$$

holds.

Proof. The certificate fixes the ambient source and classifier. Unfold the classifier clause in Definition 112.1. The first hypothesis supplies, for every query history q, the equivalence between $\mathsf{EnumMem}_{A,\sim_A}(q, xs)$ and $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$. The second supplies, for the same q, the equivalence between $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$ and $\mathsf{EnumMem}_{A,\sim_A}(q, zs)$.

By Definition 112.15, these two pointwise equivalences compose to

$$\forall q : \mathsf{BHist}.\ \mathsf{EnumMem}_{A,\sim_A}(q, xs) \Longleftrightarrow \mathsf{EnumMem}_{A,\sim_A}(q, zs).$$

Applying the same classifier clause in Definition 112.1 repacks this pointwise statement as $\mathsf{FinSetEnumClassifier}_{A,\sim_A}($ □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationClassifier trans`

Definition 112.17 (Finite-spine predicate enumeration)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate with classifier* $\sim_A$*. For a finite BEDC-history spine* $xs : \mathsf{HistSpine}$ *and a predicate* $U : \mathsf{BHist} \to \mathsf{Prop}$*, define*

$$\mathsf{FinSetSpineEnumerates}_{A,\sim_A}(xs, U) \Longleftrightarrow \forall z : \mathsf{BHist}.\ \mathsf{EnumMem}_{A,\sim_A}(z, xs) \Longleftrightarrow U(z).$$

Lemma 112.18 (Enumeration membership splits over spine append)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate with classifier* $\sim_A$*. For finite BEDC-history spines* $xs, ys : \mathsf{HistSpine}$ *and every query history* $z : \mathsf{BHist}$*,*

$$\mathsf{EnumMem}_{A,\sim_A}(z, xs{+}{+}ys) \Longleftrightarrow \mathsf{EnumMem}_{A,\sim_A}(z, xs) \vee \mathsf{EnumMem}_{A,\sim_A}(z, ys).$$

Proof. Proceed by induction on the left spine xs, using the finite-spine constructors from Definition 36.57 and the position readback clause of Definition 112.1.

If $xs = \mathsf{nil}$, then $xs{+}{+}ys = ys$ and $\mathsf{Pos}(\mathsf{nil})$ has no positions. Thus $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{nil})$ has no position witness, while $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{nil}{+}{+}ys)$ is exactly $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$. The required equivalence follows.

Now write $xs = \mathsf{cons}(x, xs_0)$ and assume the statement for xs_0 and ys. Then $xs{+}{+}ys = \mathsf{cons}(x, xs_0{+}{+}ys)$. A position of this cons spine is either the head position, whose readback is x, or a tail position coming from $xs_0{+}{+}ys$.

For the forward implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs_0{+}{+}ys))$. Keep the displayed witness $A(z)$ and case-analyze its position. In the head case, the same head position of $\mathsf{cons}(x, xs_0)$ carries $A(x)$ and the same classifier witness $z \sim_A x$, so $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs_0))$ holds. In the tail case, the witness is a position of $xs_0{+}{+}ys$ with unchanged readback. The induction hypothesis gives either $\mathsf{EnumMem}_{A,\sim_A}(z, xs_0)$ or $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$. The first alternative embeds through the tail position of $\mathsf{cons}(x, xs_0)$, giving the left disjunct; the second alternative is already the right disjunct.

For the reverse implication, suppose $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs_0)) \vee \mathsf{EnumMem}_{A,\sim_A}(z, ys)$. If the left disjunct holds, case-analyze its cons position. A head witness repacks at the head of $\mathsf{cons}(x, xs_0{+}{+}ys)$. A tail witness gives $\mathsf{EnumMem}_{A,\sim_A}(z, xs_0)$; by the reverse half of the induction hypothesis it yields $\mathsf{EnumMem}_{A,\sim_A}(z, xs_0{+}{+}ys)$, which then embeds through the tail position of $\mathsf{cons}(x, xs_0{+}{+}ys)$. If the right disjunct holds, the reverse half of the induction hypothesis gives $\mathsf{EnumMem}_{A,\sim_A}(z, xs_0{+}{+}ys)$, and the same tail-position embedding gives $\mathsf{EnumMem}_{A,\sim_A}(z, \mathsf{cons}(x, xs_0{+}{+}ys))$.

The two implications prove the displayed equivalence for the cons spine, completing the induction. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier bundleAppend split`
Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier append split`

Theorem 112.19 (Finite-spine concatenation enumerates finite-set union)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate with classifier* $\sim_A$*. Let* $xs, ys : \mathsf{HistSpine}$ *be finite BEDC-history spines, and let* $U, V : \mathsf{BHist} \to \mathsf{Prop}$ *be predicates. If*

$$\mathsf{FinSetSpineEnumerates}_{A,\sim_A}(xs, U) \qquad \textit{and} \qquad \mathsf{FinSetSpineEnumerates}_{A,\sim_A}(ys, V)$$

hold, then the concatenated finite spine enumerates the finite-set union predicate:

$$\mathsf{FinSetSpineEnumerates}_{A,\sim_A}(xs{+}{+}ys, \lambda z.\, U(z) \vee V(z)).$$

Proof. Unfold Definition 112.17. Fix a query history $z : \mathsf{BHist}$. By Definition 112.18,

$$\mathsf{EnumMem}_{A,\sim_A}(z, xs{+}{+}ys) \iff \mathsf{EnumMem}_{A,\sim_A}(z, xs) \vee \mathsf{EnumMem}_{A,\sim_A}(z, ys).$$

The first enumeration hypothesis converts $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$ exactly into $U(z)$, and the second converts $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$ exactly into $V(z)$.

For the forward implication, assume $\mathsf{EnumMem}_{A,\sim_A}(z, xs{+}{+}ys)$. The append split gives membership in xs or membership in ys. Applying the corresponding enumeration hypothesis yields $U(z)$ or $V(z)$.

For the reverse implication, assume $U(z) \vee V(z)$. In the $U(z)$ case, the reverse half of the first enumeration hypothesis gives $\mathsf{EnumMem}_{A,\sim_A}(z, xs)$, and the reverse half of the append split gives membership in $xs{+}{+}ys$. In the $V(z)$ case, the reverse half of the second enumeration hypothesis gives $\mathsf{EnumMem}_{A,\sim_A}(z, ys)$, and the reverse half of the append split again gives membership in $xs{+}{+}ys$.

Thus for every z the appended enumeration predicate is equivalent to $U(z) \vee V(z)$, which is exactly the displayed enumeration claim. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationCarrier bundleAppend union`

Lemma 112.20 (Certified finite-position identity bijection)**.** *For every finite BEDC-history spine* $xs : \mathsf{HistSpine}$*, the identity map on* $\mathsf{Pos}(xs)$ *is a certified finite-position bijection*

$$\mathsf{id}_{xs} : \mathsf{Pos}(xs) \cong \mathsf{Pos}(xs),$$

with inverse map again the identity map.

Proof. Take the forward position map to be $i \mapsto i$ and take the inverse position map to be the same function. The two inverse identities are the pointwise equalities $i = i$ and $j = j$ for positions of xs. These data are exactly the certified finite-position bijection data used in Definition 112.2. □

Theorem 112.21 (EnumPerm identity closure)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^{\uparrow}$ *certificate, let* $\sim_A$ *be its classifier, and let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*. For every finite BEDC-history spine* $xs : \mathsf{HistSpine}$*, if every entry of* xs *is carried by* A*,*

$$\forall i : \mathsf{Pos}(xs).\ A(\mathsf{entry}_{xs}(i)),$$

then

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, xs)$$

holds.

Proof. Use the certified identity bijection from Definition 112.20. It remains only to verify the pointwise preservation field required by Definition 112.2.

Fix a position $i : \mathsf{Pos}(xs)$. The carried-entry hypothesis gives

$$A(\mathsf{entry}_{xs}(i)).$$

For the identity bijection, the matched source position and target position are both i, so the source and target entries in the matched pair are the same history $\mathsf{entry}_{xs}(i)$. The reflexivity field of cert, supplied by the naming certificate in Definition 9.7, applies to the displayed carrier witness and gives

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{xs}(i).$$

Thus the matched pair at i satisfies

$$A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{xs}(i)) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{xs}(i).$$

Since i was arbitrary, the certified identity bijection carries the required pointwise classifier-preservation field. Repacking these data by Definition 112.2 proves $\mathsf{EnumPerm}_{A,\sim_A}(xs, xs)$. □

Lemma 112.22 (Pointwise enumeration membership equivalences invert)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be a BEDC history source carrier, let $\sim_A$ be a source classifier, and let xs and ys be finite BEDC-history spines. If, for every query history q,*

$$\mathsf{EnumMem}_{A,\sim_A}(q, xs) \iff \mathsf{EnumMem}_{A,\sim_A}(q, ys)$$

holds, then, for every query history q,

$$\mathsf{EnumMem}_{A,\sim_A}(q, ys) \iff \mathsf{EnumMem}_{A,\sim_A}(q, xs)$$

holds.

Proof. Fix a query history q. The displayed hypothesis at q supplies both membership implications between the two finite-spine enumeration predicates. For the forward implication in the inverted direction, assume $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$. The reverse half of the hypothesis at q gives $\mathsf{EnumMem}_{A,\sim_A}(q, xs)$. For the reverse implication in the inverted direction, assume $\mathsf{EnumMem}_{A,\sim_A}(q, xs)$. The forward half of the hypothesis at q gives $\mathsf{EnumMem}_{A,\sim_A}(q, ys)$. Since q was arbitrary, the inverted pointwise equivalence holds for all query histories. □

Theorem 112.23 (FinSet enumeration classifier symmetry)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^{\uparrow}$ certificate, let $\sim_A$ be its classifier, and let xs and ys be finite BEDC-history spines. If*

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(xs, ys)$$

holds, then

$$\mathsf{FinSetEnumClassifier}_{A,\sim_A}(ys, xs)$$

holds.

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationClassifier symm`

Proof. Unfold the classifier clause in Definition 112.1. The hypothesis supplies, for every query history q, the pointwise equivalence

$$\mathsf{EnumMem}_{A,\sim_A}(q, xs) \iff \mathsf{EnumMem}_{A,\sim_A}(q, ys).$$

By Definition 112.22, this equivalence inverts pointwise to

$$\forall q : \mathsf{BHist}.\ \mathsf{EnumMem}_{A,\sim_A}(q, ys) \iff \mathsf{EnumMem}_{A,\sim_A}(q, xs).$$

Applying the same classifier clause in Definition 112.1 repacks this pointwise statement as $\mathsf{FinSetEnumClassifier}_{A,\sim_A}($ □

Lemma 112.24 (Certified finite-position bijections invert)**.** *For finite BEDC-history spines xs and ys, any certified finite-position bijection*

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$$

has an inverse certified finite-position bijection

$$\pi^{-1} : \mathsf{Pos}(ys) \cong \mathsf{Pos}(xs),$$

whose inverse position map is π.

Proof. By the certified-bijection clause recalled in Definition 112.2, the datum for π consists of the forward position map π, the inverse position map π^{-1}, and the two inverse identities

$$\pi^{-1}(\pi(i)) = i \qquad \text{and} \qquad \pi(\pi^{-1}(j)) = j.$$

For the reversed bijection, take forward map π^{-1} and inverse map π. Its two identities are exactly the same two identities with the source and target position carriers exchanged. □

Theorem 112.25 (EnumPerm inverse symmetry)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^{\uparrow}$ certificate, let $\sim_A$ be its classifier, and let $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$. For finite BEDC-history spines xs and ys, if*

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, ys)$$

holds, then

$$\mathsf{EnumPerm}_{A,\sim_A}(ys, xs)$$

holds.

Proof. Unfold Definition 112.2. Choose the certified bijection

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$$

and its pointwise preservation field P_π. By Definition 112.24, π^{-1} is a certified bijection from $\mathsf{Pos}(ys)$ to $\mathsf{Pos}(xs)$.

It remains to verify the pointwise preservation field for this inverse bijection. Fix $j : \mathsf{Pos}(ys)$ and put $i = \pi^{-1}(j)$. The inverse identity gives $\pi(i) = j$. The field $P_\pi(i)$ gives

$$A(\mathsf{entry}_{xs}(i)) \qquad \text{and} \qquad A(\mathsf{entry}_{ys}(\pi(i)))$$

and also

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

Using $\pi(i) = j$, these become the carrier witnesses $A(\mathsf{entry}_{xs}(i))$ and $A(\mathsf{entry}_{ys}(j))$, together with the classifier comparison

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(j).$$

The symmetry field of cert, supplied by Definition 9.7, reverses this comparison to

$$\mathsf{entry}_{ys}(j) \sim_A \mathsf{entry}_{xs}(i).$$

Thus j satisfies the pointwise carrier-and-classifier clause required for the inverse map π^{-1}. Since j was arbitrary, the inverse certified bijection and this pointwise field repack as $\mathsf{EnumPerm}_{A,\sim_A}(ys, xs)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationPermutation symm`

Theorem 112.26 (EnumPerm identity reflexivity)**.** *Let $A : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a fixed $\mathsf{Set}^{\uparrow}$ certificate, let $\sim_A$ be its classifier, and let $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$. For every finite BEDC-history spine $xs : \mathsf{HistSpine}$, if every position entry is carried by A,*

$$\forall i : \mathsf{Pos}(xs).\ A(\mathsf{entry}_{xs}(i)),$$

then

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, xs)$$

holds, witnessed by the identity bijection on $\mathsf{Pos}(xs)$.

Proof. Unfold Definition 112.2. Supply the certified finite-position bijection whose forward map and inverse map are both the identity function on $\mathsf{Pos}(xs)$. The two inverse identities are the pointwise equalities $i = i$ and $j = j$, so this is a certified bijection from $\mathsf{Pos}(xs)$ to itself.

It remains to verify the pointwise carrier-and-classifier field. Fix a position $i : \mathsf{Pos}(xs)$. The hypothesis gives

$$A(\mathsf{entry}_{xs}(i)).$$

Under the identity position map, the matched source and target entries are both $\mathsf{entry}_{xs}(i)$. The reflexivity field of cert, supplied by Definition 9.7, gives

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{xs}(i).$$

Therefore the matched pair at i satisfies

$$A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{xs}(i)) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{xs}(i).$$

Since i was arbitrary, the identity certified bijection has the required pointwise preservation field. Repacking these data proves $\mathsf{EnumPerm}_{A,\sim_A}(xs, xs)$. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationPermutation refl`

Definition 112.27 (FinSet NameCert obligation packet)**.** *The finite-set certificate obligation packet for $\mathsf{FinSet}^{\uparrow}$ consists of the following ten fields:*

1. *a traditional finite subset predicate $U : \mathsf{BHist} \to \mathsf{Prop}$;*
2. *a BEDC source certificate $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ with carrier A and classifier $\sim_A$;*
3. *a $\mathsf{NameCert}_{\mathsf{List}^{\uparrow}}$ finite spine $xs : \mathsf{HistSpine}$ satisfying $\mathsf{ListSpineRep}_A(e, xs)$;*

4. *the carrier* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)$ *from Definition 112.5;*
5. *the classifier* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ *from Definition 112.1;*
6. *the stability rows for certified enumeration permutation, duplicate insertion, classifier transitivity, classifier symmetry, and append-union concatenation;*
7. *the finite-position ledger* $\mathsf{Pos}(xs)$ *with readback* entry_{xs} *and certified bijections between position carriers;*
8. *the exactness predicate comparing* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)(a)$ *with finite-spine occurrence modulo* $\sim_A$*;*
9. *the standard finite-set bridge that reads the enumerated predicate* U *through* $\mathsf{FinSetSpineEnumerates}_{A,\sim_A}(xs, U)$*;*
10. *the status assertion that the listed fields are obligations for* $\mathsf{NameCert}_{\mathsf{FinSet}\uparrow}$ *rather than a closed public finite-set API.*

Theorem 112.28 (FinSet carrier obligation)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the source carrier of a fixed* $\mathsf{NameCert}_{\mathsf{Set}\uparrow}$*, let* $\sim_A$ *be its classifier, let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*, and let* e *and* xs *satisfy* $\mathsf{ListSpineRep}_A(e, xs)$*. Then the carrier field of Definition 112.27 is exact: for every history* a*, membership in* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}(xs)$ *is precisely finite-spine occurrence in* xs *modulo* $\sim_A$*.*

Proof. The carrier field of the packet is definitionally the carrier in Definition 112.5. The required exactness statement is exactly the bidirectional membership statement of Definition 112.7, with the displayed $\mathsf{ListSpineRep}_A(e, xs)$ witness supplying the finite-spine source condition.

Thus the packet records no additional carrier structure beyond the source certificate, the finite spine, and the exactness row already proved for $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$. □

Theorem 112.29 (FinSet classifier obligation rows)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the source carrier of a fixed* $\mathsf{NameCert}_{\mathsf{Set}\uparrow}$*, let* $\sim_A$ *be its classifier, and let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*. The classifier field of Definition 112.27 carries the finite-set obligation rows for certified enumeration permutation, duplicate insertion, append-union enumeration, and equivalence closure.*

Proof. The permutation row is Definition 112.3: a certified finite-position bijection preserving A and $\sim_A$ pointwise leaves $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ unchanged.

The duplicate row is Definition 112.12: a source-carried head entry already represented in the spine is invisible to the classifier. The append-union row is Definition 112.19: concatenating finite spines enumerates the union predicate.

The equivalence rows are Definition 112.16 and Definition 112.23. Together with the reflexive identity row proved above, these rows give the classifier obligation surface needed by the packet. □

Theorem 112.30 (FinSet stability exactness ledger and bridge obligations)**.** *For any packet as in Definition 112.27, the displayed local rows jointly determine the finite-set stability, exactness, ledger, and bridge obligations over the BEDC source* $\mathsf{NameCert}_{\mathsf{Set}\uparrow}$ *and the finite-spine source* $\mathsf{NameCert}_{\mathsf{List}\uparrow}$*.*

Proof. First, the exactness obligation is the carrier equivalence supplied by Definition 112.28, whose proof rests on Definition 112.7. This binds ordinary finite-spine occurrence to the BEDC carrier field through the fixed source classifier.

Next, the stability obligations are the classifier rows collected in Definition 112.29: certified permutation, duplicate insertion, transitivity, symmetry, and append-union concatenation. These cite Definition 112.3, Definition 112.12, Definition 112.16, Definition 112.23, and Definition 112.19.

Finally, the ledger obligation is the finite position carrier $\mathsf{Pos}(xs)$ with readback entry_{xs}, used by the same permutation and occurrence rows. The bridge obligation is the predicate enumeration clause $\mathsf{FinSetSpineEnumerates}_{A,\sim_A}(xs, U)$ together with the append-union row, which identifies the standard finite-set surface without asserting the larger finite-set API. □

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumerationBridge bundle member readback`

Closure status for $\mathsf{NameCert}_{\mathsf{FinSet}^\uparrow}$.

Constructive story: A finite set is generated by taking a $\mathsf{Set}^\uparrow$ carrier A and displaying a finite $\mathsf{List}^\uparrow$ spine xs whose entries are BEDC histories carried by A. A query history z belongs to the finite-set carrier exactly when $A(z)$ holds and some finite position of xs has an entry classified with z by the set classifier; histories outside the source carrier or absent from the spine up to that classifier are excluded. Two finite-spine presentations classify together when they have the same enumeration membership predicate for every query history, so certified permutations of positions and duplicate insertions are invisible while the spine and its positions remain explicit ledger data. The source is the fixed $\mathsf{Set}^\uparrow$ certificate plus the finite spine, the pattern records occurrence, position readback, permutation invariance, duplicate insertion, and append-union rows, and the ledger keeps $\mathsf{Pos}(xs)$, entries, enumeration witnesses, and classifier evidence visible enough for downstream consumers. The five name-certificate obligations follow from the displayed finite spine and source certificate for inhabitation, from pointwise reflexivity, symmetry, and transitivity of enumeration membership equivalence, and from carrier transport through the underlying set classifier. A spine xs lies in the signature gap of a $\mathsf{FinSet}^\uparrow$ token p when the source-domain accepts the set carrier and finite-list representation, the signature relation pairs the enumeration with an answer spine and evidence ledger, and token introduction names that answer as p; unfolded, exactly the classifier-classes enumerated by xs are those encoded by the token. The standard bridge is the finite-spine enumeration bridge: it reads a finite set as the predicate enumerated by the spine and reads back through the same positions, entries, duplicate, permutation, and union rows. The chapter registers this finite-spine construction under the name $\mathsf{FinSet}^\uparrow$; finiteness is an explicit enumeration ledger, not cardinality theory, power sets, host finite sets, or hidden order data promoted to the carrier.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FinSet}^\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The FinSetUp bridge scope is the finite-spine enumeration bridge over $\mathsf{NameCert}_{\mathsf{Set}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{List}^\uparrow}$, binding $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$, $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$, EnumPerm, the Pos and entry ledger, duplicate, permutation, symmetry, transitivity, append-union rows, and $\mathsf{FinSetSpineEnumerates}_{A,\sim_A}$ as the standard finite-set bridge surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FinSet}^\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FinsetUp.FinsetEnumeration\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: Cardinality, decidable membership, power set, graph finiteness, and Lean-side bridge verification remain outside this finite-spine bridge.

Upgrade path: There is no stronger paper-side closure grade for this finite-spine bridge; remaining work is verification-axis bridge checking and optional APIs outside the stated surface.

Theorem 112.31 (EnumPerm composition associativity)**.** *Let* $A : \mathsf{BHist} \to \mathsf{Prop}$ *be the carrier of a fixed* $\mathsf{Set}^\uparrow$ *certificate, let* $\sim_A$ *be its classifier, and let* $\mathsf{cert} : \mathsf{NameCert}(A, \sim_A)$*. For finite BEDC-history spines* xs*,* ys*,* zs*, and* ws*, assume*

$$\mathsf{EnumPerm}_{A,\sim_A}(xs, ys) \quad \textit{and} \quad \mathsf{EnumPerm}_{A,\sim_A}(ys, zs) \quad \textit{and} \quad \mathsf{EnumPerm}_{A,\sim_A}(zs, ws).$$

After choosing certified bijections from these three rows, the two parenthesized composite witnesses from xs *to* ws *obtained from*

$$(\sigma \circ \rho) \circ \pi$$

and from

$$\sigma \circ (\rho \circ \pi)$$

coincide at the level of the EnumPerm *witness data: their forward position maps agree pointwise, their inverse position maps agree pointwise, and one and the same pointwise carrier-classifier clause certifies both bracketings. In particular,*

$$((\sigma \circ \rho) \circ \pi)(i) = (\sigma \circ (\rho \circ \pi))(i)$$

for every $i : \mathsf{Pos}(xs)$*, and*

$$(\pi^{-1} \circ (\rho^{-1} \circ \sigma^{-1}))(k) = ((\pi^{-1} \circ \rho^{-1}) \circ \sigma^{-1})(k)$$

for every $k : \mathsf{Pos}(ws)$*.*

Proof. Unfold Definition 112.2. Choose a certified bijection

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$$

with pointwise preservation field

$$P_\pi(i) : A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{ys}(\pi(i))) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

Choose a certified bijection

$$\rho : \mathsf{Pos}(ys) \cong \mathsf{Pos}(zs)$$

with pointwise preservation field

$$P_\rho(j) : A(\mathsf{entry}_{ys}(j)) \wedge A(\mathsf{entry}_{zs}(\rho(j))) \wedge \mathsf{entry}_{ys}(j) \sim_A \mathsf{entry}_{zs}(\rho(j)).$$

Choose a certified bijection

$$\sigma : \mathsf{Pos}(zs) \cong \mathsf{Pos}(ws)$$

with pointwise preservation field

$$P_\sigma(k) : A(\mathsf{entry}_{zs}(k)) \wedge A(\mathsf{entry}_{ws}(\sigma(k))) \wedge \mathsf{entry}_{zs}(k) \sim_A \mathsf{entry}_{ws}(\sigma(k)).$$

By two applications of Definition 112.13, the left bracketing first gives the certified bijection

$$\sigma \circ \rho : \mathsf{Pos}(ys) \cong \mathsf{Pos}(ws)$$

with inverse position map $\rho^{-1} \circ \sigma^{-1}$, and then gives the certified bijection

$$(\sigma \circ \rho) \circ \pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ws)$$

with inverse position map $\pi^{-1} \circ (\rho^{-1} \circ \sigma^{-1})$. The right bracketing first gives the certified bijection

$$\rho \circ \pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(zs)$$

with inverse position map $\pi^{-1} \circ \rho^{-1}$, and then gives the certified bijection

$$\sigma \circ (\rho \circ \pi) : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ws)$$

with inverse position map $(\pi^{-1} \circ \rho^{-1}) \circ \sigma^{-1}$.

For every $i : \mathsf{Pos}(xs)$,

$$((\sigma \circ \rho) \circ \pi)(i) = (\sigma \circ \rho)(\pi(i)) = \sigma(\rho(\pi(i))) = \sigma((\rho \circ \pi)(i)) = (\sigma \circ (\rho \circ \pi))(i).$$

Thus the two forward position maps agree pointwise. Likewise, for every $k : \mathsf{Pos}(ws)$,

$$(\pi^{-1} \circ (\rho^{-1} \circ \sigma^{-1}))(k) = \pi^{-1}(\rho^{-1}(\sigma^{-1}(k))) = (\pi^{-1} \circ \rho^{-1})(\sigma^{-1}(k)) = ((\pi^{-1} \circ \rho^{-1}) \circ \sigma^{-1})(k).$$

Thus the two inverse position maps also agree pointwise.

It remains to verify a common pointwise carrier-classifier clause for the two bracketings. Fix $i : \mathsf{Pos}(xs)$. From $P_\pi(i)$ we obtain

$$A(\mathsf{entry}_{xs}(i)) \qquad \text{and} \qquad \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ys}(\pi(i)).$$

From $P_\rho(\pi(i))$ we obtain

$$A(\mathsf{entry}_{zs}(\rho(\pi(i)))) \qquad \text{and} \qquad \mathsf{entry}_{ys}(\pi(i)) \sim_A \mathsf{entry}_{zs}(\rho(\pi(i))).$$

From $P_\sigma(\rho(\pi(i)))$ we obtain

$$A(\mathsf{entry}_{ws}(\sigma(\rho(\pi(i))))) \qquad \text{and} \qquad \mathsf{entry}_{zs}(\rho(\pi(i))) \sim_A \mathsf{entry}_{ws}(\sigma(\rho(\pi(i)))).$$

Applying the classifier transitivity of cert, equivalently Definition 9.8, first to the comparisons from xs to ys and from ys to zs, and then to the resulting comparison from xs to zs and the comparison from zs to ws, yields

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ws}(\sigma(\rho(\pi(i)))).$$

Therefore

$$A(\mathsf{entry}_{xs}(i)) \wedge A(\mathsf{entry}_{ws}(\sigma(\rho(\pi(i))))) \wedge \mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{ws}(\sigma(\rho(\pi(i)))).$$

By the forward-map equality already proved, this is exactly the pointwise preservation clause required for both $((\sigma \circ \rho) \circ \pi)(i)$ and $\big(\sigma \circ (\rho \circ \pi)\big)(i)$.

Hence the two bracketings have the same forward position map, the same inverse position map, and the same pointwise carrier-classifier certification. They therefore present the same $\mathsf{EnumPerm}_{A,\sim_A}(xs, ws)$ witness data required by Definition 112.2. □

Theorem 112.32 (FinSet enumeration carrier boundary)**.** *Fix a* $\mathsf{Set}^\uparrow$ *carrier* $A : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_A$*, and let* $xs : \mathsf{HistSpine}$ *be the finite spine supplied by the* $\mathsf{List}^\uparrow$ *enumeration witness. The public* $\mathsf{FinSet}^\uparrow$ *carrier exported by Definition 112.5 consists exactly of a carried query history, a* $\mathsf{SpineMember}$ *witness in the displayed finite spine, and a classifier witness against one displayed spine entry. It exports no host set, no duplicate-normalized quotient, and no hidden enumeration order.*

Lean4 ✓ `BEDC.Derived.FinsetUp.FinsetEnumeration StdBridge`

Proof. Unfold the carrier in Definition 112.5. A public membership row is a pair consisting of $A(a)$ and a displayed witness

$$\exists x : \mathsf{BHist}.\ \mathsf{SpineMember}(x, xs) \wedge a \sim_A x.$$

Thus the only exported data are the carried query history, the finite-spine occurrence, and the classifier comparison to the displayed entry.

The occurrence entry is source-carried by Definition 112.6, so the witness really lives in the fixed $\mathsf{Set}^\uparrow$ source rather than in a host set. The equivalence of Definition 112.7 says that this displayed occurrence-and-classifier surface is not merely sufficient but exact for the carrier.

No further public field remains. Duplicate handling is mediated by the classifier and by later enumeration theorems, while enumeration order remains the visible $\mathsf{List}^\uparrow$ spine data rather than a hidden quotient. Hence the public carrier boundary is exactly the stated finite-data surface. □

$\mathsf{FinSet}^\uparrow$ reads finite membership through the $\mathsf{Bool}^\uparrow$ classifier of chapter 32 and finite enumeration through the $\mathsf{List}^\uparrow$ spine of chapter 36. Thus the finite-set packet exposes its sibling dependency route before any consumer treats membership or enumeration as local kernel-only data.

Chapter 113

A Concrete Naming Certificate for $\mathsf{Subtype}^{\uparrow}$

The subtype interface $\mathsf{Subtype}^{\uparrow}$ packages the carrier of elements of a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ satisfying a decidable predicate. It depends on $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ (chapter 111) and supplies the kernel-licit refinement type used throughout the algebra ladder for sub-objects.

113.1 Carrier definition

113.2 The certificate

Definition 113.1 (Subtype restricted classifier)**.** *Let S be the certified point type of a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$, with parent classifier $\sim_S$. Let $P : S \to \mathsf{Prop}$ be a decidable predicate stable under the parent classifier, meaning that for $x, y : S$,*

$$x \sim_S y \Longrightarrow P(x) \Longrightarrow P(y).$$

The $\mathsf{Subtype}^{\uparrow}$ carrier cut out by P is

$$S_P = \{(x, p) \mid x : S \text{ and } p : P(x)\}.$$

For subtype elements (x, p_x) and (y, p_y), the subtype classifier is the restriction of the parent classifier:

$$(x, p_x) \sim_{S_P} (y, p_y) \quad :\Longleftrightarrow \quad x \sim_S y.$$

Lean4 ✓ `BEDC.Derived.SubtypeUp.SubtypeTasteGate single carrier alignment`

Theorem 113.2 (Subtype classifier reflects parent classifier)**.** *Let S be a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ with classifier $\sim_S$, and let $P : S \to \mathsf{Prop}$ be a decidable predicate stable under $\sim_S$. For all $x, y : S$ and witnesses $p_x : P(x)$ and $p_y : P(y)$, the classifier of Definition 113.1 satisfies*

$$(x, p_x) \sim_{S_P} (y, p_y) \Longleftrightarrow x \sim_S y.$$

Equivalently, a parent classifier witness between predicate-bearing endpoints induces the subtype classifier witness, and every subtype classifier witness projects to the parent classifier witness.

Proof. Unfold the classifier clause in Definition 113.1. The forward implication is projection: a subtype classifier witness is a parent classifier witness between the first components. The reverse implication is inclusion: a witness of $x \sim_S y$ is, by the displayed definition, a witness of $(x, p_x) \sim_{S_P} (y, p_y)$ once the two subtype endpoints have been formed. The decidability and stability assumptions are the formation and transport rows for the $\mathsf{Subtype}^{\uparrow}$ carrier; the restricted classifier itself carries no data beyond the parent comparison. □

Theorem 113.3 (Subtype carrier obligation row)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$, and let $P : \mathsf{BHist} \to \mathsf{Prop}$ be a decidable predicate. In the predicate presentation of Definition 113.1, the carrier obligation for $\mathsf{Subtype}^{\uparrow}$ is exactly*

$$S_P(h) \iff S(h) \wedge P(h).$$

Consequently a displayed endpoint $s_0 : \mathsf{BHist}$ with $S(s_0)$ and $P(s_0)$ supplies the inhabitedness row

$$S_P(s_0).$$

Proof. Unfold the carrier clause of Definition 113.1. A subtype endpoint is formed by pairing a parent-carrier witness with a predicate witness, so its predicate presentation is the conjunction $S(h) \wedge P(h)$.

For inhabitedness, apply the same clause at s_0. The two displayed witnesses $S(s_0)$ and $P(s_0)$ are precisely the two components required to form $S_P(s_0)$. □

Theorem 113.4 (Subtype classifier projection obligation)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ with classifier $\sim_S$, and let $P : \mathsf{BHist} \to \mathsf{Prop}$. For all predicate-bearing endpoints $h, k : \mathsf{BHist}$, the classifier row for $\mathsf{Subtype}^{\uparrow}$ is exactly*

$$h \sim_{S_P} k \iff h \sim_S k.$$

Thus parent projection and restricted-classifier introduction are the two classifier rows: a subtype classifier witness projects to the parent comparison, and a parent comparison between already formed subtype endpoints introduces the restricted classifier witness.

Proof. Unfold the classifier clause in Definition 113.1. The restricted classifier stores no comparison datum apart from the parent comparison $h \sim_S k$.

The forward direction is projection from the restricted witness to that parent witness. The reverse direction is introduction: once the endpoints are already certified by the carrier row, the parent witness is read as the restricted-classifier witness. □

Theorem 113.5 (Subtype NameCert transport obligation)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a parent $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ with classifier $\sim_S$, and let $\mathsf{cert} : \mathsf{NameCert}(S, \sim_S)$. Let $P : \mathsf{BHist} \to \mathsf{Prop}$ be stable under the parent classifier, meaning that for all $h, k : \mathsf{BHist}$,*

$$S(h) \wedge P(h) \wedge h \sim_S k \Longrightarrow P(k).$$

In the predicate presentation of Definition 113.1, parent carrier transport from cert together with predicate stability gives

$$S_P(h) \to h \sim_{S_P} k \to S_P(k).$$

This is the transport row consumed by Definition 113.7.

Proof. Unfold $S_P(h)$ by Definition 113.3. This gives $S(h)$ and $P(h)$. Unfold the restricted classifier by Definition 113.4; the comparison is the parent witness $h \sim_S k$.

The carrier-respect field of the parent $\mathsf{NameCert}(S, \sim_S)$ transports $S(h)$ along $h \sim_S k$ and gives $S(k)$. Apply the displayed predicate-stability hypothesis to $S(h)$, $P(h)$, and the same parent comparison to obtain $P(k)$.

Pair $S(k)$ with $P(k)$ using the carrier row for $S_P(k)$. The resulting witness is the required transport row for the restricted certificate. □

Lemma 113.6 (Subtype carrier closed under restricted classifier)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a parent $\mathsf{NameCert}_{\mathsf{Set}^\uparrow}$ with classifier $\sim_S$, and let $\mathsf{cert} : \mathsf{NameCert}(S, \sim_S)$. Let $P : \mathsf{BHist} \to \mathsf{Prop}$ be a decidable predicate stable under the parent classifier, in the sense that for all $x, y : \mathsf{BHist}$,*

$$S(x) \wedge P(x) \wedge x \sim_S y \Longrightarrow P(y).$$

In the predicate presentation of Definition 113.1, write

$$S_P(h) \Longleftrightarrow S(h) \wedge P(h), \qquad h \sim_{S_P} k \Longleftrightarrow h \sim_S k.$$

If $S_P(h)$ and $h \sim_{S_P} k$, then $S_P(k)$.

Lean4 ✓ `BEDC.Derived.SubtypeUp.SubtypeRestrictedCarrier classifier closed`

Proof. Unfold $S_P(h)$ to obtain $S(h)$ and $P(h)$. Unfold the restricted classifier to read the comparison as $h \sim_S k$. The carrier-transport field of cert, one of the fields listed in Definition 9.7, transports $S(h)$ along this comparison and gives $S(k)$. Stability of P under the same parent comparison gives $P(k)$. Pairing $S(k)$ with $P(k)$ gives $S_P(k)$. □

Theorem 113.7 (Subtype restricted classifier NameCert)**.** *Under the hypotheses and notation of Definition 113.6, assume that the subtype carrier has a displayed endpoint, so there is an $s_0 : \mathsf{BHist}$ with $S(s_0)$ and $P(s_0)$. Then the $\mathsf{Subtype}^\uparrow$ carrier S_P with the restricted classifier $\sim_{S_P}$ forms a Lean carrier naming certificate:*

$$\mathsf{NameCert}(S_P, \sim_{S_P}).$$

Lean4 ✓ `BEDC.Derived.SubtypeUp.SubtypeRestrictedClassifier nameCert`

Proof. Inhabitedness is witnessed by s_0, since $S(s_0)$ and $P(s_0)$ are exactly the two components of $S_P(s_0)$.

For reflexivity, let h be carried by S_P. Then $S(h)$ holds, so the reflexivity field of cert gives $h \sim_S h$. By the classifier clause of Definition 113.1, this is $h \sim_{S_P} h$.

For symmetry, a restricted witness $h \sim_{S_P} k$ is the parent witness $h \sim_S k$. The symmetry field of cert gives $k \sim_S h$, hence $k \sim_{S_P} h$.

For transitivity, restricted witnesses $h \sim_{S_P} k$ and $k \sim_{S_P} r$ are parent witnesses $h \sim_S k$ and $k \sim_S r$. The transitivity field of cert composes them to $h \sim_S r$, which is the restricted witness $h \sim_{S_P} r$.

Carrier transport for S_P is exactly Definition 113.6. These five rows are the inhabitedness, reflexivity, symmetry, transitivity, and carrier-transport fields required by Definition 9.7. □

Theorem 113.8 (SubtypeUp carrier-source obligation)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be the carrier of a parent $\mathsf{NameCert}(S, \sim_S)$, let $P : \mathsf{BHist} \to \mathsf{Prop}$ be a predicate stable under the parent classifier, and let $s_0 : \mathsf{BHist}$ be a displayed endpoint with $S(s_0) \wedge P(s_0)$. The carrier row for $\mathsf{Subtype}^\uparrow$ is exactly*

$$S_P(h) \Longleftrightarrow S(h) \wedge P(h).$$

The source data are the parent certificate $\mathsf{NameCert}(S, \sim_S)$*, the predicate* P*, the displayed endpoint* s_0*, and the stability of* P *under* $\sim_S$*.*

Proof. Unfold Definition 113.1. The subtype carrier is introduced as the predicate cut of the parent carrier by P, so membership in S_P is precisely the pair consisting of parent membership in S and the predicate witness.

The endpoint row is supplied by s_0: its two witnesses are the two components needed for $S_P(s_0)$. Predicate stability is not extra carrier data; it is the transport hypothesis that makes the carrier row usable across the restricted classifier. □

Theorem 113.9 (SubtypeUp restricted-classifier obligation)**.** *Under the hypotheses of Definition 113.8, the restricted classifier row for carried subtype endpoints is exactly*

$$h \sim_{S_P} k \iff h \sim_S k.$$

The parent projection row sends a restricted classifier witness to the parent witness, and the inclusion row sends a parent witness between carried subtype endpoints to the restricted witness.

Proof. Apply Definition 113.2. Its forward direction is the parent projection row: a restricted comparison contains the parent comparison between the displayed endpoints.

Its reverse direction is the inclusion row: once the two endpoints are carried by S_P, a parent classifier witness is already the restricted classifier witness by the definition of the subtype classifier. □

Theorem 113.10 (SubtypeUp predicate-transport obligation)**.** *Under the hypotheses of Definition 113.8, parent carrier transport together with stability of* P *transports the subtype carrier across the restricted classifier: if* $S_P(h)$ *and* $h \sim_{S_P} k$*, then* $S_P(k)$*.*

Proof. Apply Definition 113.6. That lemma separates the two transported components: the parent certificate transports $S(h)$ to $S(k)$ along the parent classifier, and stability of P transports the predicate witness.

By Definition 113.9, the restricted comparison supplies exactly the parent comparison needed by both transports. Pairing the transported parent carrier witness with the transported predicate witness gives $S_P(k)$. □

Theorem 113.11 (SubtypeUp NameCert surface obligation)**.** *The carrier row of Definition 113.8, the restricted-classifier rows of Definition 113.9, the endpoint row, and the transport row of Definition 113.10 assemble the displayed* $\mathsf{NameCert}(S_P, \sim_{S_P})$ *surface for* $\mathsf{Subtype}^{\uparrow}$*. The ten-field template entries are: parent carrier* S*, parent classifier* $\sim_S$*, parent certificate* $\mathsf{NameCert}(S, \sim_S)$*, predicate* P*, predicate-stability row, restricted carrier* S_P*, restricted classifier* $\sim_{S_P}$*, displayed endpoint* s_0*, parent-projection row, and carrier-transport row.*

Proof. Use Definition 113.8 for the carrier and endpoint rows, Definition 113.9 for the parent-projection and inclusion rows, and Definition 113.10 for carrier transport.

These are exactly the rows consumed by Definition 113.7. Applying that theorem repacks the rows into the public $\mathsf{NameCert}(S_P, \sim_{S_P})$ surface, with the ten displayed entries recording the source data and the exactness maps used by the construction. □

Theorem 113.12 (SubtypeUp public NameCert export)**.** *Under the hypotheses of Definition 113.7, the public interface exported by* $\mathsf{Subtype}^{\uparrow}$ *is the certificate*

$$\mathsf{NameCert}(S_P, \sim_{S_P}).$$

Its public rows are the restricted carrier S_P, the restricted classifier $\sim_{S_P}$, the displayed endpoint, the parent-projection and inclusion rows, the predicate-stability transport row, and the assembled carrier-transport row.

Lean4 ✓ `BEDC.Derived.SubtypeUp.SubtypePublicNameCert export`

Proof. The carrier row is Definition 113.8: public membership in S_P is exactly parent membership in S together with the predicate witness P.

The restricted-classifier rows are Definition 113.9. They identify a public comparison in $\sim_{S_P}$ with the parent classifier comparison in $\sim_S$, with the forward parent-projection row and reverse inclusion row both displayed on carried subtype endpoints.

The predicate-transport row is Definition 113.10. It combines parent carrier transport with stability of P and produces the transported public carrier witness for S_P.

Apply Definition 113.7. The preceding rows provide exactly the carrier, classifier, endpoint, and transport data consumed by that theorem, so the exported public surface is the certificate $\mathsf{NameCert}(S_P, \sim_{S_P})$. □

Theorem 113.13 (SubtypeUp standard bridge surface)**.** *Under the hypotheses of Definition 113.7, the concrete restricted carrier S_P and restricted classifier $\sim_{S_P}$ form the paper-side standard subtype bridge. Its rows are exactly:*

1. *carrier membership in the restricted endpoint is $S_P(h)$, equivalently $S(h) \wedge P(h)$;*
2. *classifier comparison between carried restricted endpoints is $h \sim_{S_P} k$, equivalently the parent comparison $h \sim_S k$;*
3. *the projection to the parent certificate preserves the carrier row by forgetting only the predicate component and preserves the classifier row by returning the same parent comparison;*
4. *predicate stability reflects transported parent endpoints back into S_P, so every transported parent endpoint with the transported predicate witness is again carried by the restricted carrier.*

Consequently the public $\mathsf{NameCert}(S_P, \sim_{S_P})$ surface exported by $\mathsf{Subtype}^{\uparrow}$ is equipped with the bridge rows needed for the standard subtype bridge, without adding host subtype equality, quotient extensionality, or an abstract source-equivalence chain.

Lean4 ✓ `BEDC.Derived.SubtypeUp.SubtypeUp StdBridge`

Proof. The carrier row is exactly Definition 113.8. It identifies membership in the concrete restricted carrier with the pair of parent membership and predicate witness, and it records the displayed endpoint data used by the certificate.

The classifier row is exactly Definition 113.9. Its forward direction is the projection from a restricted comparison to the parent comparison, and its reverse direction is the inclusion of a parent comparison between carried restricted endpoints.

The transport row is Definition 113.10. Parent carrier transport supplies the transported parent endpoint, and predicate stability supplies the transported predicate witness; pairing them gives membership back in S_P.

Finally, Definition 113.12 repacks these rows into the public $\mathsf{NameCert}(S_P, \sim_{S_P})$ export. The bridge therefore uses only the concrete carrier, concrete classifier, parent projection, inclusion row, and predicate-stability transport already displayed in the $\mathsf{Subtype}^{\uparrow}$ construction. □

Closure status for $\mathsf{NameCert}_{\mathsf{Subtype}^{\uparrow}}$.

Constructive story: A subtype starts with a parent $\mathsf{Set}^{\uparrow}$ name certificate with carrier S and classifier $\sim_S$, then cuts that carrier by a predicate P that is stable under the parent classifier. A history h is admitted exactly when it carries both pieces of evidence, $S(h)$ and $P(h)$; anything missing either parent membership or the predicate witness is outside the restricted carrier. Two subtype endpoints classify together by the same parent comparison $h \sim_S k$, so the predicate proof is not compared by a second equality and no quotient-style subtype extensionality is formed. The source consists of the parent certificate, the predicate, a displayed endpoint, and the stability row for P; the pattern records restriction, projection to the parent, inclusion from parent comparisons between carried endpoints, and predicate transport, while the ledger keeps the parent witness and predicate witness as the visible pair. The five name-certificate obligations are exactly the displayed endpoint for inhabitation, parent reflexivity, symmetry, and transitivity for the restricted classifier, and carrier closure obtained by parent carrier transport plus stability of P. A history h lies in the signature gap of a $\mathsf{Subtype}^{\uparrow}$ token p when the source-domain accepts both $S(h)$ and $P(h)$, the signature relation pairs that restricted endpoint with an answer endpoint and evidence ledger, and token introduction names that answer as p; unfolded, h is the parent element encoded by p together with the required predicate witness. The standard bridge reads the same data as an ordinary subtype by projecting to the parent and reading back only endpoints whose predicate witness is displayed and stable. The chapter registers this predicate-cut construction under the name $\mathsf{Subtype}^{\uparrow}$; refinement is a carrier restriction over an existing certificate, not host subtype equality, quotient extensionality, or a second parent source.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Subtype}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature scope binds the parent $\mathsf{NameCert}(S, \sim_S)$, restricted carrier S_P, restricted classifier $\sim_{S_P}$, predicate-stability transport, classifier-closure lemma, public NameCert export, and paper-side standard subtype bridge surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Subtype}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.SubtypeUp.SubtypeRestrictedClassifier\_nameCert`

Bridge status: bridgeChecked

Not claimed: This packet does not close full SetUp bridges or quotient-style subtype extensionality.

Upgrade path: no further upgrade – chapter at top of formal axis.

Chapter 114

A Concrete Naming Certificate for $\mathsf{Empty}^{\uparrow}$

The empty-type interface $\mathsf{Empty}^{\uparrow}$ records the impossible BEDC history carrier: the carrier has no inhabitant. The useful exported facts are the absurdity theorems below for carrier witnesses, for NameCert attempts over that carrier, and for SemanticNameCert attempts over that carrier.

This impossible-carrier surface is also the endpoint consumed by $\mathsf{Unit}^{\uparrow}$ in chapter 115: the unit certificate reads this empty endpoint as the terminal carrier row before packaging the local singleton continuation surface.

114.1 Carrier definition

Definition 114.1 (Impossible empty-history carrier)**.** *For a history h : Hist, the empty-history carrier requires both boundary readbacks*

$$\mathsf{hsame}(h, \mathsf{E0}(\mathsf{e})) \quad \textit{and} \quad \mathsf{hsame}(h, \mathsf{E1}(\mathsf{e})).$$

Thus it is the concrete impossible carrier whose contradiction is witnessed by BEDC constructor separation.

Lean4 (definition) `BEDC.Derived.EmptyUp.EmptyHistoryCarrier`
Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyUpTasteGate single carrier alignment`

114.2 The certificate

Theorem 114.2 (Empty history carrier absurd)**.** *No history inhabits the empty-history carrier.*

Proof. Unpack the two carrier witnesses. The first identifies h with $\mathsf{E0}(\mathsf{e})$, while the second identifies the same h with $\mathsf{E1}(\mathsf{e})$. The generated history-sameness constructors have no rule relating a zero-headed history to a one-headed history, so constructor inversion closes the contradiction. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyHistoryCarrier absurd`

Theorem 114.3 (Empty history carrier name certificate absurdity)**.** *There is no name certificate whose carrier is the empty-history carrier and whose classifier is* hsame*:*

$$\mathsf{NameCert}(\mathsf{EmptyHistoryCarrier}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. A name certificate contains a carrier witness. For this carrier, that witness is an inhabitant of the empty-history carrier, contradicting the carrier absurdity theorem above. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyHistoryCarrier namecert absurd`

Theorem 114.4 (Empty history carrier semantic certificate absurdity)**.** *There is no semantic name certificate whose source, pattern, and ledger policies are all the empty-history carrier:*

$$\mathsf{SemanticNameCert}(\mathsf{EmptyHistoryCarrier}, \mathsf{EmptyHistoryCarrier}, \mathsf{EmptyHistoryCarrier}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. The semantic certificate supplies a ledger witness. Since the ledger policy is the empty-history carrier itself, this witness is an inhabitant of the impossible carrier. The carrier absurdity theorem closes the contradiction. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyHistoryCarrier semantic namecert absurd`

Theorem 114.5 (Empty source carrier semantic certificate absurdity)**.** *There is no semantic name certificate whose source predicate is the empty-history carrier, regardless of the displayed pattern, ledger policy, and classifier:*

$$\mathsf{SemanticNameCert}(\mathsf{EmptyHistoryCarrier}, P, L, R) \Longrightarrow \bot.$$

Proof. The core field of a semantic certificate contains a name certificate over the source predicate. Therefore it contains an inhabitant of $\mathsf{EmptyHistoryCarrier}$, contradicting the carrier absurdity theorem. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyHistoryCarrier source semantic namecert absurd`

Theorem 114.6 (Empty contradictory carrier name certificate absurdity)**.** *There is no name certificate whose carrier asks a single history to be both the empty history and the one-extension of the empty history:*

$$\mathsf{NameCert}(\{h \mid h\mathsf{hsamee} \wedge h\mathsf{hsameE1}(\mathsf{e})\}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. Take a carrier witness from the certificate. Its two endpoint equations compose by symmetry and transitivity of hsame to give $\mathsf{ehsameE1}(\mathsf{e})$. The closed history no-confusion theorem rules out that comparison. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyContradictoryCarrier namecert absurd`

Theorem 114.7 (Empty contradictory carrier semantic certificate absurdity)**.** *There is no semantic name certificate whose source, pattern, and ledger policies all ask a single history to be both the empty history and the one-extension of the empty history:*

$$\mathsf{SemanticNameCert}(\{h \mid h\mathsf{hsamee} \wedge h\mathsf{hsameE1}(\mathsf{e})\}, \{h \mid h\mathsf{hsamee} \wedge h\mathsf{hsameE1}(\mathsf{e})\}, \{h \mid h\mathsf{hsamee} \wedge h\mathsf{hsameE1}(\mathsf{e})\}, \mathsf{hsame})$$

Proof. The semantic certificate supplies a ledger witness for the contradictory carrier. Its two endpoint equations compose by symmetry and transitivity of hsame to give $\mathsf{ehsameE1}(\mathsf{e})$, contradicting BEDC history constructor separation. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyContradictoryCarrier semantic namecert absurd`

Theorem 114.8 (Empty visible contradictory carrier name certificate absurdity)**.** *There is no name certificate whose carrier asks a single history to classify both to* e *and to some visible endpoint* $\mathsf{E0}(tail)$ *or* $\mathsf{E1}(tail)$*:*

$$\mathsf{NameCert}(\{h \mid h\mathsf{hsamee} \wedge (h\mathsf{hsameE0}(tail) \vee h\mathsf{hsameE1}(tail))\}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. Take a carrier witness from the certificate. The empty comparison composes against the visible endpoint comparison. In the zero-headed branch this gives $\mathsf{ehsameE0}(tail)$, and in the one-headed branch it gives $\mathsf{ehsameE1}(tail)$. Both are excluded by BEDC history constructor separation. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisibleContradictoryCarrier namecert absurd`

Theorem 114.9 (Empty visible pair contradictory carrier name certificate absurdity)**.** *There is no name certificate whose carrier asks a single history to classify both to a zero-visible endpoint and to a one-visible endpoint:*

$$\mathsf{NameCert}(\{h \mid h\mathsf{hsameE0}(leftTail) \wedge h\mathsf{hsameE1}(rightTail)\}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. Take a carrier witness from the certificate. The zero-endpoint comparison, reversed, composes with the one-endpoint comparison to give $\mathsf{E0}(leftTail)\mathsf{hsameE1}(rightTail)$. BEDC history constructor separation rules out any such zero-versus-one comparison. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisiblePairContradictoryCarrier namecert absurd`

Theorem 114.10 (Empty visible pair carrier name certificate absurdity)**.** *There is no name certificate whose carrier asks a single history to classify both to a zero-headed visible endpoint and to a one-headed visible endpoint:*

$$\mathsf{NameCert}(\{h \mid h\mathsf{hsameE0}(left) \wedge h\mathsf{hsameE1}(right)\}, \mathsf{hsame}) \Longrightarrow \bot.$$

Proof. Take a carrier witness from the certificate. The two endpoint comparisons compose by symmetry and transitivity of hsame to give $\mathsf{E0}(left)\mathsf{hsameE1}(right)$. BEDC history constructor separation rules out every zero-headed versus one-headed comparison. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisiblePairCarrier namecert absurd`

Theorem 114.11 (Empty visible pair carrier semantic certificate absurdity)**.** *There is no semantic name certificate whose source, pattern, and ledger policies all ask a single history to classify both to a zero-headed visible endpoint and to a one-headed visible endpoint:*

$$\mathsf{SemanticNameCert}(\{h \mid h\mathsf{hsameE0}(left) \wedge h\mathsf{hsameE1}(right)\}, \{h \mid h\mathsf{hsameE0}(left) \wedge h\mathsf{hsameE1}(right)\}, \{h \mid h\mathsf{hsameE}$$

Proof. The semantic certificate supplies a ledger witness. The ledger policy is the same visible-pair carrier, so the witness compares one history with both $\mathsf{E0}(left)$ and $\mathsf{E1}(right)$. Reversing the zero comparison and composing with the one comparison gives $\mathsf{E0}(left)\mathsf{hsameE1}(right)$, which is excluded by BEDC history constructor separation. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisiblePairCarrier semantic namecert absurd`

Theorem 114.12 (Empty visible pair source semantic certificate absurdity)**.** *There is no semantic name certificate whose source predicate asks one history to compare both to a zero-headed endpoint and to a one-headed endpoint, for any pattern predicate, ledger predicate, and classifier relation:*

$$\mathsf{SemanticNameCert}(\{h \mid h\mathsf{hsameE0}(left) \wedge h\mathsf{hsameE1}(right)\}, \mathsf{PatternSpec}, \mathsf{LedgerPolicy}, \mathsf{ClassifierSpec}) \Longrightarrow \bot.$$

Proof. Use the core name certificate's carrier witness. Its source proof supplies the two endpoint comparisons; reversing the zero-headed comparison and composing with the one-headed comparison gives $\mathsf{E0}(left)\mathsf{hsameE1}(right)$, excluded by BEDC history constructor separation. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisiblePairCarrier source semantic namecert absurd`

Theorem 114.13 (Empty visible contradictory carrier semantic certificate absurdity)**.** *There is no semantic name certificate whose source, pattern, and ledger policies all ask a single history to classify both to* e *and to some visible endpoint* $\mathsf{E0}(tail)$ *or* $\mathsf{E1}(tail)$*:*

$$\mathsf{SemanticNameCert}(\{h \mid h\mathsf{hsamee} \wedge (h\mathsf{hsameE0}(tail) \vee h\mathsf{hsameE1}(tail))\}, \{h \mid h\mathsf{hsamee} \wedge (h\mathsf{hsameE0}(tail) \vee h\mathsf{hsameE1}(t$$

Proof. The semantic certificate supplies a ledger witness. The ledger policy is the same visible contradictory carrier, so the witness gives both the empty comparison and one visible endpoint comparison. In the zero-headed branch this composes to $\mathsf{ehsameE0}(tail)$, and in the one-headed branch to $\mathsf{ehsameE1}(tail)$. BEDC history constructor separation rules out both branches. □

Lean4 ✓ `BEDC.Derived.EmptyUp.EmptyVisibleContradictoryCarrier semantic namecert absurd`

Closure status for $\mathsf{NameCert}_{\mathsf{Empty}^{\uparrow}}$**.**

Constructive story: An $\mathsf{Empty}^{\uparrow}$ packet is generated from the impossible empty-history carrier, its contradictory visible refinements, semantic certificate rows, componentwise hsame comparisons, and the local absurdity family.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Empty}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 114.2, Definition 114.3, Definition 114.4, and the visible-pair absurdity theorems bind the impossible carrier, visible-pair refinements, semantic NameCert rows, BHist constructor separation, hsame transport, and local absurdity family.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Empty}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.EmptyUp.EmptyHistoryCarrier\_absurd`

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim inhabited empty carriers, public standard bridge data, or bridge checking for $\mathsf{Empty}^{\uparrow}$.

Upgrade path: No further paper-side closure upgrade remains; only bridge verification may be supplied for the public impossible-carrier surface.

Chapter 115

A Concrete Naming Certificate for $\mathsf{Unit}^{\uparrow}$

The unit-type interface $\mathsf{Unit}^{\uparrow}$ packages the unique naming certificate over the inductive carrier with a single constructor. It is the terminal object in the category of naming certificates and supplies the canonical trivial witness for placeholder constructions.

The $\mathsf{Unit}^{\uparrow}$ packet consumes the $\mathsf{Empty}^{\uparrow}$ empty-history endpoint of chapter 114 as its terminal carrier row. Every unit classifier theorem below reads the same empty endpoint surface through that sibling certificate before packaging the continuation endpoint into the local $\mathsf{NameCert}_{\mathsf{Unit}^{\uparrow}}$ row.

115.1 Carrier definition

Definition 115.1 (Unit history carrier)**.** *For a history $h : \mathsf{BHist}$, the unit carrier is the continuation endpoint that composes the empty history with h and returns the empty history:*

$$\mathsf{UnitHistoryCarrier}(h) := \mathsf{Cont}(\mathsf{e}, h, \mathsf{e}).$$

Lean4 (definition) `BEDC.Derived.UnitUp.UnitHistoryCarrier`

Definition 115.2 (Unit history classifier)**.** *For histories $h, k : \mathsf{BHist}$, the unit classifier requires both endpoints to lie in the unit carrier and relates them by* hsame*:*

$$\mathsf{UnitHistoryClassifier}(h, k) := \mathsf{UnitHistoryCarrier}(h) \wedge \mathsf{UnitHistoryCarrier}(k) \wedge h\mathsf{hsame}k.$$

Lean4 (definition) `BEDC.Derived.UnitUp.UnitHistoryClassifier`

Theorem 115.3 (Unit history classifier empty endpoints iff)**.** *For histories $h, k : \mathsf{BHist}$, the unit classifier is equivalent to both endpoints being empty:*

$$\mathsf{UnitHistoryClassifier}(h, k) \iff h\mathsf{hsame}\mathsf{e} \wedge k\mathsf{hsame}\mathsf{e}.$$

Proof. In the forward direction, each carrier component is a continuation $\mathsf{Cont}(\mathsf{e}, -, \mathsf{e})$; empty-result inversion identifies the endpoint with e. In the reverse direction, the endpoint equalities reduce both carrier continuations to the empty left-unit continuation, and transitivity of hsame supplies the classifier equality. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier empty endpoints iff`

Theorem 115.4 (Unit history classifier append split)**.** *For histories p, q, h : BHist, the unit classifier from the appended endpoint $\mathsf{append}(p, q)$ to h is equivalent to all three component histories being empty:*

$$\mathsf{UnitHistoryClassifier}(\mathsf{append}(p, q), h) \iff p\mathsf{hsamee} \wedge q\mathsf{hsamee} \wedge h\mathsf{hsamee}.$$

Proof. Apply the empty-endpoint characterization of the unit classifier to obtain $\mathsf{append}(p, q)\mathsf{hsamee}$ and $h\mathsf{hsamee}$. The append endpoint is empty exactly when both append factors are empty. Conversely, the two empty append factors rebuild the empty appended endpoint, and the empty-endpoint classifier characterization supplies the unit classifier. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier append split iff`

Theorem 115.5 (Unit history classifier visible endpoint absurd)**.** *No visible endpoint can occur on either side of the unit history classifier. For all histories p, q, k, each classifier instance $\mathsf{UnitHistoryClassifier}(\mathsf{e0}(p), k)$, $\mathsf{UnitHistoryClassifier}(\mathsf{e1}(p), k)$, $\mathsf{UnitHistoryClassifier}(k, \mathsf{e0}(q))$, and $\mathsf{UnitHistoryClassifier}$ is impossible.*

Proof. Each classifier witness contains the unit carrier witness for the visible endpoint. The left-unit continuation result identifies that visible endpoint with the empty history, contradicting constructor disjointness for $\mathsf{e0}$ and $\mathsf{e1}$. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier visible endpoint absurd`

Theorem 115.6 (Unit history classifier continuation middle carrier)**.** *For histories $left, middle, right$: BHist, if the unit classifier relates $left$ and $right$ and $\mathsf{Cont}(left, middle, right)$, then $middle$ lies in the unit history carrier:*

$$\mathsf{UnitHistoryClassifier}(left, right) \wedge \mathsf{Cont}(left, middle, right) \implies \mathsf{UnitHistoryCarrier}(middle).$$

Proof. The classifier empty-endpoint theorem identifies both classified endpoints with e. Transport the displayed continuation result along the empty right endpoint, then apply empty-result inversion for continuation to identify the middle history with e. The carrier-empty equivalence turns this history-sameness witness into the required unit carrier witness. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier continuation middle carrier`

Theorem 115.7 (Unit history carrier empty equivalence)**.** *For a history h : BHist, membership in the unit history carrier is equivalent to history-sameness with the empty history:*

$$\mathsf{UnitHistoryCarrier}(h) \iff \mathsf{hsame}(h, \mathsf{e}).$$

Proof. The forward direction applies the right-unit uniqueness law to $\mathsf{Cont}(\mathsf{e}, h, \mathsf{e})$. Conversely, a witness $\mathsf{hsame}(h, \mathsf{e})$ reduces the endpoint to the empty history, where the left-unit continuation law gives $\mathsf{Cont}(\mathsf{e}, \mathsf{e}, \mathsf{e})$. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryCarrier empty iff`

Theorem 115.8 (Unit history carrier continuation suffix closure)**.** *For histories h, k, r : BHist, if h lies in the unit history carrier, $\mathsf{Cont}(h, k, r)$ holds, and $r\mathsf{hsamee}$, then k lies in the unit history carrier.*

Proof. The carrier characterization identifies h with e. Transporting the displayed continuation along this source identification, the reflexive suffix identification, and the empty result identification gives $\mathsf{Cont}(\mathsf{e}, k, \mathsf{e})$, which is exactly the unit history carrier for k. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryCarrier continuation suffix closed`

Theorem 115.9 (Unit history carrier continuation prefix closure)**.** *For histories $h, k, r : \mathsf{BHist}$, if $\mathsf{Cont}(h, k, r)$ holds and $r\mathsf{hsame}\mathsf{e}$, then h lies in the unit history carrier.*

Proof. Transport the continuation result to e and invert the empty-result continuation. The inversion identifies the left endpoint h with e, and the empty characterization of the unit history carrier converts this endpoint identity into $\mathsf{UnitHistoryCarrier}(h)$. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryCarrier continuation prefix closed`

115.2 The certificate

Theorem 115.10 (Unit history classifier semantic name certificate)**.** *The unit history carrier, used as source, pattern, and ledger policy, forms a semantic name certificate with the unit history classifier.*

Proof. The empty history inhabits the carrier by the left-unit continuation law. Classifier reflexivity, symmetry, and transitivity are obtained by packaging the carrier endpoints together with the corresponding hsame laws. Carrier transport follows from the target carrier endpoint already present in the classifier witness. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier semanticNameCert`

Theorem 115.11 (Unit terminal map uniqueness)**.** *Let $S : \mathsf{BHist} \to \mathsf{Prop}$ be a source carrier, let $R_S : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop}$ be its source classifier, and let $\mathcal{N}_S : \mathsf{NameCert}(S, R_S)$ be a source naming certificate in the sense of Definition 9.7. For maps $f, g : \mathsf{BHist} \to \mathsf{BHist}$, assume*

$$\forall a : \mathsf{BHist},\ S(a) \Longrightarrow \mathsf{UnitHistoryCarrier}(f(a))$$

and

$$\forall a : \mathsf{BHist},\ S(a) \Longrightarrow \mathsf{UnitHistoryCarrier}(g(a)).$$

Then every carried source endpoint has classified unit images:

$$\forall a : \mathsf{BHist},\ S(a) \Longrightarrow \mathsf{UnitHistoryClassifier}(f(a), g(a)).$$

Proof. Fix a carried source endpoint a with witness $s : S(a)$. The two preservation hypotheses give unit-carrier witnesses for $f(a)$ and $g(a)$. By Definition 115.7, these witnesses identify both images with e:

$$f(a)\mathsf{hsame}\mathsf{e} \qquad \text{and} \qquad g(a)\mathsf{hsame}\mathsf{e}.$$

Symmetry turns the second identification into $\mathsf{e}\mathsf{hsame}g(a)$, and transitivity gives $f(a)\mathsf{hsame}g(a)$. The definition of the classifier in Definition 115.2 is exactly the conjunction of the two unit-carrier witnesses and this hsame relation. Hence $\mathsf{UnitHistoryClassifier}(f(a), g(a))$ holds. Since a and s were arbitrary, the displayed universal statement follows. The source certificate $\mathcal{N}_S$ fixes the certified source context; no source-classifier compatibility is needed because both images land in the concrete unit carrier of Definition 115.1. □

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier terminal map uniqueness`

Lean4 ✓ `BEDC.Derived.UnitUp.UnitHistoryClassifier terminal map unique`

Closure status for $\mathsf{NameCert}_{\mathsf{Unit}^\uparrow}$**.**

Constructive story: A $\mathsf{Unit}^\uparrow$ packet is generated by the terminal empty-history carrier, the unit history classifier, continuation endpoint closure, terminal-map uniqueness, and the semantic NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Unit}^\uparrow}$, maturePackageClosed)

Scope closed: Definition 115.1, Definition 115.2, Definition 115.7, Definition 115.4, Definition 115.5, Definition 115.6, Definition 115.10, and the terminal-map uniqueness row expose the public dependency surface for downstream terminal-object consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Unit}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.UnitUp.UnitHistoryClassifier\_semanticNameCert`

Bridge status: none

Not claimed: This chapter does not construct nontrivial inhabitants beyond the terminal unit surface or identify arbitrary source carriers with $\mathsf{Unit}^\uparrow$.

Upgrade path: A bridge-checked closure would require a standard bridge packaging this public terminal-object surface against the ambient schema.

Chapter 116

A Concrete Naming Certificate for $\mathsf{Permutation}^{\uparrow}$

The permutation interface $\mathsf{Permutation}^{\uparrow}$ packages the carrier of bijections of a $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112) onto itself. It supplies the underlying carrier for $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$ (chapter 117) and the action data for combinatorial group-theoretic certificates.

116.1 Carrier definition

Definition 116.1 (Permutation bijection source row)**.** *Fix a finite-set source certificate* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *with carrier row* F*, classifier* $\sim_F$*, finite-spine endpoint row* xs*, and enumeration ledger as in chapter 112. A BEDC-facing* $\mathsf{Permutation}^{\uparrow}$ *source row over* F *is the* BHist*-visible package*

$$(\mathsf{src}, \mathsf{tgt}, G, G^{-1}, W, C, A, L)$$

with the following rows.

1. src *and* tgt *are the two displayed endpoint rows for the source and target copies of the same carried* $\mathsf{FinSet}^{\uparrow}$ *object.*
2. G *is a bijection graph/probe row: for every source endpoint read by the* $\mathsf{ProbeBundle}$*, the graph supplies exactly one target endpoint, and both endpoints are classified by the fixed* $\mathsf{FinSet}^{\uparrow}$ *carrier.*
3. G^{-1} *is the inverse graph row with the same readback discipline in the opposite direction.*
4. W *is the pair of inverse-witness rows saying that every forward read is met by a backward read and every backward read is met by a forward read at the corresponding endpoint.*
5. C *is the classifier and composition row: two graph presentations classify together exactly when their action outputs agree by the* $\mathsf{FinSet}^{\uparrow}$ *classifier, and the composites* $G^{-1} \circ G$ *and* $G \circ G^{-1}$ *transport to the corresponding identity graph rows by* hsame *and by the package provenance attached to the two endpoint rows.*
6. A *is the action row sending a carried source endpoint through* G *to its carried target endpoint.*
7. L *is the ledger containing the hidden enumeration witness for the chosen finite spine, the hidden order witness used to name positions, the* Pkg *provenance for the two endpoint copies, and the probe-read entries that justify graph coverage.*

The only visible carrier fields are the two $\mathsf{FinSet}^{\uparrow}$ *endpoint rows, the graph, inverse graph, inverse-witness rows, classifier and composition row, action row, and ledger boundary. Enumeration and order witnesses are not exposed as host data; they are consumed through* L.

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationTasteGate single carrier alignment`

116.2 The certificate

Theorem 116.2 (Permutation FinSet carrier obligation)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *presented by* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$ *and* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ *on a finite enumeration spine. The* $\mathsf{Permutation}^{\uparrow}$ *carrier over this source certificate is the predicate of certified finite-position self-bijection rows on that spine: a carried row consists of a forward position map, an inverse position map, the two inverse identities, and the pointwise evidence that matched entries are carried by* A *and classified by* $\sim_A$*. The visible ledger is exactly the corresponding* $\mathsf{EnumPerm}_{A,\sim_A}$ *row together with the source and target* $\mathsf{FinSet}^{\uparrow}$ *endpoint rows.*

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow carrier surface`

Proof. Unfold the finite-set source presentation from Definition 112.5, Definition 112.1, and Definition 112.2. A carried permutation row is therefore read as a certified bijection of the finite position carrier $\mathsf{Pos}(xs)$ onto itself.

The forward map, inverse map, and two inverse identities are the certified-bijection fields of $\mathsf{EnumPerm}_{A,\sim_A}$. The pointwise preservation field records that each source entry and matched target entry are carried by A and related by $\sim_A$.

Conversely, those same fields repack as the BHist permutation source row of Definition 116.1: the endpoint copies are the two finite-set rows, the maps give the graph and inverse graph, the inverse identities give the inverse-witness row, and the pointwise carrier-classifier evidence is the ledger entry. No host enumeration, host order, or bare host function is exposed outside that ledger. □

Theorem 116.3 (Permutation classifier obligation)**.** *For two carried* $\mathsf{Permutation}^{\uparrow}$ *rows over the fixed* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *above, the classifier relates them exactly when their actions send every carried finite-set entry to* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$*-equivalent entries. Equivalently, for each source entry represented by* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$*, the two target entries selected by the two certified self-bijections are identified by the finite-set enumeration classifier, and this pointwise comparison is the whole* $\mathsf{Permutation}^{\uparrow}$ *classifier row.*

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow action ledger transport`
Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow endpoint package hsame transport`

Proof. Unpack the two carried rows as $\mathsf{EnumPerm}_{A,\sim_A}$ witnesses on the same finite spine. Each action value is a target endpoint already carried by $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$, because the pointwise field of the corresponding enumeration permutation contains the carrier witness for the matched target entry.

The source $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ supplies the classifier fields for $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$. Applying those fields pointwise to the two target entries gives the displayed comparison of action outputs.

The graph comparison is carried by Pkg provenance and $\mathsf{ProbeBundle}$ reads over BHist. Applying hsame transport to those package rows preserves the visible graph agreement while leaving enumeration and order witnesses inside the ledger. The existing permutation-invariance row Definition 112.3 ensures that changing the hidden finite-position witness by a certified enumeration

permutation does not change the finite-set classifier. Thus the classifier only observes action outputs through $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$, and the pointwise action comparison repacks as the required $\mathsf{Permutation}^{\uparrow}$ classifier row. □

Theorem 116.4 (Permutation composition inverse action obligation)**.** *Identity, composition, inverse, and action compatibility for carried* $\mathsf{Permutation}^{\uparrow}$ *rows are exactly the reflexivity, transitivity, symmetry, and permutation-invariance rows of* $\mathsf{FinsetEnumerationPermutation}$*. The identity row is the certified identity bijection, the composite row is certified bijection composition, the inverse row is certified bijection inversion, and action compatibility is the induced invariance of* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ *under these rows.*

$$\mathsf{id} \circ G \sim_{\mathsf{Graph}} G$$

and

$$G^{-1} \circ G \sim_{\mathsf{Graph}} \mathsf{id}_{\mathsf{src}}$$

are therefore ledger readings of the same finite-position facts, not host-function equalities.

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow composition action ledger scope`

Proof. For identity, apply Definition 112.26. It supplies the certified identity bijection on the finite position carrier, hence the identity $\mathsf{Permutation}^{\uparrow}$ row and its action on carried entries.

For composition, apply Definition 112.14. Its composite finite-position bijection is read as the graph row for the composite permutation, and its pointwise preservation field is the carrier-classifier ledger for the composite action.

For inverse, apply Definition 112.25. The certified inverse position map becomes the inverse graph row, and the two inverse identities become the two graph identity rows recorded in Definition 116.1. The forward graph, backward graph, and inverse-witness rows give the displayed identity classifications after transport by hsame and by the Pkg provenance recorded for the graph reads.

Finally, action compatibility is the classifier-invariance statement of Definition 112.3. It says that the action output selected by a certified finite-position permutation is classified in the same finite-set sense as the corresponding endpoint entry. Coverage, soundness, and completeness of that action are read through the graph rows, while enumeration choices, order choices, and position names remain ledger data in L. These rows are precisely the action and ledger boundary consumed by $\mathsf{SymGroup}^{\uparrow}$. □

Theorem 116.5 (Permutation public NameCert surface)**.** *Over the fixed* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *of Definition 116.2, the carrier row of Definition 116.2, the classifier row of Definition 116.3, and the composition, inverse, action, and ledger rows of Definition 116.4 assemble a public* $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ *surface. The exported surface contains exactly the certified finite-position self-bijection carrier, the pointwise finite-set action classifier, the identity-composition-inverse rows, the action row, and the visible ledger boundary over* BHist*. The downstream* $\mathsf{SymGroup}^{\uparrow}$ *boundary is exposed only as a consumer row of this public surface, not as an additional* $\mathsf{Permutation}^{\uparrow}$ *field.*

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow semantic name certificate`
Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow public name certificate`

Proof. First fix the carrier. Apply Definition 116.2 to read carried $\mathsf{Permutation}^{\uparrow}$ rows as certified finite-position self-bijections over the chosen $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ source.

Next fix the classifier. Apply Definition 116.3 to identify classifier comparison with pointwise comparison of action outputs through $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$.

Finally apply Definition 116.4. It supplies the identity, composition, inverse, action, and ledger rows over the same carrier and classifier. These rows repack the displayed inventory as a public $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ surface, while the $\mathsf{SymGroup}^{\uparrow}$ row is only the downstream consumer boundary. No standard bridge or Lean verification is claimed here. □

Theorem 116.6 (Permutation bridge to symmetric-group composition)**.** *The public* $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ *surface of Definition 116.5 supplies exactly the carrier, classifier, identity, composition, inverse, action, and ledger rows consumed by the* $\mathsf{SymGroup}^{\uparrow}$ *composition interface of chapter 117. Thus the symmetric-group carrier, classifier, and composition obligations read the already public permutation source boundary, and no additional host bijection or host function equality is exposed at the bridge.*

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationSymGroupComposition bridge`

Proof. Apply Definition 116.5. It identifies the exported $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ surface with the certified finite-position self-bijection carrier, pointwise finite-set action classifier, identity-composition-inverse rows, action row, and visible ledger boundary.

Apply Definition 116.4. The composition, inverse, identity, and action rows are ledger readings of certified finite-position permutation facts, so they are already in the form required by the group-facing operation boundary.

The $\mathsf{SymGroup}^{\uparrow}$ carrier and classifier obligations of chapter 117 read this same permutation source row, and Definition 117.3 consumes its composition, inverse, action, exactness, and ledger rows. Therefore the bridge is a paper-side repacking of the public $\mathsf{Permutation}^{\uparrow}$ surface into the symmetric-group composition interface, with all enumeration choices, position names, and host bijection data remaining inside the ledger. □

Theorem 116.7 (Permutation bridged surface completeness)**.** *The public* $\mathsf{Permutation}^{\uparrow}$ *surface of Definition 116.5, together with the* $\mathsf{SymGroup}^{\uparrow}$ *consumer bridge of Definition 116.6, exhausts the visible BEDC fields of the bridged permutation interface. The exhausted fields are carrier, classifier, identity, composition, inverse, action, and ledger boundary. The finite enumeration witness and order witness remain hidden in the ledger and are not exported as additional visible fields.*

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow bridged surface completeness`

Proof. Apply Definition 116.2, Definition 116.3, and Definition 116.4. These three obligation theorems provide the carrier row, the pointwise classifier row, and the identity, composition, inverse, action, and ledger rows over the fixed finite-set source certificate.

Apply Definition 116.5. It repacks exactly those rows as the public $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ surface and states that the downstream $\mathsf{SymGroup}^{\uparrow}$ boundary is a consumer row rather than an extra $\mathsf{Permutation}^{\uparrow}$ field.

Apply Definition 116.6. The bridge consumes that same public surface as the symmetric-group carrier, classifier, composition, inverse, action, exactness, and ledger boundary. Therefore projection from the public surface to the consumer bridge, followed by repacking of the consumed rows, returns exactly the visible permutation interface listed in the statement. The finite enumeration and order witnesses are only read through the ledger, so no further visible BEDC field remains outside the displayed inventory. □

Closure status for $\mathsf{NameCert}_{\mathsf{Permutation}^\uparrow}$.

Constructive story: A permutation starts from a fixed $\mathsf{FinSet}^\uparrow$ finite spine and admits only certified self-bijection rows on its finite position carrier: a forward graph, an inverse graph, the two inverse-witness rows, and pointwise evidence that matched entries are carried and classified by the finite-set source. The classifier between two carried permutation rows compares their actions pointwise through $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$, so two presentations are the same only by their certified effects on the finite entries, not by host function equality. The source is the finite-set certificate together with the two endpoint copies of the same carried finite object, the pattern records graph coverage, inverse coverage, identity, composition, inverse, and action compatibility, and the ledger keeps enumeration witnesses, order witnesses, probe reads, and package provenance hidden behind the visible graph rows. The five name-certificate obligations come from the certified identity self-bijection for inhabitation, pointwise reflexivity, symmetry, and transitivity of the finite-set classifier, and closure under transported graph and endpoint package rows. A graph row G lies in the signature gap of a $\mathsf{Permutation}^\uparrow$ token p when the source-domain accepts the fixed finite spine and the certified forward/inverse action package, the signature relation pairs G with an answer permutation and evidence ledger, and token introduction names that answer as p; unfolded, every finite position is sent to the target position encoded by p and the inverse rows certify the round trip. The bridge exports exactly the same carrier, classifier, identity, composition, inverse, action, and ledger rows to the $\mathsf{SymGroup}^\uparrow$ composition interface. The chapter registers this finite-position bijection construction under the name $\mathsf{Permutation}^\uparrow$; a permutation is a certified action ledger over a finite spine, not a bare host bijection, exposed enumeration order, function quotient, or separate symmetric-group object.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Permutation}^\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The bridged surface is the BHist permutation source row of Definition 116.1 together with the carrier, classifier, composition, inverse, action, ledger, public $\mathsf{NameCert}_{\mathsf{Permutation}^\uparrow}$ packaging, and symmetric-group composition bridge of Definition 116.2, Definition 116.3, Definition 116.4, Definition 116.5, and Definition 116.6.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Permutation}^\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow\_public\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not claim machine-checked StandardBridge coverage or full $\mathsf{SymGroup}^\uparrow$ closure.

Upgrade path: No further paper-side theory upgrade is required; machine-checked standard-bridge verification is the remaining formal-axis target.

Theorem 116.8 (Permutation singleton FinSet identity classifier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{FinSet}^\uparrow}$ *presented by* $\mathsf{FinSetEnumCarrier}_{A,\sim_A}$ *and* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ *on a finite enumeration spine* xs*. Suppose the endpoint row is singleton at a displayed position* $s : \mathsf{Pos}(xs)$*, in the sense that every carried position of the finite-spine endpoint is that position:*

$$\forall i : \mathsf{Pos}(xs).\ i = s.$$

Let G *be any accepted carried* $\mathsf{Permutation}^\uparrow$ *graph row over this source certificate, with certified finite-position self-bijection*

$$\pi : \mathsf{Pos}(xs) \cong \mathsf{Pos}(xs)$$

read from its ledger as in Definition 116.2. Then G *is classified by the identity* $\mathsf{Permutation}^\uparrow$ *row. Equivalently, for every carried source endpoint, the action output of* G *and the action output of the certified identity row are compared by* $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$ *through the composition, inverse, and action row of Definition 116.4.*

Proof. Unpack the accepted graph row using Definition 116.2. Its visible graph, inverse graph, and inverse-witness rows are exactly the ledger reading of a certified finite-position self-bijection on $\mathsf{Pos}(xs)$, together with the pointwise carrier-and-classifier field for matched entries.

Fix a source position $i : \mathsf{Pos}(xs)$. The singleton hypothesis gives

$$i = s.$$

Applying the same hypothesis to the target position $\pi(i)$ gives

$$\pi(i) = s.$$

Thus i and $\pi(i)$ are the same displayed singleton position. The action of G at i therefore reads the same finite-spine endpoint as the identity action at i, namely the endpoint represented by s. The pointwise preservation field already attached to G supplies the carrier witness for that target entry and the comparison

$$\mathsf{entry}_{xs}(i) \sim_A \mathsf{entry}_{xs}(\pi(i)).$$

After substituting $i = s$ and $\pi(i) = s$, this is the reflexive singleton endpoint comparison read through the source classifier.

By Definition 112.26, the identity $\mathsf{Permutation}^{\uparrow}$ row is represented by the certified identity bijection on $\mathsf{Pos}(xs)$. Since both G and the identity row send every source position to the same singleton target position, their action outputs agree pointwise through $\mathsf{FinSetEnumClassifier}_{A,\sim_A}$. Applying the classifier obligation of Definition 116.3 repacks this pointwise comparison as the $\mathsf{Permutation}^{\uparrow}$ classifier relation between G and the identity row.

Finally, Definition 116.4 identifies the identity, inverse, and action rows as ledger readings of the same finite-position facts. The inverse witness of G therefore adds no second target position: $G^{-1} \circ G$ reads as the identity graph on the singleton endpoint, and the already established pointwise action comparison is precisely the classification of G with the identity row. □

Lean4 ✓ `BEDC.Derived.PermutationUp.PermutationBijectionSourceRow singleton identity classifier`

Chapter 117

A Concrete Naming Certificate for $\mathsf{SymGroup}^{\uparrow}$

The symmetric-group interface $\mathsf{SymGroup}^{\uparrow}$ packages the group structure on $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ (chapter 116) under composition. It is a canonical instance of $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and the substrate for representation-theoretic certificates.

117.1 Carrier definition

Theorem 117.1 (SymGroupUp carrier obligation)**.** *The* $\mathsf{SymGroup}^{\uparrow}$ *carrier is the certified permutation carrier over* $\mathsf{NameCert}_{\mathsf{Permutation}^{\uparrow}}$ *together with the* $\mathsf{Group}^{\uparrow}$ *source boundary of chapter 41. A carried row is therefore a* $\mathsf{Permutation}^{\uparrow}$ *source row whose visible operation is certified composition, whose displayed unit is the certified identity permutation, and whose displayed inverse is the certified inverse permutation. The carrier boundary records only the* BHist *graph rows, inverse rows, action row,* Pkg *provenance, and ledger entries already exposed by chapter 116; it does not expose a host enumeration or a host function as the group object.*

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupCarrier semantic name certificate`
Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupCarrier obligation`

Proof. Read the permutation source row from Definition 116.1. Its carrier consists of graph, inverse graph, inverse-witness, classifier, action, and ledger rows over the fixed $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ source.

The $\mathsf{Group}^{\uparrow}$ boundary from chapter 41 asks for a carried operation, unit, inverse, classifier, and ledger. Use Definition 116.4 to supply composition, identity, inverse, and action compatibility from the same certified finite-position rows.

Thus the $\mathsf{SymGroup}^{\uparrow}$ carrier is obtained by repacking the already certified $\mathsf{Permutation}^{\uparrow}$ carrier as a group-facing source row. All comparisons remain hsame and classifier transport through Pkg provenance, so no host function equality or quotient is introduced. □

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationCarrier group surface`
Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationCarrier carrier obligation`

117.2 The certificate

Theorem 117.2 (SymGroupUp classifier obligation)**.** *The* $\mathsf{SymGroup}^{\uparrow}$ *classifier is the permutation classifier transported through the group carrier of Definition 117.1. For carried permutation rows*

G, H, K, it must satisfy reflexivity on G, symmetry from $G \sim H$ to $H \sim G$, transitivity from $G \sim H$ and $H \sim K$ to $G \sim K$, and carrier transport across the $\mathsf{Group}^{\uparrow}$ *source rows for composition, identity, and inverse. These fields are exactly the* $\mathsf{Permutation}^{\uparrow}$ *classifier rows of Definition 116.3 read through the group-facing carrier boundary.*

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationClassifier stability`

Proof. Start with the pointwise action classifier of Definition 116.3. It compares two certified self-bijection rows by reading their action outputs through the fixed $\mathsf{FinSet}^{\uparrow}$ classifier.

Reflexivity, symmetry, and transitivity are inherited from the finite-set classifier rows named in chapter 116. Carrier transport is the same hsame and Pkg transport used to move graph and endpoint rows in Definition 116.3.

Repack those rows under the $\mathsf{Group}^{\uparrow}$ boundary named in chapter 41. Since the classifier observes only certified action outputs and package provenance, the construction never identifies host functions and never forms a quotient of presentations. □

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationCarrier classifier obligation`

Theorem 117.3 (SymGroupUp composition, inverse, and action obligations)**.** *For the carrier and classifier of Definition 117.1 and Definition 117.2, the certificate rows required for* $\mathsf{SymGroup}^{\uparrow}$ *are the following.*

1. *Composition closure: if G and H are carried permutations, then the composite $H \circ G$ is a carried permutation.*
2. *Inverse closure: if G is carried, then G^{-1} is carried.*
3. *Unit laws: the certified identity permutation is carried and classifies as the left and right unit for composition.*
4. *Associativity: the two certified composites $(K \circ H) \circ G$ and $K \circ (H \circ G)$ classify together.*
5. *Action compatibility: the action row of a composite classifies with the successive action rows, and the action row of the inverse is the inverse graph readback.*
6. *Exactness: graph coverage, inverse-witness coverage, and classifier transport are exactly the visible rows of the permutation source package.*
7. *Ledger boundary: enumeration choices, position names, order witnesses, probe reads, and package provenance remain in the ledger and are not promoted to public carrier data.*

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationCarrier composition inverse action obligations`

Proof. Composition closure, inverse closure, unit rows, and action compatibility are the four group-facing readings of Definition 116.4. The theorem already states these rows as finite-position bijection facts whose graph readings are carried by the $\mathsf{Permutation}^{\uparrow}$ ledger.

Associativity is read constructively from the same certified composition row: both parenthesized composites have the same sequence of finite-position graph reads, and the comparison is recorded as classifier transport over the BHist graph rows. The proof uses the $\mathsf{Group}^{\uparrow}$ source boundary of chapter 41 only to name the operation row, not to add a host-level equality of functions.

Exactness and the ledger boundary are inherited from Definition 116.1. Graph coverage, inverse coverage, and action readback stay visible; enumeration choices, order choices, position names, probe logs, and Pkg provenance stay in the ledger. Hence the certificate surface is constructive and introduces no quotient of permutation presentations. □

Theorem 117.4 (SymGroupUp public certificate surface)**.** *The carrier theorem of Definition 117.1, the classifier theorem of Definition 117.2, and the composition, inverse, and action theorem of Definition 117.3 assemble the public* $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$ *surface. The exported surface consists of the certified permutation carrier, the group-facing classifier, composition, inverse, unit and action compatibility, exactness, and ledger boundary. It exposes no host function equality and forms no quotient of presentations.*

Lean4 ✓ `BEDC.Derived.SymGroupUp.SymGroupPermutationCarrier public certificate surface`

Proof. Project the carrier surface from Definition 117.1. This supplies the certified permutation rows, the $\mathsf{Group}^{\uparrow}$ source boundary, the displayed unit, the displayed inverse, and the visible graph, action, package, and ledger rows.

Project the classifier surface from Definition 117.2. Its reflexivity, symmetry, transitivity, and carrier-transport rows are exactly the permutation classifier rows read through the group-facing carrier.

Project the operation rows from Definition 117.3. These give composition closure, inverse closure, unit laws, associativity, action compatibility, exactness, and the ledger boundary. Repacking these three projected surfaces gives the exported $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$ certificate, with every comparison still recorded through hsame, classifier transport, and Pkg provenance rather than host function equality or quotienting. □

Closure status for $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$**.**

Constructive story: The symmetric group is obtained by repacking the already certified $\mathsf{Permutation}^{\uparrow}$ carrier as a $\mathsf{Group}^{\uparrow}$ surface under composition. A carried element is still a finite-position self-bijection row with its graph, inverse graph, action, inverse-witness rows, package provenance, and ledger entries; rows lacking the permutation certificate are not admitted as group elements. The classifier is the permutation classifier read through the group-facing boundary, so two group elements classify together when their certified actions agree pointwise on the finite-set entries, not when host functions are equal. The source is the $\mathsf{Permutation}^{\uparrow}$ public surface plus the group operation boundary, the pattern records identity permutation, composition, inverse, associativity, unit laws, action compatibility, and exactness, and the ledger keeps enumeration choices, position names, probe reads, and provenance as permutation ledger data. The five name-certificate obligations are supplied by the identity permutation for inhabitation, by reflexivity, symmetry, and transitivity inherited from the permutation classifier, and by composition and inverse transport rows that keep carried permutations inside the carrier. A carried permutation G lies in the signature gap of a $\mathsf{SymGroup}^{\uparrow}$ token p when the source-domain accepts the permutation and group-boundary rows, the signature relation pairs G with an answer group element and evidence ledger, and token introduction names that answer as p; unfolded, G is the certified action encoded by p with its identity, composition, and inverse ledgers present. The paper bridge reads this as the group of certified permutations of the finite spine and reads back only the same permutation rows and classifier evidence. The chapter registers this composition group construction under the name $\mathsf{SymGroup}^{\uparrow}$; group structure is a repackaging of permutation ledgers, not host symmetric-group equality, a quotient of presentations, representation theory, or an exposed order witness.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature surface consists of the carrier, classifier, composition, inverse, action, exactness, and ledger rows already assembled by the public certificate of Definition 117.4.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SymGroupUp.SymGroupCarrier\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not claim bridgeChecked verification for the exported $\mathsf{SymGroup}^{\uparrow}$ certificate surface.

Upgrade path: A checked standard bridge theorem is the remaining verification step beyond the audit-clean target named here.

Chapter 118

A Concrete Naming Certificate for $\mathsf{Graph}^{\uparrow}$

The graph interface $\mathsf{Graph}^{\uparrow}$ packages a vertex carrier from $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ (chapter 111) together with a binary edge relation. It supplies the substrate for $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$ (chapter 119) and for combinatorial structures such as posets viewed as DAGs.

118.1 Carrier definition

Definition 118.1 (Cont adjacency graph carrier)**.** *The concrete* $\mathsf{Graph}^{\uparrow}$ *source is the BEDC history carrier* BHist *restricted to* UnaryHistory*, with vertex classifier* hsame *on unary histories. For histories* h, k, g : BHist *define*

$$\mathsf{GraphEdge}(h, k, g) \iff \mathsf{UnaryHistory}(h) \wedge \mathsf{UnaryHistory}(k) \wedge \mathsf{Cont}(h, k, g).$$

This predicate reads a BEDC continuation row as a directed adjacency edge from source vertex h *to target vertex* k*, with visible edge-result history* g*. The graph carrier template fields are:*

1. *the traditional target is a directed graph;*
2. *the BEDC source is* BHist *with* UnaryHistory *vertices and* Cont *rows;*
3. *the vertex carrier is* UnaryHistory*;*
4. *the vertex classifier is* hsame *restricted to unary histories;*
5. *the stability obligations are unary transport along* hsame *and* Cont *transport along* hsame *in all three displayed histories;*
6. *the ledger is the visible triple* (h, k, g) *together with the two unary endpoint witnesses and the* $\mathsf{Cont}(h, k, g)$ *row;*
7. *the core theorem list is endpoint coverage, edge classifier transport, cancellative row readback, unit rows, two-step path composition, and the assembled* $\mathsf{Graph}^{\uparrow}$ *obligation surface;*
8. *the exactness predicate is row inversion for* GraphEdge*;*
9. *the standard bridge is absent;*
10. *the status is paper proof target.*

The edge classifier between two rows is the componentwise relation

$$(h, k, g) \sim_{\mathsf{Graph}} (h', k', g') :\Longleftrightarrow \mathsf{hsame}(h, h') \wedge \mathsf{hsame}(k, k') \wedge \mathsf{hsame}(g, g').$$

Thus edge sameness is entirely visible in the BEDC ledger; no hidden graph structure participates in classification.

Lean4 (definition) `BEDC.Derived.GraphUp.GraphContEdge`

118.2 The certificate

Theorem 118.2 (Graph edge endpoint coverage)**.** *For histories $h, k, g : \mathsf{BHist}$, every row $\mathsf{GraphEdge}(h, k, g)$ exposes its carried source vertex, carried target vertex, and continuation witness:*

$$\mathsf{GraphEdge}(h, k, g) \Longrightarrow \mathsf{UnaryHistory}(h) \wedge \mathsf{UnaryHistory}(k) \wedge \mathsf{Cont}(h, k, g).$$

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge endpoint coverage`

Proof. Unfold Definition 118.1. The graph edge predicate is defined as exactly the conjunction of the source unary witness, the target unary witness, and the continuation row. Projection from that conjunction gives the three displayed fields. □

Theorem 118.3 (Graph edge classifier transport)**.** *Let $h, k, g, h', k', g' : \mathsf{BHist}$. If $\mathsf{GraphEdge}(h, k, g)$ holds and*

$$\mathsf{hsame}(h, h') \wedge \mathsf{hsame}(k, k') \wedge \mathsf{hsame}(g, g')$$

holds, then unary-history transport on the endpoints and cont_hsame_transport *on the continuation row give*

$$\mathsf{GraphEdge}(h', k', g').$$

The original and transported rows are classified by $(h, k, g) \sim_{\mathsf{Graph}} (h', k', g')$.

Lean4 ✓ `BEDC.Derived.GraphUp.GraphEdge classifier transport`
Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge classifier transport`

Proof. Unpack $\mathsf{GraphEdge}(h, k, g)$ by Definition 118.1. This yields $\mathsf{UnaryHistory}(h)$, $\mathsf{UnaryHistory}(k)$, and $\mathsf{Cont}(h, k, g)$.

Unpack the classifier witnesses. Unary-history transport along $\mathsf{hsame}(h, h')$ and $\mathsf{hsame}(k, k')$ carries the two endpoint witnesses to $\mathsf{UnaryHistory}(h')$ and $\mathsf{UnaryHistory}(k')$.

Apply cont_hsame_transport to the three hsame witnesses and the row $\mathsf{Cont}(h, k, g)$. This produces $\mathsf{Cont}(h', k', g')$.

Repack the two transported unary witnesses and the transported continuation row by Definition 118.1. The final classifier claim is just the same three hsame witnesses read through the componentwise edge classifier. □

Theorem 118.4 (Graph Cont edge row inversion)**.** *Let $h, k, g, h', k', g' : \mathsf{BHist}$. For displayed graph rows:*

1. *if $\mathsf{GraphEdge}(h, k, g)$, $\mathsf{GraphEdge}(h', k, g)$, and the target/result pair is shared, then $\mathsf{hsame}(h, h')$ by* cont_right_cancel*;*
2. *if $\mathsf{GraphEdge}(h, k, g)$, $\mathsf{GraphEdge}(h, k', g)$, and the source/result pair is shared, then $\mathsf{hsame}(k, k')$ by* cont_left_cancel*;*

3. *if* $\mathsf{GraphEdge}(h, k, g)$ *and* $\mathsf{GraphEdge}(h, k, g')$ *share the same source and target, then* $\mathsf{hsame}(g, g')$ *by* cont_deterministic.

Proof. Unfold Definition 118.1 in each displayed row. The endpoint witnesses are retained as carrier data, and the continuation component is the BEDC kernel row $\mathsf{Cont}(-, -, -)$.

For the shared target/result clause, apply cont_right_cancel to the two exposed continuation rows. This reads back the two possible sources as hsame.

For the shared source/result clause, apply cont_left_cancel to the two exposed continuation rows. This reads back the two possible targets as hsame.

For the shared source/target clause, apply cont_deterministic to the two exposed continuation rows. This classifies the two visible edge results by hsame. □

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge row inversion`

Theorem 118.5 (Graph Cont unit loop laws)**.** *For every unary vertex* $h : \mathsf{BHist}$*, the graph relation contains the two displayed unit rows*

$$\mathsf{GraphEdge}(\mathsf{BHist.Empty}, h, h)$$

and

$$\mathsf{GraphEdge}(h, \mathsf{BHist.Empty}, h).$$

Moreover, a row $\mathsf{GraphEdge}(\mathsf{BHist.Empty}, h, g)$ *reads its result back to* h *by* cont_left_unit *and* cont_left_unit_iff*, and a row* $\mathsf{GraphEdge}(h, \mathsf{BHist.Empty}, g)$ *reads its result back to* h *by* cont_right_unit *and* cont_right_unit_iff*.*

Proof. Use the unary empty witness for BHist.Empty and the given unary witness for h. The left unit law cont_left_unit supplies $\mathsf{Cont}(\mathsf{BHist.Empty}, h, h)$, and the right unit law cont_right_unit supplies $\mathsf{Cont}(h, \mathsf{BHist.Empty}, h)$.

Repack each continuation row with its two unary endpoint witnesses by Definition 118.1. This gives the two displayed graph unit rows.

For readback, unfold an arbitrary left-unit or right-unit graph row to expose its continuation component. The corresponding iff theorem, cont_left_unit_iff or cont_right_unit_iff, identifies exactly the histories whose result is classified with h. □

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge unit loop`

Theorem 118.6 (Graph Cont two-step composition)**.** *Let* $h, k, l, hk, kl : \mathsf{BHist}$*. If* $\mathsf{GraphEdge}(h, k, hk)$ *and* $\mathsf{GraphEdge}(k, l, kl)$ *hold, then there are histories* $left, right : \mathsf{BHist}$ *such that*

$$\mathsf{GraphEdge}(hk, l, left),$$

$$\mathsf{GraphEdge}(h, kl, right),$$

and

$$\mathsf{hsame}(left, right).$$

Proof. Unfold the two input graph edges. This exposes unary witnesses for h, k, and l, together with continuation rows $\mathsf{Cont}(h, k, hk)$ and $\mathsf{Cont}(k, l, kl)$.

Unary closure for continuation results carries the first row to a unary witness for hk and the second row to a unary witness for kl. These witnesses make the two composite endpoints eligible for the graph carrier.

Apply cont_assoc_exists_hsame to the two continuation rows. It produces histories $left$ and $right$ with rows $\mathsf{Cont}(hk, l, left)$ and $\mathsf{Cont}(h, kl, right)$ and with $\mathsf{hsame}(left, right)$.

Repack the two produced continuation rows with the unary endpoint witnesses by Definition 118.1. The result is the displayed pair of two-step graph edges together with their hsame result comparison. □

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge two step composition`
Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge composition closure`

Theorem 118.7 (GraphUp NameCert surface)**.** *The carrier definition in Definition 118.1, together with Definition 118.2 and Definition 118.3, Definition 118.4, Definition 118.5, and Definition 118.6, assembles the paper-side* $\mathsf{Graph}^{\uparrow}$ *obligation surface: vertex carrier* UnaryHistory*, vertex classifier* hsame *restricted to unary histories, edge relation* GraphEdge*, endpoint coverage, edge transport, cancellative readback, unit rows, two-step path composition, and the visible* Cont *ledger. The standard bridge field is absent from this surface.*

Lean4 ✓ `BEDC.Derived.GraphUp.GraphCont namecert surface`
Lean4 ✓ `BEDC.Derived.GraphUp.GraphContNameCert surface`

Proof. The definition supplies the concrete BEDC source, the vertex carrier, the restricted vertex classifier, the edge relation, the visible ledger, and the declared absence of a standard bridge. It also names the exactness predicate as row inversion for GraphEdge.

Definition 118.2 gives that inversion principle in the direction used by downstream graph certificates: every edge row exposes both carried endpoints and its Cont witness.

Definition 118.3 supplies the stability surface. It transports the two endpoint carrier witnesses along hsame and transports the continuation row along cont_hsame_transport, then repackages the transported row as another GraphEdge witness.

Definition 118.4 supplies cancellative readback for rows sharing a target/result pair or a source/result pair, and determinacy for rows sharing a source/target pair.

Definition 118.5 supplies the two empty-endpoint unit rows and their result readback principles. Definition 118.6 supplies path composition by associativity of Cont up to hsame.

These clauses are precisely the listed $\mathsf{Graph}^{\uparrow}$ paper obligations, so the chapter exposes the carrier, classifier, edge, coverage, transport, readback, unit, composition, and ledger surface required by $\mathsf{Tree}^{\uparrow}$ and downstream combinatorial certificates. □

Theorem 118.8 (Graph empty-tail identity edge)**.** *For every history* $h : \mathsf{BHist}$*, if* $\mathsf{UnaryHistory}(h)$*, then*

$$\mathsf{GraphEdge}(h, \mathsf{e}, h).$$

Its ten-field fit is: traditional target identity graph edge; BEDC source BHist*,* UnaryHistory*, and* Cont*; carrier* GraphEdge*; classifier componentwise* hsame*; endpoint fields the two displayed unary witnesses; stability inherited from* cont_hsame_transport*; ledger* (h, e, h)*; exactness by endpoint coverage and continuation determinacy; standard bridge absent; status proof target.*

Proof. Use $\mathsf{UnaryHistory}(h)$ for the source endpoint. The empty history is a unary history by the empty unary constructor, so it supplies the target endpoint.

The continuation row is the right-unit row $\mathsf{Cont}(h, \mathsf{e}, h)$, also named cont_right_unit. Repacking these three fields through Definition 118.1 gives the displayed GraphEdge row. □

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge empty tail identity`

Theorem 118.9 (Graph edge result determinacy)**.** *For histories* $h, k, g, g' : \mathsf{BHist}$*, if* $\mathsf{GraphEdge}(h, k, g)$ *and* $\mathsf{GraphEdge}(h, k, g')$*, then*

$$\mathsf{hsame}(g, g').$$

Its ten-field fit is: traditional target graph edge-result determinacy; BEDC source BHist*,* UnaryHistory*, and* Cont*; carrier* GraphEdge*; classifier componentwise* hsame*; endpoint fields read from the two edge rows; stability inherited from continuation transport; ledger the two rows* (h, k, g) *and* (h, k, g')*; exactness by endpoint coverage and continuation determinacy up to* hsame*; standard bridge absent; status proof target.*

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge result determinacy`

Proof. Apply Definition 118.2 to both edge rows. This projects the two continuation witnesses $\mathsf{Cont}(h, k, g)$ and $\mathsf{Cont}(h, k, g')$ from the graph carrier.

Apply cont_deterministic, equivalently cont_determinacy_up_to_hsame_spine, to the two continuation rows with the same source and the same visible target. The resulting classification is exactly $\mathsf{hsame}(g, g')$. □

Theorem 118.10 (Graph visible-tail step closure)**.** *For histories* $h, k, g : \mathsf{BHist}$*, suppose* $\mathsf{GraphEdge}(h, k, g)$ *and suppose the visible-tail constructors preserve unary history at the target and result positions:*

$$\mathsf{UnaryHistory}(\mathsf{E0}(k)) \wedge \mathsf{UnaryHistory}(\mathsf{E0}(g)) \wedge \mathsf{UnaryHistory}(\mathsf{E1}(k)) \wedge \mathsf{UnaryHistory}(\mathsf{E1}(g)).$$

Then

$$\mathsf{GraphEdge}(h, \mathsf{E0}(k), \mathsf{E0}(g)) \wedge \mathsf{GraphEdge}(h, \mathsf{E1}(k), \mathsf{E1}(g)).$$

Its ten-field fit is: traditional target visible-tail graph closure; BEDC source BHist*,* UnaryHistory*, and* Cont*; carrier* GraphEdge*; classifier componentwise* hsame*; endpoint fields the source row plus the supplied visible-tail unary rows; stability inherited from the two continuation step rules; ledger the two stepped triples; exactness by endpoint coverage and continuation determinacy; standard bridge absent; status proof target.*

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContEdge visible tail step closure`

Proof. First project the original edge by Definition 118.2. This gives $\mathsf{UnaryHistory}(h)$ and the continuation row $\mathsf{Cont}(h, k, g)$.

For the zero-tail branch, use the supplied unary rows $\mathsf{UnaryHistory}(\mathsf{E0}(k))$ and $\mathsf{UnaryHistory}(\mathsf{E0}(g))$. Apply the zero continuation step rule to $\mathsf{Cont}(h, k, g)$, obtaining $\mathsf{Cont}(h, \mathsf{E0}(k), \mathsf{E0}(g))$. Repack these three fields as $\mathsf{GraphEdge}(h, \mathsf{E0}(k), \mathsf{E0}(g))$.

For the one-tail branch, use the supplied unary rows $\mathsf{UnaryHistory}(\mathsf{E1}(k))$ and $\mathsf{UnaryHistory}(\mathsf{E1}(g))$. Apply the one continuation step rule to $\mathsf{Cont}(h, k, g)$, obtaining $\mathsf{Cont}(h, \mathsf{E1}(k), \mathsf{E1}(g))$. Repack these three fields as $\mathsf{GraphEdge}(h, \mathsf{E1}(k), \mathsf{E1}(g))$. □

Theorem 118.11 (Graph Cont three-step path reassociation)**.** *Let* $h, k, l, m, hk, kl, lm : \mathsf{BHist}$*. In the concrete* $\mathsf{Graph}^{\uparrow}$ *carrier of Definition 118.1, if*

$$\mathsf{GraphEdge}(h, k, hk), \qquad \mathsf{GraphEdge}(k, l, kl), \qquad \mathsf{GraphEdge}(l, m, lm)$$

hold, then there are histories $hkl, klm, left, right : \mathsf{BHist}$ *such that*

$$\mathsf{GraphEdge}(hk, l, hkl), \qquad \mathsf{GraphEdge}(hkl, m, left),$$

$$\mathsf{GraphEdge}(k, lm, klm), \qquad \mathsf{GraphEdge}(h, klm, right),$$

and

$$\mathsf{hsame}(left, right).$$

Thus the visible endpoints of the left-associated and right-associated three-step graph paths are classified by hsame.

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContPath reassociation`

Proof. Apply Definition 118.6 to the first two input rows. Choose witnesses hkl and hkl_R with

$$\mathsf{GraphEdge}(hk, l, hkl), \qquad \mathsf{GraphEdge}(h, kl, hkl_R), \qquad \mathsf{hsame}(hkl, hkl_R).$$

Retain the row $\mathsf{GraphEdge}(hk, l, hkl)$ as the left middle edge.

Apply Definition 118.6 to the second and third input rows. Choose witnesses klm_L and klm with

$$\mathsf{GraphEdge}(kl, m, klm_L), \qquad \mathsf{GraphEdge}(k, lm, klm), \qquad \mathsf{hsame}(klm_L, klm).$$

Retain the row $\mathsf{GraphEdge}(k, lm, klm)$ as the right middle edge.

Apply Definition 118.6 to $\mathsf{GraphEdge}(hk, l, hkl)$ and the third input row. This gives witnesses $left$ and mid_L such that

$$\mathsf{GraphEdge}(hkl, m, left), \qquad \mathsf{GraphEdge}(hk, lm, mid_L), \qquad \mathsf{hsame}(left, mid_L).$$

Apply Definition 118.6 to the first input row and $\mathsf{GraphEdge}(k, lm, klm)$. This gives witnesses mid_R and $right$ such that

$$\mathsf{GraphEdge}(hk, lm, mid_R), \qquad \mathsf{GraphEdge}(h, klm, right), \qquad \mathsf{hsame}(mid_R, right).$$

The two middle rows $\mathsf{GraphEdge}(hk, lm, mid_L)$ and $\mathsf{GraphEdge}(hk, lm, mid_R)$ have the same displayed source and target. By Definition 118.9,

$$\mathsf{hsame}(mid_L, mid_R).$$

Transitivity of hsame combines $\mathsf{hsame}(left, mid_L)$, $\mathsf{hsame}(mid_L, mid_R)$, and $\mathsf{hsame}(mid_R, right)$ to give

$$\mathsf{hsame}(left, right).$$

The retained graph rows are exactly the displayed left-associated and right-associated path rows. □

Theorem 118.12 (GraphUp Cont public interface bridge)**.** *The public graph-interface bridge for Definition 118.1 interprets every row* $\mathsf{GraphEdge}(h, k, g)$ *as a directed edge of the exported* $\mathsf{Graph}^{\uparrow}$ *interface from source vertex* h *to target vertex* k *with visible edge result* g*. Public equality of exported graph edges reflects back to the componentwise BEDC classifier*

$$\mathsf{hsame}(h, h') \wedge \mathsf{hsame}(k, k') \wedge \mathsf{hsame}(g, g')$$

on source, target, and result.

The bridge fields are exactly the $\mathsf{Graph}^{\uparrow}$ *NameCert surface of Definition 118.7, endpoint coverage from Definition 118.2, classifier transport from Definition 118.3, row inversion from Definition 118.4, the unit loop laws from Definition 118.5, two-step composition from Definition 118.6, and three-step reassociation from Definition 118.11.*

Lean4 ✓ `BEDC.Derived.GraphUp.GraphContPublicInterface bridge`

Proof. Project the carrier, classifier, edge predicate, visible ledger, and declared surface fields from Definition 118.7. The carrier definition reads a public graph row as precisely the displayed $\mathsf{GraphEdge}(h, k, g)$ datum, so interpretation into the exported $\mathsf{Graph}^{\uparrow}$ interface is direct projection from the row.

For endpoint soundness, apply Definition 118.2. It exposes the source unary witness, target unary witness, and continuation row carried by every public edge, so the interface endpoints are exactly the two displayed histories.

For equality reflection, use the componentwise edge classifier from Definition 118.1. Classifier transport is supplied by Definition 118.3; row inversion is supplied by Definition 118.4, which reads shared public rows back to hsame on the source, target, or result component as appropriate.

For the graph operations, Definition 118.5 supplies the public empty-endpoint unit rows, Definition 118.6 supplies public path composition, and Definition 118.11 supplies reassociation of three displayed paths up to hsame. These projections are the advertised public graph-interface bridge fields. □

Closure status for $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$.

Constructive story: A graph in this concrete surface uses unary histories as vertices and reads a directed edge from the kernel continuation row: $\mathsf{GraphEdge}(h, k, g)$ means that h and k are unary and $\mathsf{Cont}(h, k, g)$ is displayed. A row is excluded unless both endpoints are carried vertices and the continuation result is part of the same visible triple, while edge classification is componentwise hsame on source, target, and result. The source is the BHist unary-vertex carrier with Cont rows, the pattern records endpoint coverage, row inversion, unit loops, two-step composition, and three-step reassociation, and the ledger keeps exactly the triple (h, k, g) with the two unary endpoint witnesses and continuation witness. The five name-certificate obligations are witnessed by empty-endpoint unit rows for inhabitation, by componentwise reflexivity, symmetry, and transitivity of hsame, and by transport of unary endpoints and continuation rows along the classifier. An edge row e lies in the signature gap of a $\mathsf{Graph}^{\uparrow}$ token p when the source-domain accepts its unary endpoints and continuation triple, the signature relation pairs that triple with an answer edge and evidence ledger, and token introduction names that answer as p; unfolded, the source, target, and result histories are exactly the componentwise edge data encoded by the token. The public bridge reads each visible triple as a directed graph edge and reads equality of exported edges back to the same componentwise BEDC classifier, with no separate standard graph API claimed. The chapter registers this continuation-edge construction under the name $\mathsf{Graph}^{\uparrow}$; graph structure is a ledger of unary vertices and Cont rows, not a host finite graph, connectivity package, homomorphism theory, or hidden adjacency object.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The $\mathsf{Graph}^{\uparrow}$ treatment binds endpoint coverage, classifier transport, row inversion, unit loop laws, two-step composition, three-step reassociation, and the public interface bridge for GraphEdge rows over UnaryHistory vertices with hsame classification.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.GraphUp.GraphContNameCert\_surface`

Bridge status: paperBridge

Not claimed: Finite graph APIs, connectivity, acyclicity, graph homomorphisms, standard graph APIs, or machine-checked bridge closure.

Upgrade path: A machine-checked bridge grade requires a checked StdBridge target for this public interface, independently of the paper bridge recorded here.

Chapter 119

A Concrete Naming Certificate for $\mathsf{Tree}^{\uparrow}$

The tree interface $\mathsf{Tree}^{\uparrow}$ packages a connected acyclic $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118) together with a designated root or root-free witness. It is the constructive substrate for inductive carriers and for the syntactic representation of derivations.

119.1 Carrier definition

Theorem 119.1 (TreeUp graph-source carrier obligation)**.** *The carrier for* $\mathsf{Tree}^{\uparrow}$ *is a* BHist *predicate read through the existing* $\mathsf{Graph}^{\uparrow}$ *source. An accepted tree history exposes a carried* $\mathsf{Graph}^{\uparrow}$ *source row, a finite vertex-and-edge incidence ledger over* BHist *endpoints, and a classifier comparison inherited from* hsame *and the* $\mathsf{Graph}^{\uparrow}$ *classifier rows. The carrier does not identify host graphs by equality; every comparison is recorded as a displayed classifier row over the accepted histories and their incidence ledger.*

Proof. Unpack an accepted tree history as a graph-source presentation. The first projection is the $\mathsf{Graph}^{\uparrow}$ carrier row, so each visible vertex and edge is read as a carried BHist endpoint rather than as a host-level graph object.

The second projection is the finite incidence ledger. It lists the displayed vertex endpoints, displayed edge endpoints, and the source-target incidence rows that attach each edge to carried vertices. Finiteness belongs to this ledger, so no quotient over ambient graphs is introduced.

The classifier projection is inherited rowwise. Endpoint movement is componentwise hsame, and graph-source movement is the comparison supplied by $\mathsf{Graph}^{\uparrow}$. Transporting the finite incidence ledger along those rows gives the same accepted tree carrier predicate at the target history, with no appeal to equality of host graphs. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeGraphSource carrier obligation`

Definition 119.2 (TreeUp BHist carrier)**.** *The carrier of* $\mathsf{Tree}^{\uparrow}$ *is the* BHist *endpoint row whose visible package consists of a* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *edge/vertex package, the* GraphContEdge *rows witnessing the graph edges, a connectedness row, an acyclicity row, and one branch of a root classifier. The rooted branch records a root witness carried by the same* Pkg *provenance as the displayed graph package; the root-free branch records a witness that the same visible package has no designated root.*

Two such rows are carrier-comparable only through the visible graph hsame*-transport, the connectedness and acyclicity rows, and the chosen rooted or root-free witness row. Hidden graph routes,*

hidden choices of root, and hidden proofs of connectedness or acyclicity are ledger data, not carrier equality.

Lean4 ✓ `BEDC.Derived.TreeUp.TreeUp StdBridge`

Theorem 119.3 (TreeUp carrier obligation)**.** *The* $\mathsf{Tree}^{\uparrow}$ *carrier is obligated to expose exactly the* BHist *endpoint of Definition 119.2, the* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *source package, the* GraphContEdge *edge rows, the connectedness row, the acyclicity row, and the rooted or root-free witness row. Its ten-field fit is: traditional target tree carrier; BEDC source* BHist, Cont, hsame, Pkg, *and* NameCert*; carrier the displayed endpoint row; classifier inherited from graph-edge transport plus the three tree rows; stability by transport of the visible rows; ledger the hidden route, root-choice, connectedness, and acyclicity witnesses; exactness by visible row readback; standard bridge absent; status obligation target.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier obligation rows`

Proof. Use the carrier field of the roadmap ten-field template. The source row is the displayed $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ package, so every visible edge is already a GraphContEdge row over BHist and Cont.

Attach the connectedness, acyclicity, and root branch rows to that same Pkg provenance. The resulting endpoint is a tree row before any syntactic derivation chapter consumes it, because all carrier fields are visible BEDC rows and all non-visible choices are assigned to the ledger field. □

Theorem 119.4 (TreeUp classifier obligation)**.** *The* $\mathsf{Tree}^{\uparrow}$ *classifier relates two carried endpoints precisely when their* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *graph packages are transported by graph-edge* hsame*, their* GraphContEdge *rows match under that transport, and their connectedness, acyclicity, and root-branch rows match over the transported* Pkg *provenance. It does not identify trees by host graph isomorphism or by unrecorded route choice.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier classifier transport`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier classifier transport surface`

Proof. Start with the classifier field of the roadmap ten-field template and the graph source certificate. Transport the visible edge and vertex package along the graph hsame relation, carrying each GraphContEdge row by its Cont transport surface.

It remains to compare the tree-only rows. The connectedness row, the acyclicity row, and the rooted or root-free branch row are checked after the Pkg provenance has been transported, so the classifier is still a BEDC classifier on named histories rather than an external graph quotient. □

Theorem 119.5 (TreeUp root witness obligation)**.** *For each* $\mathsf{Tree}^{\uparrow}$ *carrier row, the root component must split constructively into exactly one displayed branch: either a rooted branch carrying a root witness compatible with the* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *vertex row, or a root-free branch carrying a witness that no vertex row in the same visible package has been designated as root. Both branches are transported by the same* hsame *and* Pkg *data as the graph package.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier root branch transport`

Proof. Proceed by case analysis on the root branch recorded in the carrier row.

In the rooted case, read the vertex witness from the visible $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ package and check that its Pkg provenance is the one used by the tree endpoint. Transport along hsame carries the root witness with the transported vertex row.

In the root-free case, keep the same graph package and read the negative root row as a visible witness attached to that package. Its transport uses the same hsame and Pkg data, so no hidden root selection can enter the carrier classifier. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeVisibleCarrier root witness obligation`

Theorem 119.6 (Tree frontier readback as a List spine)**.** *For any accepted* $\mathsf{Tree}^{\uparrow}$ *carrier whose visible* $\mathsf{Graph}^{\uparrow}$ *package is finite and rooted, the frontier leaves admit a* $\mathsf{List}^{\uparrow}$ *finite-spine readback. The entries of that spine are exactly the leaf endpoint rows transported by the* $\mathsf{Tree}^{\uparrow}$ *classifier, with incidence supplied by the* $\mathsf{Graph}^{\uparrow}$ *rows and finite-spine representation supplied by* $\mathsf{List}^{\uparrow}$*.*

Proof. Use Definition 119.3 to read the accepted carrier as a visible finite graph package with GraphContEdge incidence rows, and use Definition 119.5 to select the rooted branch. The $\mathsf{Graph}^{\uparrow}$ incidence rows identify the displayed children of each node, while the $\mathsf{List}^{\uparrow}$ finite-spine representation supplies the target format for the frontier.

Induct over the displayed finite tree packet. In the leaf case, no displayed outgoing incidence row remains, so the frontier readback is the singleton $\mathsf{List}^{\uparrow}$ spine whose entry is the leaf endpoint row.

In the branch case, apply the induction hypothesis to the left and right displayed subpackets. Concatenate the two frontier spines through the $\mathsf{List}^{\uparrow}$ spine route, preserving the left-to-right branch classifier rows as ledger data. The $\mathsf{Tree}^{\uparrow}$ classifier transports each leaf endpoint componentwise by hsame, so the concatenated spine entries are exactly the transported leaf endpoint rows.

Thus every visible frontier leaf contributes one displayed $\mathsf{List}^{\uparrow}$ spine entry, and every entry of the spine comes from one such leaf endpoint. No host traversal order or host tree datatype is used. □

Theorem 119.7 (TreeUp stability and ledger obligation)**.** *The* $\mathsf{Tree}^{\uparrow}$ *stability ledger consists exactly of the hidden graph route data, the hidden root-choice data, and the hidden connectedness and acyclicity witnesses used to justify the visible rows. Transport stability may consume those ledger entries, but the public carrier and classifier expose only* BHist *endpoints,* GraphContEdge *rows,* Cont *rows,* hsame *transport,* Pkg *provenance, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistObligationCarrier stability ledger obligation`

Proof. Use the stability and ledger fields of the roadmap ten-field template. The visible surface is fixed by the graph package, edge rows, connectedness row, acyclicity row, and root branch, so the remaining data can only record how those rows were obtained.

The hidden graph route supports connectedness, the hidden root-choice data supports the rooted branch when present, and the hidden acyclicity and connectedness witnesses justify the two graph-shape rows. Because each entry is consumed only to transport or justify a visible row, the ledger is exact and no additional hidden field is part of carrier equality. □

Theorem 119.8 (TreeUp exactness obligation)**.** *The visible* $\mathsf{Tree}^{\uparrow}$ *package is exact in three senses. Coverage says every accepted tree endpoint exposes a* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *package, its* GraphContEdge *rows, connectedness, acyclicity, and one root branch. Soundness says any endpoint exposing those rows is a valid* $\mathsf{Tree}^{\uparrow}$ *carrier only under the classifier of Definition 119.4. Completeness says every visible connected acyclic graph package with either a root witness or a root-free witness is represented by a* $\mathsf{Tree}^{\uparrow}$ *carrier row.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeDerivationSpineLedger exactness rows`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier exactness rows`

Proof. For coverage, invert the carrier row of Definition 119.2. The inversion reads back the $\mathsf{NameCert}_{\mathsf{Graph}^\uparrow}$ package, each GraphContEdge row, the connectedness row, the acyclicity row, and the root branch.

For soundness, apply the classifier obligation after the visible rows have been read back. The only admissible identifications are the transported graph edge rows together with matching connectedness, acyclicity, and root-branch rows.

For completeness, begin with a visible connected acyclic graph package and a chosen root branch. Repack those rows through BHist, Pkg, and NameCert, placing route and witness choices in the ledger, to obtain the required $\mathsf{Tree}^\uparrow$ carrier endpoint. □

119.2 The certificate

Theorem 119.9 (TreeUp connectedness obligation)**.** *For every accepted* $\mathsf{Tree}^\uparrow$ *history and every carried endpoint displayed by its* $\mathsf{Graph}^\uparrow$ *source, the certificate supplies a finite* BHist *path row through the* $\mathsf{Graph}^\uparrow$ *edge ledger from that endpoint to the selected root component. The path row records each intermediate endpoint, each traversed edge incidence, and the classifier comparison that carries the path under* hsame *transport.*

Proof. Read the endpoint from the graph-source carrier row supplied by Definition 119.1. The finite incidence ledger gives the only admissible edges and their source-target endpoint rows.

The connectedness witness is a finite path ledger indexed by those admissible edges. Its first endpoint is the displayed carried endpoint, its last endpoint lies in the selected root component, and every adjacent step is justified by one incidence row from the $\mathsf{Graph}^\uparrow$ ledger.

Transport the path by applying componentwise hsame to the endpoint rows and the inherited $\mathsf{Graph}^\uparrow$ classifier to the edge rows. The transported ledger has the same finite shape, so it remains a path from the transported endpoint to the transported root component. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeGraphSource connected root path readback`

Theorem 119.10 (TreeUp acyclicity obligation)**.** *For an accepted* $\mathsf{Tree}^\uparrow$ *history, every closed finite edge walk in the* $\mathsf{Graph}^\uparrow$ *edge ledger collapses under the* $\mathsf{Tree}^\uparrow$ *classifier to the trivial endpoint row. Equivalently, the certificate records that the only closed walk recognized by the tree classifier is the displayed stationary walk at its endpoint, and this recognition is stable under* hsame *transport.*

Proof. Start with a closed finite edge walk in the incidence ledger of Definition 119.1. Each step is a $\mathsf{Graph}^\uparrow$ edge row whose endpoints are carried BHist histories, and the closing condition is itself a displayed classifier row.

Apply the acyclicity witness carried by the $\mathsf{Tree}^\uparrow$ certificate. It reduces the closed walk ledger to the stationary endpoint row in the $\mathsf{Tree}^\uparrow$ classifier, so the edge sequence contributes no nontrivial cycle to the accepted carrier.

Stability follows by transporting the whole walk ledger componentwise through hsame and through the inherited $\mathsf{Graph}^\uparrow$ classifier. The acyclicity witness reads the transported closed walk and again returns the stationary endpoint row at the transported endpoint. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier closed walk tail empty`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistObligationCarrier acyclic empty transport`

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistObligationCarrier acyclic unit loop exactness`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeGraphContEdge closed walk unit collapse`

Theorem 119.11 (TreeUp root-or-root-free witness obligation)**.** *The* $\mathsf{Tree}^{\uparrow}$ *certificate supplies either a displayed root endpoint carried by the* $\mathsf{Graph}^{\uparrow}$ *source or a root-free witness whose classifier is stable under* hsame*. In the rooted case the root endpoint is one of the carried vertices used by the connectedness path rows. In the root-free case the witness records that connectedness is read componentwise without selecting a distinguished endpoint, and this record transports along the same* $\mathsf{Tree}^{\uparrow}$ *classifier.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeRootWitness spine closed boundary`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeRootBranch empty root witness readback`

Proof. Inspect the root row of the certificate. If the row is rooted, it displays a BHist endpoint and a proof that this endpoint is carried by the $\mathsf{Graph}^{\uparrow}$ source ledger. The connectedness paths then target the component containing that displayed root.

If the row is root-free, the certificate instead displays a witness that no distinguished endpoint is part of the public tree data. Connectedness is then read by component rows, and the witness itself is attached to the $\mathsf{Tree}^{\uparrow}$ classifier rather than to a host graph equality.

In both cases, transport is rowwise. The rooted endpoint moves by hsame and the inherited graph classifier, while the root-free witness moves by the stability field attached to the $\mathsf{Tree}^{\uparrow}$ classifier. Thus the certificate retains the same rooted or root-free form after transport. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeRootOrRootFreeWitness closed walk boundary`

Theorem 119.12 (TreeUp NameCert obligation surface)**.** *The carrier row of Definition 119.1, the connectedness row of Definition 119.9, the acyclicity row of Definition 119.10, and the root-or-root-free row of Definition 119.11 assemble the paper-side* $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$ *obligation surface. The surface names the stability, ledger, exactness, and dependency fields required for the certified tree interface: stability is* hsame *and inherited* $\mathsf{Graph}^{\uparrow}$ *transport; ledger data are finite vertex, edge, incidence, path, closed-walk, and root rows; exactness says every public tree row is read from those ledgers; and dependencies are only the* BHist *substrate,* hsame*, and the* $\mathsf{Graph}^{\uparrow}$ *source certificate.*

Proof. Begin with the graph-source carrier obligation. It supplies the accepted BHist predicate, the inherited $\mathsf{Graph}^{\uparrow}$ classifier, and the finite incidence ledger for visible vertices and edges.

Add the connectedness obligation. Its finite path rows show that every carried endpoint reaches the selected root component through the same edge ledger, and its transport clause supplies the corresponding stability row.

Add the acyclicity and root-or-root-free obligations. Acyclicity gives the closed-walk exactness clause, while the final witness records whether the certificate is rooted or root-free and how that row transports under hsame.

These projections cover the named carrier, classifier, stability, ledger, exactness, and dependency rows. Since every row is read from BHist, hsame, and the $\mathsf{Graph}^{\uparrow}$ source certificate, the assembled surface does not require host graph equality or any additional bridge field. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier semantic name certificate`

Theorem 119.13 (TreeUp carrier and classifier obligations)**.** *The* $\mathsf{Tree}^{\uparrow}$ *carrier data refine the* $\mathsf{Graph}^{\uparrow}$ Cont*-adjacency carrier of Definition 118.1 to displayed finite* Cont*-path rows over* BHist

whose vertices satisfy UnaryHistory*. Its classifier is inherited from the* $\mathsf{Graph}^{\uparrow}$ *endpoint/path classifier and is transported componentwise by* hsame*: two displayed tree-path rows are admissibly compared only when their source vertex, target vertex, visible path ledger, and every exposed* GraphEdge *step are identified through the same* hsame *classifier used by* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.TreeUp.TreeDerivationSpineLedger steps unary`

Proof. The obligation is the carrier-and-classifier portion of the roadmap ten-field template.

1. Traditional target: a finite tree path carrier for $\mathsf{Tree}^{\uparrow}$.
2. BEDC source: BHist with UnaryHistory vertices, Cont rows, and the $\mathsf{Graph}^{\uparrow}$ NameCert edge predicate.
3. Carrier: displayed finite rows of GraphEdge from Definition 118.1, read as finite Cont-path ledgers.
4. Classifier: the $\mathsf{Graph}^{\uparrow}$ endpoint/path classifier, transported componentwise by hsame on vertices, edge results, and path ledgers.
5. Stability: transport of every displayed Cont row through the hsame transport surface already carried by $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$.
6. Ledger: the source and target histories, the finite list of exposed GraphEdge rows, and the visible path-result history.
7. Core theorem list: carrier refinement, classifier inheritance, and path-row transport.
8. Exactness: a carried tree path is exactly its finite $\mathsf{Graph}^{\uparrow}$ row display over BHist.
9. Standard bridge: none.
10. Status: paper obligation.

Thus $\mathsf{Tree}^{\uparrow}$ does not introduce a second carrier beside $\mathsf{Graph}^{\uparrow}$. It selects the finite displayed Cont-path rows and reads their classifier through the same hsame-based NameCert surface. □

Theorem 119.14 (TreeUp connectedness and acyclicity obligations)**.** *For* $\mathsf{Tree}^{\uparrow}$*, connectedness is the obligation to supply, for every pair of carried vertices, a finite* GraphEdge *path package between them. Acyclicity is the obligation that every nontrivial closed finite path row reads through* hsame *as impossible at the tree classifier: any displayed closed path must collapse to the trivial unit loop supplied by* $\mathsf{Graph}^{\uparrow}$*. The connected and acyclic rows are scoped by the* $\mathsf{Graph}^{\uparrow}$ *unit-loop laws, the two-step composition surface, and the three-step path reassociation surface.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier closed path unit loop`

Proof. The obligation is the path-law portion of the roadmap ten-field template.

1. Traditional target: connected acyclic graph data.
2. BEDC source: BHist, UnaryHistory, Cont, and the $\mathsf{Graph}^{\uparrow}$ NameCert rows.
3. Carrier: the finite GraphEdge path packages named in Definition 119.13.
4. Classifier: hsame on endpoints and visible path ledgers, inherited from the $\mathsf{Graph}^{\uparrow}$ endpoint/path classifier.
5. Stability: path extension, transport, and reassociation through hsame.

6. Ledger: the chosen finite path between two carried vertices, or the displayed closed path whose nontriviality is being tested.
7. Core theorem list: connected path existence, unit-loop collapse, two-step composition, and three-step reassociation.
8. Exactness: the connectedness row exposes exactly a finite GraphEdge path, and the acyclicity row rejects exactly the nontrivial closed path rows.
9. Standard bridge: none.
10. Status: paper obligation.

The unit case is read through Definition 118.5. Composite paths are assembled through Definition 118.6, and adjacent reassociations are compared through Definition 118.11.

The acyclicity obligation then says that any closed finite row whose source and target are identified by hsame must be the unit-loop row in the displayed $\mathsf{NameCert}_{\mathsf{Graph}^\uparrow}$ ledger. Every nontrivial closed row is therefore outside the accepted $\mathsf{Tree}^\uparrow$ certificate surface. □

Theorem 119.15 (TreeUp root, ledger, and exactness obligations)**.** *The* $\mathsf{Tree}^\uparrow$ *certificate must expose exactly the following rows: a root-or-root-free witness, a syntactic-representation carrier row, the finite path witnesses of Definition 119.14, the acyclicity witnesses of Definition 119.14, and the dependency rows inherited from* $\mathsf{Graph}^\uparrow$*. These rows are precisely the ledger and exactness surface for* $\mathsf{Tree}^\uparrow$*: every accepted tree certificate is read back to those displayed rows, and every displayed row is classified by the* $\mathsf{Graph}^\uparrow$ hsame *endpoint/path classifier over* BHist *and* UnaryHistory*.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeRootLedger derivation spine boundary`

Proof. The obligation is the provenance-and-exactness portion of the roadmap ten-field template.

1. Traditional target: a rooted or root-free tree certificate with syntactic representation.
2. BEDC source: BHist, UnaryHistory, Cont, and the dependency surface of $\mathsf{NameCert}_{\mathsf{Graph}^\uparrow}$.
3. Carrier: the finite tree-path carrier of Definition 119.13, augmented by a root-or-root-free witness and a syntactic-representation carrier row.
4. Classifier: the $\mathsf{Graph}^\uparrow$ classifier transported through hsame on roots, endpoints, path rows, and representation ledgers.
5. Stability: transport of root status, path witnesses, acyclicity witnesses, and representation rows along the inherited classifier.
6. Ledger: the root witness, representation row, connectedness paths, acyclicity witnesses, and dependency rows.
7. Core theorem list: root coverage, root-free coverage, ledger readback, path exactness, acyclicity exactness, and dependency exactness.
8. Exactness: no additional tree datum is accepted beyond the displayed ledger rows, and each displayed ledger row is sufficient for the certificate boundary.
9. Standard bridge: none.
10. Status: paper obligation.

The root-or-root-free witness determines the public orientation of the tree carrier, while the syntactic-representation carrier row records the derivation syntax surface that consumes $\mathsf{Tree}^{\uparrow}$.

The path witnesses and acyclicity witnesses are exactly the rows named in Definition 119.14. The remaining dependency rows are the $\mathsf{Graph}^{\uparrow}$ carrier, classifier, unit-loop, two-step composition, and three-step reassociation rows. Repacking this list gives the full $\mathsf{Tree}^{\uparrow}$ ledger, and exactness says that the certificate contains no hidden data outside this displayed hsame-classified NameCert boundary. □

Definition 119.16 (Tree obligation surface)**.** *Fix a BEDC source history sort* BHist *and a graph certificate source* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *as in chapter 118. A concrete* $\mathsf{Tree}^{\uparrow}$ *obligation record consists of the following rows on histories:*

1. $\mathsf{TreeCarrier}(h)$ *is the* BHist *predicate saying that* h *carries a* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *graph row, a connectedness row, an acyclicity row, a root-or-root-free witness row, and a syntactic-representation row whose visible nodes are histories.*
2. $\mathsf{TreeClassifier}(h, k)$ *is* $\mathsf{hsame}(h, k)$ *together with transport of the graph-source, connectedness, acyclicity, root-or-root-free, and syntactic-representation rows from* h *to* k *and back along* hsame*.*
3. *The ledger records exactly three hidden rows: the graph presentation supplied by* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$*, the root witness or explicit root-free witness, and the derivation-spine syntax read over* BHist *nodes.*

The obligation surface is scoped over the existing seed row , so it introduces no new kernel primitive and no independent object equality beyond hsame*.*

Lean4 (definition) `BEDC.Derived.TreeUp.TreeObligationSurface`

Theorem 119.17 (Tree graph-source obligation)**.** *For every history* h*,* $\mathsf{TreeCarrier}(h)$ *exposes the underlying* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *source row. If* $\mathsf{TreeClassifier}(h, k)$ *holds, then this graph-source row is transported from* h *to* k *along* $\mathsf{hsame}(h, k)$*, and the reverse transport is supplied by the symmetric* hsame *witness contained in the same classifier row.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeGraphSource obligation rows`

Proof. Unpack $\mathsf{TreeCarrier}(h)$ from Definition 119.16. Its first component is the graph certificate source row, so the carrier projection directly exposes the $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ datum.

Now unpack $\mathsf{TreeClassifier}(h, k)$. The classifier contains $\mathsf{hsame}(h, k)$ and the declared row transport for the graph source. Symmetry of hsame supplies the reverse endpoint comparison, and the seed scope fixes that the transported source is the same graph-source row rather than a second graph presentation. □

Theorem 119.18 (Tree carrier-classifier obligation)**.** *On carried histories,* TreeClassifier *is reflexive, symmetric, and transitive, and it transports* TreeCarrier*: if* $\mathsf{TreeCarrier}(h)$ *and* $\mathsf{TreeClassifier}(h, k)$ *hold, then* $\mathsf{TreeCarrier}(k)$ *holds with the graph-source, connectedness, acyclicity, root-or-root-free, and syntactic-representation rows transported along* $\mathsf{hsame}(h, k)$*.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeObligationSurface classifier transport`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier classifier transport obligation`

Proof. Reflexivity uses reflexivity of hsame on BHist and the identity transport of each row in Definition 119.16. The graph source comes from $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$; the connectedness, acyclicity, root-or-root-free, and syntactic-representation rows are carried unchanged at the same endpoint.

Symmetry uses symmetry of hsame. Each row transport stored in $\mathsf{TreeClassifier}(h, k)$ is part of a two-sided transport package, so reversing the endpoint comparison reverses the carrier rows without changing the visible ledger.

Transitivity composes the two hsame witnesses and then composes the corresponding row transports. The composed transport carries exactly the graph-source, connectedness, acyclicity, root-or-root-free, and syntactic-representation rows named by the surface, so carrier transport follows by repacking those transported rows as $\mathsf{TreeCarrier}(k)$. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier classifier obligation`

Theorem 119.19 (Tree root-witness obligation)**.** *Every* $\mathsf{TreeCarrier}(h)$ *supplies exactly one admissible root row: either a designated root witness compatible with the carried* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *source or an explicit root-free witness row. This witness row is stable under* TreeClassifier*, so* $\mathsf{TreeClassifier}(h, k)$ *transports the same root-or-root-free alternative from* h *to* k *along* hsame*.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeRootWitness spine extension exactness`

Proof. The carrier row in Definition 119.16 includes the root-or-root-free witness as a named component of the tree certificate. The alternative is admissible because it is read against the same $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ source row exposed by Definition 119.17.

For stability, unpack $\mathsf{TreeClassifier}(h, k)$. Its row-transport component explicitly includes the root-or-root-free row, and the endpoint relation is $\mathsf{hsame}(h, k)$. Transport therefore preserves the chosen alternative, while the ledger component records that no additional root presentation is introduced. □

Theorem 119.20 (Tree stability-ledger obligation)**.** *Let* u *be a visible derivation-spine extension with* $\mathsf{UnaryHistory}(u)$*, and suppose* $\mathsf{Cont}(h, u, r)$ *is compatible with the carried graph source. If* $\mathsf{TreeCarrier}(h)$ *holds and the endpoints* r *and* k *are related by* $\mathsf{hsame}(r, k)$*, then the tree ledger rows transported to* k *are exactly the graph presentation, root witness, and derivation-spine syntax rows obtained by extending the visible spine by* u*.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeGraphContEdge visible spine extension transport`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier stability ledger transport`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier visible spine extension ledger`

Proof. Start with $\mathsf{TreeCarrier}(h)$ and the $\mathsf{Cont}(h, u, r)$ extension. Compatibility with the graph source says that the visible extension reads edges through the same $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ row, and $\mathsf{UnaryHistory}(u)$ keeps the appended spine inside the unary derivation shape allowed by the seed scope.

The endpoint comparison $\mathsf{hsame}(r, k)$ supplies the classifier transport target. Applying the row transports in Definition 119.16 moves the graph presentation, root witness, and derivation-spine syntax rows to k.

It remains to identify the ledger boundary. The ledger of the surface contains only those three hidden rows, so after Cont extension and hsame transport there is no extra presentation row to account for. The transported ledger is therefore exactly the extended visible-spine ledger. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeVisibleDerivationSpine extension transport`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeVisibleSpine extension ledger`

Theorem 119.21 (Tree syntactic-representation obligation)**.** *Every* $\mathsf{TreeCarrier}(h)$ *provides a syntactic derivation carrier row whose visible nodes are* BHist *histories and whose edge relation is read from the carried* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *source. Consequently the* $\mathsf{Tree}^{\uparrow}$ *certificate surface can be consumed by downstream inductive-carrier and derivation-syntax chapters without replacing the BEDC history carrier or the* hsame *classifier.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier syntactic representation`

Proof. Unpack the syntactic-representation row in Definition 119.16. Its node carrier is explicitly BHist, so every visible derivation node is already a BEDC history rather than an external graph vertex.

The edge relation is not an additional primitive. It is read from the $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ source exposed by Definition 119.17, and classifier movement is handled by hsame through Definition 119.18.

Downstream consumers therefore receive the same carrier, the same classifier, and the same visible derivation-spine syntax. Inductive-carrier arguments may use $\mathsf{UnaryHistory}$ and Cont for spine extension, while derivation-syntax arguments read edges from the graph source fixed by the existing seed scope. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreeSyntacticRepresentation carrier readback`

Theorem 119.22 (TreeUp public certificate boundary)**.** *The public* $\mathsf{Tree}^{\uparrow}$ *interface is the single package consisting exactly of the* $\mathsf{Graph}^{\uparrow}$ *source package, the* $\mathsf{GraphContEdge}$ *rows, the connectedness row, the acyclicity row, the root-or-root-free branch, the syntactic-representation row, stability transports, ledger rows, and exactness clauses established by Definition 119.3, Definition 119.4, Definition 119.5, Definition 119.7, Definition 119.8, and Definition 119.21. This boundary exports no host graph equality and no unrecorded route choice.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreeObligationSurface public certificate boundary`

Proof. The visible carrier package is supplied by Definition 119.3: it exposes the $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ source, the $\mathsf{GraphContEdge}$ rows, connectedness, acyclicity, and the rooted or root-free branch. The classifier boundary is the rowwise transport of Definition 119.4, so public comparison is only through the inherited graph package and the displayed tree rows.

The stability and ledger fields are exactly those named in Definition 119.7. They record the route, root-choice, connectedness, and acyclicity witnesses needed to justify the visible rows, while the transports keep every public component on the same BHist, hsame, Pkg, and $\mathsf{NameCert}$ surface.

Exactness comes from Definition 119.8: every accepted endpoint reads back to the displayed package, and every displayed connected acyclic graph package with one root branch repacks as a $\mathsf{Tree}^{\uparrow}$ carrier. The syntactic-representation row of Definition 119.21 adds the derivation-spine consumer surface without changing the carrier or classifier.

Thus the public package is precisely the listed rows and clauses. Host graph equality is not a public component, route choices remain ledger entries rather than exported data, and no standard bridge is included in the $\mathsf{Tree}^{\uparrow}$ boundary. □

Lean4 ✓ `BEDC.Derived.TreeUp.TreePublicCertificateBoundary semantic name certificate`

Theorem 119.23 (TreeUp public derivation-syntax bridge)**.** *The public* $\mathsf{Tree}^{\uparrow}$ *package of Definition 119.22, together with Definition 119.16 and Definition 119.21, determines a paper bridge to the external finite rooted-or-root-free tree presentation whose nodes are* BHist *histories and whose edges are the displayed* $\mathsf{GraphContEdge}$ *rows. Interpretation from* $\mathsf{Tree}^{\uparrow}$ *to the external presentation*

and re-encoding from any externally presented tree whose rows are already displayed $\mathsf{Graph}^{\uparrow}/\mathsf{Tree}^{\uparrow}$ *rows are exact up to the inherited* hsame *classifier. Neither direction exports host graph equality or hidden route choice.*

Lean4 ✓ `BEDC.Derived.TreeUp.TreePublicDerivationSyntaxBridge visible spine package`
Lean4 ✓ `BEDC.Derived.TreeUp.TreeBHistCarrier derivation syntax roundtrip`
Lean4 ✓ `BEDC.Derived.TreeUp.TreePublicDerivationSyntaxBridge round trip`

Proof. For interpretation, read the public boundary of Definition 119.22. Its visible rows give the $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ source, the displayed GraphContEdge edges, connectedness, acyclicity, the root-or-root-free branch, and the syntactic-representation row. By Definition 119.16 and Definition 119.21, the nodes of that presentation are precisely BHist histories, and the edge table is precisely the displayed graph-continuation edge table.

For re-encoding, start with an external finite rooted-or-root-free tree presentation whose nodes are already BHist histories and whose edge rows are already displayed $\mathsf{Graph}^{\uparrow}/\mathsf{Tree}^{\uparrow}$ rows. Apply Definition 119.8: the displayed graph source, edge rows, connectedness and acyclicity rows, root branch, syntactic row, stability transports, and ledger rows repack as the same public $\mathsf{Tree}^{\uparrow}$ package.

The first round trip compares the interpreted package with the original $\mathsf{Tree}^{\uparrow}$ data. Use Definition 119.4 to compare the public graph and path rows componentwise, and use Definition 119.18 to transport the tree carrier rows along the inherited hsame witness.

The second round trip compares the re-encoded external presentation with the displayed rows from which it was formed. The carrier, classifier, and syntactic-representation clauses are the same rows named in Definition 119.16; exactness prevents an additional route or graph-equality component from entering the package. Both comparisons are therefore exact only up to hsame, which is the advertised bridge classifier. □

Closure status for $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$**.**

Constructive story: A tree is accepted only after a visible $\mathsf{Graph}^{\uparrow}$ package has been equipped with finite incidence data, connectedness, acyclicity, one root-or-root-free branch, and a syntactic derivation-spine row over BHist nodes. The carrier is the displayed endpoint row carrying those graph and tree witnesses; a presentation without the graph source, the GraphContEdge rows, or the connected/acyclic/root branch evidence is outside the carrier. Two tree endpoints classify together by transporting the graph package, edge rows, connectedness, acyclicity, root-or-root-free row, and syntactic representation along hsame and the inherited $\mathsf{Graph}^{\uparrow}$ classifiers, not by host graph isomorphism. The source is the existing graph certificate together with the tree rows, the pattern records path readback to the root component, collapse of closed walks to the stationary row, root-branch transport, visible-spine extension, and derivation-syntax readback, while the ledger keeps hidden route, root-choice, connectedness, acyclicity, and syntax witnesses behind the public rows. The five name-certificate obligations use any displayed connected acyclic graph package with a root branch for inhabitation, inherit reflexivity, symmetry, and transitivity from hsame and graph classifiers, and close the carrier by transporting every listed row together. A tree history h lies in the signature gap of a $\mathsf{Tree}^{\uparrow}$ token p when the source-domain accepts its graph package and tree witnesses, the signature relation pairs it with an answer tree package and evidence ledger, and token introduction names that answer as p; unfolded, h has exactly the nodes, graph-continuation edges, connectedness, acyclicity, root alternative, and derivation spine encoded by the token. The derivation-syntax bridge reads this as an external finite rooted-or-root-free tree over BHist nodes and GraphContEdge rows, then reads back through the same public package. The chapter registers this graph-with-obligations construction under the name $\mathsf{Tree}^{\uparrow}$; a tree is a connected acyclic graph ledger with a root boundary, not host graph equality, unchecked route choice, or a separate inductive tree primitive.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public $\mathsf{Tree}^{\uparrow}$ boundary, the derivation-syntax bridge of Definition 119.23, and the visible-spine extension ledger rows identify the external finite rooted-or-root-free tree presentation over BHist nodes, GraphContEdge edge rows, Cont, hsame, Pkg, $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$, connectedness, acyclicity, root-branch rows, and derivation syntax.

Chapter 120

A Concrete Naming Certificate for $\mathsf{Seq}^{\uparrow}$

The sequence interface $\mathsf{Seq}^{\uparrow}$ packages a function $\mathsf{Nat}^{\uparrow} \to A$ for a fixed naming-certificate carrier A, together with a regularity or boundedness modulus. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28) and is the general substrate for $\mathsf{NameCert}_{\mathsf{Series}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{ConvRad}^{\uparrow}}$, and the analytic-limit certificates.

120.1 Carrier definition

Definition 120.1 (SeqUp root BHist source)**.** *Fix a certified point carrier* $\mathsf{NameCert}(A, \sim_A)$ *and the unary-index certificate* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$*. A* $\mathsf{Seq}^{\uparrow}$ *root BHist source over* A *is a BHist-indexed observation function* $s : \mathsf{Hist} \to \mathsf{Hist}$ *together with the following finite BEDC evidence:*

1. *an index witness saying that each admitted index* n *is a* $\mathsf{Nat}^{\uparrow}$ *unary history, equivalently* $\mathsf{UnaryHistory}(n)$*;*
2. *a point carrier witness* $A(s(n))$ *for every admitted unary index* n*;*
3. *an optional modulus or boundedness ledger whose entries are themselves unary histories and whose use is named by downstream consumers.*

Its ten-field fit is: traditional target sequences over a certified carrier; BEDC source $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *together with* $\mathsf{NameCert}(A, \sim_A)$*; carrier the displayed BHist observation source with point carrier evidence; classifier the pointwise* $\sim_A$ *classifier of Definition 120.2; stability inherited indexwise from the two source certificates; ledger the index witness, point carrier witnesses, and optional modulus or boundedness row; core theorem list Definition 120.3, Definition 120.4, and Definition 120.5; exactness point observation equality only up to the source classifier; standard bridge absent; status paper-level substrate for the derived namespace* BEDC.Derived.SeqUp*.*

Lean4 ✓ `BEDC.Derived.SeqUp.SeqTasteGate single carrier alignment`

Definition 120.2 (SeqUp pointwise classifier)**.** *For two* $\mathsf{Seq}^{\uparrow}$ *root BHist sources* s *and* t *over the same* $\mathsf{NameCert}(A, \sim_A)$*, define* $s \sim_{\mathsf{Seq}^{\uparrow}(A)} t$ *iff every unary index has source carrier witnesses for both point observations and a source-classifier witness between them:*

$$s \sim_{\mathsf{Seq}^{\uparrow}(A)} t \quad \Longleftrightarrow \quad \forall n,\ \mathsf{UnaryHistory}(n) \Rightarrow \big(A(s(n)) \wedge A(t(n)) \wedge s(n) \sim_A t(n)\big).$$

No convergence, summability, completeness, or host-function extensionality is part of this classifier.

120.2 The certificate

Theorem 120.3 (SeqUp carrier and classifier obligations)**.** *For every certified point carrier* $\mathsf{NameCert}(A, \sim_A)$ *and every* $\mathsf{Seq}^{\uparrow}$ *root BHist source* s *over* A*, the source supplies the point carrier projection* $A(s(n))$ *at each unary index* n*. The pointwise classifier* $\sim_{\mathsf{Seq}^{\uparrow}(A)}$ *is reflexive, symmetric, and transitive on carried* $\mathsf{Seq}^{\uparrow}$ *sources, with all three witnesses inherited indexwise from the reflexivity, symmetry, and transitivity fields of* $\mathsf{NameCert}(A, \sim_A)$*.*

Lean4 ✓ `BEDC.Derived.SeqUp.SeqPointwiseClassifier rows`

Proof. For the carrier projection, unfold Definition 120.1. The second displayed field gives $A(s(n))$ whenever the index witness supplies $\mathsf{UnaryHistory}(n)$.

For reflexivity, fix a carried source s and a unary index n. The carrier projection gives $A(s(n))$, and the reflexivity field of $\mathsf{NameCert}(A, \sim_A)$ gives $s(n) \sim_A s(n)$.

For symmetry, use the same unary index. A witness of $s \sim_{\mathsf{Seq}^{\uparrow}(A)} t$ contains $A(s(n))$, $A(t(n))$, and $s(n) \sim_A t(n)$; applying source symmetry gives $t(n) \sim_A s(n)$ while retaining the two carrier witnesses.

For transitivity, combine the two pointwise witnesses at the same unary index. Their source-classifier components are composable by transitivity in $\mathsf{NameCert}(A, \sim_A)$, and their carrier components provide the carried endpoints required by Definition 120.2. □

Theorem 120.4 (SeqUp pointwise transport obligation)**.** *Let* s *and* t *be* $\mathsf{Seq}^{\uparrow}$ *root BHist sources over* $\mathsf{NameCert}(A, \sim_A)$*. If* $s \sim_{\mathsf{Seq}^{\uparrow}(A)} t$ *and* s *is carried pointwise, then* t *is carried pointwise. Equivalently, for every unary index* n*, the source carrier witness* $A(s(n))$ *transports along the point classifier witness* $s(n) \sim_A t(n)$ *to a carrier witness* $A(t(n))$*.*

Proof. Fix a unary index n. Project the pointwise classifier witness of Definition 120.2; it supplies $A(s(n))$, $A(t(n))$, and $s(n) \sim_A t(n)$.

The named transport obligation uses only the carrier-transport field of the point certificate. Apply carrier transport in $\mathsf{NameCert}(A, \sim_A)$ to the carried source endpoint $A(s(n))$ and the classifier witness $s(n) \sim_A t(n)$. The result is $A(t(n))$. □

Lean4 ✓ `BEDC.Derived.SeqUp.SeqPointwiseClassifier target source`

Theorem 120.5 (SeqUp downstream boundary)**.** *Every downstream consumer of* $\mathsf{Seq}^{\uparrow}$*, including* $\mathsf{Series}^{\uparrow}$*,* $\mathsf{ConvRad}^{\uparrow}$*, and analytic-limit certificates, may read only the following data from a* $\mathsf{Seq}^{\uparrow}$ *source: point observations* $s(n)$*, unary index evidence* $\mathsf{UnaryHistory}(n)$*, pointwise classifier transport along* $\sim_{\mathsf{Seq}^{\uparrow}(A)}$*, and the optional modulus or boundedness ledger named in Definition 120.1. Such a consumer may not infer convergence, summability, holomorphicity, completeness, or any host-function principle from* $\mathsf{Seq}^{\uparrow}$ *alone.*

Lean4 ✓ `BEDC.Derived.SeqUp.SeqRootSource downstream boundary`

Proof. Unfold the carrier definition and classifier definition. The carrier exposes a BHist observation function, unary-index evidence, point carrier evidence, and an optional unary-valued ledger; the classifier exposes exactly the pointwise source-classifier witnesses.

The analytic properties listed in the statement are absent from the ten-field fit: exactness is point observation equality up to $\sim_A$, the standard bridge is absent, and the ledger is limited to index and modulus or boundedness evidence. Therefore any consumer requiring convergence, summability, holomorphicity, completeness, or a host-function principle must introduce that requirement in its own certificate rather than extracting it from $\mathsf{Seq}^{\uparrow}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$**.**

Constructive story: A sequence over a certified point carrier is carried as a visible observation function from unary histories to point histories: each admitted index must be a $\mathsf{Nat}^{\uparrow}$ unary history, and each observed value must be accepted by the fixed point carrier. The classifier is pointwise rather than extensional over host functions: two sequence sources classify together when every unary index has carrier witnesses on both sides and the two observations are related by the point certificate's classifier. The source covers exactly these BHist observation functions with unary-index evidence, point-carrier evidence, and an optional unary modulus or boundedness row, while the pattern records indexwise projection, pointwise comparison, pointwise transport, and the downstream boundary read by series and analytic-limit certificates. The ledger keeps the unary index witnesses, point carrier witnesses, and optional modulus entries visible, so nonemptiness is inherited from any carried source, reflexivity, symmetry, and transitivity are inherited index by index from the point certificate, and carrier closure is just point-carrier transport at each unary index. A history package h lies in the signature gap of a $\mathsf{Seq}^{\uparrow}$ token p when the source-domain accepts its observation source, the signature relation pairs its pointwise observations and modulus ledger with an answer package, and the token-introduction relation names that package as p; unfolded, every unary index must expose the point value and optional modulus encoded by the token. The chapter registers this pointwise observation construction under the name $\mathsf{Seq}^{\uparrow}$; it introduces no convergence, summability, completeness, holomorphicity, or host-function extensionality.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public scope exports the root BHist source, pointwise classifier, pointwise transport, optional modulus ledger, and downstream consumer boundary of Definition 120.3, Definition 120.4, and Definition 120.5.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SeqUp.SeqPointwiseClassifier\_rows`

Bridge status: none

Not claimed: This chapter does not close convergence, summability, completeness, or host-function extensionality for sequence objects.

Upgrade path: No further paper theory-axis upgrade is recorded for this chapter; bridge verification remains a separate formal-axis matter.

Chapter 121

A Concrete Naming Certificate for $\mathsf{Series}^{\uparrow}$

The series interface $\mathsf{Series}^{\uparrow}$ packages the partial-sum sequence of a $\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$ (chapter 120) over an additive carrier together with explicit convergence moduli. It is the real-and-general counterpart of $\mathsf{NameCert}_{\mathsf{CplxSer}^{\uparrow}}$ (chapter 69).

121.1 Carrier definition

Theorem 121.1 (Series source carrier boundary obligation)**.** *The* $\mathsf{Series}^{\uparrow}$ *source carrier is the* $\mathsf{Seq}^{\uparrow}$ *source carrier together with additive-carrier rows over* BHist*. A carried row consists of a sequence certificate* $\mathcal{S} : \mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$*, a summand stream* $a : \mathsf{BHist}$ *accepted by that source, an additive carrier row* $A : \mathsf{BHist}$*, and a displayed action row saying that every unary summand observation of* a *lands in* A*. The classifier is the restriction of the* $\mathsf{Seq}^{\uparrow}$ *stream classifier together with* hsame *on the additive carrier row; no ambient real-number carrier, host sequence, or external summability predicate is part of the source carrier.*

Proof. Project the $\mathsf{Seq}^{\uparrow}$ certificate to obtain the stream carrier, stream classifier, and unary observation rows. Pair these projections with the displayed additive-carrier row over BHist.

The restriction of the classifier is componentwise: the sequence component is transported by the $\mathsf{Seq}^{\uparrow}$ source classifier, and the additive component is transported by hsame. Repacking those two rows gives exactly the announced carrier boundary without importing a host-level series object. □

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesSourceCarrierBoundary obligation`

Theorem 121.2 (Series partial-sum obligation)**.** *For every carried* $\mathsf{Series}^{\uparrow}$ *source row, the partial-sum row is a unary prefix family* $s : \mathsf{BHist} \to \mathsf{BHist}$ *generated from the summand stream by finite* Cont*-compatible prefixes. The zero prefix is the additive zero row, the successor prefix is obtained by appending one summand observation through the additive operation row, and prefix comparison is transported by the* $\mathsf{Seq}^{\uparrow}$ *stream classifier and by* hsame *on the additive carrier. Thus partial sums are BEDC ledger rows, not hidden evaluations of an external infinite sum.*

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesPartialSumLedger step transport`
↪ variant `BEDC.Derived.SeriesUp.SeriesPartialSum transport`

Proof. Start from the unary index witness supplied by the $\mathsf{Seq}^{\uparrow}$ observation surface. The empty prefix is read as the additive zero row, and the successor case appends the next observed summand using the additive operation row.

Compatibility with Cont is by induction on the unary prefix length. The base case is the zero prefix, and the successor step composes the previous prefix ledger with the next summand observation. Classifier transport follows by applying the $\mathsf{Seq}^{\uparrow}$ stream classifier to the summand slot and hsame transport to the additive row. □

121.2 The certificate

Theorem 121.3 (Series modulus stability obligation)**.** *A convergence modulus for a carried* $\mathsf{Series}^{\uparrow}$ *row is an explicit unary bound* $\mu : \mathsf{BHist} \to \mathsf{BHist}$ *such that, for every unary precision row* k *and every pair of unary indices beyond* $\mu(k)$*, the corresponding partial-sum rows are classified by the additive carrier at precision* k*. If two summand streams are classified by the* $\mathsf{Seq}^{\uparrow}$ *stream classifier, the same displayed modulus row transports to the classified stream by the partial-sum classifier of Definition 121.2. The modulus is therefore stable under the source classifier and remains a visible BEDC row.*

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesModulusStability transport`
↪ variant `BEDC.Derived.SeriesUp.SeriesPartialSum pointwise hsame deterministic`

Proof. Unpack the modulus as a unary history transformer together with its bound witness for pairs of sufficiently long prefixes. The witness refers only to partial-sum rows and the additive classifier, so it is scoped by Definition 121.1 and Definition 121.2.

For classifier stability, transport the summand observations along the $\mathsf{Seq}^{\uparrow}$ stream classifier. The partial-sum obligation transports each finite prefix, and the additive classifier transports the comparison at precision k. The same unary bound row $\mu(k)$ can therefore be reused after transport. □

Theorem 121.4 (Series ledger exactness obligation)**.** *The* $\mathsf{Series}^{\uparrow}$ *ledger contains exactly the* $\mathsf{Seq}^{\uparrow}$ *source certificate, the additive-carrier row, the hidden summand-prefix rows, the partial-sum rows, the explicit modulus rows, the stream-classifier transport rows, and the additive-classifier comparison rows. Coverage says every accepted public series row exposes one such ledger; soundness says every ledger row is produced by those BEDC primitives; completeness says any package with precisely those rows is accepted by the* $\mathsf{Series}^{\uparrow}$ *obligation surface. No comparison with* $\mathsf{CplxSer}^{\uparrow}$*, no host summability theorem, and no standard bridge is included in this ledger.*

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesPartialSum result unary`

Proof. Coverage is obtained by projecting an accepted public row into its source certificate, additive-carrier row, summand-prefix display, partial-sum display, and modulus display.

Soundness reads each projected component back through the corresponding BEDC primitive: $\mathsf{Seq}^{\uparrow}$ supplies stream observations, Cont supplies finite prefix composition, hsame supplies classifier transport, and the additive carrier supplies zero, addition, and comparison rows.

Completeness is the reverse packing. Given exactly those rows, assemble the carrier boundary, the partial-sum family, and the modulus stability witness, then record them as the public $\mathsf{Series}^{\uparrow}$ obligation surface. Since every accepted row is accounted for in this package, the dependency surface is exact. □

Theorem 121.5 (SeriesUp public name certificate)**.** *The* $\mathsf{Series}^{\uparrow}$ *source carrier boundary, partial-sum obligation, modulus stability obligation, and ledger exactness obligation assemble into the public* $\mathsf{NameCert}_{\mathsf{Series}^{\uparrow}}$ *surface. The public certificate exposes exactly the* $\mathsf{Seq}^{\uparrow}$ *source row, the additive carrier row, finite* Cont *partial-sum routes, explicit unary modulus rows, classifier transports, and ledger rows recorded in Definition 121.1, Definition 121.2, Definition 121.3, and Definition 121.4.*

It does not include a $\mathsf{CplxSer}^{\uparrow}$ *comparison, a host summability theorem, or a standard bridge claim.*

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesPartialSum public name certificate`

Proof. First apply Definition 121.1. This supplies the $\mathsf{Seq}^{\uparrow}$ source certificate, the summand stream, the additive carrier row, and the source classifier surface for the public name certificate.

Next apply Definition 121.2 and Definition 121.3. The first theorem supplies the finite Cont partial-sum routes, while the second supplies explicit unary modulus rows and their classifier transports.

Finally apply Definition 121.4. Its coverage, soundness, and completeness clauses say that these rows are exactly the public ledger rows accepted by the $\mathsf{Series}^{\uparrow}$ surface. Repacking the four scoped obligation rows into the $\mathsf{NameCert}_{\mathsf{Series}^{\uparrow}}$ fields gives the public certificate and leaves complex-series comparisons, host summability, and standard bridges outside the exposed boundary. □

Theorem 121.6 (SeriesUp standard bridge schema row)**.** *The public* $\mathsf{Series}^{\uparrow}$ *certificate admits a paper bridge row to the standard partial-sum/modulus schema. The bridge maps the visible* $\mathsf{Seq}^{\uparrow}$ *summand stream to the schema source stream, the additive carrier row to the schema carrier, the finite* Cont *partial-sum routes to the schema partial-sum field, the explicit unary modulus rows to the schema modulus field, and the additive-classifier comparison rows to the schema comparison field. This bridge exports no* $\mathsf{CplxSer}^{\uparrow}$ *comparison and no host summability theorem.*

Proof. First apply Definition 121.5. It identifies the public $\mathsf{Series}^{\uparrow}$ surface as the $\mathsf{Seq}^{\uparrow}$ source row, additive carrier row, finite Cont partial sums, explicit unary moduli, classifier transports, and ledger exactness rows.

Now read those rows against the standard partial-sum/modulus schema. The summand stream fills the schema source, the additive carrier fills the carrier slot, the Cont routes fill the finite partial-sum slot, the unary modulus rows fill the modulus slot, and the additive-classifier rows fill the comparison slot.

The preceding public certificate keeps complex-series comparisons, host summability, and extra standard fields outside the exposed boundary. Therefore the bridge is exactly a paper row from the visible $\mathsf{Series}^{\uparrow}$ certificate to the standard partial-sum/modulus schema, with no $\mathsf{CplxSer}^{\uparrow}$ comparison and no host summability theorem. □

Lean4 ✓ `BEDC.Derived.SeriesUp.SeriesPartialSum schema bridge endpoint unary`

BEDC.Derived.SeriesUp.SeriesPartialSumLedger_step_transport

Closure status for $\mathsf{NameCert}_{\mathsf{Series}^{\uparrow}}$.

Constructive story: A series source is carried by taking a $\mathsf{Seq}^{\uparrow}$ summand stream over an additive carrier and displaying, for every unary index, both the summand observation and the additive row in which partial sums will live. The classifier is componentwise: the stream is compared by the $\mathsf{Seq}^{\uparrow}$ pointwise classifier and the additive carrier row by hsame, so no host sequence, ambient real carrier, or external summability predicate enters the carrier. The source covers exactly the sequence certificate, summand stream, additive carrier, and unary observation action rows, while the pattern generates partial sums as finite Cont-compatible prefixes: the empty prefix is the additive zero row and each successor prefix appends the next observed summand through the additive operation. The ledger keeps the $\mathsf{Seq}^{\uparrow}$ source certificate, hidden summand-prefix rows, partial-sum rows, explicit unary convergence moduli, stream-classifier transports, and additive-classifier comparisons, and those rows give nonemptiness, reflexive/symmetric/transitive comparison, and carrier closure by inherited pointwise

transport. A history h lies in the signature gap of a Series$^{\uparrow}$ token p when the source-domain accepts its summand stream and additive row, the signature relation pairs the displayed partial-sum family and modulus ledger with an answer history, and the token-introduction relation names that answer as p; unfolded, h is accepted precisely when its finite prefixes and modulus rows match the token's series package. The chapter registers this partial-sum ledger construction under the name Series$^{\uparrow}$, exports its public certificate theorem, and gives the paper bridge row from the visible series certificate to the standard partial-sum/modulus schema; it includes no comparison with CplxSer$^{\uparrow}$ and no host summability theorem.

Theory closure: TheoryGate(NameCert$_{\mathsf{Series}\uparrow}$, maturePackageClosed)

Scope closed: The mature paper scope binds the NameCert$_{\mathsf{Seq}\uparrow}$ source row, additive-carrier rows, finite Cont partial sums, explicit unary moduli, stream-classifier stability, public certificate theorem, ledger exactness, and paper bridge to the standard partial-sum/modulus schema.

Formal verification: FormalStatus(NameCert$_{\mathsf{Series}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.SeriesUp.SeriesPartialSumLedger\_step\_transport`

Bridge status: paperBridge

Not claimed: This chapter does not claim a CplxSer$^{\uparrow}$ comparison, a host summability theorem, or a Lean-checked standard bridge.

Upgrade path: The next verification step is a Lean-checked standard bridge for the same partial-sum ledger and modulus-stability surface.

Chapter 122

A Concrete Naming Certificate for $\mathsf{Derivative}^{\uparrow}$

The derivative interface $\mathsf{Derivative}^{\uparrow}$ packages the constructive pointwise derivative of a function between metric carriers, with explicit modulus relating ε to the difference-quotient tolerance. It is the real and general counterpart of $\mathsf{NameCert}_{\mathsf{CplxDiff}^{\uparrow}}$ (chapter 67).

122.1 Carrier definition

Definition 122.1 (Derivative metric quotient)**.** *For histories $f, z, h, q, dist : \mathsf{BHist}$, the derivative metric quotient carrier holds when f, z, q, h, and $dist$ are unary histories, h is complex-nonzero, q is the continuation result of f by the step h, and $dist$ is the continuation result of h by the quotient q:*

$$\mathsf{UnaryHistory}(f) \wedge \mathsf{UnaryHistory}(z) \wedge \mathsf{CplxNonZero}(h) \wedge \mathsf{UnaryHistory}(q) \wedge \mathsf{Cont}(f, h, q) \wedge \mathsf{UnaryHistory}(h) \wedge \mathsf{UnaryHistory}(d$$

Lean4 (definition) `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient`

Theorem 122.2 (Derivative metric quotient history transport)**.** *For histories $f, f', z, z', h, h', q, q', dist, dist' :$ BHist, if each source component is classifier-equal to its primed component, then a derivative metric quotient for $(f, z, h, q, dist)$ transports to a derivative metric quotient for $(f', z', h', q', dist')$. The transported package also reads back the complex difference quotient, the metric distance witness, and the two displayed continuation ledgers:*

$$\mathsf{CplxDiffQuot}(f', z', h', q'), \qquad \mathsf{MetricDistanceWitness}(h', q', dist'), \qquad \mathsf{Cont}(f', h', q'), \qquad \mathsf{Cont}(h', q', dist').$$

Proof. Destructure the derivative metric quotient into its unary carriers, the complex nonzero step proof, and the two continuation ledgers. Transport unary carriers along the five hsame assumptions. The nonzero proof for h' composes a hypothetical $h'\mathsf{hsame}e$ with $h\mathsf{hsame}h'$. The difference ledger transports along the function, step, and quotient equalities. The metric ledger transports as the continuation field of the concrete metric distance witness built from h, q, $dist$, and $\mathsf{Cont}(h, q, dist)$. Reassembling these transported fields gives all stated components. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient hsame transport`

Theorem 122.3 (Derivative metric quotient function prefix closure)**.** *For histories* $p, f, z, h, q, dist$: BHist*, if* p *is unary and* $\mathsf{DerivativeMetricQuotient}(f, z, h, q, dist)$ *holds, then the function and quotient histories may be prefixed together while the step and point remain fixed:*

$$\mathsf{DerivativeMetricQuotient}(\mathsf{append}(p, f), z, h, \mathsf{append}(p, q), \mathsf{append}(h, \mathsf{append}(p, q))).$$

Proof. Unpack the derivative metric quotient into unary carriers, the complex-nonzero step proof, and the two continuation ledgers. Unary closure under append gives the prefixed function and prefixed quotient carriers. The function ledger $\mathsf{Cont}(f, h, q)$ is transported through the shared prefix by reassociating $\mathsf{append}(p, \mathsf{append}(f, h))$ with $\mathsf{append}(\mathsf{append}(p, f), h)$. The metric distance component is then rebuilt canonically from the original unary step, the prefixed quotient, and the defining continuation $\mathsf{Cont}(h, \mathsf{append}(p, q), \mathsf{append}(h, \mathsf{append}(p, q)))$. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient function prefix closed`

Theorem 122.4 (Derivative metric quotient distance continuation depth)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h, q, dis$ *holds, then its metric distance ledger exposes* $\mathsf{Cont}(h, q, dist)$*, and the displayed metric-distance depth is the sum of the step depth and quotient depth:*

$$\mathsf{MetricDistanceDepth}(dist) = \mathsf{MetricDistanceDepth}(h) + \mathsf{MetricDistanceDepth}(q).$$

Proof. Destructure the derivative metric quotient into its two continuation ledgers and unary carriers. The fields for h, q, $dist$, and $\mathsf{Cont}(h, q, dist)$ form the concrete metric-distance witness, whose checked depth-add theorem computes the displayed distance depth. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient distance cont depth add`

Theorem 122.5 (Derivative empty-function quotient step readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(\mathsf{e}, z, h, q, dist)$ *holds, then the quotient result reads back to the step, the metric ledger is* $\mathsf{Cont}(h, q, dist)$*, and the displayed distance reads back to* $\mathsf{append}(h, h)$*:*

$$q\mathsf{hsame}h \wedge \mathsf{Cont}(h, q, dist) \wedge dist\mathsf{hsameappend}(h, h).$$

Proof. The function continuation ledger is $\mathsf{Cont}(\mathsf{e}, h, q)$, so left-unit readback gives $q\mathsf{hsame}h$. The metric field is the displayed ledger $\mathsf{Cont}(h, q, dist)$, hence $dist\mathsf{hsameappend}(h, q)$. Appending the recovered equality $q\mathsf{hsame}h$ under the fixed left context h identifies this with $\mathsf{append}(h, h)$. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient empty function step readback`

Theorem 122.6 (Derivative metric quotient distance result is nonempty)**.** *For histories* $f, z, h, q, dist$: BHist*, a derivative metric quotient cannot have a metric-distance result classified as* e*.*

Proof. Unpack the derivative metric quotient. Its metric ledger is a continuation $\mathsf{Cont}(h, q, dist)$, while the step field says that h is complex-nonzero. Transport the continuation result along $dist\mathsf{hsame}\mathsf{e}$. Empty-result inversion for Cont forces $h\mathsf{hsame}\mathsf{e}$, contradicting the complex-nonzero step witness. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient distance result nonempty`

Theorem 122.7 (Derivative metric quotient distance visible-context readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h,$ *holds and the distance history is displayed inside a common visible left and right append context equal to the same context around core, then* $dist\mathsf{hsame}core$*. The readback core is also not* hsame-*equal to* e*.*

Proof. Reassociate both visible displays and cancel the common append contexts around the distance and the core. This gives $dist\mathsf{hsame}core$. A hypothetical empty core transports back to an empty distance result, contradicting the checked non-emptiness theorem for derivative metric quotient distance results. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient distance visible context readback`

Theorem 122.8 (Derivative metric quotient quotient visible-context readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h,$ *holds and the quotient history is displayed inside a common visible left and right append context equal to the same context around core, then* $q\mathsf{hsame}core$*. The readback core is also not* hsame*-equal to* e*.*

Proof. Reassociate both visible displays and cancel the common append contexts around the quotient and the core. This gives $q\mathsf{hsame}core$. A hypothetical empty core transports back to an empty quotient result, contradicting the checked quotient non-emptiness component of derivative metric quotients. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient quotient visible context readback`

Theorem 122.9 (Derivative metric quotient point visible-context readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h, q,$ *holds and the point history is displayed inside a common visible left and right append context equal to the same context around core, then* $z\mathsf{hsame}core$ *and the readback core is unary.*

Proof. Reassociate both visible displays and cancel the common append contexts around the point and the core. This gives $z\mathsf{hsame}core$. The point unary carrier from the derivative metric quotient then transports across the recovered classifier equality. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient point visible context readback`

Theorem 122.10 (Derivative metric quotient step visible-context readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h, q,$ *holds and the step history is displayed inside a common visible left and right append context equal to the same context around core, then* $h\mathsf{hsame}core$*. The readback core is unary and is not* hsame*-equal to* e*.*

Proof. Reassociate both visible displays and cancel the common append contexts around the step and the core. This gives $h\mathsf{hsame}core$. The unary carrier for the step transports across this equality to the core. A hypothetical empty core transports back to an empty step, contradicting the complex-nonzero field of the derivative metric quotient. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient step visible context readback`

Theorem 122.11 (Derivative metric quotient function visible-context readback)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z,$ *holds and the function history is displayed inside a common visible left and right append context equal to the same context around core, then* $f\mathsf{hsame}core$ *and the readback core is unary.*

Proof. Reassociate both visible displays and cancel the common append contexts around the function and the core. This gives $f\mathsf{hsame}core$. The function unary carrier from the derivative metric quotient then transports across the recovered classifier equality. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient function visible context readback`

Theorem 122.12 (Derivative metric quotient distance is non-empty)**.** *If* $\mathsf{DerivativeMetricQuotient}(f, z, h, q, dist)$ *holds, then neither the quotient* q *nor the displayed distance* $dist$ *is* hsame*-equal to* e*.*

Proof. The quotient component is a concrete complex difference quotient, whose nonzero step forbids an empty continuation result. For the distance component, transporting a hypothetical $dist\mathsf{hsamee}$ into the continuation ledger $\mathsf{Cont}(h, q, dist)$ yields an empty result ledger. Empty-result inversion forces $h\mathsf{hsamee}$, contradicting the complex nonzero step field. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient quotient distance nonempty`

Theorem 122.13 (Derivative metric quotient result deterministic)**.** *For histories* $f, z, h, q, q', dist, dist' :$ BHist*, two derivative metric quotient witnesses with the same function, point, and step determine the same quotient and displayed metric-distance result up to* hsame*. The four continuation ledgers*

$$\mathsf{Cont}(f, h, q), \qquad \mathsf{Cont}(f, h, q'), \qquad \mathsf{Cont}(h, q, dist), \qquad \mathsf{Cont}(h, q', dist')$$

are exposed together with $q\mathsf{hsame}q'$ *and* $dist\mathsf{hsame}dist'$*.*

Proof. Destructure the two derivative metric quotient witnesses. Determinism of $\mathsf{Cont}(f, h, \cdot)$ identifies the two quotient histories. Transport the second metric ledger along that quotient equality, then apply determinism of $\mathsf{Cont}(h, q, \cdot)$ to identify the displayed distance histories. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient result deterministic`

Theorem 122.14 (Derivative metric quotient hsame-step result determinacy)**.** *For histories* $f, z, h, h', q, q', dist, di$ BHist*, if* $h\mathsf{hsame}h'$ *and*

$$\mathsf{DerivativeMetricQuotient}(f, z, h, q, dist) \qquad \textit{and} \qquad \mathsf{DerivativeMetricQuotient}(f, z, h', q', dist')$$

hold, then $q\mathsf{hsame}q'$ *and* $dist\mathsf{hsame}dist'$*. The exposed continuation ledgers are*

$$\mathsf{Cont}(f, h, q), \qquad \mathsf{Cont}(f, h', q'), \qquad \mathsf{Cont}(h, q, dist), \qquad \mathsf{Cont}(h', q', dist').$$

Proof. Destructure the two derivative metric quotient witnesses. Transport the second function continuation ledger along $h\mathsf{hsame}h'$ and apply continuation determinism to identify q with q'. Then transport the second metric continuation ledger along both the step equality and the quotient equality, and apply continuation determinism again to identify $dist$ with $dist'$. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient hsame step result deterministic`

Theorem 122.15 (Derivative same-quotient step and distance determinacy)**.** *For histories* $f, z, h, h', q, dist, dist' :$ BHist*, two derivative metric quotient witnesses with the same function, point, and quotient determine the same step and displayed metric-distance result up to* hsame*. The continuation ledgers*

$$\mathsf{Cont}(f, h, q), \qquad \mathsf{Cont}(f, h', q), \qquad \mathsf{Cont}(h, q, dist), \qquad \mathsf{Cont}(h', q, dist')$$

are exposed together with $h\mathsf{hsame}h'$ *and* $dist\mathsf{hsame}dist'$*.*

Proof. Read both derivative metric quotient witnesses as complex difference quotient witnesses with the same quotient. Determinism of the shared quotient identifies the two step histories and exposes both function continuation ledgers. Transport the second metric continuation ledger back along the step equality, then apply continuation determinism to identify the displayed distance histories. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient same quotient step distance deterministic`

Theorem 122.16 (Visible derivative quotient steps cannot share a quotient)**.** *If*

$$\mathsf{DerivativeMetricQuotient}(f, z, \mathsf{E0}(p), out, dist_0) \quad \textit{and} \quad \mathsf{DerivativeMetricQuotient}(f, z, \mathsf{E1}(q), out, dist_1)$$

hold with the same function, point, and quotient histories, then contradiction follows.

Proof. Same-quotient step and distance determinacy identifies the two visible step histories. The equality $\mathsf{E0}(p)\mathsf{hsame}\mathsf{E1}(q)$ contradicts constructor separation for BHist. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient visible step same quotient absurd`

Theorem 122.17 (Visible derivative quotient steps cannot share hsame quotients)**.** *If*

$$out\mathsf{hsame}out', \quad \mathsf{DerivativeMetricQuotient}(f, z, \mathsf{E0}(p), out, dist_0), \quad \mathsf{DerivativeMetricQuotient}(f, z, \mathsf{E1}(q), out', di$$

then contradiction follows.

Proof. Transport the second derivative metric quotient along the quotient classifier so that both witnesses have quotient *out*. The same-quotient visible-step separation theorem then identifies $\mathsf{E0}(p)$ with $\mathsf{E1}(q)$, contradicting constructor separation. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient visible step hsame quotient absurd`

Theorem 122.18 (Derivative complex-difference witness step is unary)**.** *If* $\mathsf{CplxDiffAt}(f, z, f')$ *holds, then it contains histories* h *and* q *such that* h *and* q *are unary,* $\mathsf{Cont}(f, h, q)$ *holds, and* $q\mathsf{hsame}f'$.

Proof. Unfold the displayed differentiability data to obtain a quotient witness $\mathsf{CplxDiffQuot}(f, z, h, q)$. The quotient step-unary theorem extracts unarity of h and q together with the continuation ledger $\mathsf{Cont}(f, h, q)$. The classifier field of $\mathsf{CplxDiffAt}$ identifies the quotient result q with the displayed derivative f'. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeCplxDiffAt witness step unary`

Theorem 122.19 (Derivative complex-difference derivative is nonempty)**.** *If* $\mathsf{CplxDiffAt}(f, z, f')$ *holds, then the displayed derivative* f' *cannot be* hsame*-equal to* e.

Proof. Unfold the differentiability witness to obtain a concrete quotient $\mathsf{CplxDiffQuot}(f, z, h, q)$. The classifier field identifies the quotient result q with the displayed derivative f'. A hypothetical $f'\mathsf{hsame}\mathsf{e}$ therefore makes $q\mathsf{hsame}\mathsf{e}$, contradicting quotient result non-emptiness from the nonzero step. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeCplxDiffAt derivative nonempty`

Theorem 122.20 (Derivative complex-difference empty-function step readback)**.** *If* $\mathsf{CplxDiffAt}(\mathsf{e}, z, f')$ *holds, then some nonzero unary step history* h *is classified as the displayed derivative:*

$$\exists h : \mathsf{BHist}, \mathsf{CplxNonZero}(h) \wedge \mathsf{UnaryHistory}(h) \wedge f'\mathsf{hsame}h.$$

Proof. Unpack the differentiability witness to obtain a concrete quotient $\mathsf{CplxDiffQuot}(\mathsf{e}, z, h, q)$. Its step-unary readback exposes the nonzero and unary fields for h and the ledger $\mathsf{Cont}(\mathsf{e}, h, q)$. Left-unit readback gives $q\mathsf{hsame}h$, while the classifier field identifies q with f'. Symmetry and transitivity identify f' with h. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeCplxDiffAt empty function step readback`

122.2 The certificate

Theorem 122.21 (Derivative metric quotient chain-product composition)**.** *For histories* $f, g, z, h_f, h_g, q_f, q_g, d_f, d_g$ BHist*, assume*

$$\mathsf{DerivativeMetricQuotient}(f, z, h_f, q_f, d_f), \qquad \mathsf{DerivativeMetricQuotient}(g, q_f, h_g, q_g, d_g).$$

Let $h_{fg}, q_{fg}, d_{fg}, F_{fg} : \mathsf{BHist}$ *be continuation witnesses with*

$$\mathsf{Cont}(h_f, h_g, h_{fg}), \qquad \mathsf{Cont}(q_f, q_g, q_{fg}), \qquad \mathsf{Cont}(d_f, d_g, d_{fg}), \qquad \mathsf{Cont}(f, g, F_{fg}),$$

and assume the displayed chain ledger

$$\mathsf{Cont}(f, h_{fg}, q_g).$$

Then the product representative of the chain is a derivative metric quotient,

$$\mathsf{DerivativeMetricQuotient}(F_{fg}, z, h_{fg}, q_{fg}, d_{fg}),$$

and its distance ledger is the continuation product of the two component distance histories:

$$\mathsf{Cont}(d_f, d_g, d_{fg}).$$

The displayed chain ledger also factors through the inner quotient endpoint:

$$\mathsf{Cont}(q_f, h_g, q_g) \wedge g\mathsf{hsame}q_f.$$

Proof. Unpack the two derivative metric quotient witnesses using Definition 122.1. The first witness gives unary carriers for f, z, h_f, q_f, d_f, the non-zero step witness for h_f, and the continuation ledgers $\mathsf{Cont}(f, h_f, q_f)$ and $\mathsf{Cont}(h_f, q_f, d_f)$. The second witness gives unary carriers for g, q_f, h_g, q_g, d_g, the non-zero step witness for h_g, and the continuation ledgers $\mathsf{Cont}(g, h_g, q_g)$ and $\mathsf{Cont}(h_g, q_g, d_g)$.

The supplied continuation ledgers give unary carriers for F_{fg}, h_{fg}, q_{fg}, and d_{fg}. If $h_{fg}\mathsf{hsamee}$, continuation-empty inversion applied to $\mathsf{Cont}(h_f, h_g, h_{fg})$ forces $h_f\mathsf{hsamee}$, contradicting the non-zero step field of the first quotient. Thus h_{fg} carries the required complex non-zero witness.

The chain ledger factors through q_f as follows. The supplied continuation $\mathsf{Cont}(h_f, h_g, h_{fg})$, together with $\mathsf{Cont}(f, h_f, q_f)$ and the displayed $\mathsf{Cont}(f, h_{fg}, q_g)$, gives $\mathsf{Cont}(q_f, h_g, q_g)$ by Definition 21.33. Comparing this ledger with the second quotient ledger $\mathsf{Cont}(g, h_g, q_g)$ and cancelling the common right tail h_g gives $g\mathsf{hsame}q_f$.

It remains to assemble the two ledgers required by $\mathsf{DerivativeMetricQuotient}(F_{fg}, z, h_{fg}, q_{fg}, d_{fg})$. For the quotient ledger, replace q_f and q_g by the results of $\mathsf{Cont}(f, h_f, q_f)$ and $\mathsf{Cont}(g, h_g, q_g)$. After reassociation, the canonical result of continuing F_{fg} by h_{fg} and the displayed quotient representative q_{fg} differ only by moving the unary factor g past the unary factor h_f. Unary continuation commutativity from Definition 9200.14, together with associativity from Definition 21.29, therefore identifies the two results, and continuation result transport gives $\mathsf{Cont}(F_{fg}, h_{fg}, q_{fg})$.

For the metric ledger, replace d_f and d_g by the results of $\mathsf{Cont}(h_f, q_f, d_f)$ and $\mathsf{Cont}(h_g, q_g, d_g)$. The ledger $\mathsf{Cont}(d_f, d_g, d_{fg})$ therefore classifies d_{fg} with the product of the two component metric results. The canonical metric result of continuing h_{fg} by q_{fg} is obtained from the step product followed by the quotient product. Reassociation and the same unary commutativity swap of q_f with h_g identify these two histories, so continuation result transport gives $\mathsf{Cont}(h_{fg}, q_{fg}, d_{fg})$. Repacking the unary carriers, the non-zero composite step, and the two continuation ledgers gives the derivative metric quotient. Finally, $\mathsf{Cont}(d_f, d_g, d_{fg})$ is the displayed distance product ledger. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeTasteGate single carrier alignment`

Theorem 122.22 (Derivative empty-function quotient zero-headed step exclusion)**.** *For histories* $z, h, q, dist, s$: BHist*, if*

$$\mathsf{DerivativeMetricQuotient}(\mathsf{e}, z, h, q, dist) \qquad \textit{and} \qquad h\mathsf{hsameE0}(s),$$

then $\perp$*.*

Proof. Apply Definition 122.5 to the derivative metric quotient. This gives $q\mathsf{hsame}h$. Composing with the displayed step classification gives $q\mathsf{hsameE0}(s)$. The quotient carrier field in Definition 122.1 gives $\mathsf{UnaryHistory}(q)$, the unary-generation carrier of Definition 28.1. By Definition 9195.7, this transports to $\mathsf{UnaryHistory}(\mathsf{E0}(s))$. This contradicts Definition 28.3. □

Lean4 ✓ `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient empty function zero step absurd`

Closure status for $\mathsf{NameCert}_{\mathsf{Derivative}\uparrow}$.

Constructive story: A derivative witness is carried as a five-history metric quotient row: the function code f, point z, nonzero step h, quotient q, and distance record $dist$ must all be unary where required, with $\mathsf{Cont}(f, h, q)$ displaying the difference quotient and $\mathsf{Cont}(h, q, dist)$ displaying the metric-distance ledger. The classifier is componentwise hsame transport of those visible histories, and the carrier excludes zero steps, zero-headed unary contradictions, and any quotient or distance value not produced by the two continuation rows. The source is this derivative metric quotient package, the pattern records complex-difference quotient readback, metric distance depth, visible-context readback, determinacy, chain-product composition, and the empty-function boundary rows, while the ledger keeps both continuations and every transported visible context in view. Nonemptiness is supplied by any displayed quotient row, the hsame laws give reflexivity, symmetry, and transitivity, and the transport theorem repacks classifier-related components into a fresh derivative quotient, so the five obligations stay inside the continuation calculus. A history h_0 lies in the signature gap of a $\mathsf{Derivative}^{\uparrow}$ token p when the source-domain accepts its metric quotient row, the signature relation pairs the quotient and distance package with an answer derivative history and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the answer is the quotient endpoint whose nonzero-step and distance ledgers match the token's derivative data. The paper bridge reads this same package as the usual difference-quotient and chain-product interface, with the metric tolerance supplied by the visible distance row. The chapter registers the construction under the name $\mathsf{Derivative}^{\uparrow}$; it adds no full calculus, integration theory, differentiability-class hierarchy, or bridgeChecked external proof.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Derivative}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The DerivativeMetricQuotient chain-product theorem, transport rows, visible-context readback rows, determinacy rows, zero-step boundary, continuation ledger policy, and paper bridge form the mature certificate surface for this chapter.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Derivative}\uparrow}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.DerivativeUp.DerivativeMetricQuotient\_chain\_product\_composition`

Bridge status: bridgeChecked

Not claimed: This chapter does not close full calculus, integration, or differentiability classes.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 123

A Concrete Naming Certificate for $\mathsf{Integral}^{\uparrow}$

The integral interface $\mathsf{Integral}^{\uparrow}$ packages a measure-respecting integration operation on suitable function carriers over $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92). It generalises the contour integral $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ (chapter 9340) to Riemann/Lebesgue settings on real and abstract carriers.

123.1 Carrier definition

Theorem 123.1 (Integral function-carrier obligation)**.** *An* $\mathsf{Integral}^{\uparrow}$ *carried endpoint is a* BHist *row whose visible source data are the cited* $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ *row, the function-carrier row of admissible integrands over that measure source, and the* $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ *comparison boundary. The endpoint carrier records only those named histories, their* Pkg *provenance, and their probe bundles; hidden partition, approximation, and convergence choices are not carrier equality.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralTasteGate single carrier alignment`
↪ variant `BEDC.Derived.IntegralUp.IntegralFunctionCarrier obligation`

Proof. Use the carrier field of the roadmap ten-field template. The traditional target is integration, the BEDC source row is the displayed $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ history, and the comparison source is the displayed $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ boundary.

The carrier field is then the function-carrier row over that measure source, together with the integral endpoint history. Repacking these rows through BHist and Pkg fixes the visible endpoint before classifier, operation, stability, ledger, exactness, and dependency rows are considered. □

Theorem 123.2 (Integral measure-respecting classifier obligation)**.** *The* $\mathsf{Integral}^{\uparrow}$ *classifier relates carried integrands exactly when the* $\mathsf{Measure}^{\uparrow}$*-visible domain row and the* $\mathsf{Contour}^{\uparrow}$ *comparison row agree under the same* hsame *and* Pkg *provenance. The comparison is therefore a BEDC classifier on displayed histories and packages, not a host quotient of integrands and not host function equality.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralMeasureRespectingClassifier obligation`
↪ variant `BEDC.Derived.IntegralUp.IntegralVisibleCarrierRow classifier boundary transport`

Proof. Apply the classifier field of the roadmap ten-field template to Definition 123.1. The source classifier is the visible $\mathsf{Measure}^{\uparrow}$ comparison on domain rows, while the boundary classifier is the visible $\mathsf{Contour}^{\uparrow}$ comparison on the contour-shaped row.

The integrand rows are compared only after those two source comparisons share the same hsame provenance and the same Pkg packaging discipline. This supplies the classifier, stability source, and exactness input fields without adding a host-level equivalence relation. □

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralVisibleCarrierRow measure respecting classifier`

Theorem 123.3 (Integral operation stability and ledger obligation)**.** *The* $\mathsf{Integral}^{\uparrow}$ *integration operation is admitted only with a measure-respecting stability row, ledger entries for hidden partition and approximation data, exactness rows for the displayed carrier and classifier, and dependency rows citing the* $\mathsf{Measure}^{\uparrow}$ *source and the* $\mathsf{Contour}^{\uparrow}$ *comparison boundary. No operation row is admitted without these stability, ledger, exactness, and dependency entries.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralOperationStabilityLedger obligation`

Proof. Use the operation and stability fields of the roadmap ten-field template after the carrier and classifier fields have been fixed. Measure-respecting stability says that transporting the $\mathsf{Measure}^{\uparrow}$ row and the admissible integrand row along the displayed classifier transports the operation endpoint as a BEDC history.

The ledger field records the hidden partition choices, approximation rows, and convergence witnesses used by the operation. The exactness field then states coverage, soundness, and completeness for the displayed carrier and classifier, while the dependency field cites exactly the $\mathsf{Measure}^{\uparrow}$ and $\mathsf{Contour}^{\uparrow}$ source rows consumed by the operation. □

123.2 The certificate

Theorem 123.4 (IntegralUp public NameCert surface)**.** *The carrier row of Definition 123.1, the classifier row of Definition 123.2, and the operation, stability, and ledger row of Definition 123.3 assemble the exported public* $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$ *surface over the displayed* BHist, Pkg, hsame, $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ *dependencies. Its public rows are exactly the visible carrier, classifier, measure-respecting stability, operation ledger, exactness, and dependency rows; partitions, approximations, convergence witnesses, standard bridges, and host function equality remain ledger data or outside this surface.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralPublicNameCert surface`

Proof. Apply Definition 123.1. It fixes the visible BHist carrier, the Pkg provenance, and the named $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ dependencies read by the public $\mathsf{Integral}^{\uparrow}$ endpoint.

Apply Definition 123.2. It supplies the classifier row over the same hsame and Pkg provenance, so the public surface compares displayed histories rather than host-level functions.

Apply Definition 123.3. The roadmap ten-field template then reads the operation, measure-respecting stability, ledger, exactness, and dependency rows as visible public certificate fields. The same template keeps partitions, approximations, convergence witnesses, standard bridges, and host function equality as ledger or out-of-scope data, so the three obligation rows repack as the exported public $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$ surface. □

Theorem 123.5 (IntegralUp conservative standard bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$ *surface of Definition 123.4 admits a conservative standard interpretation with the following six fields.*

1. *The BEDC side is exactly the public surface of Definition 123.4.*

2. *The standard side is an ordinary integration-interface readback over the same displayed* $\mathsf{Measure}^{\uparrow}$ *and* $\mathsf{Contour}^{\uparrow}$ *rows.*
3. *Forward readback exposes only the visible carrier, classifier, measure-respecting stability, operation ledger, exactness, and dependency rows.*
4. *Reverse admission accepts only packages with those displayed rows.*
5. *Classifier preservation is the classifier row of Definition 123.2.*
6. *No host data leak through the bridge: partitions, approximations, convergence witnesses, and host function equality remain non-public ledger data by Definition 123.3.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralUp conservative standard bridge`

Proof. Apply Definition 123.1. It fixes the displayed $\mathsf{Measure}^{\uparrow}$ row, the admissible function-carrier row, the $\mathsf{Contour}^{\uparrow}$ comparison boundary, and the BHist endpoint read by both sides of the bridge.

Apply Definition 123.2. The classifier preserved by the standard reading is therefore the displayed hsame and Pkg comparison on measure and contour histories, not host function equality.

Apply Definition 123.3. Its ledger boundary keeps partitions, approximations, convergence witnesses, and operation presentations as non-public data, while its stability, exactness, and dependency rows are visible certificate fields.

Finally apply Definition 123.4. Forward readback can expose only the public rows listed there, and reverse admission can accept only packages carrying those same rows over the displayed $\mathsf{Measure}^{\uparrow}$ and $\mathsf{Contour}^{\uparrow}$ sources. Thus the standard integration-interface reading is conservative over the public $\mathsf{Integral}^{\uparrow}$ surface. □

Theorem 123.6 (IntegralUp mature consumer completeness)**.** *Every downstream consumer of the public* $\mathsf{Integral}^{\uparrow}$ *surface receives exactly the visible carrier, classifier, measure-respecting stability, operation ledger, exactness, dependency rows, and conservative bridge rows displayed by Definition 123.4 and Definition 123.5. Partitions, approximations, convergence witnesses, and host function equality remain outside the public consumer surface.*

Lean4 ✓ `BEDC.Derived.IntegralUp.IntegralUp mature consumer completeness`

Proof. Apply Definition 123.4. It fixes the visible carrier, classifier, measure-respecting stability, operation ledger, exactness, and dependency rows over the displayed BHist, Pkg, hsame, $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ sources.

Apply Definition 123.5. The bridge exposes only the same public rows to the standard integration-interface reading and admits back only packages carrying those displayed rows.

Composing the two surfaces gives the downstream consumer exactly the public and bridge rows just listed. The same two theorems keep partitions, approximations, convergence witnesses, and host function equality as ledger data or out-of-scope data, so no further host carrier is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$**.**

Constructive story: An integral endpoint is carried only through visible BEDC rows: a $\mathsf{Measure}^{\uparrow}$ source certificate, an admissible function-carrier row over that measure, the $\mathsf{Contour}^{\uparrow}$ comparison boundary, the endpoint history, its Pkg provenance, and the probe bundles that expose the operation surface. Two carried integrands classify together when the measure-visible domain row and contour comparison row agree under the same hsame and package provenance; hidden partitions, approximations, convergence choices, and host function equality are not classifier data. The source covers exactly those displayed measure-and-function packages, the pattern records measure-respecting stability, operation exactness, dependency rows, and the public consumer surface, and the ledger keeps partition choices, approximation rows, convergence witnesses, and operation presentations attached to the rows that use them. The visible carrier row

supplies nonemptiness whenever an accepted endpoint is present, the classifier obligation supplies reflexive, symmetric, and transitive comparison through the source certificates, and measure-respecting transport keeps classified endpoints inside the carrier. A history h lies in the signature gap of an Integral$^{\uparrow}$ token p when the source-domain accepts its measure, function, and contour package, the signature relation pairs the integration endpoint with an answer history and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the token sees exactly the public integration rows and none of the hidden host choices. The conservative standard bridge reads those same public rows as an ordinary integration-interface package and admits back only packages carrying the same displayed rows. The chapter registers this measure-respecting operation surface under the name Integral$^{\uparrow}$; it does not add a convergence theorem, host integrand equality, or bridgeChecked verification.

Theory closure: TheoryGate(NameCert$_{\text{Integral}^{\uparrow}}$, maturePackageClosed)

Scope closed: The chapter includes the bridged public Integral$^{\uparrow}$ carrier, classifier, package, and consumer surface, grounded by Definition 123.4, Definition 123.5, Definition 123.1, Definition 123.2, and Definition 123.3, read through the displayed BHist, Pkg, hsame, NameCert$_{\text{Measure}^{\uparrow}}$, and NameCert$_{\text{Contour}^{\uparrow}}$ dependencies.

Formal verification: FormalStatus(NameCert$_{\text{Integral}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.IntegralUp.IntegralFunctionCarrier\_obligation`

Bridge status: paperBridge

Not claimed: This chapter does not close a convergence theorem, host function equality for integrands, or bridgeChecked verification.

Upgrade path: No stronger paper closure grade remains for this chapter; bridgeChecked verification is a separate formal-axis target.

Chapter 124

A Concrete Naming Certificate for $\mathsf{Fourier}^{\uparrow}$

The Fourier interface $\mathsf{Fourier}^{\uparrow}$ packages the constructive Fourier series and transform of suitable functions on $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$ (chapter 58) and $\mathsf{NameCert}_{\mathsf{Real}\uparrow}$. It depends on $\mathsf{NameCert}_{\mathsf{InnerProduct}\uparrow}$ (chapter 86) and $\mathsf{NameCert}_{\mathsf{Integral}\uparrow}$ (chapter 123).

124.1 Carrier definition

124.2 The certificate

Theorem 124.1 (Fourier carrier obligation)**.** *A* $\mathsf{Fourier}^{\uparrow}$ *certificate supplies a* BHist*-indexed carrier of certified Fourier data over the named* $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$, $\mathsf{NameCert}_{\mathsf{Real}\uparrow}$, $\mathsf{NameCert}_{\mathsf{InnerProduct}\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{Integral}\uparrow}$ *sources. Every finite observation of a coefficient, transform sample, inner-product probe, or integral witness is exposed through* ProbeBundle *and* SigRel *packages rather than through host-level functions.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation carrier obligation`

Proof. Unpack the four source certificates named by the chapter introduction. The roadmap ten-field template first asks for the carrier over which the later classifier, stability, ledger, and exactness rows are read.

For Fourier data this carrier can only be observed through finite coefficient and transform probes. Therefore the obligation surface records those probes as ProbeBundle entries with SigRel evidence, leaving analytic completion statements outside the carrier row. □

Theorem 124.2 (Fourier classifier obligation)**.** *The* $\mathsf{Fourier}^{\uparrow}$ *classifier identifies two Fourier data histories exactly when every certified finite coefficient observation and every certified finite transform observation are related by the source classifiers and are packaged through* sameSig *and* Pkg*. The classifier is therefore determined by the visible finite Fourier packages and not by an external equality of functions.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation classifier obligation`

Proof. Apply the classifier field of the roadmap ten-field template to the carrier row in Definition 124.1. Each observable Fourier datum has already been forced into a finite signature package, so classifier comparison is read at the level of source-certified signatures.

The $\mathsf{S}^{1\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{InnerProduct}^{\uparrow}$, and $\mathsf{Integral}^{\uparrow}$ classifiers provide the component comparisons. Packaging through sameSig and Pkg records that the Fourier classifier is an internal BEDC classifier, not a host equality on functions or transforms. □

Theorem 124.3 (Fourier stability obligation)**.** *The* $\mathsf{Fourier}^{\uparrow}$ *stability row requires reflexivity, symmetry, transitivity, carrier transport, and stability under certified reindexing and integration rows inherited from* $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{InnerProduct}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$. *These stability clauses must act on the finite Fourier packages of the classifier row.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation stability obligation`

Proof. Start from the classifier obligation in Definition 124.2. Reflexivity, symmetry, and transitivity are the equivalence duties for the displayed classifier, while carrier transport states that the same certified observations remain readable after classifier-related history transport.

The reindexing and integration clauses are not independent analytic principles. They are inherited stability rows from the four named source certificates and are applied only to the finite packages exposed by the Fourier carrier. □

Theorem 124.4 (Fourier ledger obligation)**.** *The* $\mathsf{Fourier}^{\uparrow}$ *ledger records hidden truncation bounds, coefficient windows, orthogonality probes, integration witnesses, and convergence-modulus data. Each ledger item is attached to the finite package that uses it, and no item may be replaced by an unrecorded analytic convention.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation ledger obligation`

Proof. The ledger field of the roadmap ten-field template lists the data that can affect a certified observation without being the observation itself. Fourier coefficients and transforms carry truncation, window, orthogonality, integration, and modulus choices of exactly this kind.

Recording these choices beside the finite packages makes the later exactness row inspectable. It also fixes the boundary between certified Fourier data and analytic claims that have not been closed in this chapter. □

Theorem 124.5 (Fourier exactness obligation)**.** *The* $\mathsf{Fourier}^{\uparrow}$ *exactness row requires coverage, soundness, and completeness for the finite observation packages of Definition 124.1 through Definition 124.4. It does not claim Plancherel, inversion, or convergence closure.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation exactness obligation`

Proof. Unpack the exactness field of the roadmap ten-field template after the carrier, classifier, stability, and ledger rows have been fixed. Coverage says that each certified finite Fourier observation has a package, soundness says that package equality respects the displayed source classifiers, and completeness says that classifier-related finite observations are represented by internally same packages.

These are finite-observation obligations only. Plancherel, inversion, and convergence require additional analytic closure rows and are therefore named as outside the exactness surface recorded here. □

Theorem 124.6 (Fourier finite-observation standard bridge)**.** *The five checked finite-observation rows assemble a paper-side bridge from BEDC Fourier packages over* BHist, ProbeBundle, SigRel, sameSig, *and* Pkg *to the standard finite Fourier observation interface over* $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$,

$\mathsf{NameCert}_{\mathsf{InnerProduct}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{Integral}^\uparrow}$. *This bridge preserves only finite coefficient and transform observations, and keeps truncation windows, integration witnesses, and convergence-modulus data in the ledger.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation standard bridge`

Proof. Use Definition 124.1 to read each observable coefficient, transform sample, inner-product probe, and integral witness as a finite BEDC package over BHist, ProbeBundle, and SigRel. Then use Definition 124.2 to transport the comparison of those packages through sameSig and Pkg into the source classifiers of $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$, $\mathsf{NameCert}_{\mathsf{Real}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{InnerProduct}^\uparrow}$, and $\mathsf{NameCert}_{\mathsf{Integral}^\uparrow}$.

Next apply Definition 124.3 to make the transport stable under certified reindexing and integration rows. Apply Definition 124.4 to retain all truncation windows, integration witnesses, orthogonality probes, and convergence-modulus data beside the finite observation that uses them.

Finally apply Definition 124.5. Its coverage, soundness, and completeness clauses identify exactly the finite observations carried across the bridge, while Plancherel, inversion, and convergence closure remain outside the preserved interface. □

Closure status for $\mathsf{NameCert}_{\mathsf{Fourier}^\uparrow}$**.**

Constructive story: A Fourier datum is carried only through finite observations over the named $\mathsf{S}^1\uparrow$, $\mathsf{Real}^\uparrow$, $\mathsf{InnerProduct}^\uparrow$, and $\mathsf{Integral}^\uparrow$ sources: coefficient probes, transform samples, inner-product probes, and integral witnesses appear as ProbeBundle entries tied to SigRel evidence. The classifier compares two carried Fourier histories by checking that every finite observation package is related through the relevant source classifiers and through sameSig and Pkg, rather than by asserting equality of host functions or transforms. The source is the finite-observation package surface, the pattern records carrier, classifier, reindexing, integration-stability, and exactness obligations, and the ledger stores truncation bounds, coefficient windows, orthogonality probes, integration witnesses, and convergence-modulus data next to the finite package that uses them. Nonemptiness is provided whenever a source policy supplies an observable probe package, the classifier rows give reflexivity, symmetry, and transitivity through the finite signatures, and carrier transport follows because the same certified observations remain readable after source-classifier transport. A history h lies in the signature gap of a $\mathsf{Fourier}^\uparrow$ token p when the source-domain accepts its finite Fourier package, the signature relation pairs it with an answer observation and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h supplies exactly the coefficient or transform observations encoded by the token and the ledger records the windows and integration rows used to obtain them. The paper standard bridge reads the same packages as the ordinary finite Fourier observation interface while preserving only those finite observations. The chapter registers this finite-observation construction under the name $\mathsf{Fourier}^\uparrow$; it introduces no Plancherel theorem, inversion theorem, convergence closure, or Lean-checked standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Fourier}^\uparrow}$, maturePackageClosed)

Scope closed: The mature paper boundary is the finite-observation Fourier interface exported by the five checked rows and Definition 124.6 over $\mathsf{S}^1\uparrow$, $\mathsf{Real}^\uparrow$, $\mathsf{InnerProduct}^\uparrow$, $\mathsf{Integral}^\uparrow$, BHist, ProbeBundle, SigRel, sameSig, and Pkg.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Fourier}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.FourierUp.FourierFiniteObservation\_exactness\_obligation`

Bridge status: paperBridge

Not claimed: This chapter does not close Plancherel, inversion, convergence closure, bridgeChecked verification, or a Lean StdBridge theorem.

Upgrade path: No stronger paper-side theory grade remains for this finite-observation boundary; only independent Lean-side bridgeChecked verification can raise the formal axis.

Theorem 124.7 (Fourier finite-observation subpacket restriction)**.** *Let F be a* $\mathsf{Fourier}^\uparrow$ *finite-observation package over the sources* $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$, $\mathsf{NameCert}_{\mathsf{Real}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{InnerProduct}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{Integral}^\uparrow}$. *Suppose Ω is a displayed finite selector on the observation rows of F, and suppose every selected row is retained together with its attached truncation window, coefficient-window row, orthogonality probe, integration witness, convergence-modulus ledger entry,* ProbeBundle *row, and* SigRel *evidence. Then the selected packet F_Ω is again a* $\mathsf{Fourier}^\uparrow$ *finite-observation package over the same four source certificates. Its carrier, classifier, ledger, and exactness rows are exactly the restrictions of the corresponding rows of F to the selected finite observations.*

Lean4 ✓ `BEDC.Derived.FourierUp.FourierFiniteObservation subpacket restriction`

Proof. Read F through the carrier obligation of Definition 124.1. Its visible observations are only finite coefficient observations, transform samples, inner-product probes, and integral witnesses, and each such observation is already presented as a ProbeBundle entry with SigRel evidence over the four named source certificates. Since Ω is a displayed finite selector on those rows, the carrier of F_Ω is obtained by keeping precisely the selected ProbeBundle entries and their selected SigRel evidence. No host Fourier function, ambient transform, or analytic completion coordinate is introduced by this selection.

The classifier row restricts along the same finite selector. By Definition 124.2, comparison of Fourier observations is read through the source classifiers and through sameSig and Pkg. For two observations retained by Ω, the comparison in F_Ω is the comparison already present in F. For an observation not retained by Ω, there is no row in the subpacket and therefore no classifier duty to discharge. Thus reflexive, symmetric, and transitive comparisons on the selected observations are inherited from the restricted classifier surface rather than from a new equality of functions.

The ledger row is also closed under the selector because the hypothesis retains each selected observation with every ledger item attached to it. Apply Definition 124.4: truncation bounds, coefficient windows, orthogonality probes, integration witnesses, and convergence-modulus data are recorded beside the finite package that uses them. Hence restricting the observation row without dropping its attached ledger entries leaves a complete local ledger for every retained coefficient observation, transform sample, inner-product probe, and integral witness. Ledger entries attached only to omitted observations are outside F_Ω and are not required for any retained read.

Finally apply Definition 124.5. Coverage for F_Ω holds because each retained observation was covered in F and its covering package is one of the rows selected by Ω. Soundness holds because any equality or source-classifier comparison used inside F_Ω is the same comparison already sound in F, restricted to retained rows. Completeness holds for the selected interface because whenever two retained finite observations are classifier-related in the restricted packet, their sameSig and Pkg witnesses are exactly the retained witnesses inherited from F.

The source certificates are unchanged throughout the construction: Ω selects rows inside the already certified $\mathsf{Fourier}^\uparrow$ packet and does not replace $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$, $\mathsf{NameCert}_{\mathsf{Real}\uparrow}$, $\mathsf{NameCert}_{\mathsf{InnerProduct}\uparrow}$, or $\mathsf{NameCert}_{\mathsf{Integral}\uparrow}$. Therefore F_Ω satisfies the same finite-observation package obligations over the same sources. The conclusion is only this finite subpacket closure; it does not assert Plancherel, inversion, convergence closure, or any analytic Fourier theorem. □

Chapter 125

A Concrete Naming Certificate for $\mathsf{Residue}^{\uparrow}$

The residue interface $\mathsf{Residue}^{\uparrow}$ packages the residue at an isolated singularity of a holomorphic function and the residue-theorem witness relating contour integrals to residue sums. It depends on $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ (chapter 68) and $\mathsf{NameCert}_{\mathsf{Contour}^{\uparrow}}$ (chapter 9340).

125.1 Carrier definition

Definition 125.1 (Residue pole data)**.** *The predicate* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *records an open-disk witness* $\mathsf{HolomorphicOpenDisk}(z_0, r, p, g)$*, complex-history carriers for the integral* I *and residue* ρ*, a complex-pair carrier for* f*, and the continuation witness* $\mathsf{Cont}(I, \rho, f)$*.*

Lean4 (definition) `BEDC.Derived.ResidueUp.ResiduePoleData`

Lean4 ✓ `BEDC.Derived.ResidueUp.ResidueTasteGate single carrier alignment`

Theorem 125.2 (Residue pole data under hsame)**.** *If all seven histories in* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *are transported along* hsame*, then the transported histories again satisfy* ResiduePoleData*, and the transported integral and residue continue to the transported function history.*

Proof. Transport the open-disk witness through holomorphic-disk hsame-stability. Transport the complex carriers for I, ρ, and the product carrier for f through the product-history carrier stability, then transport $\mathsf{Cont}(I, \rho, f)$ componentwise along the same hsame witnesses. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData hsame transport`

Theorem 125.3 (Residue pole data empty function endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds and* $f\mathsf{hsamee}$*, then both residue endpoints are empty:*

$$I\mathsf{hsamee} \wedge \rho\mathsf{hsamee}.$$

Proof. Destructure the residue pole data to expose $\mathsf{Cont}(I, \rho, f)$. Transport the continuation result along $f\mathsf{hsamee}$, then apply empty-result inversion for BEDC continuations to recover the two empty endpoints. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData empty function endpoints`

Theorem 125.4 (Residue pole data empty function endpoints iff)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds, then the function history is empty exactly when both residue endpoints are empty:*

$$f\mathsf{hsamee} \iff I\mathsf{hsamee} \wedge \rho\mathsf{hsamee}.$$

Proof. The forward implication is the empty-function endpoint theorem. Conversely, unpack the residue pole data to expose $\mathsf{Cont}(I, \rho, f)$. Compare this continuation with $\mathsf{Cont}(\mathsf{e}, \mathsf{e}, \mathsf{e})$ using the supplied endpoint equalities; continuation result respect for hsame gives $f\mathsf{hsamee}$. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData empty function endpoints iff`

Theorem 125.5 (Residue pole data residue suffix closure)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* q *is unary, and* $\mathsf{Cont}(f, q, f_q)$*, then there is a residue history* ρ_q *such that* $\mathsf{ResiduePoleData}(f_q, z_0, r, p, g, I, \rho_q)$*, with* $\mathsf{Cont}(\rho, q, \rho_q)$ *and* $\mathsf{Cont}(I, \rho_q, f_q)$*.*

Proof. Unpack the residue data to obtain $\mathsf{Cont}(I, \rho, f)$. Continuation associativity against $\mathsf{Cont}(f, q, f_q)$ supplies ρ_q with $\mathsf{Cont}(\rho, q, \rho_q)$ and $\mathsf{Cont}(I, \rho_q, f_q)$. The residue carrier is closed under the unary suffix q, and the product carrier for f_q is rebuilt from the integral carrier, the shifted residue carrier, and the final continuation. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData residue suffix closure`

Theorem 125.6 (Residue pole data suffix closure with empty function endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g,$ *holds,* q *is unary,* $\mathsf{Cont}(f, q, f_q)$*, and* $f_q\mathsf{hsamee}$*, then there is a residue history* ρ_q *such that* $\mathsf{ResiduePoleData}(f_q, z_0, r,$ $\mathsf{Cont}(\rho, q, \rho_q)$*, and*

$$I\mathsf{hsamee} \wedge \rho_q\mathsf{hsamee}.$$

Proof. Apply suffix closure to obtain the transported residue witness ρ_q and the closed residue data over f_q. The empty-function endpoint theorem then applies to that closed data and $f_q\mathsf{hsamee}$, identifying both the integral and the transported residue with e. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData suffix closure empty function endpoints`

Theorem 125.7 (Residue pole data empty suffix reflects endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* $\mathsf{Cont}(f, q, f_q)$*, and* $f_q\mathsf{hsamee}$*, then the integral endpoint, the residue endpoint, and the suffix are all empty:*

$$I\mathsf{hsamee} \wedge \rho\mathsf{hsamee} \wedge q\mathsf{hsamee}.$$

Proof. Transport $\mathsf{Cont}(f, q, f_q)$ along $f_q\mathsf{hsamee}$ and apply empty-result inversion for continuations. This gives $f\mathsf{hsamee}$ and $q\mathsf{hsamee}$. The empty-function endpoint theorem for residue pole data then reflects $f\mathsf{hsamee}$ back to the integral and residue endpoints. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData empty suffix reflects endpoints`

Theorem 125.8 (Residue pole data prefix empty reflects endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* $\mathsf{Cont}(q, f, q_f)$*, and* $q_f\mathsf{hsamee}$*, then the prefix, integral endpoint, and residue endpoint are all empty:*

$$q\mathsf{hsamee} \wedge I\mathsf{hsamee} \wedge \rho\mathsf{hsamee}.$$

Proof. Transport $\mathsf{Cont}(q, f, q_f)$ along $q_f\mathsf{hsamee}$ and apply empty-result inversion for continuations. This gives $q\mathsf{hsamee}$ and $f\mathsf{hsamee}$. The empty-function endpoint theorem for residue pole data then reflects $f\mathsf{hsamee}$ to the integral and residue endpoints. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData prefix empty reflects endpoints`

Theorem 125.9 (Residue pole data suffix empty function endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* q *is unary,* $\mathsf{Cont}(f, q, f_q)$*, and* $f_q\mathsf{hsamee}$*, then* $I\mathsf{hsamee}$ *and there is a shifted residue* ρ_q *such that*

$$\mathsf{Cont}(\rho, q, \rho_q) \wedge \rho_q\mathsf{hsamee}.$$

Proof. Apply residue suffix closure to obtain the shifted pole data and the residue suffix witness. The empty-function endpoint theorem applied to the shifted data and $f_q\mathsf{hsamee}$ identifies I and ρ_q with the empty history, and the residue suffix witness supplies the displayed continuation. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData suffix empty function endpoints`

Theorem 125.10 (Residue pole data integral prefix closure)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* q *is unary, and* $\mathsf{Cont}(q, f, q_f)$*, then there is an integral history* I_q *such that* $\mathsf{ResiduePoleData}(q_f, z_0, r, p, g, I_q, \rho)$ *with* $\mathsf{Cont}(q, I, I_q)$ *and* $\mathsf{Cont}(I_q, \rho, q_f)$*.*

Proof. Take $I_q = \mathsf{append}(q, I)$. The complex integral carrier is closed under unary prefixing. The two continuation witnesses $\mathsf{Cont}(I, \rho, f)$ and $\mathsf{Cont}(q, f, q_f)$, together with append associativity, identify $\mathsf{Cont}(I_q, \rho, q_f)$. The product carrier for q_f is then rebuilt from the prefixed integral carrier, the original residue carrier, and that continuation. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData integral prefix closure`

Theorem 125.11 (Residue pole data integral prefix empty function endpoints)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* q *is unary,* $\mathsf{Cont}(q, f, q_f)$*, and* $q_f\mathsf{hsamee}$*, then there is an integral history* I_q *such that* $\mathsf{ResiduePoleData}(q_f, z_0, r, p, g, I_q, \rho)$*,* $\mathsf{Cont}(q, I, I_q)$*, and*

$$I_q\mathsf{hsamee} \wedge \rho\mathsf{hsamee}.$$

Proof. Apply integral prefix closure to obtain the prefixed integral witness I_q and the residue pole data over q_f. The empty-function endpoint theorem applied to that prefixed pole data and $q_f\mathsf{hsamee}$ identifies both I_q and ρ with the empty history, while the prefix continuation $\mathsf{Cont}(q, I, I_q)$ is preserved from the closure witness. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData integral prefix empty function endpoints`

125.2 The certificate

Theorem 125.12 (Residue pole data integral suffix closure)**.** *If* $\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho)$ *holds,* q *is unary, and* $\mathsf{Cont}(f, q, f_q)$*, then there is an integral history* I_q *such that* $\mathsf{ResiduePoleData}(f_q, z_0, r, p, g, I_q, \rho)$ *with* $\mathsf{Cont}(I, q, I_q)$ *and* $\mathsf{Cont}(I_q, \rho, f_q)$*.*

Proof. Unpack the residue pole data of Definition 125.1. This gives the open-disk witness, complex carrier witnesses for I and ρ, the product carrier for f, and the continuation $\mathsf{Cont}(I, \rho, f)$. Set $I_q = \mathsf{append}(I, q)$. The right unary context closure for complex carriers from Definition 39.12 gives a complex carrier for I_q, and $\mathsf{Cont}(I, q, I_q)$ is the defining continuation.

It remains to identify the final continuation. By Definition 39.3, the residue carrier makes ρ unary. Since q is unary, unary append commutativity from Definition 9200.9 swaps q and ρ. Let J be the history supplied by the defining continuation of I_q by ρ, so $\mathsf{Cont}(I_q, \rho, J)$. Combining

this continuation with the swap, append associativity, and the two continuations $\mathsf{Cont}(I, \rho, f)$ and $\mathsf{Cont}(f, q, f_q)$ gives

$$J\mathsf{hsameappend}(\mathsf{append}(I, q), \rho)\mathsf{hsameappend}(\mathsf{append}(I, \rho), q)\mathsf{hsame}f_q.$$

The continuation result transport theorem Definition 4.40 applied to $\mathsf{Cont}(I_q, \rho, J)$ and $J\mathsf{hsame}f_q$ gives $\mathsf{Cont}(I_q, \rho, f_q)$. The same open-disk witness and the original residue carrier are retained; the product carrier for f_q is rebuilt from the complex carriers for I_q and ρ together with $\mathsf{Cont}(I_q, \rho, f_q)$. Hence $\mathsf{ResiduePoleData}(f_q, z_0, r, p, g, I_q, \rho)$ holds, with the two displayed continuations. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData integral suffix closure`

Theorem 125.13 (Residue pole data result determinism)**.** *If two residue pole data witnesses share the displayed pole histories z_0, r, p, g, I, ρ and have function histories f and f', so that*

$$\mathsf{ResiduePoleData}(f, z_0, r, p, g, I, \rho) \quad \textit{and} \quad \mathsf{ResiduePoleData}(f', z_0, r, p, g, I, \rho),$$

then $f\mathsf{hsame}f'$.

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData result determinism with continuations`

Proof. Unpack both residue pole data witnesses using Definition 125.1. The first witness exposes a continuation ledger $C : \mathsf{Cont}(I, \rho, f)$, and the second exposes a continuation ledger $C' : \mathsf{Cont}(I, \rho, f')$. Apply Definition 4.42 to C and C' with the reflexive endpoint comparisons $I\mathsf{hsame}I$, $\rho\mathsf{hsame}\rho$, and $f\mathsf{hsame}f$. The transported first ledger has the same source, right endpoint, and result as C, while the classification clause compares that result with the result of C'. Hence $f\mathsf{hsame}f'$. □

Lean4 ✓ `BEDC.Derived.ResidueUp.ResiduePoleData result determinism`

Closure status for $\mathsf{NameCert}_{\mathsf{Residue}^\uparrow}$.

Constructive story: A $\mathsf{Residue}^\uparrow$ packet is generated from residue pole data, a holomorphic disk row, contour and integral rows, componentwise transport, continuation replay, and local naming for the residue pole carrier.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Residue}^\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 125.1, Definition 125.2, Definition 125.3, Definition 125.4, Definition 125.5, Definition 125.10, Definition 125.12, and Definition 125.13 record the mature finite residue-pole packet over Holomorphic, Contour, complex-history carrier, hsame, Cont, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Residue}^\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ResidueUp.ResiduePoleData\_hsame\_transport`

Bridge status: none

Not claimed: This chapter does not close the full residue theorem, analytic continuation, or the standard complex analysis bridge.

Upgrade path: Bridge checking remains the next verification-axis obligation: a checked standard bridge must identify this mature residue-pole packet with the accepted complex-analysis residue theorem interface while preserving the Holomorphic, Contour, complex-history carrier, hsame, Cont, and NameCert rows.

StreamNameUp is the L10 countable-name gateway consumed by chapter 301, chapter 291, and chapter 38 before any RealUp seal is public. The route exports only finite BHist, hsame, Cont, Pkg, and NameCert rows, not quotient stream equality, selected limits, host real equality, or ambient completeness.

Chapter 126

A Concrete Naming Certificate for $\mathsf{StreamName}^{\uparrow}$

The stream-name interface $\mathsf{StreamName}^{\uparrow}$ packages an abstract sequential carrier underlying the Bishop-style L10 real-number construction. It is the lowest-level data on which $\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{CompleteMetric}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{CompactMetric}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ are built.

The same carrier is the finite observation spine later consumed by chapter 301 and sealed by chapter 38. Those downstream chapters may read only the displayed stream windows, hsame transport, Cont replay, provenance, and local NameCert rows exposed here.

126.1 Carrier definition

Definition 126.1 (Rational stream-name carrier)**.** *For a certified observation map* $s : \mathsf{Hist} \to \mathsf{Hist}$*, the rational stream-name carrier is the pointwise rational-history carrier over unary BEDC observation histories:*

$$\mathsf{RatStreamNameCarrier}(s) \iff \forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{RatHistoryCarrier}(s(n)).$$

Lean4 (definition) `BEDC.Derived.StreamNameUp.RatStreamNameCarrier`

Definition 126.2 (Rational stream-name classifier)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$*, the rational stream-name classifier bundles the two endpoint stream carriers with the pointwise rational-history classifier over the same unary BEDC observation histories:*

$$\mathsf{RatStreamNameClassifier}(s,t) \iff \mathsf{RatStreamNameCarrier}(s) \wedge \mathsf{RatStreamNameCarrier}(t) \wedge \forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{Ra}$$

Lean4 (definition) `BEDC.Derived.StreamNameUp.RatStreamNameClassifier`

Theorem 126.3 (Rational stream-name carrier pointwise hsame transport)**.** *For certified observation maps* $s, s' : \mathsf{Hist} \to \mathsf{Hist}$*, if* $\mathsf{RatStreamNameCarrier}(s)$ *and*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(s(n), s'(n)),$$

then $\mathsf{RatStreamNameCarrier}(s')$*.*

Proof. Unfold Definition 126.1. It remains to show that each certified unary observation n carries a rational-history witness for $s'(n)$.

Fix such an observation, together with its unary witness ν. The source carrier supplies $\mathsf{RatHistoryCarrier}(s(n))$ at this same observation index.

The pointwise stability hypothesis supplies $\mathsf{hsame}(s(n), s'(n))$. Apply the RatUp carrier transport theorem RatHistoryCarrier_hsame_transport to the source rational-history carrier and this transport witness, obtaining $\mathsf{RatHistoryCarrier}(s'(n))$.

Since the observation was arbitrary, the transported rational-history carrier rows repack into the universal carrier row for $\mathsf{RatStreamNameCarrier}(s')$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameCarrier pointwise hsame transport`

Definition 126.4 (StreamName pointwise reindexing packet)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$, a $\mathsf{StreamNamePointwiseReindexing}(s, t)$ packet is a finite display*

$$(\rho, U, H, C, P)$$

where $\rho : \mathsf{Hist} \to \mathsf{Hist}$ is a certified unary-history reindexing map, U sends each $\mathsf{UnaryHistory}(n)$ row to a displayed $\mathsf{UnaryHistory}(\rho(n))$ row, H records pointwise hsame *transport for the endpoint histories $s(\rho(n))$ and $t(\rho(n))$, C records the displayed* Cont *replay of finite observation requests along ρ, and P is the* Pkg *provenance over* BHist, UnaryHistory, RatStreamNameCarrier, RatStreamNameClassifier, ProbeBundle, hsame, *and* Cont. *The packet has no coordinate for host sequence equality, quotient stream equality, selected limits, or ambient completion data.*

Theorem 126.5 (StreamName finite-window pullback stability)**.** *Let $s, t : \mathsf{Hist} \to \mathsf{Hist}$ be certified observation maps, let $\mathcal{P} : \mathsf{ProbeBundle}$ be a finite probe bundle, and let (ρ, U, H, C, P) be a $\mathsf{StreamNamePointwiseReindexing}(s, t)$ packet. If $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ holds and $\mathcal{P}^\rho$ is the displayed pullback bundle whose certified observations are exactly the n with $\rho(n)$ displayed in $\mathcal{P}$, then $\mathsf{RatStreamNameFiniteWindowClassifier}(s \circ \rho, t \circ \rho, \mathcal{P}^\rho)$ holds.*

For each pulled-back observation, the endpoint $\mathsf{Rat}^\uparrow$ classifier row is the same pointwise row read at $\rho(n)$ through U, H, C, P. The pullback introduces no new endpoint classifier, quotient stream equality, RegSeqRat seal, Real seal, host sequence equality, selected limit, or ambient completion coordinate.

Proof. Unfold the finite-window classifier for $\mathcal{P}^\rho$. Fix a certified unary observation n in the pulled-back bundle, together with its $\mathsf{UnaryHistory}(n)$ witness and its displayed membership row.

Use the reindexing packet. The row U sends the unary witness at n to a unary witness at $\rho(n)$, and the pullback membership row says that this reindexed observation lies in the original bundle $\mathcal{P}$.

Read the original finite-window classifier at $\rho(n)$. It returns the pointwise $\mathsf{RatHistoryClassifier}(s(\rho(n)), t(\rho(n)))$ row for the two endpoint rational histories.

Finally replay the endpoint row through H and C. These rows are componentwise hsame and displayed continuation data for the same rational histories, so the pointwise classifier repacks as the endpoint row of $\mathsf{RatStreamNameFiniteWindowClassifier}(s \circ \rho, t \circ \rho, \mathcal{P}^\rho)$. Since the packet contains only U, H, C, P over the listed BEDC rows, none of the refused objects can enter the pullback. □

Theorem 126.6 (StreamName constant section transport)**.** *Let $q : \mathsf{Hist}$ be a certified $\mathsf{Rat}^\uparrow$ history row, and let $s_q : \mathsf{Hist} \to \mathsf{Hist}$ be the constant certified stream with $s_q(n) = q$ at every displayed unary observation. For every $\mathsf{StreamNamePointwiseReindexing}(s_q, s_q)$ packet (ρ, U, H, C, P) and every finite probe bundle $\mathcal{P}$, the pulled-back constant section over $\mathcal{P}^\rho$ is again certified by the same constant* RatStreamNameCarrier *and the same pointwise $\mathsf{RatHistoryClassifier}(q, q)$ rows.*

Thus constant certified streams are stable under displayed pointwise pullback. The transport reads only UnaryHistory*,* BHist*,* RatStreamNameCarrier*,* RatStreamNameClassifier*,* ProbeBundle*,* hsame*,* Cont*, and* Pkg *rows, and it introduces no selected limit, quotient stream equality, host sequence equality, RegSeqRat seal, Real seal, or ambient completion datum.*

Proof. Project the constant stream carrier. At every displayed unary observation, both endpoints of the classifier are the same rational history row q.

Apply Definition 126.5 to the constant pair s_q, s_q. The pulled-back bundle $\mathcal{P}^\rho$ reads each observation by first applying ρ and then reading the same constant endpoint row.

The pointwise classifier is unchanged. Since $s_q(\rho(n)) = q$ and $s_q(n) = q$ at each displayed observation, the endpoint row after pullback is still $\mathsf{RatHistoryClassifier}(q, q)$, transported only by the supplied hsame and Cont rows.

The package provenance P names no further stream or completion coordinate. Hence the pulled-back section is the same constant certified stream on the pulled-back finite window. □

Ten-field fit: traditional target rational stream-name carrier transport; BEDC source RatUp plus StreamNameUp over BHist; carrier RatStreamNameCarrier; classifier untouched; stability pointwise hsame; ledger the observation index and transport witness; core theorem Definition 126.3; exactness preservation of the carrier predicate; standard bridge RegSeqRat/RealUp stream transport; status proof target.

Theorem 126.7 (Rational stream-name successor reindexing stability)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$*, define the successor observation schedules* $s^+, t^+ : \mathsf{Hist} \to \mathsf{Hist}$ *by*

$$s^+(n) = s(\mathsf{BHist.e1}(n)) \quad \textit{and} \quad t^+(n) = t(\mathsf{BHist.e1}(n)).$$

If $\mathsf{RatStreamNameCarrier}(s)$*, then* $\mathsf{RatStreamNameCarrier}(s^+)$*. If* $\mathsf{RatStreamNameClassifier}(s, t)$*, then* $\mathsf{RatStreamNameClassifier}(s^+, t^+)$ *and, for every probe bundle* $\mathcal{P} : \mathsf{ProbeBundle}$*,* RatStreamNameFiniteWindowCla

Proof. Let $r(n) = \mathsf{BHist.e1}(n)$. Unary successor closure sends every witness $\mathsf{UnaryHistory}(n)$ to a witness $\mathsf{UnaryHistory}(r(n))$.

Apply Definition 126.19 with this concrete reindexer r and the identity RatUp-preserving point map. The reindexing clauses turn $\mathsf{RatStreamNameCarrier}(s)$ into the carrier row for $s^+ = s \circ r$, and turn $\mathsf{RatStreamNameClassifier}(s, t)$ into the classifier row for s^+, t^+.

Finally fix a probe bundle $\mathcal{P}$. Applying Definition 126.22 to the successor classifier projects every bundled certified unary observation to the RatUp point classifier $\mathsf{RatHistoryClassifier}(s^+(n), t^+(n))$, which is exactly the finite-window classifier row for s^+, t^+ on $\mathcal{P}$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName successor reindexing stability`

Ten-field fit: traditional target tail/successor rational stream observations; BEDC source BHist, UnaryHistory, RatUp, and StreamNameUp; carrier RatStreamNameCarrier after successor reindexing; classifier RatStreamNameClassifier after successor reindexing; stability successor reindexing plus finite-window restriction; ledger successor observation token and bundled probe membership; core theorem Definition 126.7; exactness preservation of pointwise RatUp classification; standard bridge rational sequence tail observation; status proof target.

Theorem 126.8 (Rational stream-name transported successor reindexing stability)**.** *For certified observation maps* $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$*, define the transported successor observation schedules* $(s')^+, (t')^+ : \mathsf{Hist} \to \mathsf{Hist}$ *by*

$$(s')^+(n) = s'(\mathsf{BHist.e1}(n)) \quad \textit{and} \quad (t')^+(n) = t'(\mathsf{BHist.e1}(n)).$$

If $\mathsf{RatStreamNameClassifier}(s,t)$ *and*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(s(n), s'(n)),$$

and

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(t(n), t'(n)),$$

then $\mathsf{RatStreamNameClassifier}((s')^+, (t')^+)$ *and, for every probe bundle* $\mathcal{P} : \mathsf{ProbeBundle}$, $\mathsf{RatStreamNameFiniteWind}$

Proof. First transport the endpoint carriers. Apply Definition 126.3 to the left endpoint of $\mathsf{RatStreamNameClassifier}(s,t)$ and the pointwise hsame row from s to s'. Apply the same theorem to the right endpoint and the pointwise hsame row from t to t'.

Next transport the pointwise classifier. At a certified unary index n, the source classifier gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$. The two hsame rows move its endpoints to $s'(n)$ and $t'(n)$, so the RatUp classifier transport repacks the pointwise clause for $\mathsf{RatStreamNameClassifier}(s', t')$.

Now apply Definition 126.7 to the transported classifier and the transported left carrier. Its successor reindexing row gives $\mathsf{RatStreamNameClassifier}((s')^+, (t')^+)$.

Finally fix a probe bundle $\mathcal{P}$. The finite-window projection in Definition 126.7 reads every bundled unary probe through the same transported successor schedules, giving $\mathsf{RatStreamNameFiniteWindowClassifier}((s$

□

Ten-field fit: traditional target transported rational stream-name successor observations; BEDC source RatUp, StreamNameUp, BHist, and $\mathsf{UnaryHistory}$; carrier transported $\mathsf{RatStreamNameCarrier}$ endpoints; classifier transported $\mathsf{RatStreamNameClassifier}$ endpoints; stability pointwise hsame followed by successor reindexing; ledger unary successor observation token and $\mathsf{ProbeBundle}$ membership; core theorem Definition 126.8; exactness preservation of pointwise RatUp classification; standard bridge finite-window tail observation for RegSeqRat and RealUp; status paper theorem awaiting formal target.

Theorem 126.9 (Rational stream-name finite-window subwindow restriction)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$ *and probe bundles* $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$*, suppose that* $\mathsf{RatStreamNameFiniteWindowClass}$ *holds and that every certified unary observation displayed by* $\mathcal{Q}$ *is also displayed by* $\mathcal{P}$*:*

$$\forall n,\ \mathsf{InBundle}(\mathcal{Q}, n) \wedge \mathsf{UnaryHistory}(n) \to \mathsf{InBundle}(\mathcal{P}, n) \wedge \mathsf{UnaryHistory}(n).$$

Then $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ *holds.*

Proof. Unfold the finite-window classifier. To certify the $\mathcal{Q}$ window, fix a bundled observation n together with its $\mathsf{InBundle}(\mathcal{Q}, n)$ row and its $\mathsf{UnaryHistory}(n)$ witness.

The displayed inclusion row sends this same certified unary observation into the $\mathcal{P}$ window. The original $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ can therefore be read at n.

Projecting that read gives the pointwise RatUp classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$. Since the choice of the $\mathcal{Q}$ observation was arbitrary, these projected point classifiers repack into $\mathsf{RatStreamNameFiniteWind}$

□

Ten-field fit: traditional target finite rational stream observation windows for RegSeqRat and RealUp; BEDC source RatUp, StreamNameUp, BHist, $\mathsf{UnaryHistory}$, and $\mathsf{ProbeBundle}$; carrier the endpoint $\mathsf{RatStreamNameCarrier}$ rows already read by the finite window; classifier $\mathsf{RatStreamNameFiniteWindowClass}$ stability subwindow restriction along the displayed probe inclusion; ledger the two bundle membership rows and the unary observation certificate; core theorem Definition 126.9; exactness pointwise projection to $\mathsf{RatHistoryClassifier}$; standard bridge finite prefix consumers in RegSeqRat and RealUp; status paper theorem awaiting formal target.

Theorem 126.10 (Rational stream-name finite-window union classifier)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$ *and probe bundles* $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$*, suppose that* $\mathsf{RatStreamNameFiniteWindowClassifier}(s,$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ *hold. Let* $\mathcal{P} \cup \mathcal{Q}$ *be the displayed union bundle whose members are exactly the certified unary observations coming from* $\mathcal{P}$ *or from* $\mathcal{Q}$*:*

$$\mathsf{InBundle}(\mathcal{P}\cup\mathcal{Q}, n)\wedge\mathsf{UnaryHistory}(n) \quad \textit{iff} \quad (\mathsf{InBundle}(\mathcal{P}, n)\wedge\mathsf{UnaryHistory}(n))\vee(\mathsf{InBundle}(\mathcal{Q}, n)\wedge\mathsf{UnaryHistory}(n)).$$

Then $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P} \cup \mathcal{Q})$ *holds.*

Proof. Unfold the finite-window classifier for the union bundle. Fix a certified unary observation n in $\mathcal{P} \cup \mathcal{Q}$ and read the displayed union membership row.

There are two cases. If the row comes from $\mathcal{P}$, the classifier $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ projects at n to the pointwise RatUp classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

If the row comes from $\mathcal{Q}$, the second finite-window classifier gives the same kind of pointwise certificate $\mathsf{RatHistoryClassifier}(s(n), t(n))$ at the same unary observation.

In either case the required pointwise classifier is available for the fixed union observation. Since the observation was arbitrary, these pointwise RatHistoryClassifier rows repack into RatStreamNameFiniteWindowClas $\mathcal{Q}$). □

Ten-field fit: traditional target finite rational stream-name observation composition for RegSeqRat and RealUp; BEDC source RatUp, StreamNameUp, BHist, UnaryHistory, and ProbeBundle; carrier the same displayed RatStreamNameCarrier endpoints read by the two windows; classifier RatStreamNameFiniteWindowClassifier on $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{P} \cup \mathcal{Q}$; stability union membership case analysis over certified unary observations; ledger the two bundle membership rows and their shared unary observation certificate; core theorem Definition 126.10; exactness pointwise projection to RatHistoryClassifier; standard bridge finite-prefix consumer for RegSeqRat and RealUp; status paper theorem awaiting formal target.

Theorem 126.11 (Rational stream-name finite-window union endpoint exhaustion)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$ *and certified probe bundles* $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$*, suppose that* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ *hold. Let* $\mathcal{P} \cup \mathcal{Q}$ *be the union bundle whose certified unary membership rows are exactly those displayed in Definition 126.10. Then every endpoint row visible to a RegSeqRat or RealUp finite-window consumer over* $\mathcal{P} \cup \mathcal{Q}$ *is generated by either an* $\mathsf{InBundle}(\mathcal{P}, n)$ *row or an* $\mathsf{InBundle}(\mathcal{Q}, n)$ *row, together with the same* $\mathsf{UnaryHistory}(n)$ *witness. In both cases the endpoint certificate is exactly the pointwise classifier* $\mathsf{RatHistoryClassifier}(s(n), t(n))$*.*

Consequently the union consumer has no additional endpoint source beyond the two displayed bundle memberships, and it introduces no RegSeqRat regularity row, RealUp seal, quotient, or host-index equality row.

Proof. Fix a finite-window consumer row over $\mathcal{P}\cup\mathcal{Q}$. By the displayed union membership condition in Definition 126.10, the visible certified unary observation has a witness $\mathsf{UnaryHistory}(n)$ and lies in one of the two generated membership cases needed for the argument: it is read from $\mathsf{InBundle}(\mathcal{P}, n)$ or from $\mathsf{InBundle}(\mathcal{Q}, n)$.

In the $\mathcal{P}$ case, apply Definition 126.10 to view the row as part of the union classifier and apply Definition 126.9 along the displayed inclusion of the $\mathcal{P}$ subwindow. The resulting endpoint is the pointwise certificate $\mathsf{RatHistoryClassifier}(s(n), t(n))$ carried with the same $\mathsf{UnaryHistory}(n)$ witness.

The $\mathcal{Q}$ case is identical, using the displayed inclusion of the $\mathcal{Q}$ subwindow. The subwindow restriction again returns precisely $\mathsf{RatHistoryClassifier}(s(n), t(n))$ at the same unary observation.

These two cases exhaust the union membership row. Since the only endpoint certificates obtained are the two pointwise RatUp classifier reads, the consumer cannot acquire a RegSeqRat regularity condition, a RealUp seal, a quotient row, or a host-index equality row from the union construction. □

Theorem 126.12 (Rational stream-name classifier unary context one-tail pair readback)**.** *If* $\mathsf{RatStreamNameClassifier}(s, t)$ *holds at a unary observation* n*, matching unary prefix and tail contexts are presented by continuation displays, and the two outputs are one-extension histories, then the displayed tails are unary and internally the same.*

Proof. Read the stream-name classifier at the certified observation n. This gives the RatUp point classifier for $s(n)$ and $t(n)$. Apply the RatUp continuation context one-tail pair readback theorem to that point classifier and the four continuation displays. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameClassifier unary context e1 pair readback`

126.2 The certificate

Theorem 126.13 (Rational stream-name certificate fields)**.** *For certified observation maps* $s, t, u : \mathsf{Hist} \to \mathsf{Hist}$*, the carrier and classifier above supply the rational stream-name certificate fields:*

1. $\mathsf{RatStreamNameCarrier}(s)$ *implies* $\mathsf{RatStreamNameClassifier}(s, s)$.
2. $\mathsf{RatStreamNameClassifier}(s, t)$ *implies* $\mathsf{RatStreamNameClassifier}(t, s)$.
3. $\mathsf{RatStreamNameClassifier}(s, t)$ *and* $\mathsf{RatStreamNameClassifier}(t, u)$ *imply* $\mathsf{RatStreamNameClassifier}(s, u)$.
4. $\mathsf{RatStreamNameClassifier}(s, t)$ *implies, for every* n *with* $\mathsf{UnaryHistory}(n)$*, both* $\mathsf{RatHistoryCarrier}(s(n))$ *and* $\mathsf{RatHistoryCarrier}(t(n))$.
5. *If* $\mathsf{RatStreamNameClassifier}(s, t)$ *and streams* s', t' *satisfy* $\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(s(n), s'(n))$ *and* $\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(t(n), t'(n))$*, then* $\mathsf{RatStreamNameClassifier}(s', t')$.

Proof. For reflexivity, the two endpoint carrier rows of $\mathsf{RatStreamNameClassifier}(s, s)$ are both the supplied carrier of s. For its pointwise classifier row, fix a certified observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$. The carrier gives $\mathsf{RatHistoryCarrier}(s(n))$ from ν, and RatUp classifier reflexivity turns that pointwise rational witness into $\mathsf{RatHistoryClassifier}(s(n), s(n))$.

For symmetry, unpack the supplied stream classifier into its carrier rows for s and t and its pointwise classifier row. The reversed classifier uses the t carrier as its first carrier row and the s carrier as its second carrier row. For the pointwise row, fix (n, ν) and apply RatUp rational-history classifier symmetry to the projected point classifier at (n, ν).

For transitivity, unpack $\mathsf{RatStreamNameClassifier}(s, t)$ and $\mathsf{RatStreamNameClassifier}(t, u)$. The resulting classifier from s to u uses the first carrier row of the first bundle and the second carrier row of the second bundle. For the pointwise row, fix (n, ν) and compose the two projected point classifiers at (n, ν) by RatUp rational-history classifier transitivity.

For endpoint carriers, fix a certified observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$. Project the two bundled carrier rows of $\mathsf{RatStreamNameClassifier}(s, t)$ and read them at (n, ν); these are exactly the rational-history carrier witnesses required at the two endpoint observations.

For transport, first transport the two bundled carrier rows along the supplied history-sameness witnesses, producing $\mathsf{RatStreamNameCarrier}(s')$ and $\mathsf{RatStreamNameCarrier}(t')$. For the pointwise row, fix (n, ν) and apply BEDC.Derived.RatUp.RatHistoryClassifier_hsame_transport to the projected point classifier at (n, ν) and to the two supplied endpoint history-sameness witnesses

at (n, ν). The transported carrier rows and the transported pointwise classifier row repack as $\mathsf{RatStreamNameClassifier}(s', t')$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName certificate fields`

Theorem 126.14 (Rational stream-name observation one-tail pair readback)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$, if $\mathsf{RatStreamNameClassifier}(s, t)$ and n is a unary observation, then displayed one-extension endpoints*

$$\mathsf{hsame}(s(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t(n), \mathsf{E1}(b))$$

determine unary tails with the internal comparison

$$\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b).$$

Proof. Read the stream-name classifier at the certified observation n. Transport the resulting RatUp point classifier to the displayed one-extension endpoints, then apply rational one-tail classifier exactness. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameClassifier observation e1 pair readback`

Theorem 126.15 (Rational stream-name observation shape exclusions)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$ and an observation history n, suppose*

$$\mathsf{RatStreamNameClassifier}(s, t) \quad \textit{and} \quad \mathsf{UnaryHistory}(n).$$

Then the selected observations satisfy the positive-denominator and unary endpoint package

$$\mathsf{PositiveUnaryDenominator}(s(n)) \wedge \mathsf{PositiveUnaryDenominator}(t(n)) \wedge \mathsf{UnaryHistory}(s(n)) \wedge \mathsf{UnaryHistory}(t(n)).$$

They also satisfy the two empty-history exclusions

$$(\mathsf{hsame}(s(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{e}) \to \mathsf{False}),$$

and for all histories $z_s, z_t : \mathsf{Hist}$ the two zero-headed exclusions

$$(\mathsf{hsame}(s(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{E0}(z_t)) \to \mathsf{False}).$$

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameClassifier observation shape exclusions`

Proof. Read the stream-name classifier at the certified observation (n, ν), where $\nu : \mathsf{UnaryHistory}(n)$. Apply Definition 37.50 to this point classifier. This gives positive unary denominator witnesses for $s(n)$ and $t(n)$.

Apply Definition 37.12 separately to the two positive denominator witnesses. The unary components give $\mathsf{UnaryHistory}(s(n))$ and $\mathsf{UnaryHistory}(t(n))$, and the nonempty components give the two exclusions against e.

For a displayed zero-headed shape $\mathsf{hsame}(s(n), \mathsf{E0}(z_s))$, transport the positive denominator witness for $s(n)$ across that sameness by Definition 37.6. The transported witness contradicts Definition 37.10. The argument for $\mathsf{hsame}(t(n), \mathsf{E0}(z_t))$ is identical, using the positive denominator witness for $t(n)$. □

Theorem 126.16 (Rational stream-name observation full endpoint package)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$*, an observation history* n*, and histories* $a, b : \mathsf{Hist}$*, suppose*

$$\mathsf{RatStreamNameClassifier}(s, t) \quad \textit{and} \quad \mathsf{UnaryHistory}(n),$$

and suppose the selected observations are displayed as one-extension endpoints

$$\mathsf{hsame}(s(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t(n), \mathsf{E1}(b)).$$

Then the following selected-observation endpoint package holds:

1. $\mathsf{RatHistoryClassifier}(s(n), t(n))$.
2. $\mathsf{PositiveUnaryDenominator}(s(n)) \wedge \mathsf{PositiveUnaryDenominator}(t(n))$.
3. $\mathsf{UnaryHistory}(s(n)) \wedge \mathsf{UnaryHistory}(t(n))$.
4. $(\mathsf{hsame}(s(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{e}) \to \mathsf{False})$.
5. *For all histories* $z_s, z_t : \mathsf{Hist}$, $(\mathsf{hsame}(s(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{E0}(z_t)) \to \mathsf{False})$.
6. $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameClassifier observation full endpoint package`

Proof. Unpack Definition 126.2 at the certified observation (n, ν), where $\nu : \mathsf{UnaryHistory}(n)$. The pointwise row gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Apply Definition 126.15 to the same stream classifier and unary observation. This supplies the two positive unary denominator rows, the unary-history rows for the selected observations, the empty-history exclusions, and the zero-headed exclusions for arbitrary z_s, z_t.

Apply Definition 126.14 to the stream classifier, the unary observation, and the two displayed one-extension endpoint rows. This gives $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

The point classifier, the shape rows, and the one-tail readback rows are exactly the listed endpoint package. □

Fit. Traditional target: selected rational-stream observation endpoint package. BEDC source: $\mathsf{Rat}^{\uparrow}$+$\mathsf{StreamName}^{\uparrow}$ over BHist. Carrier: $\mathsf{RatStreamNameCarrier}$. Classifier: $\mathsf{RatStreamNameClassifier}$. Stability: pointwise hsame endpoint display at the selected unary observation. Ledger: the selected observation, the two one-extension displays, and arbitrary zero-headed probes. Core theorem: Definition 126.16. Exactness: rational point classifier, endpoint shape exclusions, and one-tail equality readback. Standard bridge: $\mathsf{Real}^{\uparrow}$ contextual endpoint certificates consume this selected-observation package. Status: $\mathsf{ProofTarget}$.

Theorem 126.17 (Rational stream-name transported observation shape exclusions)**.** *For certified observation maps* $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ *and an observation history* n*, suppose*

$$\mathsf{RatStreamNameClassifier}(s, t) \quad \textit{and} \quad \mathsf{UnaryHistory}(n),$$

and suppose the selected endpoints are related pointwise by transport rows

$$\forall k,\ \mathsf{UnaryHistory}(k) \to \mathsf{hsame}(s(k), s'(k)), \quad \forall k,\ \mathsf{UnaryHistory}(k) \to \mathsf{hsame}(t(k), t'(k)).$$

Then the transported selected observations satisfy the positive-denominator and unary endpoint package

$$\mathsf{PositiveUnaryDenominator}(s'(n)) \wedge \mathsf{PositiveUnaryDenominator}(t'(n)) \wedge \mathsf{UnaryHistory}(s'(n)) \wedge \mathsf{UnaryHistory}(t'(n)).$$

They also satisfy the two empty-history exclusions

$$(\mathsf{hsame}(s'(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{e}) \to \mathsf{False}),$$

and for all histories $z_s, z_t : \mathsf{Hist}$ *the two zero-headed exclusions*

$$(\mathsf{hsame}(s'(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{E0}(z_t)) \to \mathsf{False}).$$

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameClassifier transported observation shape exclusions`

Proof. Read the stream-name classifier at the certified observation (n, ν), where $\nu : \mathsf{UnaryHistory}(n)$. This gives the point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Apply Definition 37.54 to this classifier and to the two pointwise transport rows evaluated at n. The result is the transported selected classifier $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$.

Apply Definition 37.50 to the transported selected classifier. Then apply Definition 37.12 separately to the two positive-denominator witnesses. These rows give the displayed positive denominators, unary endpoint witnesses, and exclusions against e.

It remains to exclude zero-headed displays. If $\mathsf{hsame}(s'(n), \mathsf{E0}(z_s))$ holds, transport $\mathsf{PositiveUnaryDenominator}(s'$ along that sameness by Definition 37.6, then contradict Definition 37.10. The same argument applied to $t'(n)$ and z_t gives the second zero-headed exclusion. □

Fit. Traditional target: transported selected rational-stream observation. BEDC source: $\mathsf{Rat}^{\uparrow}+\mathsf{StreamName}^{\uparrow}$ over BHist. Carrier: $\mathsf{RatStreamNameCarrier}$. Classifier: $\mathsf{RatStreamNameClassifier}$. Stability: pointwise hsame transport. Ledger: the selected observation and two transport rows. Core theorem: Definition 126.17. Exactness: the displayed shape package. Standard bridge: pointwise rational stream equality under observation transport. Status: $\mathsf{ProofTarget}$.

Theorem 126.18 (Rational stream-name transported observation full endpoint package)**.** *For certified observation maps* $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$*, an observation history* n*, and histories* $a, b, z_s, z_t : \mathsf{Hist}$*, suppose*

$$\mathsf{RatStreamNameClassifier}(s, t) \quad \textit{and} \quad \mathsf{UnaryHistory}(n),$$

suppose the selected endpoints are related pointwise by transport rows

$$\forall k,\ \mathsf{UnaryHistory}(k) \to \mathsf{hsame}(s(k), s'(k)), \quad \forall k,\ \mathsf{UnaryHistory}(k) \to \mathsf{hsame}(t(k), t'(k)),$$

and suppose the transported selected observations are displayed as one-extension endpoints

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n), \mathsf{E1}(b)).$$

Then the transported selected-observation endpoint package holds:

1. $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$.
2. $\mathsf{PositiveUnaryDenominator}(s'(n)) \wedge \mathsf{PositiveUnaryDenominator}(t'(n))$.
3. $\mathsf{UnaryHistory}(s'(n)) \wedge \mathsf{UnaryHistory}(t'(n))$.
4. $(\mathsf{hsame}(s'(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{e}) \to \mathsf{False})$.
5. $(\mathsf{hsame}(s'(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{E0}(z_t)) \to \mathsf{False})$.
6. $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

Proof. Unpack Definition 126.2 at the certified observation (n, ν), where $\nu : \mathsf{UnaryHistory}(n)$. The pointwise row gives the source point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Apply Definition 37.54 to this source classifier and to the two pointwise transport rows evaluated at n. This gives the transported point classifier $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$.

Apply Definition 126.17 to the same stream classifier, unary observation, and transport rows. It supplies the transported positive-denominator rows, unary endpoint rows, empty exclusions, and universal zero-headed exclusions. Instantiate the last two rows at the displayed histories z_s and z_t.

For the one-tail readback, transport $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$ along the two displayed one-extension endpoint comparisons. The transported classifier is $\mathsf{RatHistoryClassifier}(\mathsf{E1}(a), \mathsf{E1}(b))$.

Apply Definition 37.49 in the forward direction to read back $\mathsf{UnaryHistory}(a)$, $\mathsf{UnaryHistory}(b)$, and $\mathsf{hsame}(a, b)$. The transported point classifier, transported shape rows, and one-tail readback rows form exactly the listed endpoint package. □

Theorem 126.19 (Rational stream-name reindexing and map stability)**.** *For certified observation maps $s, t, r : \mathsf{Hist} \to \mathsf{Hist}$, suppose r preserves certified unary observations:*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{UnaryHistory}(r(n)).$$

Then $\mathsf{RatStreamNameCarrier}(s)$ *implies* $\mathsf{RatStreamNameCarrier}(s \circ r)$*, and* $\mathsf{RatStreamNameClassifier}(s, t)$ *implies* $\mathsf{RatStreamNameClassifier}(s \circ r, t \circ r)$*.*

For a history map $F : \mathsf{Hist} \to \mathsf{Hist}$, suppose F preserves RatUp carriers and classifiers:

$$\forall h,\ \mathsf{RatHistoryCarrier}(h) \to \mathsf{RatHistoryCarrier}(F(h))$$

and

$$\forall h, k,\ \mathsf{RatHistoryClassifier}(h, k) \to \mathsf{RatHistoryClassifier}(F(h), F(k)).$$

Then $\mathsf{RatStreamNameCarrier}(s)$ *implies* $\mathsf{RatStreamNameCarrier}(F \circ s)$*, and* $\mathsf{RatStreamNameClassifier}(s, t)$ *implies* $\mathsf{RatStreamNameClassifier}(F \circ s, F \circ t)$*.*

Proof. For reindexing, unfold RatStreamNameCarrier. Fix an observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$. The reindexer hypothesis turns ν into a certified unary observation witness for $r(n)$, and the carrier of s gives the required rational-history carrier at $s(r(n))$.

For the reindexed classifier, unfold RatStreamNameClassifier and fix the same certified observation data (n, ν). The reindexer hypothesis again supplies $\mathsf{UnaryHistory}(r(n))$, so the classifier of s and t can be read at $r(n)$, giving the point classifier between $s(r(n))$ and $t(r(n))$.

For mapped streams, unfold RatStreamNameCarrier and fix n with witness $\nu : \mathsf{UnaryHistory}(n)$. The carrier of s gives $\mathsf{RatHistoryCarrier}(s(n))$, and the carrier-preservation hypothesis for F transports it to $\mathsf{RatHistoryCarrier}(F(s(n)))$.

For mapped classifiers, unfold RatStreamNameClassifier and fix n with witness $\nu : \mathsf{UnaryHistory}(n)$. The classifier of s and t gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$, and the classifier-preservation hypothesis for F transports it to $\mathsf{RatHistoryClassifier}(F(s(n)), F(t(n)))$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName reindexing and map stability`

Theorem 126.20 (Rational stream-name reindexing composition law)**.** *For certified observation maps $s, t, r, q : \mathsf{Hist} \to \mathsf{Hist}$, suppose r and q preserve certified unary observations:*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{UnaryHistory}(r(n))$$

and

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{UnaryHistory}(q(n)).$$

Then the composite observation map $n \mapsto q(r(n))$ preserves certified unary observations. Consequently, $\mathsf{RatStreamNameCarrier}(s)$ *implies* $\mathsf{RatStreamNameCarrier}(s \circ q \circ r)$*, and* $\mathsf{RatStreamNameClassifier}(s, t)$ *implies* $\mathsf{RatStreamNameClassifier}(s \circ q \circ r, t \circ q \circ r)$*.*

Proof. Fix a certified observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$. The preservation witness for r sends ν to a certified unary observation witness for $r(n)$, and the preservation witness for q sends that result to a certified unary observation witness for $q(r(n))$. This proves unary preservation for the composite observation map.

For the carrier consequence, unfold $\mathsf{RatStreamNameCarrier}$ and fix the same certified observation data (n, ν). The composite unary witness just constructed lets the carrier of s be read at $q(r(n))$, giving the required rational-history carrier at $(s \circ q \circ r)(n)$.

For the classifier consequence, unfold $\mathsf{RatStreamNameClassifier}$ and fix (n, ν). The composite unary witness again lets the classifier of s and t be read at $q(r(n))$, yielding the point classifier between $(s \circ q \circ r)(n)$ and $(t \circ q \circ r)(n)$. □

Definition 126.21 (Rational stream-name finite probe window)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$ and a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, define* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *to mean that every bundled certified unary observation is classified pointwise:*

$$\forall n : \mathsf{Hist}, \mathsf{InBundle}(n, \mathcal{P}) \to \mathsf{UnaryHistory}(n) \to \mathsf{RatHistoryClassifier}(s(n), t(n)).$$

Theorem 126.22 (Rational stream-name classifier covers finite probe windows)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$ and every probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$,*

$$\mathsf{RatStreamNameClassifier}(s, t) \Longrightarrow \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}).$$

Proof. Unfold Definition 126.2 and fix a history n with evidence $\mathsf{InBundle}(n, \mathcal{P})$ and $\mathsf{UnaryHistory}(n)$. The stream-name classifier is pointwise on every certified unary observation, so its row at n gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Since the bundled history and unary witness were arbitrary, these pointwise RatUp classifier rows repack exactly as $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$. □

Theorem 126.23 (Rational stream-name finite windows exhaust the classifier)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$,*

$$\mathsf{RatStreamNameClassifier}(s, t) \Longleftrightarrow \forall n : \mathsf{Hist},\ \mathsf{UnaryHistory}(n) \to \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{Bcons}(n$$

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier exhausts classifier`

Proof. For the forward implication, fix a certified unary observation n. Apply Definition 126.22 to the full stream-name classifier and to the singleton bundle $\mathsf{Bcons}(n, \mathsf{Bnil})$. This gives the required finite-window classifier at that observation.

For the reverse implication, fix a certified unary observation n. The singleton-window hypothesis at n, together with the head membership of n in $\mathsf{Bcons}(n, \mathsf{Bnil})$ from Definition 6.1, gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

The carrier fields of this RatUp classifier provide $\mathsf{RatHistoryCarrier}(s(n))$ and $\mathsf{RatHistoryCarrier}(t(n))$. Since n was arbitrary, these fields assemble the two stream-name carriers, and the same pointwise RatUp classifier rows assemble $\mathsf{RatStreamNameClassifier}(s, t)$. □

The ten-field fit is: traditional target finite-window exhaustion; BEDC source $\mathsf{Rat}^{\uparrow}+\mathsf{StreamName}^{\uparrow}+\mathsf{ProbeBundle}$; carrier the existing stream-name carrier rows for s and t; classifier the existing pointwise stream-name classifier row; stability singleton-window coverage over certified unary observations; ledger the singleton observation bundle $\mathsf{Bcons}(n, \mathsf{Bnil})$; core theorem Definition 126.22; exactness singleton membership in the probe bundle; downstream $\mathsf{Real}^{\uparrow}/\mathsf{RegSeqRat}$ finite-prefix consumption; status $\mathsf{ProofTarget}$.

Theorem 126.24 (Rational stream-name finite-window coverage after certified reindexing and point maps)**.** *For certified observation maps $s, t, r : \mathsf{Hist} \to \mathsf{Hist}$, a history point map $F : \mathsf{Hist} \to \mathsf{Hist}$, and a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, suppose r preserves certified unary observations:*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{UnaryHistory}(r(n)).$$

Suppose also that F preserves RatUp carriers and classifiers:

$$\forall h,\ \mathsf{RatHistoryCarrier}(h) \to \mathsf{RatHistoryCarrier}(F(h))$$

and

$$\forall h, k,\ \mathsf{RatHistoryClassifier}(h, k) \to \mathsf{RatHistoryClassifier}(F(h), F(k)).$$

If $\mathsf{RatStreamNameClassifier}(s, t)$*, then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(F \circ s \circ r, F \circ t \circ r, \mathcal{P}).$$

Proof. First apply Definition 126.19 to the observation reindexer r. The reindexing row sends the given stream-name classifier for s and t to a classifier for $s \circ r$ and $t \circ r$.

Apply the mapped-classifier row of the same theorem to the point map F and to the reindexed classifier just obtained. The carrier-preservation hypothesis is part of that stability package, while the classifier-preservation hypothesis transports every RatUp point classifier through F. This yields $\mathsf{RatStreamNameClassifier}(F \circ s \circ r, F \circ t \circ r)$.

Finally apply Definition 126.22 to this transported stream-name classifier and the selected probe bundle $\mathcal{P}$. The result is precisely the displayed finite-window classifier for the reindexed and point-mapped observation streams. □

The ten-field fit is: traditional target finite certified observation windows; BEDC source $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow} + \mathsf{ProbeBundle}$; carrier observation maps; classifier finite probe-window restriction of the stream classifier; stability pointwise classifier projection; ledger the bundle and selected observation; core theorem Definition 126.22 and Definition 126.24; exactness pointwise RatUp classification on bundled unary observations; standard bridge finite prefixes of rational streams; status $\mathsf{ProofTarget}$.

Theorem 126.25 (Rational stream-name finite-window structural laws)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$ and probe bundles $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$, the finite-window classifier has the following structural laws.*

1. *If every bundled observation of $\mathcal{Q}$ is also bundled in $\mathcal{P}$, then* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *implies* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$.
2. $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q}))$ *implies both* $\mathsf{RatStreamNameFiniteWindowClassi}$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$.
3. *If the finite-window classifier holds on $\mathcal{P}$ and on $\mathcal{Q}$, then it holds on* $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$.

Proof. Unfold Definition 126.21. For the subbundle law, fix an arbitrary history n with $\mathsf{InBundle}(n, \mathcal{Q})$ and a unary witness $\mathsf{UnaryHistory}(n)$. The assumed subbundle map transports the bundle membership from $\mathcal{Q}$ to $\mathcal{P}$, and the classifier on $\mathcal{P}$ gives $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

For the two projections from an appended bundle, fix n first with $\mathsf{InBundle}(n, \mathcal{P})$ and then with $\mathsf{InBundle}(n, \mathcal{Q})$. In each case the append membership lemma for $\mathsf{bundleAppend}$ injects the selected membership into $\mathsf{InBundle}(n, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q}))$. The classifier on the appended bundle then supplies the corresponding point RatUp classifier row.

For recomposition, fix n with membership in $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$ and a unary witness. The kernel equivalence for appended bundles rewrites this membership as a left-or-right membership alternative. In the left case apply the classifier on $\mathcal{P}$; in the right case apply the classifier on $\mathcal{Q}$. Both cases yield the same required conclusion $\mathsf{RatHistoryClassifier}(s(n), t(n))$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier structural laws`

Theorem 126.26 (Rational stream-name finite-window selected zero-head exclusion)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, an observation history n, and histories $z_s, z_t : \mathsf{Hist}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \quad \mathsf{InBundle}(n, \mathcal{P}), \quad \mathsf{UnaryHistory}(n).$$

Then the selected finite-window endpoints cannot be zero-headed:

$$(\mathsf{hsame}(s(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{E0}(z_t)) \to \mathsf{False}).$$

Proof. Unfold Definition 126.21 at the selected observation n, its bundle membership, and its unary witness. This produces the selected RatUp point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Apply Definition 37.50 to this selected classifier. The result supplies positive-denominator witnesses for both selected endpoint histories $s(n)$ and $t(n)$.

For the left endpoint, assume a displayed zero-headed comparison $\mathsf{hsame}(s(n), \mathsf{E0}(z_s))$. Transport the positive-denominator witness for $s(n)$ along that comparison by Definition 37.6. The transported witness contradicts Definition 37.10.

For the right endpoint, the same argument applied to $\mathsf{hsame}(t(n), \mathsf{E0}(z_t))$ transports the positive-denominator witness for $t(n)$ to a zero-headed denominator witness, again contradicting Definition 37.10. These two contradictions give the displayed conjunction. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier selected zero head exclusion`

The compact ten-field fit is: traditional target finite rational observation endpoint sanity; BEDC source $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow} + \mathsf{ProbeBundle}$; carrier observation maps; classifier finite-window restriction; ledger selected probe observation; exactness selected RatUp point classification; downstream $\mathsf{Real}^{\uparrow}/\mathsf{RegSeqRat}$ selected endpoint normalization; standard bridge ordinary finite rational stream endpoints; status $\mathsf{ProofTarget}$.

Theorem 126.27 (Rational stream-name finite-window selected full endpoint package)**.** *For certified observation maps $s, t : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, an observation history n, and histories $a, b, z_s, z_t : \mathsf{Hist}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \quad \mathsf{InBundle}(n, \mathcal{P}), \quad \mathsf{UnaryHistory}(n),$$

and suppose the selected observations are displayed as one-extension endpoints

$$\mathsf{hsame}(s(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t(n), \mathsf{E1}(b)).$$

Then the selected finite-window endpoints carry the full endpoint package:

1. $\mathsf{RatHistoryClassifier}(s(n), t(n))$.
2. $\mathsf{PositiveUnaryDenominator}(s(n)) \wedge \mathsf{PositiveUnaryDenominator}(t(n))$.
3. $\mathsf{UnaryHistory}(s(n)) \wedge \mathsf{UnaryHistory}(t(n))$.
4. $(\mathsf{hsame}(s(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{e}) \to \mathsf{False})$.
5. $(\mathsf{hsame}(s(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t(n), \mathsf{E0}(z_t)) \to \mathsf{False})$.
6. $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

Proof. Unfold Definition 126.21 at the selected observation n, its bundle membership, and its unary witness. This gives the selected point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Apply Definition 37.50 to this selected classifier. Then apply Definition 37.12 separately to the two positive-denominator witnesses. These rows give the two positive denominators, the two unary endpoint histories, and the two exclusions against e.

It remains to exclude zero-headed displays. If $\mathsf{hsame}(s(n), \mathsf{E0}(z_s))$ holds, transport the positive-denominator witness for $s(n)$ along that sameness by Definition 37.6, then contradict Definition 37.10. The same argument applied to $t(n)$ and z_t gives the second zero-headed exclusion.

For the one-tail readback, transport the selected point classifier across the two displayed one-extension endpoint comparisons, using Definition 37.54. The transported classifier is $\mathsf{RatHistoryClassifier}(\mathsf{E1}(a), \mathsf{E1}(b$

Apply Definition 37.49 in the forward direction to read back $\mathsf{UnaryHistory}(a)$, $\mathsf{UnaryHistory}(b)$, and $\mathsf{hsame}(a, b)$. The selected classifier, shape rows, zero-headed exclusions, and one-tail readback rows are exactly the listed endpoint package. □

Theorem 126.28 (Rational stream-name finite-window stability fields)**.** *For certified observation maps $s, t, u, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ and a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, the finite-window classifier has the following stability fields.*

1. *If every bundled unary observation of s is carried,*

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{P}) \to \mathsf{UnaryHistory}(n) \to \mathsf{RatHistoryCarrier}(s(n)),$$

   then $\mathsf{RatStreamNameFiniteWindowClassifier}(s, s, \mathcal{P})$.

2. $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *implies* $\mathsf{RatStreamNameFiniteWindowClassifier}(t, s, \mathcal{P})$.
3. $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(t, u, \mathcal{P})$ *imply* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, u, \mathcal{P})$.
4. *If* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *and the endpoints satisfy*

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{P}) \to \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(s(n), s'(n))$$

   and

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{P}) \to \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(t(n), t'(n)),$$

   then $\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{P})$.

Proof. Unfold Definition 126.21. For reflexivity, fix a bundled certified unary observation (n, π, ν). The given carrier row supplies $\mathsf{RatHistoryCarrier}(s(n))$, and RatUp classifier reflexivity turns that carrier witness into $\mathsf{RatHistoryClassifier}(s(n), s(n))$.

For symmetry, fix the same bundled unary observation data. The finite-window classifier from s to t supplies the point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$, and RatUp classifier symmetry reverses it.

For transitivity, fix a bundled unary observation and read the two finite-window classifiers at it. RatUp classifier transitivity composes $\mathsf{RatHistoryClassifier}(s(n), t(n))$ with $\mathsf{RatHistoryClassifier}(t(n), u(n))$, giving the point classifier from $s(n)$ to $u(n)$.

For endpoint transport, fix (n, π, ν) again. The source finite-window classifier gives $\mathsf{RatHistoryClassifier}(s(n), t(n)$ while the two endpoint transport rows give $\mathsf{hsame}(s(n), s'(n))$ and $\mathsf{hsame}(t(n), t'(n))$ at the same bundled unary observation. RatUp point classifier transport along these two hsame rows gives $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$. □

The ten-field fit is: traditional target finite rational observation-window stability; BEDC source $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow} + \mathsf{ProbeBundle}$; carrier observation maps; classifier finite-window restriction; stability the four displayed rows; ledger the finite probe bundle and endpoint transports; core theorem Definition 126.28; exactness pointwise RatUp classification; standard bridge finite prefixes of rational streams; status $\mathsf{ProofTarget}$.

Theorem 126.29 (StreamName finite-window pointwise reflexivity)**.** *Let $s : \mathsf{Hist} \to \mathsf{Hist}$ be an accepted rational StreamName carrier and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a certified finite bundle of unary observations. Then the restriction of s to $\mathcal{P}$ carries the pointwise rows*

$$\mathsf{InBundle}(n, \mathcal{P}) \to \mathsf{UnaryHistory}(n) \to \mathsf{RatHistoryClassifier}(s(n), s(n))$$

and repacks as the finite-window self-witness

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, s, \mathcal{P}).$$

The witness exposes only the displayed $\mathsf{UnaryHistory}$ *observations, bundle-membership rows, endpoint rational-history carrier rows, pointwise RatUp reflexivity,* hsame *transports already present on the window, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *rows. It contains no quotient stream, host sequence equality, selected limit, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Unfold the carrier clause of Definition 126.1. For a bundled certified unary observation n, the accepted carrier of s supplies the endpoint rational-history carrier row $\mathsf{RatHistoryCarrier}(s(n))$.

Apply the reflexivity field of Definition 126.13 pointwise at this same observation. Equivalently, the RatUp classifier reflexivity row turns the projected endpoint carrier into $\mathsf{RatHistoryClassifier}(s(n), s(n))$.

Since n was chosen with arbitrary evidence $\mathsf{InBundle}(n, \mathcal{P})$ and $\mathsf{UnaryHistory}(n)$, the pointwise rows are exactly the clauses of Definition 126.21. Repacking them therefore gives $\mathsf{RatStreamNameFiniteWindowClass}$

The surrounding handoff surface is unchanged. The finite bundle contributes only membership, unary-history, displayed transport, continuation, provenance, and naming rows, so the same finite-window self-witness is the local source row consumed by Definition 126.173 and by the $\mathsf{Real}^{\uparrow}$ finite-window boundary without importing quotient-stream equality, host sequence equality, selected limits, or completeness data. □

Theorem 126.30 (StreamName finite-window pointwise symmetry)**.** *Let $s, t : \mathsf{Hist} \to \mathsf{Hist}$ be accepted rational StreamName carriers and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a certified finite bundle of unary observations. If* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *holds, then the same displayed bundle rows, unary observations, endpoint carrier rows, pointwise RatUp symmetry,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows repack as*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(t, s, \mathcal{P}).$$

The repacked classifier contains no quotient stream, host sequence equality, selected limit, or $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Unfold Definition 126.21. A bundled certified unary observation n supplies the same membership evidence $\mathsf{InBundle}(n, \mathcal{P})$, the same unary-history witness, and the two endpoint rational-history carrier rows already exposed by the source finite window.

At this observation, apply the symmetry field of Definition 126.13 to the displayed pointwise RatUp classifier row $\mathsf{RatHistoryClassifier}(s(n), t(n))$. This yields the reversed point classifier $\mathsf{RatHistoryClassifier}(t(n), s(n))$ without changing the finite bundle or the endpoint carriers.

Since the observation and bundle-membership evidence were arbitrary, the reversed pointwise rows satisfy exactly the clauses of Definition 126.21 for the ordered pair (t, s). Repack them with the unchanged hsame transports, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows.

All data remain finite-window data. No quotient stream, host sequence equality, selected limit, or $\mathsf{Real}^{\uparrow}$ completeness witness is read or introduced. □

Theorem 126.31 (StreamName finite-window pointwise transitivity)**.** *Let $s, t, u : \mathsf{Hist} \to \mathsf{Hist}$ be accepted rational StreamName carriers and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a certified finite bundle of unary observations. If $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ and $\mathsf{RatStreamNameFiniteWindowClassifier}(t, u, \mathcal{P})$ hold over this same finite bundle, then the displayed finite-window rows compose pointwise to*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, u, \mathcal{P}).$$

The composition uses only pointwise RatUp transitivity and the displayed finite-window rows; it adds no quotient stream, host sequence equality, selected limit, or $\mathsf{Real}^{\uparrow}$ completeness row.

Proof. Unfold Definition 126.21 for the two source windows. A bundled certified unary observation n in $\mathcal{P}$ reads a point classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$ from the first window and a point classifier $\mathsf{RatHistoryClassifier}(t(n), u(n))$ from the second.

Apply the transitivity field of Definition 126.13 at this same observation. The middle endpoint carrier row is the displayed $t(n)$ row already shared by the two windows, so the RatUp point classifiers compose to $\mathsf{RatHistoryClassifier}(s(n), u(n))$.

Because both hypotheses use the same finite bundle $\mathcal{P}$, no membership transport or window refinement is needed. The composed pointwise rows therefore satisfy exactly the clauses of Definition 126.21 for (s, u).

Repack the unchanged bundle-membership rows, unary observations, endpoint carrier rows, hsame transports, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows. The resulting witness remains a finite-window classifier and does not import quotient-stream equality, host sequence equality, selected limits, or completeness data. □

Theorem 126.32 (Rational stream-name finite-window transported selected full endpoint package)**.** *For certified observation maps $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, a selected bundled unary observation n, and histories $a, b, z_s, z_t : \mathsf{Hist}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \quad \mathsf{InBundle}(n, \mathcal{P}), \quad \mathsf{UnaryHistory}(n),$$

and suppose the bundled pointwise transport rows

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{P}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(s(m), s'(m))$$

and

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{P}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(t(m), t'(m))$$

hold. If the transported selected observations are displayed as one-extension endpoints

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n), \mathsf{E1}(b)),$$

then the transported selected finite-window endpoints carry the full endpoint package:

1. $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$.
2. $\mathsf{PositiveUnaryDenominator}(s'(n)) \wedge \mathsf{PositiveUnaryDenominator}(t'(n))$.
3. $\mathsf{UnaryHistory}(s'(n)) \wedge \mathsf{UnaryHistory}(t'(n))$.
4. $(\mathsf{hsame}(s'(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{e}) \to \mathsf{False})$.
5. $(\mathsf{hsame}(s'(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(t'(n), \mathsf{E0}(z_t)) \to \mathsf{False})$.
6. $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

Proof. First transport the finite-window classifier. For every bundled unary observation m, use the given transport row at m for the left endpoint and the corresponding row at m for the right endpoint. The endpoint-transport field of Definition 126.28 then gives

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{P}).$$

Now apply Definition 126.27 to this transported classifier, the selected bundle membership of n, the unary witness for n, and the displayed one-extension endpoints of $s'(n)$ and $t'(n)$. Its six conclusions are exactly the transported selected endpoint package listed above. □

The compact ten-field fit is: traditional target transported finite rational observation endpoint package; BEDC source $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow} + \mathsf{ProbeBundle}$; carrier certified observation maps; classifier finite-window restriction; stability bundled hsame transport; ledger selected bundled unary probe observation and displayed transported endpoints; core theorems Definition 126.28 and Definition 126.27; exactness transported selected RatUp point classification with positive denominators, shape exclusions, and one-tail agreement; standard bridge ordinary finite rational stream endpoint transport; status $\mathsf{ProofTarget}$.

Theorem 126.33 (Rational stream-name finite-window transported composite endpoint package)**.** *For certified observation maps $s, t, u, s', u' : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, a selected bundled unary observation n, and histories $a, b, z_s, z_u : \mathsf{Hist}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \quad \mathsf{RatStreamNameFiniteWindowClassifier}(t, u, \mathcal{P}), \quad \mathsf{InBundle}(n, \mathcal{P}),$$

and suppose the bundled pointwise transport rows

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{P}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(s(m), s'(m))$$

and

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{P}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(u(m), u'(m))$$

hold. If the transported composite endpoints are displayed as one-extension endpoints

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(u'(n), \mathsf{E1}(b)),$$

then the transported composite finite-window endpoints carry the full endpoint package:

1. $\mathsf{RatHistoryClassifier}(s'(n), u'(n))$.
2. $\mathsf{PositiveUnaryDenominator}(s'(n)) \wedge \mathsf{PositiveUnaryDenominator}(u'(n))$.
3. $\mathsf{UnaryHistory}(s'(n)) \wedge \mathsf{UnaryHistory}(u'(n))$.
4. $(\mathsf{hsame}(s'(n), \mathsf{e}) \to \mathsf{False}) \wedge (\mathsf{hsame}(u'(n), \mathsf{e}) \to \mathsf{False})$.

5. $(\mathsf{hsame}(s'(n), \mathsf{E0}(z_s)) \to \mathsf{False}) \wedge (\mathsf{hsame}(u'(n), \mathsf{E0}(z_u)) \to \mathsf{False})$.

6. $\mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{hsame}(a, b)$.

Proof. First compose the finite-window classifiers. The transitivity field of Definition 126.25 applies to the rows from s to t and from t to u, giving

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, u, \mathcal{P}).$$

Next transport the composed classifier. Use the bundled pointwise transport row from s to s' for the left endpoint and the row from u to u' for the right endpoint. The endpoint-transport field of Definition 126.28 gives

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', u', \mathcal{P}).$$

Finally apply Definition 126.27 to the transported classifier, the bundle membership of n, the unary witness for n, and the displayed one-extension endpoints of $s'(n)$ and $u'(n)$. Its six endpoint rows are exactly the package listed above. □

The compact ten-field fit is: traditional target composite transported finite rational observation endpoint package; BEDC source $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow} + \mathsf{ProbeBundle}$; carrier certified observation maps; classifier finite-window RegSeqRat span; stability bundled hsame transport across the selected endpoints; ledger selected bundled unary probe observation, composite middle map, and displayed transported endpoints; core theorems Definition 126.25, Definition 126.28, and Definition 126.27; exactness transported RatUp point classification with positive denominators, shape exclusions, and one-tail agreement; standard bridge ordinary finite rational RegSeqRat stream endpoint transport; status $\mathsf{ProofTarget}$.

Theorem 126.34 (StreamNameUp transported window public readback)**.** *For certified observation maps $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, a selected bundled unary observation n, and histories $a, b, z_s, z_t : \mathsf{Hist}$, suppose the hypotheses of Definition 126.32 hold. Then the selected transported finite-window endpoint package is exactly the public finite-window $\mathsf{StreamName}^{\uparrow}$ readback surface for s' and t' at the bundled unary observation n. Its public rows are*

1. $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$;

2. *positive unary denominators for $s'(n)$ and $t'(n)$;*

3. *unary-history rows for $s'(n)$ and $t'(n)$;*

4. *empty-endpoint exclusions for $s'(n)$ and $t'(n)$;*

5. *zero-headed endpoint exclusions for $s'(n)$ and $t'(n)$;*

6. *unary one-tail agreement for the displayed tails a and b.*

No additional host stream, quotient endpoint, or RegSeqRat-internal witness is part of this readback surface.

Proof. Apply Definition 126.32 to the displayed transport hypotheses, bundle membership, unary witness, and one-extension endpoints.

The cited theorem already returns the six endpoint rows listed above: RatHistoryClassifier, positive denominators, unary endpoint shape, empty exclusion, zero-headed exclusion, and one-tail agreement. Repack these rows as the public finite-window $\mathsf{StreamName}^{\uparrow}$ readback interface, leaving the transport proofs and selected-bundle witness in the ledger. □

Theorem 126.35 (StreamNameUp transported subwindow public readback)**.** *For certified observation maps $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$, probe bundles $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$, a selected bundled unary observation n, and histories $a, b, z_s, z_t : \mathsf{Hist}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$$

and suppose every certified unary observation displayed by $\mathcal{Q}$ is also displayed by $\mathcal{P}$. Suppose also

$$\mathsf{InBundle}(n, \mathcal{Q}), \quad \mathsf{UnaryHistory}(n),$$

together with the bundled pointwise transport rows

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{Q}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(s(m), s'(m))$$

and

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{Q}) \to \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(t(m), t'(m)).$$

If the selected transported observations are displayed as one-extension endpoints

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n), \mathsf{E1}(b)),$$

then the transported $\mathcal{Q}$ subwindow exposes the same public finite-window $\mathsf{StreamName}^{\uparrow}$ readback surface at n:

1. $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$*;*
2. *positive unary denominators for $s'(n)$ and $t'(n)$;*
3. *unary-history rows for $s'(n)$ and $t'(n)$;*
4. *empty-endpoint exclusions for $s'(n)$ and $t'(n)$;*
5. *zero-headed endpoint exclusions for $s'(n)$ and $t'(n)$;*
6. *unary one-tail agreement for the displayed tails a and b.*

No observation outside the subwindow $\mathcal{Q}$ is exported by this readback surface.

Proof. First restrict the ambient finite-window classifier. Apply Definition 126.9 to the $\mathcal{P}$ classifier and the displayed inclusion of certified unary observations from $\mathcal{Q}$ into $\mathcal{P}$. This gives

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}).$$

Next apply Definition 126.32 to the restricted classifier, the selected $\mathcal{Q}$ bundle membership of n, the unary witness for n, the pointwise transport rows over $\mathcal{Q}$, and the displayed one-extension endpoints of $s'(n)$ and $t'(n)$.

The cited package supplies exactly the six public rows: RatHistoryClassifier, positive denominators, unary endpoint shape, empty exclusion, zero-headed exclusion, and one-tail agreement. Repack those rows as the public $\mathsf{StreamName}^{\uparrow}$ subwindow readback, while the ambient window and inclusion row remain certificate ledger data. □

Theorem 126.36 (StreamNameUp transported composite window public readback)**.** *For certified observation maps $s, t, u, s', u' : \mathsf{Hist} \to \mathsf{Hist}$, a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, a selected bundled unary observation n, and histories $a, b, z_s, z_u : \mathsf{Hist}$, suppose the hypotheses of Definition 126.33 hold. Then the composed classifier path from s through t to u, with transported endpoints s' and u', exposes exactly the same public finite-window $\mathsf{StreamName}^{\uparrow}$ readback surface at n. Its public rows are*

1. $\mathsf{RatHistoryClassifier}(s'(n), u'(n))$;
2. *positive unary denominators for* $s'(n)$ *and* $u'(n)$;
3. *unary-history rows for* $s'(n)$ *and* $u'(n)$;
4. *empty-endpoint exclusions for* $s'(n)$ *and* $u'(n)$;
5. *zero-headed endpoint exclusions for* $s'(n)$ *and* $u'(n)$;
6. *unary one-tail agreement for the displayed tails* a *and* b.

The intermediate classifier map t *remains ledger data and is not exported as an extra public endpoint.*

Proof. Apply Definition 126.33. Its proof composes the structural finite-window classifier laws, transports the composed endpoint classifier, and then invokes the selected endpoint package.

The resulting six rows are RatHistoryClassifier, positive denominators, unary endpoint shape, empty exclusion, zero-headed exclusion, and one-tail agreement for the transported endpoints $s'(n)$ and $u'(n)$. Exposing exactly these rows gives the public composite $\mathsf{StreamName}^{\uparrow}$ readback interface, while the middle map and transport chain stay in the certificate ledger. □

Theorem 126.37 (StreamName two-route selected endpoint agreement)**.** *For certified observation maps* $s, t, u, s', t', u' : \mathsf{Hist} \to \mathsf{Hist}$*, a common probe bundle* $\mathcal{P} : \mathsf{ProbeBundle}$*, a selected bundled unary observation* n*, and displayed one-extension endpoint tails* $a, b, c, z_s, z_t, z_u : \mathsf{Hist}$*, suppose the hypotheses of Definition 126.32 hold for the route from* s *to* t *with transported endpoints* s' *and* t'*:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \quad \mathsf{InBundle}(n, \mathcal{P}), \quad \mathsf{UnaryHistory}(n),$$

the bundled pointwise transport rows for s *to* s' *and* t *to* t'*, and the displayed endpoint rows*

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n), \mathsf{E1}(b)).$$

Suppose also that the same selected unary observation and common bundle satisfy the hypotheses of Definition 126.32 for the route from s *to* u *with transported endpoints* s' *and* u'*:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, u, \mathcal{P}),$$

the bundled pointwise transport rows for s *to* s' *and* u *to* u'*, and the displayed endpoint rows*

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(u'(n), \mathsf{E1}(c)).$$

Then the two exported right tails of the selected transported readbacks agree:

$$\mathsf{hsame}(b, c).$$

Proof. Apply Definition 126.32 to the s to t route. Its selected endpoint package includes the one-tail agreement row $\mathsf{hsame}(a, b)$ for the displayed endpoints of $s'(n)$ and $t'(n)$.

Apply the same theorem to the s to u route over the same bundle and selected unary observation. The selected endpoint package for this route includes the one-tail agreement row $\mathsf{hsame}(a, c)$ for $s'(n)$ and $u'(n)$.

Use symmetry of hsame on $\mathsf{hsame}(a, b)$ to obtain $\mathsf{hsame}(b, a)$, and then compose it by transitivity with $\mathsf{hsame}(a, c)$. The resulting relation is $\mathsf{hsame}(b, c)$, which is exactly the agreement of the two exported right tails. □

Theorem 126.38 (StreamNameUp transported window common-refinement public readback)**.** *For certified rational stream observations* $s_1, t_1, s'_1, t'_1, s_2, t_2, s'_2, u'_2 : \mathsf{Hist} \to \mathsf{Hist}$*, let* $\mathcal{P}$ *be a common probe bundle and let* $\mathcal{Q}_1, \mathcal{Q}_2 : \mathsf{ProbeBundle}$ *be two transported finite windows displayed as subwindows of* $\mathcal{P}$*. Suppose* $\mathsf{RatStreamNameFiniteWindowClassifier}(s'_1, t'_1, \mathcal{P})$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(s'_2,$ *hold, and suppose each certified unary observation of* $\mathcal{Q}_i$ *is carried by* $\mathcal{P}$*. If selected observations* n_1 *and* n_2 *belong to* $\mathcal{Q}_1$ *and* $\mathcal{Q}_2$ *with unary endpoint rows and displayed one-tail witnesses, then the two selected public readback surfaces are projections of the same common-refinement finite-window classifier over* $\mathcal{P}$*. Each projection exposes exactly the public rows*

1. *the appropriate* RatHistoryClassifier *row;*
2. *positive denominators for the two selected endpoint histories;*
3. *unary endpoint rows for the selected histories;*
4. *empty-endpoint exclusions;*
5. *zero-headed endpoint exclusions;*
6. *one-tail agreement for the displayed endpoint tails.*

The common bundle, the subwindow inclusion rows, and the transport rows remain ledger data, not additional public endpoints.

Proof. First restrict the common classifiers to the two displayed subwindows. Apply Definition 126.9 to the classifier over $\mathcal{P}$ and the inclusion row $\mathcal{Q}_1 \subseteq \mathcal{P}$ to obtain the finite-window classifier on $\mathcal{Q}_1$. Apply the same theorem to $\mathcal{Q}_2 \subseteq \mathcal{P}$ for the second window.

Next read the selected observations. For the single transported window, apply Definition 126.34 at n_1. For the composite transported window, apply Definition 126.36 at n_2. These two readbacks expose the RatHistoryClassifier rows, positive denominators, unary endpoint rows, empty and zero-headed exclusions, and one-tail agreement.

The common-refinement claim is exactly the fact that both selected readbacks were obtained after projecting finite-window classifiers from the same bundle $\mathcal{P}$. The inclusions $\mathcal{Q}_i \subseteq \mathcal{P}$ and all transport rows are used to choose and compare projections; they are retained in the ledger and do not become public endpoints. □

Theorem 126.39 (StreamNameUp common-refinement denominator and shape agreement)**.** *For certified rational stream observations* $s, t, u, s', t', u' : \mathsf{Hist} \to \mathsf{Hist}$*, a common probe bundle* $\mathcal{P} : \mathsf{ProbeBundle}$*, selected bundled unary observations* n_1, n_2*, and displayed one-extension endpoint tails* $a, b, c : \mathsf{Hist}$*, suppose two finite-window public readback surfaces are obtained from the same common refinement over* $\mathcal{P}$*. Suppose the first surface exposes the transported endpoints* $s'(n_1)$ *and* $t'(n_1)$ *through*

$$\mathsf{hsame}(s'(n_1), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n_1), \mathsf{E1}(b)),$$

and the second surface exposes the same transported observation endpoint and right endpoint through

$$\mathsf{hsame}(s'(n_2), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(u'(n_2), \mathsf{E1}(c)).$$

If the two selected observations name the same transported observation endpoint under hsame*, then the selected public rows agree: their* RatHistoryClassifier *rows are the two projections of the same common-refinement classifier, their positive-denominator rows name* hsame*-equal endpoint histories, their unary endpoint-shape rows name* hsame*-equal endpoint histories, their empty and zero-headed exclusions are the corresponding exclusion rows for those same histories, and their*

displayed one-tail agreement rows have hsame*-equal right tails. In particular the finite-window denominator data and endpoint-shape data exported to* $\mathsf{Real}^{\uparrow}$ *or* RegSeqRat *consumers do not depend on which selected public readback surface of the common refinement is used.*

Proof. First apply Definition 126.38 to the two selected surfaces. This identifies both readbacks as public projections of the same finite-window classifier over $\mathcal{P}$, with the subwindow inclusions and transport rows kept in the ledger.

Next apply Definition 126.34 to each selected surface. For each projection it supplies exactly the six exported rows: RatHistoryClassifier, positive denominators, unary endpoint shape, empty exclusion, zero-headed exclusion, and one-tail agreement for the displayed tails.

Finally use Definition 126.37 on the two routes that share the transported observation endpoint. The theorem gives $\mathsf{hsame}(b, c)$ for the two displayed right tails. Repack the two readback packages along this tail agreement and along the shared endpoint hsame-row; the classifier, denominator, shape, exclusion, and one-tail rows are therefore the same public rows up to hsame. □

The compact ten-field fit is: traditional target common refinement of transported rational observation windows; BEDC source $\mathsf{Rat}^{\uparrow}$+$\mathsf{StreamName}^{\uparrow}$+ProbeBundle; carrier certified observation maps; classifier common-refinement finite-window restriction; stability subwindow restriction plus endpoint transport; ledger bundle inclusions and selected observations; exactness public endpoint readback; standard bridge finite RegSeqRat and RealUp observation windows; status ProofTarget.

Theorem 126.40 (StreamNameUp successor-reindexed selected endpoint package)**.** *Let* $s, t : \mathsf{Hist} \to \mathsf{Hist}$ *be certified rational stream-name observations. Suppose* $\mathsf{RatStreamNameClassifier}(s, t)$*,* $\mathsf{UnaryHistory}(n)$*,* $\mathsf{hsame}(s(\mathsf{E1}(n)), \mathsf{E1}(a))$*, and* $\mathsf{hsame}(t(\mathsf{E1}(n)), \mathsf{E1}(b))$*. For the successor-reindexed observations* $s^+(m) = s(\mathsf{E1}(m))$ *and* $t^+(m) = t(\mathsf{E1}(m))$*, the selected endpoint at* n *exposes the finite-window endpoint package:*

1. $\mathsf{RatHistoryClassifier}(s^+(n), t^+(n))$*;*
2. *positive unary denominators for* $s^+(n)$ *and* $t^+(n)$*;*
3. *unary endpoint rows for* $s^+(n)$ *and* $t^+(n)$*;*
4. *empty-endpoint exclusions for* $s^+(n)$ *and* $t^+(n)$*;*
5. *zero-headed endpoint exclusions for* $s^+(n)$ *and* $t^+(n)$*;*
6. *unary one-tail agreement for the displayed endpoint tails* a *and* b*.*

The package is selected at the visible successor observation; it exports no completion object, metric witness, or regular-sequence datum.

Proof. Apply Definition 126.7 to the classifier row $\mathsf{RatStreamNameClassifier}(s, t)$. This gives the successor-reindexed classifier row for s^+ and t^+.

Next apply Definition 126.27 to that reindexed classifier, the unary row for n, and the displayed hsame endpoint facts for $s(\mathsf{E1}(n))$ and $t(\mathsf{E1}(n))$.

The selected finite-window package supplies exactly the six rows listed in the statement. Repack them under the successor observation names $s^+(n)$ and $t^+(n)$, keeping the reindexing proof in the ledger. □

Theorem 126.41 (StreamNameUp successor-reindexed window public readback)**.** *Under the hypotheses of Definition 126.40, the successor-reindexed selected endpoint package is precisely the public finite-window* $\mathsf{StreamName}^{\uparrow}$ *readback for observing* s *and* t *one unary step later. The public*

surface consists of the reindexed RatHistoryClassifier row, positive denominators, unary endpoint rows, empty and zero-headed exclusions, and one-tail agreement for a and b.

This readback deliberately excludes $\mathsf{Real}^{\uparrow}$ *completion data,* $\mathsf{RegSeqRat}$ *regularity data, metric witnesses, and any standard bridge claim. Those objects may consume the finite window, but they are not exported by the successor readback itself.*

Proof. Use Definition 126.40 to obtain the six visible endpoint rows for the successor observation.

The public readback interface records only rows visible at the finite unary window. Therefore the classifier, positivity, endpoint-shape, exclusion, and tail-agreement rows are exported, while completion, regularity, metric, and bridge data remain outside this certificate. □

Theorem 126.42 (StreamNameUp transported successor selected endpoint readback)**.** *Let* $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ *be certified observation maps. Suppose* $\mathsf{RatStreamNameClassifier}(s, t)$ *and suppose the pointwise transported unary rows*

$$\forall m,\ \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(s(m), s'(m))$$

and

$$\forall m,\ \mathsf{UnaryHistory}(m) \to \mathsf{hsame}(t(m), t'(m))$$

hold. For a unary observation n with $\mathsf{UnaryHistory}(n)$ *and histories* $a, b, z_s, z_t : \mathsf{Hist}$*, suppose the transported selected endpoints are displayed as*

$$\mathsf{hsame}(s'(\mathsf{E1}(n)), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(\mathsf{E1}(n)), \mathsf{E1}(b)).$$

For the transported successor schedules $(s')^+(m) = s'(\mathsf{E1}(m))$ *and* $(t')^+(m) = t'(\mathsf{E1}(m))$*, the selected successor observation at n exposes the following finite-window endpoint rows:*

1. $\mathsf{RatHistoryClassifier}((s')^+(n), (t')^+(n))$*;*
2. *positive unary denominators for* $(s')^+(n)$ *and* $(t')^+(n)$*;*
3. *unary endpoint rows for* $(s')^+(n)$ *and* $(t')^+(n)$*;*
4. *empty-endpoint exclusions for* $(s')^+(n)$ *and* $(t')^+(n)$*;*
5. *zero-headed endpoint exclusions for* $(s')^+(n)$ *and* $(t')^+(n)$*;*
6. *unary one-tail agreement for the displayed endpoint tails a and b.*

The readback is a finite transported successor window. It exports no $\mathsf{Real}^{\uparrow}$ *completion object,* $\mathsf{RegSeqRat}$ *regularity datum, metric witness, or standard bridge claim.*

Proof. First apply Definition 126.8 to the classifier row $\mathsf{RatStreamNameClassifier}(s, t)$ and to the two pointwise hsame transport rows. This gives the successor classifier and, for each probe bundle, the finite-window classifier for the transported successor schedules $(s')^+$ and $(t')^+$.

Next view n as the selected successor observation. Apply Definition 126.27 to that transported finite-window classifier, the unary row for n, and the displayed endpoint rows $\mathsf{hsame}((s')^+(n), \mathsf{E1}(a))$ and $\mathsf{hsame}((t')^+(n), \mathsf{E1}(b))$.

The selected endpoint package supplies the RatHistoryClassifier row, the positive denominators, the unary endpoint rows, the empty and zero-headed exclusions, and the one-tail agreement. The transport rows and the successor reindexing proof remain ledger data; they are not RealUp completion data. □

Theorem 126.43 (StreamNameUp transported successor common-refinement readback)**.** *Let* $s_1, t_1, s_1', t_1', s_2, t_2, s_2', u_2' : \mathsf{Hist} \to \mathsf{Hist}$ *be certified rational stream-name observation maps. Let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a common transported finite-window classifier, and let* $\mathcal{Q}_1, \mathcal{Q}_2 : \mathsf{ProbeBundle}$ *be successor windows projected from* $\mathcal{P}$*. Suppose the two transported successor observations are selected at unary histories* n_1, n_2 *and expose displayed endpoint tails* $a_1, b_1, a_2, c_2 : \mathsf{Hist}$ *by*

$$\mathsf{hsame}((s_1')^+(n_1), \mathsf{E1}(a_1)), \qquad \mathsf{hsame}((t_1')^+(n_1), \mathsf{E1}(b_1)),$$

and

$$\mathsf{hsame}((s_2')^+(n_2), \mathsf{E1}(a_2)), \qquad \mathsf{hsame}((u_2')^+(n_2), \mathsf{E1}(c_2)).$$

If both successor windows are projected from the same common finite-window classifier over $\mathcal{P}$*, the transported successor readbacks have the same public finite-window surface up to* hsame*: their public denominator rows, unary endpoint-shape rows, empty and zero-headed exclusion rows, and one-tail agreement rows are the two projections of the same common-refinement classifier. The common bundle and the pointwise transport rows remain ledger data over* $\mathsf{Rat}^{\uparrow}$+$\mathsf{StreamName}^{\uparrow}$+ProbeBundle*,* UnaryHistory*,* hsame*, and transported finite-window classifiers.*

Proof. First read the common refinement before taking the successor-selected public surface. Apply Definition 126.38 to the two successor subwindows $\mathcal{Q}_1, \mathcal{Q}_2$ inside the common bundle $\mathcal{P}$. This identifies both selected windows as projections of one transported finite-window classifier, with bundle inclusions and transport rows retained in the ledger.

Next build the successor endpoint packages. Apply Definition 126.40 to the underlying successor schedules for each selected observation. The result is the finite-window endpoint package at the visible unary successor, carrying the classifier, denominator, endpoint-shape, exclusion, and one-tail rows.

Finally transport the selected packages. Apply Definition 126.42 to replace the source successor schedules by the pointwise transported schedules. Because both transported successor packages were already projected from the same common finite-window classifier, the public denominator, endpoint-shape, exclusion, and one-tail rows are identified by the same hsame rows that identify the selected transported endpoints. No completion object, metric witness, regularity datum, or standard bridge row is exported. □

Theorem 126.44 (StreamName transported window RegSeqRat RealUp feed)**.** *Let* $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ *be certified rational StreamName observation maps, and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a selected transported finite-window request. Suppose its public endpoint readback is supplied by one of Definition 126.34, Definition 126.36, or Definition 126.43. Then the exported transported rows form exactly the downstream finite-window feed consumed by Definition 38.251, Definition 38.314, and Definition 38.320.*

The feed consists of the selected RatHistoryClassifier *row, the positive unary denominator rows, the unary endpoint-shape rows, the empty and zero-headed endpoint exclusions, the one-tail agreement row, the selected* ProbeBundle *and* InBundle *membership row, and the finite* Cont *and* hsame *transport ledger. These are precisely the RegSeqRat seal inputs and the RealUp finite-window boundary inputs. No host* Nat *index, quotient representative, completion object, metric witness, or* $\mathsf{Real}^{\uparrow}$ *completeness datum is exported.*

Proof. Project the public endpoint rows from the chosen StreamName transported readback theorem. In the direct public case these rows are read from Definition 126.34; in the composite case they are read from Definition 126.36; in the successor common-refinement case they are read from Definition 126.43.

In each case the projected packet has the same finite-window shape: a selected ProbeBundle, its InBundle membership row, a RatHistoryClassifier endpoint row, positive unary denominator rows, unary endpoint-shape rows, empty and zero-headed exclusions, and one-tail agreement. The Cont acceptance row and the pointwise hsame comparisons remain attached as the transport ledger.

Pass that packet through Definition 38.251. The seal reads the finite-window classifier and selected bundle row together with the displayed endpoint and denominator rows, so it introduces no host index or quotient representative.

Finally repack the same sealed packet through Definition 38.314 and Definition 38.320. These RealUp boundary theorems consume only the finite StreamName packet and its transport ledger, so no completion object, metric witness, or completeness datum is added. □

Theorem 126.45 (StreamName RealUp terminal seal boundary)**.** *Let $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ be certified rational StreamName maps, and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a selected transported finite-window request. Suppose a terminal finite-window $\mathsf{Real}^{\uparrow}$ seal consumer receives its endpoint readback from one of Definition 126.34, Definition 126.36, or Definition 126.43. Then the terminal consumer factors through exactly the finite packet listed in Definition 126.44: the selected* RatHistoryClassifier *row, positive unary denominator rows, unary endpoint-shape rows, endpoint exclusions, one-tail agreement, the selected* ProbeBundle *and* InBundle *membership rows, and the finite* Cont *and* hsame *ledger rows.*

Consequently the terminal seal exposes no host Nat *index, quotient representative, completion object, metric witness, order row, arithmetic row, standard bridge, or $\mathsf{Real}^{\uparrow}$ completeness datum.*

Proof. Begin with the chosen endpoint readback. By Definition 126.44, the three admissible readback sources have the same finite downstream feed: a selected ProbeBundle with its InBundle membership row, the RatHistoryClassifier endpoint classifier, positive unary denominator rows, unary endpoint-shape rows, endpoint exclusions, one-tail agreement, and the attached Cont and hsame transport ledger.

Apply Definition 38.251 to this feed. The RegSeqRat seal exactness theorem can read only the displayed finite classifier, bundle, endpoint, denominator, exclusion, tail-agreement, and transport rows. It therefore has no row from which to recover a host index or a quotient representative.

Next pass the same packet through Definition 38.314. The exhaustion obligation consumes the selected finite window and its transport ledger, so the consumer remains inside the finite StreamName-to-RegSeqRat packet.

Finally apply Definition 38.320. The boundary inventory contains exactly the packet rows just named and no further terminal consumer row. Since the inventory has no slot for completion objects, metric witnesses, order or arithmetic rows, standard bridges, or $\mathsf{Real}^{\uparrow}$ completeness data, none of those objects is exposed by the terminal seal. □

Theorem 126.46 (StreamName RealUp terminal seal scope readback)**.** *Let $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ be certified rational StreamName maps, and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a selected transported finite-window request. Suppose a terminal finite-window $\mathsf{Real}^{\uparrow}$ seal consumer is obtained from the StreamName terminal seal boundary of Definition 126.45. Then every scope row available to that consumer factors through exactly the carried StreamName finite-window classifier, the selected endpoint package, the transported denominator package, the RegSeqRat dyadic ledger rows, the* hsame *transport rows, the* Cont *provenance row, and the source* Pkg *rows.*

No readback from this terminal scope exposes a host Nat *index, quotient representative, completion object, metric row, or standard bridge row. Thus the reusable scope handed to later $\mathsf{Real}^{\uparrow}$ and RegSeqRat boundary arguments is precisely the displayed finite packet and nothing outside it.*

Proof. Project the terminal packet supplied by Definition 126.45. Its available rows are the selected finite-window classifier, endpoint and denominator data, endpoint exclusions, one-tail agreement, selected ProbeBundle and InBundle membership, and the attached Cont and hsame transport ledger.

Apply Definition 126.44 to the same packet. This identifies the RegSeqRat and $\mathsf{Real}^{\uparrow}$ handoff rows as the dyadic ledger rows carried by the transported denominator package together with the endpoint classifier and the source Pkg rows already present in the StreamName readback.

Finally use Definition 38.320. Its boundary inventory has slots only for the displayed finite StreamName packet, the RegSeqRat dyadic ledger, the hsame transports, the Cont provenance, and the source package rows. Since the inventory has no slot for host Nat indices, quotient representatives, completion objects, metric rows, or standard bridge rows, the terminal scope-readback exposes none of them. □

Definition 126.47 (Constant rational stream name)**.** *For a history* $d : \mathsf{Hist}$*, write* $\mathsf{RatConstStream}_d(n) = d$ *for every unary observation history* n*.*

Lean4 (definition) `BEDC.Derived.StreamNameUp.RatStreamName constant`
Lean4 (definition) `BEDC.Derived.StreamNameUp.RatConstStream`

Theorem 126.48 (Constant rational stream-name witness)**.** *For histories* $d, e : \mathsf{Hist}$*, every certified unary observation* $n : \mathsf{Hist}$ *satisfies* $\mathsf{hsame}(\mathsf{RatConstStream}_d(n), d)$*. If* $\mathsf{RatHistoryCarrier}(d)$*, then* $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d)$ *and* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_d)$*. If* $\mathsf{RatHistoryClassifier}(d, e)$*, then* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e)$*.*

Proof. Unfold RatConstStream. For any certified unary observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$, the selected observation is definitionally the hidden seed d. History reflexivity gives $\mathsf{hsame}(\mathsf{RatConstStream}_d(n), d)$ at that point.

Unfold RatConstStream and RatStreamNameCarrier. For any certified observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$, the stream value is d, so the supplied $\mathsf{RatHistoryCarrier}(d)$ is the required pointwise carrier witness.

For the self-classifier, unfold RatStreamNameClassifier and fix n with witness $\nu : \mathsf{UnaryHistory}(n)$. The two endpoint observations are both d, and RatUp carrier-reflexivity turns the certified rational observation into $\mathsf{RatHistoryClassifier}(d, d)$.

For a classifier between two constant streams, unfold RatStreamNameClassifier and fix n with witness $\nu : \mathsf{UnaryHistory}(n)$. The endpoint observations are d and e, so the supplied $\mathsf{RatHistoryClassifier}(d, e)$ is already the required pointwise classifier witness. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName constant witness`

Theorem 126.49 (Constant rational stream certified-observation determinacy)**.** *For a history* $d : \mathsf{Hist}$ *and certified unary observations* $m, n : \mathsf{Hist}$*, the constant rational stream reads the same history at both observation sites:*

$$\mathsf{hsame}(\mathsf{RatConstStream}_d(m), \mathsf{RatConstStream}_d(n)).$$

The ten-field fit is:

1. *the traditional target is constant rational observation-name coherence;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow} + \mathsf{StreamName}^{\uparrow}$*;*
3. *the carrier is* RatConstStream *over certified unary observations;*
4. *the classifier/history relation is* hsame*;*

5. *stability is certified-observation invariance;*
6. *the ledger is the hidden rational seed plus two unary observation witnesses;*
7. *the core theorem is this determinacy statement;*
8. *exactness says both observations read back to the same seed;*
9. *the standard bridge is ordinary constant stream extensionality;*
10. *the status is* ProofTarget.

Proof. Apply the point-sameness row of Definition 126.48 to the certified observation m. This gives $\mathsf{hsame}(\mathsf{RatConstStream}_d(m), d)$.

Apply the same row to the certified observation n, obtaining $\mathsf{hsame}(\mathsf{RatConstStream}_d(n), d)$. By symmetry, this gives $\mathsf{hsame}(d, \mathsf{RatConstStream}_d(n))$.

Compose the two history-sameness witnesses by transitivity through the hidden seed d. The result is $\mathsf{hsame}(\mathsf{RatConstStream}_d(m), \mathsf{RatConstStream}_d(n))$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatConstStream certified observation determinacy`

Theorem 126.50 (Rational stream-name constant reindexing classifier)**.** *For histories* $d, e : \mathsf{Hist}$ *and an observation reindexer* $r : \mathsf{Hist} \to \mathsf{Hist}$*, suppose* r *preserves certified unary observations:*

$$\forall n,\ \mathsf{UnaryHistory}(n) \to \mathsf{UnaryHistory}(r(n)).$$

If $\mathsf{RatHistoryCarrier}(d)$*, then* $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$ *and* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStre}$ $r, \mathsf{RatConstStream}_d)$*. If* $\mathsf{RatHistoryClassifier}(d, e)$*, then* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ r)$*.*

Proof. For the carrier, unfold RatConstStream and RatStreamNameCarrier. Fix an observation history n with witness $\nu : \mathsf{UnaryHistory}(n)$. The reindexer supplies a certified unary observation witness for $r(n)$, but the reindexed constant stream still has value d, so the supplied $\mathsf{RatHistoryCarrier}(d)$ is the required pointwise carrier witness.

For the classifier against the original constant stream, unfold RatStreamNameClassifier and fix the same certified observation data (n, ν). Both stream values are d after expanding the constant stream, so RatUp carrier-reflexivity turns the carrier witness for d into the required point classifier $\mathsf{RatHistoryClassifier}(d, d)$.

For two reindexed constant streams, unfold RatStreamNameClassifier and fix n with witness $\nu : \mathsf{UnaryHistory}(n)$. The unary-preservation hypothesis certifies $r(n)$ as an admissible observation, while both endpoint stream values remain the seeds d and e. The supplied $\mathsf{RatHistoryClassifier}(d, e)$ is therefore reused pointwise. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName constant reindexing classifier`

Theorem 126.51 (Rational stream-name independently reindexed constant classifier)**.** *For histories* $d, e : \mathsf{Hist}$ *and observation schedules* $r, q : \mathsf{Hist} \to \mathsf{Hist}$*, if* $\mathsf{RatHistoryCarrier}(d)$*, then* $\mathsf{RatStreamNameCarrier}(\mathsf{RatC}$ $r)$*. If* $\mathsf{RatHistoryClassifier}(d, e)$*, then* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q)$*.*

The ten-field fit is:

1. *the traditional target is independently scheduled constant rational stream names;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *over* BHist*;*

3. *the carrier row is* RatStreamNameCarrier*;*
4. *the classifier row is* RatStreamNameClassifier*;*
5. *the schedule row is the pair of observation maps r and q;*
6. *the ledger is the two observation schedules together with the hidden rational seeds d and e;*
7. *the core theorem is this independently reindexed constant classifier;*
8. *exactness is pointwise reduction to the* $\mathsf{Rat}^{\uparrow}$ *classifier;*
9. *the downstream consumer is the* $\mathsf{Real}^{\uparrow}$ *independent reindexed constant bridge;*
10. *the status is* ProofTarget*.*

Proof. For the carrier, unfold RatConstStream and RatStreamNameCarrier. Fix an arbitrary certified unary observation n with witness $\nu : \mathsf{UnaryHistory}(n)$. The composite $\mathsf{RatConstStream}_d \circ r$ still evaluates to d, so the supplied $\mathsf{RatHistoryCarrier}(d)$ is reused as the pointwise carrier witness.

For the classifier, unfold RatConstStream and RatStreamNameClassifier. At the same kind of certified unary observation n, the left endpoint ignores $r(n)$ and evaluates to d, while the right endpoint ignores $q(n)$ and evaluates to e. Thus the supplied $\mathsf{RatHistoryClassifier}(d, e)$ is already the required pointwise classifier. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName independent reindexed constant classifier`

Theorem 126.52 (Rational stream-name independently reindexed constant point exactness)**.** *For histories $d, e : \mathsf{Hist}$ and observation maps $r, q : \mathsf{Hist} \to \mathsf{Hist}$, the pointwise stream-name carrier and classifier of independently reindexed constant streams recover exactly the RatUp history data:*

$$\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r) \iff \mathsf{RatHistoryCarrier}(d)$$

and

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q) \iff \mathsf{RatHistoryClassifier}(d, e).$$

Proof. Unfold RatConstStream and RatStreamNameCarrier. In the forward carrier direction, read the stream carrier at the empty observation e; the reindexed constant stream evaluates to the seed history d there.

In the reverse carrier direction, fix an arbitrary certified unary observation. The composite $\mathsf{RatConstStream}_d \circ r$ still evaluates to d, so the seed carrier $\mathsf{RatHistoryCarrier}(d)$ supplies the pointwise stream carrier witness.

For the classifier equivalence, unfold RatConstStream and RatStreamNameClassifier. In the forward direction, read the stream classifier at e; both independently reindexed constant streams ignore their observation maps and return the endpoint histories d and e.

In the reverse direction, the supplied $\mathsf{RatHistoryClassifier}(d, e)$ already contains the endpoint carrier data and the point classifier between d and e. At every certified unary observation, the two stream endpoints again reduce to d and e, so the same point classifier repacks into the stream-name classifier. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName independent reindexed constant point exactness`

Theorem 126.53 (Rational constant stream empty-observation exactness)**.** *For histories h, k : Hist, the pointwise stream-name carrier and classifier of constant streams are equivalent to their RatUp point data at the empty unary observation:*

$$\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_h) \iff \mathsf{RatHistoryCarrier}(\mathsf{RatConstStream}_h(\mathsf{e}))$$

and

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k) \iff \mathsf{RatHistoryClassifier}(\mathsf{RatConstStream}_h(\mathsf{e}), \mathsf{RatCon}$$

Proof. Unfold $\mathsf{RatStreamNameCarrier}$ and $\mathsf{RatConstStream}$. In the forward carrier direction, read the pointwise carrier witness at the empty unary observation e, obtaining the RatUp carrier at $\mathsf{RatConstStream}_h(\mathsf{e})$.

In the reverse carrier direction, fix an arbitrary certified unary observation. A constant stream has the same value there as at e, so the empty-observation carrier rebuilds the required pointwise carrier witness.

For the classifier equivalence, unfold $\mathsf{RatStreamNameClassifier}$ and the two constant streams. The forward direction reads the pointwise classifier witness at e.

In the reverse direction, the empty-observation classifier contains the endpoint carrier data and the point classifier between $\mathsf{RatConstStream}_h(\mathsf{e})$ and $\mathsf{RatConstStream}_k(\mathsf{e})$. At every certified unary observation, the two constant endpoints again evaluate as they do at e, so the same RatUp classifier repacks into the stream-name classifier. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatConstStream empty point exactness`

Theorem 126.54 (Rational stream-name constant arbitrary observation exactness)**.** *For histories h, k : Hist and an observation history n : Hist with $\mathsf{UnaryHistory}(n)$, the pointwise stream-name carrier and classifier of constant streams recover exactly the RatUp data at that certified observation:*

$$\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_h) \iff \mathsf{RatHistoryCarrier}(\mathsf{RatConstStream}_h(n))$$

and

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k) \iff \mathsf{RatHistoryClassifier}(\mathsf{RatConstStream}_h(n), \mathsf{RatCo}$$

Proof. Unfold $\mathsf{RatStreamNameCarrier}$ and $\mathsf{RatConstStream}$. In the forward carrier direction, read the pointwise carrier witness at the supplied certified unary observation n, obtaining the RatUp carrier at $\mathsf{RatConstStream}_h(n)$.

In the reverse carrier direction, fix an arbitrary certified unary observation m. Since $\mathsf{RatConstStream}_h(m)$ and $\mathsf{RatConstStream}_h(n)$ are both the hidden seed h, the displayed carrier at n supplies the required pointwise carrier witness at m.

For the classifier equivalence, unfold $\mathsf{RatStreamNameClassifier}$ and the two constant streams. The forward direction reads the pointwise classifier witness at the supplied certified unary observation n.

In the reverse direction, the classifier at n contains the endpoint carrier data and the point classifier between $\mathsf{RatConstStream}_h(n)$ and $\mathsf{RatConstStream}_k(n)$. At every certified unary observation m, the two constant endpoints again evaluate to the same hidden seeds, so the same RatUp classifier repacks into the stream-name classifier. □

Theorem 126.55 (Rational stream-name constant point exactness)**.** *For histories $h, k : \mathsf{Hist}$, the pointwise stream-name carrier and classifier of constant streams recover exactly the RatUp history data:*

$$\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_h) \iff \mathsf{RatHistoryCarrier}(h)$$

and

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k) \iff \mathsf{RatHistoryClassifier}(h, k).$$

Proof. Unfold $\mathsf{RatStreamNameCarrier}$ and $\mathsf{RatConstStream}$. In the forward direction, read the pointwise carrier witness at observation index 0. In the reverse direction, fix an arbitrary observation index n; since the constant stream value is h, the supplied $\mathsf{RatHistoryCarrier}(h)$ witness is exactly the required pointwise witness.

For the classifier statement, unfold $\mathsf{RatStreamNameClassifier}$ and the two constant streams. In the forward direction, read the pointwise classifier witness at observation index 0. In the reverse direction, fix an arbitrary observation index n; since the endpoint stream values are h and k, the supplied $\mathsf{RatHistoryClassifier}(h, k)$ witness is exactly the required pointwise classifier at that observation. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName constant point exactness`

Theorem 126.56 (Rational stream-name constant finite-window exactness)**.** *For histories $h, k : \mathsf{Hist}$ and a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, if the bundle contains a certified unary observation,*

$$\exists n : \mathsf{Hist},\ \mathsf{InBundle}(n, \mathcal{P}) \wedge \mathsf{UnaryHistory}(n),$$

then the finite-window classifier on the two constant streams is exactly the hidden RatUp classifier:

$$\mathsf{RatStreamNameFiniteWindowClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k, \mathcal{P}) \iff \mathsf{RatHistoryClassifier}(h, k).$$

Proof. Unfold $\mathsf{RatStreamNameFiniteWindowClassifier}$ and the two constant streams. In the forward direction, use the assumed bundled unary observation n; applying the finite-window classifier at this inhabited probe reads the point classifier between $\mathsf{RatConstStream}_h(n)$ and $\mathsf{RatConstStream}_k(n)$, which is exactly $\mathsf{RatHistoryClassifier}(h, k)$.

In the reverse direction, fix an arbitrary bundled unary observation m. After unfolding the constant streams, the supplied hidden endpoint classifier $\mathsf{RatHistoryClassifier}(h, k)$ is already the required point classifier at m. Since m was arbitrary among bundled unary observations, the finite-window classifier follows. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier constant exactness`

Theorem 126.57 (Rational constant-stream finite-window coverage)**.** *For histories $h, k : \mathsf{Hist}$ and a probe bundle $\mathcal{P} : \mathsf{ProbeBundle}$, suppose the finite window is inhabited by a certified unary observation:*

$$\exists n : \mathsf{Hist},\ \mathsf{InBundle}(n, \mathcal{P}) \wedge \mathsf{UnaryHistory}(n).$$

Then the window classifier for the two constant rational streams is covered by the hidden RatUp endpoint classifier. More precisely, $\mathsf{RatStreamNameFiniteWindowClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k, \mathcal{P})$ *determines* $\mathsf{RatHistoryClassifier}(h, k)$*, and conversely any* $\mathsf{RatHistoryClassifier}(h, k)$ *supplies the classifier row for every selected unary observation of $\mathcal{P}$.*

Proof. Apply Definition 126.56 to the inhabited ProbeBundle window. The forward implication reads the hidden endpoint classifier from any bundled unary probe.

For the converse, unfold RatConstStream. At each selected n : Hist with InBundle$(n, \mathcal{P})$ and UnaryHistory(n), both stream observations reduce to h and k. The supplied RatUp endpoint classifier is therefore exactly the point row required by RatStreamNameFiniteWindowClassifier; if the selected endpoint is displayed through hsame, use Definition 37.54 before repacking. □

Theorem 126.58 (Rational constant-stream finite-window soundness)**.** *For histories h, k : Hist, a probe bundle $\mathcal{P}$: ProbeBundle, and a certified selected observation n : Hist, if* InBundle$(n, \mathcal{P})$*,* UnaryHistory(n)*, and*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k, \mathcal{P})$$

hold, then the selected unary observation transports to the RatUp endpoint row

$$\mathsf{RatHistoryClassifier}(\mathsf{RatConstStream}_h(n), \mathsf{RatConstStream}_k(n)).$$

Proof. Unfold RatStreamNameFiniteWindowClassifier. Its soundness clause is a universal row over the selected unary observations of the ProbeBundle.

Apply that row to the displayed n, the membership witness InBundle$(n, \mathcal{P})$, and the certificate UnaryHistory(n). Unfolding RatConstStream identifies the two observed endpoints with h and k, so the returned point classifier is the desired RatUp endpoint row; the reflexive endpoint case is the RatUp classifier row of Definition 37.37. □

Theorem 126.59 (Rational constant-stream finite-window completeness)**.** *For histories h, k : Hist and a probe bundle $\mathcal{P}$: ProbeBundle, suppose the finite window is inhabited by a certified unary observation and* RatHistoryClassifier(h, k) *holds. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(\mathsf{RatConstStream}_h, \mathsf{RatConstStream}_k, \mathcal{P})$$

holds for every such certified finite window.

Proof. Apply the reverse direction of Definition 126.56. The inhabited window supplies the nonempty ProbeBundle premise, and the given RatUp endpoint classifier supplies the hidden row.

Equivalently, fix any selected unary observation. By Definition 126.48, each constant stream is the stream-name witness obtained from its hidden rational endpoint. Unfold RatConstStream; the selected observation again reads h and k, so the same endpoint classifier repacks the finite-window classifier, with component transport handled by Definition 37.54. □

Theorem 126.60 (Rational stream-name constant bridge package)**.** *For histories d, e : Hist and an arbitrary observation reindexer r : Hist $\to$ Hist, every witness ρ :* RatHistoryClassifier(d, e) *determines the concrete constant stream-name bridge package consisting of:*

1. *the carrier rows* RatStreamNameCarrier$(\mathsf{RatConstStream}_d)$ *and* RatStreamNameCarrier$(\mathsf{RatConstStream}_d \circ r)$*;*
2. *the classifier row* RatStreamNameClassifier$(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e)$*;*
3. *the reindexed classifier rows* RatStreamNameClassifier$(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_d)$ *and* RatStreamNameClassifier$(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ r)$*;*

4. *the exactness equivalence*

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e) \iff \mathsf{RatHistoryClassifier}(d, e).$$

The compact ten-field fit is:

1. *the traditional target is ordinary constant rational observation names;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *plus* $\mathsf{StreamName}^{\uparrow}$ *over* BHist*;*
3. *the carrier row is* $\mathsf{RatStreamNameCarrier}$ *on the hidden seed stream and its certified observation reindexing;*
4. *the classifier row is* $\mathsf{RatStreamNameClassifier}$ *on constant rational stream names;*
5. *the stability rows are arbitrary observation scheduling for constant streams and same-seed comparison against the unreindexed constant stream;*
6. *the ledger is the rational seed pair* (d, e) *together with the hidden observation schedule* r*;*
7. *the core theorem is this constant bridge package;*
8. *exactness is the reduction of constant stream-name classification to* $\mathsf{RatHistoryClassifier}(d, e)$*;*
9. *the standard bridge is ordinary constant rational streams read as certified stream names;*
10. *the status is* $\mathsf{ProofTarget}$.

Proof. Project the carrier witness for d from the RatUp classifier $\rho : \mathsf{RatHistoryClassifier}(d, e)$. Apply Definition 126.48 to this carrier witness to obtain the unreindexed carrier row, and apply the same theorem to ρ to obtain the unreindexed classifier between $\mathsf{RatConstStream}_d$ and $\mathsf{RatConstStream}_e$.

Next apply Definition 126.51 with the schedules r and the identity schedule. Its carrier clause supplies $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$. RatUp carrier-reflexivity turns the carrier witness for d into $\mathsf{RatHistoryClassifier}(d, d)$, and the classifier clause with endpoints d, d supplies the same-seed classifier from $\mathsf{RatConstStream}_d \circ r$ to $\mathsf{RatConstStream}_d$.

Apply the same independent reindexing theorem with schedules r and r to the endpoint classifier ρ. This supplies the classifier from $\mathsf{RatConstStream}_d \circ r$ to $\mathsf{RatConstStream}_e \circ r$.

The exactness row is precisely Definition 126.55: after expanding the two constant streams, stream-name classification is equivalent to the RatUp classifier on the two hidden histories d and e.

Repack these carrier, classifier, reindexing, and exactness witnesses with the ledger (d, e, r). The observation schedule is hidden ledger data for constant streams, because the stream value ignores the chosen schedule. The resulting object is the named bridge package for constant rational observation names. □

Theorem 126.61 (Rational stream-name constant bridge package exactness)**.** *For histories* $d, e : \mathsf{Hist}$ *and an arbitrary observation reindexer* $r : \mathsf{Hist} \to \mathsf{Hist}$*, write* $\mathsf{K}(d, e, r)$ *for the conjunction of the following concrete constant stream-name bridge rows:*

1. $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d)$*;*
2. $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$*;*
3. $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e)$*;*

4. $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_d)$;
5. $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ r)$;
6. *the exactness row*

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e) \Longleftrightarrow \mathsf{RatHistoryClassifier}(d, e).$$

Then the whole package is exact over the underlying RatUp classifier:

$$\mathsf{K}(d, e, r) \Longleftrightarrow \mathsf{RatHistoryClassifier}(d, e).$$

The compact ten-field fit is:

1. *the traditional target is* $\mathsf{StreamName}^{\uparrow}$ *constant rational observation names;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *over* BHist*;*
3. *the carrier row is the pair of carrier conjuncts in* $\mathsf{K}(d, e, r)$*;*
4. *the classifier row is the three classifier conjuncts in* $\mathsf{K}(d, e, r)$*;*
5. *the stability rows are arbitrary observation scheduling for constant streams and the two reindexed constant classifier rows;*
6. *the ledger is the triple* (d, e, r)*, with* r *retained only as hidden observation schedule data;*
7. *the core theorem is package-level exactness for constant rational stream names;*
8. *exactness is the displayed iff between* $\mathsf{K}(d, e, r)$ *and* $\mathsf{RatHistoryClassifier}(d, e)$*;*
9. *the downstream consumer is the* $\mathsf{Real}^{\uparrow}$ *constant rational embedding;*
10. *the status is* $\mathsf{ProofTarget}$.

Proof. In the forward direction, assume a witness of $\mathsf{K}(d, e, r)$. Project its unreindexed classifier row $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d, \mathsf{RatConstStream}_e)$ and its exactness row. Applying the forward half of that row gives $\mathsf{RatHistoryClassifier}(d, e)$.

In the reverse direction, assume $\rho : \mathsf{RatHistoryClassifier}(d, e)$. Apply Definition 126.60 to ρ and the arbitrary schedule r. The resulting bridge package supplies exactly the two carrier rows, the unreindexed classifier row, the two reindexed classifier rows, and the constant-point exactness row listed in $\mathsf{K}(d, e, r)$. □

Theorem 126.62 (Rational stream-name independently scheduled constant bridge package exactness)**.** *For histories* $d, e : \mathsf{Hist}$ *and arbitrary observation schedules* $r, q : \mathsf{Hist} \to \mathsf{Hist}$*, write* $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$ *for the conjunction of the following independently scheduled constant stream-name bridge rows:*

1. $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$*;*
2. $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_e \circ q)$*;*
3. $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q)$*;*
4. *the exactness row*

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q) \Longleftrightarrow \mathsf{RatHistoryClassifier}(d, e).$$

Then the independently scheduled package is exact over the underlying RatUp classifier:

$$\mathsf{K}_{\mathrm{ind}}(d, e, r, q) \iff \mathsf{RatHistoryClassifier}(d, e).$$

The compact ten-field fit is:

1. *the traditional target is independently scheduled constant rational stream names;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *plus* $\mathsf{StreamName}^{\uparrow}$ *over* BHist*;*
3. *the carrier row is the pair* $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$ *and* $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStrea}$ $q)$*;*
4. *the classifier row is* $\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q)$*;*
5. *the schedule row is the independent pair of observation schedules* r *and* q*;*
6. *the ledger is the quadruple* (d, e, r, q)*;*
7. *the core theorem is independently scheduled constant bridge package exactness;*
8. *exactness is the displayed iff between* $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$ *and* $\mathsf{RatHistoryClassifier}(d, e)$*;*
9. *the downstream consumer is the* $\mathsf{Real}^{\uparrow}$ *independent reindexed constant rational embedding;*
10. *the status is* $\mathsf{ProofTarget}$.

Proof. In the forward direction, assume a witness of $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$. Project its independently scheduled classifier row and its exactness row. Applying the forward half of that row gives $\mathsf{RatHistoryClassifier}(d, e)$.

In the reverse direction, assume $\rho : \mathsf{RatHistoryClassifier}(d, e)$. First apply Definition 126.51 with the endpoint d and schedule r to the left carrier contained in ρ. Apply the same theorem with endpoint e and schedule q to the right carrier contained in ρ. These two applications supply the carrier rows of $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$.

Next apply Definition 126.51 to ρ with the schedules r and q. This supplies the independently scheduled classifier row.

Finally apply Definition 126.52. Its classifier clause is exactly the displayed equivalence between the independently scheduled stream-name classifier and $\mathsf{RatHistoryClassifier}(d, e)$. Repacking these carrier, classifier, and exactness witnesses gives $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$. □

Theorem 126.63 (Rational stream-name independently scheduled constant bridge package transitivity)**.** *For histories* $d, e, f : \mathsf{Hist}$ *and arbitrary observation schedules* $r, q, p : \mathsf{Hist} \to \mathsf{Hist}$*, if* $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$ *and* $\mathsf{K}_{\mathrm{ind}}(e, f, q, p)$ *hold in the sense of Definition 126.62, then* $\mathsf{K}_{\mathrm{ind}}(d, f, r, p)$ *holds.*

The compact ten-field fit is:

1. *the traditional target is independently scheduled constant rational stream-name composition;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *plus* $\mathsf{StreamName}^{\uparrow}$*;*
3. *the carrier row is the endpoint pair inside the* $\mathsf{K}_{\mathrm{ind}}$ *package;*
4. *the classifier row is the independently scheduled* $\mathsf{K}_{\mathrm{ind}}$ *classifier row;*
5. *the stability row is transitivity of the package relation;*
6. *the ledger is the sextuple* (d, e, f, r, q, p)*;*
7. *the core theorem is this package transitivity;*

8. *exactness is reduction through* RatHistoryClassifier*;*
9. *the standard bridge is composition of constant rational streams;*
10. *the status is* ProofTarget.

Proof. Let κ_{de} witness $\mathsf{K}_{\mathrm{ind}}(d, e, r, q)$, and let κ_{ef} witness $\mathsf{K}_{\mathrm{ind}}(e, f, q, p)$. Apply the forward direction of Definition 126.62 to κ_{de} and κ_{ef}, obtaining $\mathsf{RatHistoryClassifier}(d, e)$ and $\mathsf{RatHistoryClassifier}(e, f)$.

Next apply Definition 37.53 to these two classifier witnesses. This composes the RatUp source data and yields $\mathsf{RatHistoryClassifier}(d, f)$.

Finally apply the reverse direction of Definition 126.62 with endpoints d, f and schedules r, p. The result repacks the two constant carrier rows, the independently scheduled classifier row, and the exactness row into $\mathsf{K}_{\mathrm{ind}}(d, f, r, p)$. □

Theorem 126.64 (Rational stream-name public certificate)**.** *The carrier* RatStreamNameCarrier *and classifier* RatStreamNameClassifier*, read over unary* BHist *observations and RatUp point carriers and classifiers, supply the public* $\mathsf{StreamName}^{\uparrow}$ *certificate with the following ten fields:*

1. *the traditional target is the certified countable rational-observation name interface;*
2. *the BEDC source is* $\mathsf{Rat}^{\uparrow}$ *over* BHist*;*
3. *the carrier row is* RatStreamNameCarrier*;*
4. *the classifier row is* RatStreamNameClassifier*;*
5. *reflexivity, symmetry, transitivity, endpoint-carrier recovery, and history-sameness transport are the rows of Definition 126.13;*
6. *reindexing stability and mapped-stream stability are the two clauses of Definition 126.19;*
7. *composed reindexing stability is Definition 126.20;*
8. *inhabited constant streams are supplied by Definition 126.48;*
9. *constant reindexing classification is Definition 126.50;*
10. *constant-point and independently reindexed constant-point exactness, with finite unary observation data in the ledger and exactness pointwise over the* $\mathsf{Rat}^{\uparrow}$ *classifier, are Definition 126.55 and Definition 126.52.*

Proof. Unfold the two public rows. The carrier row is the predicate assigning to each stream $s : \mathsf{Hist} \to \mathsf{Hist}$ the pointwise requirement $\mathsf{RatHistoryCarrier}(s(n))$ at every certified unary observation $n : \mathsf{BHist}$, and the classifier row assigns to each pair of streams the pointwise RatUp classifier between their two observed histories.

The equivalence-relation and transport rows are exactly the five clauses of Definition 126.13. They read a stream certificate at an arbitrary unary observation and apply the corresponding RatUp point theorem, so no global stream data other than the two unfolded rows is introduced.

The structural action rows come from Definition 126.19 and Definition 126.20. The first theorem handles a single certified observation reindexer and a RatUp-preserving history map; the second repacks two unary-preserving reindexers into their composite and then applies the same pointwise classifier and carrier reading.

The inhabited and constant-name rows are supplied by Definition 126.48 and Definition 126.50. The witness row uses a RatUp history carrier as the seed for a constant stream, while the reindexing row observes that every reindexed constant stream still has the same endpoint seed at each certified unary observation.

Finally, Definition 126.55 identifies the constant stream carrier and classifier with the underlying RatUp carrier and classifier, and Definition 126.52 gives the same exactness after independent observation reindexing on the two constant endpoints. Thus the ledger consists of finite unary observation data together with the pointwise RatUp witnesses, and the exactness field is pointwise over the RatUp classifier. These ten rows are precisely the public $\mathsf{StreamName}^{\uparrow}$ certificate assembled from the named component theorems. □

Theorem 126.65 (StreamName constant finite-window readback)**.** *Let q : Hist be a displayed rational-history seed and let I be a displayed finite unary observation window. A constant rational $\mathsf{StreamName}^{\uparrow}$ read over I factors pointwise through the same hidden seed q: every observed entry is classified by the $\mathsf{Rat}^{\uparrow}$ carrier row for q, the finite window ledger records only the inspected unary observations,* hsame *transport identifies each readback with q,* Cont *replay replays the same finite row family,* Pkg *provenance names the constant-stream source, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row packages these data. The packet exports no quotient stream equality, no selected limit, no countable choice, and no* $\mathsf{Real}^{\uparrow}$ *completeness assertion.*

Proof. Read the constant stream through Definition 126.47. By definition, every unary observation in the finite window I returns the same rational-history seed q.

Apply Definition 126.48 at each displayed observation. The pointwise carrier and classifier rows are therefore the $\mathsf{Rat}^{\uparrow}$ rows for the single seed q, and the hsame row transports every readback back to that seed.

The finite window contributes only the inspected observation ledger. Replay and provenance package this finite family as a local $\mathsf{StreamName}^{\uparrow}$ certificate, while no cited row contains quotient stream equality, a selected limit, countable choice, or ambient real completeness. □

126.3 StreamName constant finite-window boundary

Theorem 126.66 (StreamName constant subwindow exactness)**.** *Let a, b : Hist be rational-history endpoints and let $I \subseteq J$ be inhabited finite unary observation windows. For the constant rational stream window package on J, the restricted package on I recovers exactly the same* $\mathsf{RatHistoryClassifier}(a, b)$ *row. No extra stream classifier, completion witness, or host equality row is read by the subwindow.*

Proof. Project the finite constant stream window on J through Definition 126.9. This gives the same constant-stream carrier and classifier rows over the inhabited subwindow I.

Apply Definition 126.56 to the restricted window. Because every observation in the window reads the same two constant endpoints, the window classifier collapses to the single underlying $\mathsf{RatHistoryClassifier}(a, b)$ row.

Finally use Definition 126.301 to identify the subwindow package as a public $\mathsf{StreamName}^{\uparrow}$ finite-window interface. The interface contributes only the displayed carrier, classifier, and ledger rows, so no additional comparison or completion row is introduced. □

Theorem 126.67 (StreamName constant RealUp boundary)**.** *A finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of the constant rational stream package may read only the* $\mathsf{Rat}^{\uparrow}$ *point classifier row* $\mathsf{RatHistoryClassifier}(a, b)$ *and the finite* $\mathsf{ProbeBundle}$ *ledger carried by the* $\mathsf{StreamName}^{\uparrow}$ *window. It does not obtain a completeness claim, a Cauchy-modulus row, or any equality beyond the displayed rational point classifier.*

Proof. Start with the public finite-window interface of Definition 126.301. It exposes the window carrier, classifier, and finite ProbeBundle ledger as the only rows available to a downstream consumer.

For a constant rational stream window, apply Definition 126.66. The classifier read by any inhabited subwindow is exactly the point classifier $\mathsf{RatHistoryClassifier}(a, b)$.

Thus a $\mathsf{Real}^{\uparrow}$ finite-window consumer can depend on the rational point row and on the ledger naming the observed probes. The cited interface contains no regularity, convergence, or completion field, so those obligations remain outside this boundary. □

Theorem 126.68 (StreamName constant RegSeqRat boundary)**.** *A* RegSeqRat *construction may consume the same constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window evidence as a source of rational point-classifier and* ProbeBundle *ledger data, while the regularity rows of* RegSeqRat *remain separate obligations not supplied by the constant-window package.*

Proof. Read the finite-window evidence through Definition 126.301. The rows available at the boundary are the carried observations, the stream-name classifier, and the finite ledger.

For constant rational streams, combine Definition 126.9 with Definition 126.56. Any inhabited subwindow keeps the same endpoints and therefore recovers the same $\mathsf{RatHistoryClassifier}(a, b)$ row.

Repack these rows as the StreamName input to RegSeqRat. Since none of the cited window theorems asserts a regularity modulus, bounded variation row, or sequence-comparison law, those rows must be supplied by the RegSeqRat certificate itself. □

Theorem 126.69 (StreamName constant window overlap exactness)**.** *Let* $a, b : \mathsf{Hist}$ *be rational-history endpoints, and let* I, J *be inhabited finite unary windows for constant rational streams over the same BEDC source* BHist*. Suppose* K *is a certified common subwindow of* I *and* J*, with every probe in* K *carried by* UnaryHistory *and by the finite* ProbeBundle *ledgers of both windows. Then the restrictions of the two constant-window packages to* K *expose the same* $\mathsf{RatHistoryClassifier}(a, b)$ *row, with the StreamName comparison read through the displayed* hsame *rows on the overlap.*

Consequently, any $\mathsf{Real}^{\uparrow}$ *finite-window read surface built from the two restricted packages has the same* $\mathsf{StreamName}^{\uparrow}$ *component on* K*. The overlap surface contains only the public* $\mathsf{StreamName}^{\uparrow}$ *finite-window interface rows over* BHist*,* UnaryHistory*,* ProbeBundle*,* hsame*, and* $\mathsf{RatHistoryClassifier}(a, b)$*; it does not use a quotient, completion row, host index equality, or hidden stream datum.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameConstantWindow overlap exactness`

Proof. Restrict the I-window package to the certified overlap K. By Definition 126.66, the restricted package recovers exactly the row $\mathsf{RatHistoryClassifier}(a, b)$, because the ambient stream is constant and every probe of K is an inhabited unary observation.

Repeat the same restriction for the J-window package. The second application of Definition 126.66 yields the same endpoint row $\mathsf{RatHistoryClassifier}(a, b)$ on the same ProbeBundle overlap ledger. The displayed hsame clauses on K therefore identify the two public StreamName components without comparing host streams.

Now read both packages as possible inputs to a finite-window $\mathsf{Real}^{\uparrow}$ consumer. By Definition 126.67, such a consumer may read only the rational point-classifier row and the finite probe ledger from the constant $\mathsf{StreamName}^{\uparrow}$ window.

Finally apply Definition 38.326. Since both restricted read surfaces present the same overlap rows just listed, the RealUp finite-window surface repacks the same StreamName component over K. No quotient, completion witness, host index, or hidden stream equality is added in that repacking. □

Theorem 126.70 (StreamName constant window union exactness)**.** *Let a, b : Hist be rational-history endpoints, and let I, J be inhabited finite unary constant rational* StreamName$^{\uparrow}$ *windows over the same BEDC source* BHist*. Suppose both windows expose the row* RatHistoryClassifier(a, b)*. Then the finite union window represented by* bundleAppend(I, J) *exposes the same classifier row.*

Every selected observation of bundleAppend(I, J) *restricts back to one of the original constant-window rows. A finite-window* Real$^{\uparrow}$ *or* RegSeqRat *consumer of this union window reads only* StreamName$^{\uparrow}$*,* ProbeBundle*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*, and* RatHistoryClassifier(a, b)*. It receives no completion row, quotient, host stream equality, or hidden selector.*

Proof. Apply Definition 126.66 to the inhabited window I. Its selected constant observations all read the displayed row RatHistoryClassifier(a, b), and the subwindow proof uses only the public finite-window StreamName rows.

Apply the same subwindow exactness theorem to J. Since the endpoints are the same a, b, the second package exposes the identical rational-history classifier row, again without a host stream comparison.

Use the finite-window structural laws recorded by Definition 126.301. The bundleAppend membership law places every selected observation of the union bundle in either the I branch or the J branch, and each branch has already been reduced to the same constant-window classifier row.

Finally apply Definition 126.67 and Definition 126.68. These boundaries say that downstream Real$^{\uparrow}$ and RegSeqRat finite-window consumers can read only the listed StreamName, probe-bundle, unary-history, transport, continuation, package, and rational-history classifier rows. The appended union therefore adds no completion, quotient, host stream equality, or hidden selector. □

Theorem 126.71 (StreamName constant union RegSeqRat Real readback preservation)**.** *Let a, b : Hist be rational-history endpoints, and let I, J be inhabited finite unary constant rational windows over the same* BHist *source. Suppose both windows expose the row* RatHistoryClassifier(a, b)*. Then the union window* bundleAppend(I, J) *preserves the same selected* RegSeqRat$^{\uparrow}$ *tail read and the same finite-window* Real$^{\uparrow}$ *readback surface.*

The preserved readback surface is exactly the rows StreamName$^{\uparrow}$*,* ProbeBundle*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*, and* RatHistoryClassifier(a, b)*. It contains no completion row, quotient, host stream equality, hidden selector, or selected real limit.*

Proof. First apply Definition 126.70. The appended bundle has no classifier branch except the common row RatHistoryClassifier(a, b), because every selected observation comes from the I side or the J side and both sides expose the same endpoint row.

Next use Definition 126.68. The common classifier row and finite ProbeBundle ledger repack as the RegSeqRat$^{\uparrow}$ finite-window input, while the regularity and tail obligations remain external to the constant-window package.

Then apply Definition 126.67. The Real$^{\uparrow}$ readback uses the same rational point-classifier row and the same finite probe ledger already read by the RegSeqRat$^{\uparrow}$ boundary. It receives no completion field or selected limit from the appended window.

Finally exhaust the coordinates of the public StreamName boundary. The only rows used in the three cited results are StreamName$^{\uparrow}$, ProbeBundle, UnaryHistory, hsame, Cont, Pkg, and RatHistoryClassifier(a, b), so the union cannot contribute a quotient, host stream equality, hidden selector, completion row, or selected real limit. □

Theorem 126.72 (StreamName constant directed-overlap exactness)**.** *Let a, b : Hist be rational-history endpoints, and let $\{I_i\}_{i \in I}$ be a directed finite family of inhabited constant rational* StreamName$^{\uparrow}$ *windows over the same* BHist *source. For every certified common overlap in the directed family,*

the restricted windows expose the same RatHistoryClassifier(a, b) *row, with comparison read only through the displayed* hsame *rows and the finite* ProbeBundle *ledgers.*

Consequently, any RegSeqRat *or* Real$^{\uparrow}$ *finite-window consumer of the directed family reads only that single rational-history classifier row together with the finite* ProbeBundle *ledger. The directed system supplies no quotient row, completion row, host stream equality, hidden regularity modulus, or external finite-window selector.*

Proof. Start with one certified common overlap in the directed family. By Definition 126.69, the two restricted constant-window packages on that overlap expose the same RatHistoryClassifier(a, b) row and the same finite probe ledger.

Now pass along the directed finite family. Iterating the overlap exactness statement over the directed overlaps identifies each exposed constant-window classifier with the same endpoint row. Directedness ensures that every pair of member windows is compared inside a certified common window already carrying the displayed hsame and ProbeBundle rows.

For a RegSeqRat consumer, apply Definition 126.68. The consumer may use the constant StreamName row and the finite probe ledger, while all regularity obligations remain external to the constant-window boundary.

For a Real$^{\uparrow}$ consumer, apply Definition 126.67. It reads the same rational-history classifier row and the same finite probe ledger, with no completion or host equality data added by the directed overlap system. □

Theorem 126.73 (StreamName constant directed RegSeqRat Real tail boundary)**.** *Let* a, b : Hist *be rational-history endpoints, and let* $\{I_i\}_{i \in I}$ *be a directed finite family of inhabited constant rational* StreamName$^{\uparrow}$ *windows over one* BHist *source. Suppose every certified overlap in the directed family exposes the same* RatHistoryClassifier(a, b) *row, the same finite* ProbeBundle *ledger, and the displayed* UnaryHistory*,* hsame*,* Cont*, and* Pkg *rows.*

Then any RegSeqRat *consumer, and any finite-window* Real$^{\uparrow}$ *consumer factoring through that* RegSeqRat *surface, obtains one selected* RegSeqRat *tail-classifier row. The handoff surface is exhausted by the* StreamName$^{\uparrow}$ *finite-window rows, the selected* RegSeqRat *spine,* UnaryHistory*,* ProbeBundle*,* hsame*,* Cont*,* Pkg*, and the rational classifier* RatHistoryClassifier(a, b)*. It does not read completion, quotient, host stream equality, order or arithmetic rows, or standard bridge rows.*

Proof. First apply Definition 126.72. The directed family presents one rational-history classifier row on every certified overlap, and the comparison uses only the displayed hsame rows and finite ProbeBundle ledgers.

Next use Definition 126.68. It repacks the constant StreamName$^{\uparrow}$ evidence as the finite StreamName input that a RegSeqRat construction may consume, while leaving regularity rows as RegSeqRat obligations rather than StreamName data.

For a finite-window Real$^{\uparrow}$ consumer, use Definition 126.67. The RealUp side can read the same rational classifier and the same finite probe ledger, but it does not add completion or host-equality information to the window surface.

Finally apply Definition 38.360. The matching StreamName classifier, selected RegSeqRat spine, unary observation rows, and shared Cont/hsame ledger determine a single selected tail-classifier readback row. Since every input row in that application is one of the displayed constant-window or RegSeqRat rows, no quotient, arithmetic, order, completion, host stream equality, or standard bridge row can enter the selected-tail boundary. □

Theorem 126.74 (StreamName constant directed RealUp source uniqueness)**.** *Let* a, b : Hist *be rational-history endpoints, and let* $\{I_i\}_{i \in I}$ *and* $\{J_j\}_{j \in J}$ *be two directed finite families of inhabited*

constant rational $\mathsf{StreamName}^{\uparrow}$ *windows over the same* BHist *source. Suppose a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of the first family and a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of the second family overlap on a certified common directed subwindow* K*, with the displayed* $\mathsf{UnaryHistory}$*,* $\mathsf{ProbeBundle}$*,* hsame*,* Cont*, and* Pkg *rows inherited from both directed systems.*

Then the public $\mathsf{StreamName}^{\uparrow}$ *component exposed to the two* $\mathsf{Real}^{\uparrow}$ *consumers on* K *is uniquely the constant rational stream row determined by* $\mathsf{RatHistoryClassifier}(a, b)$ *and the finite* $\mathsf{ProbeBundle}$ *ledger on* K*. No alternative* $\mathsf{RegSeqRat}$ *source row,* $\mathsf{Real}^{\uparrow}$ *source row, or host stream row can be read at that overlap without first passing through the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window carrier and classifier.*

Proof. Restrict both directed constant-window families to the common directed subwindow K. The restricted packages still carry the same BHist source, the inherited unary observation rows, and the finite $\mathsf{ProbeBundle}$ ledgers displayed by the two original systems.

Apply Definition 126.72 to the restricted directed families. It identifies the public StreamName component on K with the single rational-history classifier row $\mathsf{RatHistoryClassifier}(a, b)$, using only the displayed hsame rows and the finite probe ledgers.

Next use Definition 126.67. A finite-window $\mathsf{Real}^{\uparrow}$ consumer may inspect only that StreamName carrier, classifier, and ledger surface. Thus the consumer has no independent access to a completion row, host stream equality, or an external source selector.

Finally apply Definition 126.73. Any $\mathsf{RegSeqRat}$ tail seen by the $\mathsf{Real}^{\uparrow}$ side is selected through the same constant StreamName finite-window rows and the displayed $\mathsf{Cont}/\mathsf{hsame}$ ledger. Therefore every available RealUp source row factors through the unique StreamName component on K. □

Theorem 126.75 (StreamName constant directed RealUp seal classifier determinacy)**.** *Let* $a, b : \mathsf{Hist}$ *be rational-history endpoints, and let* $\{I_i\}_{i \in I}$ *and* $\{J_j\}_{j \in J}$ *be directed finite inhabited constant rational* $\mathsf{StreamName}^{\uparrow}$ *window families over those endpoints. Assume that their directed overlap rows expose the same* $\mathsf{RatHistoryClassifier}(a, b)$ *row, the same finite* $\mathsf{ProbeBundle}$ *ledger, and the displayed* $\mathsf{UnaryHistory}$*,* hsame*,* Cont*, and* Pkg *rows. Let two finite-window* $\mathsf{Real}^{\uparrow}$ *seals consume these families through* $\mathsf{RegSeqRat}$ *stream-certificate spines compatible with the displayed constant-window rows.*

Then the two seals export the same $\mathsf{Real}^{\uparrow}$ *observation classifier row. The classifier factors through the constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window package, the* $\mathsf{RegSeqRat}$ *constant stream spine, and the displayed seal handoff. It reads no completion, quotient, host stream equality, hidden selector, arithmetic or order package, or standard bridge.*

Proof. First apply Definition 126.74. The two seals see the same public $\mathsf{StreamName}^{\uparrow}$ source on every common directed subwindow, namely the constant rational stream row determined by $\mathsf{RatHistoryClassifier}(a, b)$ and the shared finite $\mathsf{ProbeBundle}$ ledger.

Next use Definition 38.206. The common constant StreamName row supplies compatible $\mathsf{RegSeqRat}$ stream-certificate spines for the reindexed constant streams. Apply Definition 38.207 to those spines and to the displayed seal classifier row; the resulting package is the RealUp observation classifier exported by each finite-window seal.

Finally use Definition 126.73. That boundary keeps the selected $\mathsf{RegSeqRat}$ tail and the RealUp handoff inside the displayed $\mathsf{UnaryHistory}$, $\mathsf{ProbeBundle}$, hsame, Cont, Pkg, and rational-classifier rows. Since both seals consume exactly that finite surface, no completion, quotient, host stream equality, hidden selector, arithmetic or order package, or standard bridge can distinguish their exported classifier rows. □

Theorem 126.76 (StreamName constant directed RealUp seal terminality)**.** *Let a, b : Hist be rational-history endpoints, and let $\{I_i\}_{i\in I}$ and $\{J_j\}_{j\in J}$ be directed finite inhabited constant rational* StreamName$^{\uparrow}$ *window families over those endpoints and over the same displayed* RatHistoryClassifier(a, b) *source. Suppose their finite rows present the same* ProbeBundle *ledger, the same* UnaryHistory *observations, and the same displayed* hsame, Cont, *and* Pkg *coordinates. Fix the selected* RegSeqRat *stream-certificate spine obtained from the constant-window rows.*

Then every finite-window Real$^{\uparrow}$ *consumer preserving that constant-window source and that selected* RegSeqRat *spine factors through the unique seal-classifier row of Definition 126.75. The factorization exposes no second* Real$^{\uparrow}$ *source row, no hidden selector, no quotient stream equality, no completion witness, no arithmetic or order package, and no standard bridge row.*

Proof. Start with the directed handoff boundary. Apply Definition 126.73 to the common directed finite-window surface. It says that the RegSeqRat tail visible to a downstream RealUp consumer is already selected by the StreamName$^{\uparrow}$ finite rows, the displayed Cont/hsame ledger, and the rational-history classifier.

Next apply Definition 126.74. The Real$^{\uparrow}$ source seen at any common finite subwindow is therefore the single constant rational StreamName row determined by RatHistoryClassifier(a, b) and the shared probe ledger.

Use Definition 38.206 to identify the selected spine as the reindexed constant stream spine, and then use Definition 38.207 to package the seal classifier carried by that spine.

Finally invoke Definition 126.75. It identifies the only RealUp observation classifier available to the two constant directed seals. Since the consumer preserves the displayed source and the selected spine, its carrier coordinates are exactly the finite StreamName, RegSeqRat, unary-observation, probe-ledger, hsame, Cont, and Pkg coordinates already named above. There is therefore no remaining coordinate in which a second RealUp source row, hidden selector, quotient stream equality, completion witness, arithmetic or order package, or standard bridge row could enter. □

126.4 StreamName constant-window transport totality

Definition 126.77 (StreamName constant-window carrier)**.** *The StreamName constant-window carrier is the finite-window packet over a point carrier p :* Hist *and a finite request history W :* ProbeBundle*. Its rows are the window index rows of W, the selected observation row identifying each requested probe with the constant point p, the componentwise* hsame *comparisons between any two displayed constant-window presentations, the displayed* Cont *replay row for the window read, the* Pkg *provenance row recording the request history, and the local* NameCert$_{\text{StreamName}^{\uparrow}}$ *row naming the finite-window surface.*

The carrier is local to the finite request. It contains no quotient stream coordinate and no row comparing host streams outside the displayed window.

Theorem 126.78 (StreamName window transport totality)**.** *Every constant-window read consumed by* RegSeqRat$^{\uparrow}$ *or by* Real$^{\uparrow}$ *passes through the StreamName constant-window carrier of Definition 126.77. The exported consumer surface is exactly the point carrier row, the request-history ledger, the window-index rows, the selected observation rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and the local* NameCert$_{\text{StreamName}^{\uparrow}}$ *row.*

The transport exports no quotient stream equality, selected limit, host sequence equality, or countable-choice selector.

Proof. First read the constant window through Definition 126.67. A Real-facing consumer obtains only the rational point row and the finite probe ledger carried by the public StreamName window.

Next read the same window through Definition 126.68. A RegSeqRat-facing consumer obtains the same constant point row and finite ledger, while regularity and seal data remain outside the constant-window packet.

Apply Definition 126.81. It identifies the common handoff to RegSeqRat and RealUp as the displayed finite-window surface rather than a host stream or completion object.

The remaining coordinates are exactly the rows listed in Definition 126.77. Since the cited boundaries contain no quotient stream equality, selected limit, host sequence equality, or choice selector, the transport cannot export one. □

126.5 StreamName Real and RegSeqRat handoff

Theorem 126.79 (StreamName finite-window handoff to RegSeqRat and RealUp)**.** *Let $\mathcal{W}$ be a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window package over* Hist *whose selected observations are certified by a finite* ProbeBundle *ledger and by* InBundle *membership rows. Then the rows handed to* RegSeqRat *or finite-window* $\mathsf{Real}^{\uparrow}$ *consumers are exactly the selected* RatHistoryClassifier *rows, the finite* ProbeBundle *ledger, the* InBundle *membership rows, and the* UnaryHistory *rows naming the observed histories.*

No RegSeqRat *regularity row, no* $\mathsf{Real}^{\uparrow}$ *seal classifier, no completion object, and no host equality row is read from $\mathcal{W}$.*

Proof. Project the public StreamName boundary through Definition 126.301. That theorem lists the carrier, selected classifier, probe-bundle, membership, and unary-history rows available at the public finite-window interface.

For a finite-window $\mathsf{Real}^{\uparrow}$ consumer, apply Definition 38.314 and Definition 38.320. These RealUp rows consume the displayed finite StreamName packet and its ledger, not a completion object or a hidden host stream.

For a RegSeqRat consumer, apply Definition 38.251. The seal reads the selected finite-window classifier and bundle rows as inputs to the downstream regularity and seal surface. Since the StreamName interface theorem lists no regularity row and no seal classifier, those obligations remain outside the handoff. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier real regseq handoff`

Theorem 126.80 (StreamName singleton RegSeqRat RealUp handoff exactness)**.** *Let s, t : Hist $\to$ Hist be StreamName streams and let n : Hist be a certified unary observation. If* RatStreamNameClassifier(s, t) *holds and n is a* UnaryHistory *row, then the singleton packet* ProbeBundle.Bcons n ProbeBundle.Bnil *supplies the finite-window StreamName classifier consumed by the* RegSeqRat *and* $\mathsf{Real}^{\uparrow}$ *handoff.*

For that singleton packet, the exported consumer surface is exactly the selected rational classifier row RatHistoryClassifier$(s(n), t(n))$*, the singleton* ProbeBundle *row, the corresponding* InBundle *ledger row, the displayed* UnaryHistory *row for n, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support already present on the public StreamName side.*

The packet exports no RegSeqRat *regularity row, no* $\mathsf{Real}^{\uparrow}$ *completeness row, no quotient stream, no host sequence equality row, and no selected limit.*

Proof. Use the singleton diagonal handoff shape for rational StreamName classifiers. It turns the pointwise hypothesis RatStreamNameClassifier(s, t) and the certified unary row for n into a RatStreamNameFiniteWindowClassifier over ProbeBundle.Bcons n ProbeBundle.Bnil, with membership given by the singleton InBundle constructor.

The same shape identifies the only selected classifier row: every member of the singleton packet is judgmentally the displayed observation n, so the finite-window classifier reads the single row $\mathsf{RatHistoryClassifier}(s(n), t(n))$ and no second rational-history coordinate.

Now apply Definition 126.79 to this finite-window package. That theorem lists exactly the rows visible to RegSeqRat and finite-window $\mathsf{Real}^{\uparrow}$ consumers: selected rational classifier data, the finite probe ledger, membership rows, unary-history rows, and the displayed StreamName support rows.

Since the singleton construction supplies only those rows, all regularity, completion, quotient, host-equality, and limit data remain outside the handoff. □

Theorem 126.81 (StreamName constant-window handoff boundary)**.** *Let $a, b : \mathsf{Hist}$ be rational-history endpoints and let $\mathcal{W}$ be a constant rational* $\mathsf{StreamName}^{\uparrow}$ *finite-window package over an inhabited finite unary window. The package may seed the* RegSeqRat *stream side only by exporting the same* $\mathsf{RatHistoryClassifier}(a, b)$ *row together with its finite* ProbeBundle, InBundle, *and* UnaryHistory *ledger. A* RegSeqRat *certificate must still supply regularity rows, and a sealed* $\mathsf{Real}^{\uparrow}$ *candidate must still supply the seal classifier row.*

Proof. Apply Definition 126.67. It says that a finite-window $\mathsf{Real}^{\uparrow}$ consumer of the constant package reads only the rational point classifier and the finite probe ledger.

Apply Definition 126.68. It gives the same boundary for RegSeqRat: the constant StreamName window supplies rational point-classifier and probe-ledger data, while the regularity rows remain RegSeqRat obligations.

Finally use Definition 38.198 and Definition 38.204. These theorems place regularity and seal-interface rows on the RegSeqRat and RealUp side of the boundary, so the constant window is only a seed surface for the displayed finite rows. □

Theorem 126.82 (StreamName RegSeqRat RealUp obligation separation)**.** *Across the StreamName, RegSeqRat, and RealUp handoff, the obligation surface separates into three disjoint sources. The* $\mathsf{StreamName}^{\uparrow}$ *package contributes the stream carrier, selected rational-history classifier, finite* ProbeBundle *ledger,* InBundle *membership, and* UnaryHistory *observation rows. The* RegSeqRat *certificate contributes regularity, dyadic-tolerance, transport, and stream-spine rows. The* $\mathsf{Real}^{\uparrow}$ *seal contributes the seal classifier required by the real classifier specification.*

No finite StreamName window contributes a quotient, a completion witness, a host index equality, a RegSeqRat regularity witness, or the RealUp seal classifier.

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealRegseqObligationSeparation`

Proof. Read the StreamName part first. By Definition 126.301, and in the constant case by Definition 126.67 and Definition 126.68, the StreamName surface exposes exactly the carrier, classifier, bundle, membership, unary, and finite ledger rows.

Read the RegSeqRat part next. The regularity and dyadic-tolerance rows are listed by Definition 38.198, while Definition 38.251 describes how the selected finite-window rows are consumed at the seal boundary.

Read the RealUp part last. The seal classifier is supplied by Definition 38.204 and is consumed through Definition 38.314. Thus every downstream row is accounted for by exactly one side of the handoff, and no completion or host equality row is imported from the finite StreamName package. □

Theorem 126.83 (StreamName-RegSeqRat-Real seal composition)**.** *Let $\mathcal{W}$ be a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window package whose selected finite rows are certified by the displayed* RatHistoryClassifier, ProbeBundle, InBundle, UnaryHistory, hsame, *finite* Cont, *and* Pkg *provenance data. Let S be a*

$\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seal that consumes exactly those selected rational-history rows together with its regularity, dyadic-tolerance, transport, stream-spine, and seal-interface ledger rows. Let R be a finite-window* $\mathsf{Real}^{\uparrow}$ *ledger-boundary row that consumes the seal S.*

Then every Real-facing consumer row of R factors through exactly the selected finite rows of $\mathcal{W}$, the RegSeqRat *regularity, dyadic-tolerance, transport, stream-spine, and seal rows of S, and the* $\mathsf{Real}^{\uparrow}$ *seal-classifier ledger row. Conversely, those three displayed surfaces repack into the same Real-facing finite-window ledger boundary.*

The composed route exports no quotient stream, selected host limit, host equality, completion witness, countable-choice schedule, or ambient completeness coordinate.

Proof. First isolate the source rows. Apply Definition 126.79. It says that the public StreamName window contributes only the selected rational-history classifier rows, the finite probe ledger, bundle-membership rows, unary observations, finite transport data, and provenance rows.

Next seal those rows on the RegSeqRat side. Use Definition 38.251 to read the selected finite classifier rows as the input surface of S, and use Definition 38.204 to place the regularity, dyadic-tolerance, transport, stream-spine, and seal-interface rows on the RegSeqRat ledger side of the boundary.

Finally pass to the Real-facing row. Apply Definition 38.314 and Definition 38.320. These theorems consume the RegSeqRat seal as a finite ledger boundary and expose only the seal-classifier row required by the RealUp consumer.

The preceding three steps give the forward factorization. The converse repacking follows by reading the same cited theorems in order: the StreamName finite rows supply the source packet, the RegSeqRat exactness and interface rows rebuild the seal packet, and the RealUp boundary theorem rebuilds the finite-window ledger row. Since each cited boundary excludes quotient streams, host equalities, completion witnesses, countable-choice schedules, and ambient completeness coordinates, the composed route exports none of them. □

Theorem 126.84 (StreamName-RegSeqRat-Real finite-window seal pullback)**.** *Let $\mathcal{W}$ be a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window package whose selected rational classifier rows are consumed both by a* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seal S and by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal boundary R. Assume the two consumers read the same displayed finite rows of $\mathcal{W}$: the* ProbeBundle *ledger,* InBundle *membership rows,* UnaryHistory *observations, selected* RatHistoryClassifier *rows, displayed* hsame *comparisons, finite* Cont *routes,* Pkg *provenance, and* NameCert *support.*

Then the common consumer surface of $\mathcal{W}$, S, and R is exactly that finite displayed surface. Equivalently, the $\mathsf{RegSeqRat}^{\uparrow}$ *seal and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal pull back along the selected* $\mathsf{StreamName}^{\uparrow}$ *window to the single cover-indexed boundary carried by those* ProbeBundle*,* InBundle*,* UnaryHistory*,* RatHistoryClassifier*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The pullback boundary introduces no quotient stream, host index equality, selected limit, ambient completion, or additional $\mathsf{Real}^{\uparrow}$ *seal classifier outside the displayed finite-window ledger.*

Proof. First apply Definition 126.79. It identifies the only rows exported by the public StreamName finite window to RegSeqRat and RealUp consumers: the selected rational classifier rows, probe-bundle ledger, membership rows, unary observations, finite transport rows, provenance, and displayed public support. Thus both consumers start from the same finite StreamName surface.

Next use Definition 126.82. The separation places carrier, classifier, bundle, membership, and unary-history data on the StreamName side; regularity, dyadic-tolerance, transport, and stream-spine data on the RegSeqRat side; and the seal-classifier obligation on the RealUp side. Hence no obligation is counted twice, and no quotient, host equality, limit, or completion row can enter through the shared source.

Finally apply Definition 126.83. The composition theorem repacks the StreamName finite rows, the RegSeqRat seal rows, and the RealUp seal boundary into one Real-facing finite-window ledger. Since the two consumers were assumed to read the same displayed finite rows, this cover-indexed ledger is the required pullback boundary, with no additional RealUp seal classifier outside the displayed surface. □

Definition 126.85 (StreamName-RegSeqRat scheduled seal package)**.** *A* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}$ *scheduled seal package is the scheduled constant observation row together with three finite-window boundary rows:*

1. *the public finite-window* $\mathsf{StreamName}^{\uparrow}$ *row over* BHist *histories, its finite* $\mathsf{ProbeBundle}$ *ledger,* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *observation rows, and the displayed* hsame *comparisons between scheduled endpoints;*
2. *the* $\mathsf{RegSeqRat}$ *finite-window seal row reading the same selected* $\mathsf{RatHistoryClassifier}$ *rows and dyadic ledger rows;*
3. *the finite-window* $\mathsf{Real}^{\uparrow}$ *ledger-boundary row that consumes only the selected rational classifier rows, the probe ledger, and the unary observation rows.*

The package has no further carrier. Its consumer-facing surface is exactly the scheduled observation, finite-window StreamName row, RegSeqRat seal row, and RealUp ledger-boundary row over the displayed BHist, $\mathsf{ProbeBundle}$, $\mathsf{InBundle}$, $\mathsf{UnaryHistory}$, hsame, $\mathsf{Rat}^{\uparrow}$ *classifier, and dyadic ledger data.*

Theorem 126.86 (StreamName-RegSeqRat scheduled seal exhaustion)**.** *Every consumer row of the scheduled seal package of Definition 126.85 is projected from exactly one of the following sources: the scheduled constant observation exactness row, the scheduled window reindex row, the* $\mathsf{RegSeqRat}$ *finite-window seal exactness row, or the finite-window* $\mathsf{Real}^{\uparrow}$ *ledger-boundary row. Conversely, those four source rows repack into the scheduled seal package and determine its whole consumer-facing surface.*

No consumer row of the package exports completion data, quotient data, host index equality, a $\mathsf{RegSeqRat}$ *regularity witness beyond the finite-window seal row, or a* $\mathsf{Real}^{\uparrow}$ *seal classifier outside the displayed ledger boundary.*

Proof. First project the scheduled StreamName source. Apply Definition 126.286 to obtain the constant observation row and Definition 126.287 to identify its finite scheduled windows under reindexing.

Next project the downstream seal rows. The finite-window feed theorem Definition 126.290 places the selected $\mathsf{Rat}^{\uparrow}$ classifier rows, probe-bundle rows, membership rows, unary observation rows, and dyadic ledger rows at the common handoff. The RegSeqRat seal scope theorem Definition 126.291 says that the RegSeqRat consumer reads precisely the finite-window seal row from that handoff.

The separation theorems in this section identify the remaining boundary. Definition 126.79 gives the public finite-window StreamName row, Definition 126.81 specializes it to the constant scheduled source, and Definition 126.82 keeps the RegSeqRat and RealUp obligations disjoint.

For the reverse direction, repack the scheduled observation exactness row, the reindex row, the RegSeqRat finite-window seal exactness row, and the RealUp finite-window ledger boundary into the three displayed components of Definition 126.85. The same cited handoff and separation theorems exclude every row outside those components, so the repacked package is exhaustive. □

Theorem 126.87 (StreamName Real-RegSeq finite-overlap source stability)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be public* StreamName$^{\uparrow}$ *finite-window packages whose observation windows restrict to a certified common finite overlap K. Suppose the two restrictions expose the same* RatHistoryClassifier *rows, the same finite* ProbeBundle *ledger, the same* InBundle *membership rows, the same* UnaryHistory *observation rows, and the same displayed* hsame *comparisons on K. Then any* RegSeqRat *handoff package, and any finite-window* Real$^{\uparrow}$ *handoff package, induced by the two restrictions has the same source surface on K.*

The common source surface is only the restricted StreamName$^{\uparrow}$ *finite-window surface over those rows. It excludes every* RegSeqRat *regularity row, the* Real$^{\uparrow}$ *seal classifier, completion data, quotient data, and host index equality.*

Proof. First restrict both public StreamName packages to K. By Definition 126.79, each restricted handoff exposes only the selected rational-history classifier, finite ProbeBundle ledger, InBundle rows, and UnaryHistory rows.

The assumed overlap equality identifies exactly those rows through the displayed hsame comparisons. In the constant source case, Definition 126.69 gives the same identification from the shared constant rational endpoint row; for a general finite RealUp overlap, the overlap boundary is the one recorded by Definition 38.326.

Now apply Definition 126.82. The RegSeqRat regularity rows and the RealUp seal classifier are downstream obligations, while completion data, quotient data, and host index equality are not exported by the finite StreamName side.

Repacking the two restricted inputs therefore gives the same source handoff surface on K for either downstream consumer, with all non-source rows kept outside the overlap package. □

Theorem 126.88 (StreamName Real-RegSeq overlap unique source)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be public* StreamName$^{\uparrow}$ *finite-window packages whose restrictions to a certified finite overlap K expose the same* RatHistoryClassifier *rows, the same* ProbeBundle *ledger, the same* InBundle *membership rows, the same* UnaryHistory *observation rows, and the same displayed* hsame *rows. Then the overlap determines one StreamName source surface: every* RegSeqRat *handoff package induced from either restriction, and every finite-window* Real$^{\uparrow}$ *handoff package induced from either restriction, has that same source surface on K.*

This source surface consists only of the public finite-window StreamName$^{\uparrow}$ *rows displayed on the certified overlap. It does not include* RegSeqRat *regularity rows,* Real$^{\uparrow}$ *seal classifiers, completion data, quotient data, or host index equality.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealRegseqOverlapUniqueSource`

Proof. First restrict both public finite-window packages to the common overlap K. Definition 126.79 identifies the source-facing rows of each restriction as the rational-history classifier, probe-bundle ledger, membership rows, unary-history rows, and displayed hsame comparisons.

The hypotheses say precisely that those rows agree on K. Definition 126.87 then turns the shared restricted rows into the same source surface for every induced RegSeqRat handoff and every induced finite-window Real$^{\uparrow}$ handoff.

It remains to check that no downstream or host row is being folded into the source. Apply Definition 126.82: RegSeqRat regularity rows and RealUp seal classifiers are downstream obligations rather than StreamName source rows. The same separation keeps completion data, quotient data, and host index equality outside the handoff source.

Finally, Definition 38.326 supplies the RealUp finite-window overlap boundary used by the consumer side. Since the RealUp boundary reads the same certified overlap and the StreamName

source has already been fixed there, both induced consumer packages inherit one source handoff surface on K. □

Theorem 126.89 (StreamName RegSeqRat pointwise seal stability)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packages whose restrictions to a certified finite overlap K agree on every certified unary observation, every selected* RatHistoryClassifier *row, every* ProbeBundle *ledger row, every* InBundle *membership row, and every displayed* hsame *row. Suppose the two induced* RegSeqRat *handoff packages consume the same DyadicRatCore finite ledger over that overlap. Then the* $\mathsf{Real}^{\uparrow}$ *seal classifier rows induced from those two handoffs agree pointwise on K.*

The source used by this pointwise seal comparison is only the public $\mathsf{StreamName}^{\uparrow}$ *finite-window surface together with the consumed* RegSeqRat *dyadic ledger. The comparison does not use completion data, quotient data, host index equality, or a* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameRegseqratPointwiseSealStability`

Proof. First fix the source surface. Apply Definition 126.88 to the two restricted public StreamName packages. The hypotheses are exactly the shared finite-window rows on K, so both induced RegSeqRat handoffs and both finite-window $\mathsf{Real}^{\uparrow}$ handoffs read one source surface there.

Next fix the seal ledger. By Definition 38.262, the RegSeqRat seal reads the refined finite dyadic ledger: carried RatUp endpoints, positive unary denominators, common-radius rows, hsame and Cont provenance, and the scoped DyadicRatCore boundary. Since the two handoffs consume the same DyadicRatCore ledger, the seal input rows coincide pointwise on the overlap.

Now transport the public observation rows along the displayed comparisons. Definition 38.263 says that each hsame-transported DyadicRatCore public observation remains the same $\mathsf{Real}^{\uparrow}$ finite-window input, with the same finite ledger and RatUp endpoint faces.

Finally use classifier stability and transitivity along the displayed hsame rows. The StreamName finite-window classifiers agree on K, the dyadic seal ledger agrees on K, and the transported RealUp finite-window inputs are the same rows. Hence the induced $\mathsf{Real}^{\uparrow}$ seal classifier rows are pointwise identical on the common overlap, without importing any completion, quotient, host-index, or RealUp completeness datum. □

Theorem 126.90 (StreamName RegSeqRat pointwise seal pasting)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be certified finite* $\mathsf{StreamName}^{\uparrow}$ *windows with a certified finite overlap K. Suppose their restrictions to K agree on every certified unary observation, every selected* RatHistoryClassifier *row, every* ProbeBundle *ledger row, every* InBundle *membership row, and every displayed* hsame *row. Suppose also that the induced* RegSeqRat *handoff packages consume the same DyadicRatCore finite ledger on K. Then the* $\mathsf{Real}^{\uparrow}$ *seal classifier rows induced from the two handoffs paste to a single finite-window source surface on $\mathcal{W}_0 \cup \mathcal{W}_1$.*

The pasted surface exports only RatHistoryClassifier *rows,* ProbeBundle *ledger rows,* InBundle *membership rows,* UnaryHistory *observations,* hsame *comparisons, and the shared dyadic ledger. It exports no completion datum, quotient datum, host index equality, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First identify the common source on the overlap. Apply Definition 126.88 to the two restricted certified windows. The displayed agreement rows are exactly the finite StreamName source rows, so the overlap has one source-facing surface for both induced RegSeqRat handoffs.

Next stabilize the seal rows over that common source. By Definition 126.89, the shared DyadicRatCore finite ledger forces the $\mathsf{Real}^{\uparrow}$ seal classifier rows induced from the two handoffs to agree pointwise on every member of K.

It remains to build the union surface. Use finite ProbeBundle induction over the selected rows of $\mathcal{W}_0$ and $\mathcal{W}_1$: rows outside the overlap are inserted from their own certified window, while rows inside K are identified by the pointwise seal stability just obtained.

Finally exhaust the pasted rows. Apply Definition 126.100: every row in the handoff surface is one of the displayed pointwise RatHistoryClassifier observations, bundle and membership rows, unary observations, hsame comparisons, or dyadic ledger rows. Hence the finite union surface contains no completion, quotient, host-index, or RealUp-completeness datum. □

Theorem 126.91 (StreamName RegSeqRat pasted seal associativity)**.** *Let $\mathcal{W}_0, \mathcal{W}_1, \mathcal{W}_2$ be certified finite* StreamName$^{\uparrow}$ *windows. Suppose each adjacent pair carries a certified finite overlap, the restrictions on those overlaps agree on the certified unary observations, selected* RatHistoryClassifier *rows,* ProbeBundle *ledger rows,* InBundle *membership rows, and displayed* hsame *rows, and the three induced* RegSeqRat *handoff packages consume one shared* DyadicRatCore$^{\uparrow}$ *finite ledger on every displayed overlap. Then the two iterated pastings $(\mathcal{W}_0 \cup \mathcal{W}_1) \cup \mathcal{W}_2$ and $\mathcal{W}_0 \cup (\mathcal{W}_1 \cup \mathcal{W}_2)$ induce the same* Real$^{\uparrow}$ *seal classifier surface.*

The common pasted surface is only the finite StreamName source surface, the shared DyadicRatCore ledger, and the pointwise RegSeqRat *handoff rows exported by the three windows. It contains no completion data, quotient data, host index equality, or* Real$^{\uparrow}$ *completeness row.*

Proof. First fix the overlap sources. Apply Definition 126.88 to each certified pairwise overlap. Each overlap therefore has one StreamName source surface for the induced RegSeqRat and finite-window Real$^{\uparrow}$ handoffs.

Next stabilize the pairwise seal rows. By Definition 126.89, the shared DyadicRatCore finite ledger forces the induced Real$^{\uparrow}$ seal classifier rows to agree pointwise on every displayed overlap. These pointwise agreements are the only identifications used by either iterated pasting.

Now paste the left-associated surface. Use Definition 126.90 first on $\mathcal{W}_0$ and $\mathcal{W}_1$, then on the resulting finite union and $\mathcal{W}_2$. The second application reads the same overlap sources and the same shared dyadic ledger already fixed above.

Paste the right-associated surface in the symmetric order. The same theorem first pastes $\mathcal{W}_1$ with $\mathcal{W}_2$ and then pastes $\mathcal{W}_0$ against that finite union. Since the source surfaces and pointwise seal comparisons are the same rows, both constructions classify each member of the three-window union by the same Real$^{\uparrow}$ seal row.

Finally exhaust both iterated surfaces with Definition 126.100. Every row in either surface is one of the displayed StreamName finite-window rows, an hsame comparison, or the shared dyadic ledger row. Completion data, quotient data, host index equality, and RealUp completeness rows have no carrier coordinate in either association, so the two pasted classifier surfaces are identical. □

Theorem 126.92 (StreamName RegSeqRat Real triple-overlap pasting)**.** *Let $\mathcal{W}_0, \mathcal{W}_1, \mathcal{W}_2$ be certified finite* StreamName$^{\uparrow}$ *windows. Suppose each pair carries a certified finite overlap, and suppose the two restrictions on every displayed overlap agree on every certified unary observation, every selected* RatHistoryClassifier *row, every* ProbeBundle *ledger row, every* InBundle *membership row, every displayed* hsame *row, and every consumed* DyadicRatCore$^{\uparrow}$ *finite ledger row. Then the three induced* RegSeqRat$^{\uparrow}$ *handoff packages and the three finite-window* Real$^{\uparrow}$ *seal classifier rows paste to one finite three-window source surface.*

The exported surface is exactly the union of the three finite-window StreamName$^{\uparrow}$ *row sets, the shared dyadic ledgers on their overlaps, and the pointwise* RegSeqRat$^{\uparrow}$ *handoff rows read from those ledgers. It exports no quotient stream, host index equality, selected limit,* Real$^{\uparrow}$ *completeness row, metric-completeness datum, or bridge row.*

Proof. First fix the three pairwise sources. Apply Definition 126.88 to $(\mathcal{W}_0, \mathcal{W}_1)$, to $(\mathcal{W}_1, \mathcal{W}_2)$, and to $(\mathcal{W}_0, \mathcal{W}_2)$. The hypotheses provide exactly the displayed unary observations, classifier rows, bundle ledgers, membership rows, and hsame comparisons required on each overlap.

Next stabilize the seal classifiers on the three overlaps. By Definition 126.89, the shared consumed $\mathsf{DyadicRatCore}^{\uparrow}$ finite ledgers force the $\mathsf{Real}^{\uparrow}$ seal classifier rows induced from either side of each overlap to agree pointwise. These agreements are the only identifications used by the triple source surface.

Now form the pairwise pasted faces. Apply Definition 126.90 to each of the three pairwise unions. Each application exports only finite StreamName rows, the shared dyadic ledger rows, and the pointwise RegSeqRat handoff rows, so no quotient, host-index, selected-limit, completeness, metric, or bridge datum is introduced on a face.

It remains to identify the two possible ways of reading the three faces as a single surface. Use Definition 126.91. The left and right iterated pastings classify each member of $\mathcal{W}_0 \cup \mathcal{W}_1 \cup \mathcal{W}_2$ by the same $\mathsf{Real}^{\uparrow}$ seal row because they read the same pairwise source rows and the same dyadic ledger rows.

Finally exhaust the resulting surface. Apply Definition 126.100 on each window and on each pairwise pasted face, and use Definition 126.82 to keep downstream and ambient rows outside the source. Every exported row is therefore a row from one of the three StreamName finite windows, a shared dyadic ledger row, or a pointwise RegSeqRat handoff row. The listed quotient, host-index, selected-limit, completeness, metric-completeness, and bridge rows have no carrier coordinate in the triple source surface. □

Theorem 126.93 (StreamName RegSeqRat Real finite-cover descent exactness)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *rational windows. Suppose every pairwise certified overlap has the unique source surface of Definition 126.88, and suppose the triple overlaps satisfy the cocycle compatibility witnessed by Definition 126.92. Then the induced* $\mathsf{RegSeqRat}^{\uparrow}$ *handoffs and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal rows descend to one cover-indexed finite surface.*

The descended surface is assembled only from the displayed BMark *and* BHist *observations, selected* RatHistoryClassifier *rows,* ProbeBundle *ledger rows,* InBundle *membership rows, displayed* hsame *and* Cont *transports, consumed* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows,* Pkg *provenance, local* NameCert *rows, induced* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows, and finite-window* $\mathsf{Real}^{\uparrow}$ *seal rows. Conversely, every row of that descended surface restricts on some certified window or certified overlap to exactly one local* $\mathsf{StreamName}^{\uparrow}$ *row, one* $\mathsf{RegSeqRat}^{\uparrow}$ *dyadic-ledger row, or one finite-window* $\mathsf{Real}^{\uparrow}$ *seal row.*

No row of the construction is a quotient stream, host index equality, selected limit, countable-choice selector, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Proceed by finite induction on the cover index set I. For a singleton cover, the claim is exactly Definition 126.100: the visible surface is exhausted by the local StreamName rows, the consumed dyadic ledger, and the finite RealUp seal rows, with no quotient, host, choice, or completeness coordinate.

For the induction step, assume a descended finite surface has already been assembled over a finite subcover and adjoin one further certified window $\mathcal{W}$. On each certified overlap with the existing subcover, apply Definition 126.88 to identify the StreamName source rows, then apply Definition 126.90 to paste the induced $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows and finite-window $\mathsf{Real}^{\uparrow}$ seal rows across that common source.

The result is independent of the order in which the new overlap faces are adjoined. Indeed, whenever three windows meet, the two possible iterated pastings have the same seal classifier

surface by Definition 126.92. Thus the finite induction produces one cover-indexed surface rather than an order-indexed family of surfaces.

It remains to read the rows of the descended surface back to local data. Use Definition 126.82 to keep downstream regularity, seal, quotient, host, choice, and completeness data outside the StreamName source. Then use Definition 126.100 on every window and overlap face. Each exported row is therefore a local StreamName row, a consumed RegSeqRat dyadic-ledger row, or a finite-window RealUp seal row on a certified member of the cover, as required. □

Theorem 126.94 (StreamName RegSeqRat Real finite-cover descent support minimality)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *rational windows satisfying the hypotheses of Definition 126.93. For the descended finite surface produced there, none of the displayed support rows can be deleted while presenting the same descended surface.*

More precisely, deleting any local $\mathsf{StreamName}^{\uparrow}$ *row displayed on a cover member, any consumed* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row on an overlap, any* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row induced from such a ledger, any finite-window* $\mathsf{Real}^{\uparrow}$ *seal row, or any shared* BHist*,* hsame*,* Cont*,* Pkg*, or* NameCert *support row prevents the same cover-indexed finite surface from being presented. Quotient streams, host index equalities, selected limits, countable-choice selectors, metric-completeness rows, bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness rows cannot replace the deleted support.*

Proof. First restrict the alleged presentation of the same descended surface to a cover member containing the deleted local row. By Definition 126.93, every row of the descended surface restricts on that member or on one of its certified overlaps to a unique local $\mathsf{StreamName}^{\uparrow}$ row, consumed $\mathsf{DyadicRatCore}^{\uparrow}$ ledger row, induced $\mathsf{RegSeqRat}^{\uparrow}$ handoff row, or finite-window $\mathsf{Real}^{\uparrow}$ seal row. Thus the restricted presentation must recover exactly the deleted row if the descended surface is unchanged.

For a deleted overlap ledger or handoff row, restrict instead to an overlap face. The pairwise source is pinned by the unique-source hypotheses used in the descent theorem, and the compatibility of threefold restrictions is the one supplied by Definition 126.92. Hence two presentations of the same finite surface must read the same shared BHist, hsame, Cont, Pkg, and NameCert support rows on the overlap; omitting one of them changes the overlap face rather than merely its description.

Next apply Definition 126.100 on the affected window or overlap. The theorem exhausts the visible handoff by the StreamName source rows, the consumed dyadic ledger, and the finite seal rows, so a missing displayed row has no second source inside the handoff surface.

Finally use Definition 126.82. It keeps quotient streams, host index equalities, selected limits, countable-choice selectors, metric-completeness data, bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness outside the StreamName source and its finite-window RegSeqRat and Real faces. Those downstream or ambient rows therefore cannot substitute for the deleted support row, and the same descended finite surface cannot be presented after the deletion. □

Theorem 126.95 (StreamName RegSeqRat overlap-pasting consumer exhaustion)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be certified finite* $\mathsf{StreamName}^{\uparrow}$ *windows with certified finite overlap K. Suppose the hypotheses of Definition 126.90 hold: the two restrictions to K agree on the certified unary observations, selected* RatHistoryClassifier *rows,* ProbeBundle *ledger rows,* InBundle *membership rows, displayed* hsame *rows, and the induced* RegSeqRat *handoffs consume the same DyadicRatCore finite ledger on K. Then every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer row read from $\mathcal{W}_0 \cup \mathcal{W}_1$ is exactly one of the following rows: a row already read from $\mathcal{W}_0$, a row already read from $\mathcal{W}_1$, or an overlap row identified by Definition 126.89.*

Thus the exhausted consumer surface is precisely the finite inventory of RatHistoryClassifier *rows,* ProbeBundle *rows,* InBundle *rows,* UnaryHistory *rows,* hsame *comparisons, and shared DyadicRatCore ledger rows. It contains no completion datum, quotient datum, host-index equality, metric row, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. First paste the seal surface. Apply Definition 126.90. Its hypotheses are the displayed agreement rows on K together with the common DyadicRatCore finite ledger, so it yields one pasted finite-window source surface over $\mathcal{W}_0 \cup \mathcal{W}_1$.

Next compare the consumer rows on the overlap. By Definition 126.97, any finite-window $\mathsf{Real}^{\uparrow}$ consumer restricted to K reads the same BHist surface as the induced RegSeqRat handoff. The pointwise identifications on K are exactly those supplied by Definition 126.89.

Now run finite bundle induction over the two windows. A selected row outside K is inserted from the unique source window containing it. A selected row inside K is identified through the overlap comparison, so inserting it from either side gives the same pasted consumer row.

Finally apply Definition 126.100 to the pasted surface. It enumerates the only rows visible to RegSeqRat and finite-window $\mathsf{Real}^{\uparrow}$ consumers: rational-history classifier rows, bundle and membership rows, unary observations, hsame comparisons, and the shared dyadic ledger. The exclusion clause rules out completion, quotient, host-index, metric, and RealUp-completeness data, so the union consumer surface is exhausted exactly by the stated rows. □

Theorem 126.96 (StreamName RegSeqRat three-window seal coherence)**.** *Let* $\mathcal{W}_0$*,* $\mathcal{W}_1$*, and* $\mathcal{W}_2$ *be certified finite* $\mathsf{StreamName}^{\uparrow}$ *windows with certified finite pairwise overlaps. Suppose that on every displayed overlap the selected* RatHistoryClassifier *rows,* ProbeBundle *ledger rows,* InBundle *membership rows,* UnaryHistory *observations, displayed* hsame *comparisons, and DyadicRatCore finite ledger rows are compatible. Then the finite-window* $\mathsf{Real}^{\uparrow}$ *seal source surface obtained by pasting* $(\mathcal{W}_0 \cup \mathcal{W}_1) \cup \mathcal{W}_2$ *is the same source surface as the one obtained by pasting* $\mathcal{W}_0 \cup (\mathcal{W}_1 \cup \mathcal{W}_2)$*.*

The common surface is exhausted by the displayed finite StreamName, RegSeqRat*, and DyadicRatCore rows. No completion datum, quotient datum, host index equality, metric-completeness row, Classical principle, or ambient model datum enters the comparison.*

Proof. First compare the sources on each pairwise overlap. Apply Definition 126.88 to the certified restrictions of $\mathcal{W}_0$ and $\mathcal{W}_1$, then to the restrictions of $\mathcal{W}_1$ and $\mathcal{W}_2$, and then to the restrictions of $\mathcal{W}_0$ and $\mathcal{W}_2$. Each comparison is witnessed by the same displayed unary observations, selected classifier rows, bundle rows, membership rows, and hsame rows carried by the pairwise overlap.

Next stabilize the seal rows pointwise. Use Definition 126.89 on each overlap. The shared DyadicRatCore finite ledger rows force the induced $\mathsf{Real}^{\uparrow}$ seal rows to agree wherever two windows meet.

Now paste in the left-associated order. Apply Definition 126.90 to $\mathcal{W}_0$ and $\mathcal{W}_1$, and then apply the same theorem to the pasted surface and $\mathcal{W}_2$. The second application uses the pairwise overlap identifications already obtained to identify every row in $(\mathcal{W}_0 \cup \mathcal{W}_1) \cap \mathcal{W}_2$.

Paste in the right-associated order by the symmetric construction. The same pasting theorem first combines $\mathcal{W}_1$ with $\mathcal{W}_2$ and then combines $\mathcal{W}_0$ with that surface. Because every overlap row has already been identified by source uniqueness and pointwise seal stability, no new row can distinguish the two bracketings.

Finally exhaust both pasted surfaces. Apply Definition 126.100 to the left-associated surface and again to the right-associated surface. Both surfaces contain exactly the displayed finite rows listed in the theorem and therefore present the same source-facing $\mathsf{Real}^{\uparrow}$ seal surface. □

Theorem 126.97 (StreamName Real-RegSeq common-window consumer determinacy)**.** *Let $\mathcal{W}_0$ and $\mathcal{W}_1$ be public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packages restricting to a certified finite overlap K. Suppose that the restrictions agree on every pointwise* RatStreamNameCarrier *observation, every pointwise* RatStreamNameClassifier *observation, the finite* ProbeBundle *ledger, the* InBundle *membership rows, the certified* UnaryHistory *observations, the displayed* hsame *rows, and the consumed DyadicRatCore finite ledger over K.*

Then every induced RegSeqRat *handoff and every finite-window* $\mathsf{Real}^{\uparrow}$ *handoff determined by those packages has the same consumer-facing finite* BHist *surface on K. That surface is exhausted by the public* $\mathsf{StreamName}^{\uparrow}$ *rows together with the* RegSeqRat *and DyadicRatCore finite rows named above, and it contains no quotient datum, completion datum, host index equality, metric-completeness row, Classical datum, or standard-bridge datum.*

Proof. First identify the source. Apply Definition 126.88 to the two public finite-window restrictions on K. The hypotheses list the same pointwise carrier rows, classifier rows, bundle ledger, membership rows, unary observations, and displayed hsame comparisons, so both packages expose one source-facing StreamName surface on the overlap.

Next stabilize the seal classifier rows. Apply Definition 126.89. The common DyadicRatCore finite ledger is exactly the downstream input used by the induced RegSeqRat handoffs, so the finite-window $\mathsf{Real}^{\uparrow}$ seal rows agree pointwise over the same overlap.

Finally exhaust the consumer surface with Definition 126.100. Every row a RegSeqRat or finite-window $\mathsf{Real}^{\uparrow}$ consumer can read is one of the public StreamName point rows, the bundle and membership rows, the unary observation rows, the displayed hsame rows, or the shared DyadicRatCore ledger rows. The exclusion clause of that theorem rules out any remaining quotient, completion, host-index, metric-completeness, Classical, or standard-bridge datum. □

Theorem 126.98 (StreamName RegSeqRat visible-row exhaustion)**.** *Every finite-window row handed from* $\mathsf{StreamName}^{\uparrow}$ *to a* RegSeqRat *consumer or to a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer is exactly one of the pointwise* RatStreamNameCarrier *and* RatStreamNameClassifier *observations at certified* UnaryHistory *indices, one of the displayed componentwise* hsame *rows, one of the consumed* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite ledger rows over the same finite window, one of the finite* ProbeBundle *ledger rows, or one of the* InBundle *membership rows naming the selected observations. Conversely, these pointwise carrier/classifier rows, componentwise comparison rows, dyadic finite ledger rows, bundle ledger rows, and membership rows repack into the same consumer-facing handoff surface.*

Proof. Project the finite-window handoff with Definition 126.79. The projection lists exactly the selected rational-history classifier rows, the finite ProbeBundle ledger, the InBundle membership rows, the certified UnaryHistory observation rows, the displayed hsame comparisons, and the consumed DyadicRatCore finite ledger over the same finite window.

Identify the source rows pointwise using Definition 126.1 and Definition 126.2. The restriction and exhaustion steps are supplied by Definition 126.22 and Definition 126.23, so the finite-window rows are exactly the certified unary-index observations and their selected bundle support.

Finally use Definition 126.97. It keeps the consumed DyadicRatCore rows and the displayed hsame rows on the same public window. Repacking the listed rows through the same finite-window handoff theorem returns the original consumer-facing surface. □

Theorem 126.99 (StreamName RegSeqRat no-extra-data exclusion)**.** *The finite-window handoff surface from* $\mathsf{StreamName}^{\uparrow}$ *to a* RegSeqRat *consumer or to a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer contains no host index equality, quotient datum, completion datum, metric-completeness row, Classical*

datum, standard-bridge row, selected limit, or ambient Real$^{\uparrow}$ *completeness row.* RegSeqRat *regularity and the* Real$^{\uparrow}$ *seal classifier remain downstream obligations, while the DyadicRatCore ledger, displayed* hsame *rows, finite bundle ledger, and membership rows are the visible finite handoff data.*

Proof. Start from Definition 126.82. It separates the source-facing StreamName rows from downstream RegSeqRat regularity and finite-window Real$^{\uparrow}$ seal obligations, so neither downstream obligation can be read as hidden StreamName source data.

Use Definition 126.88 on the same finite window. The unique-source clause rules out alternate host-index, quotient, or completion coordinates for a surface with the displayed pointwise rows, comparisons, bundle rows, membership rows, and finite ledger.

The finite-window handoff theorem Definition 126.79 supplies only the listed public rows, and Definition 126.97 keeps the consumed DyadicRatCore ledger on that window. No metric-completeness row, Classical datum, bridge row, selected limit, or ambient Real$^{\uparrow}$ completeness row is introduced by these finite constructors. □

Theorem 126.100 (StreamName RegSeqRat pointwise handoff exhaustion)**.** *Every finite-window row handed from* StreamName$^{\uparrow}$ *to a* RegSeqRat *consumer or to a finite-window* Real$^{\uparrow}$ *consumer is exhausted by the pointwise* RatStreamNameCarrier *and* RatStreamNameClassifier *observations at certified* UnaryHistory *indices, the displayed componentwise* hsame *rows, the consumed DyadicRatCore finite ledger rows over the same finite window, the finite* ProbeBundle *ledger, and the* InBundle *membership rows naming the selected observations. Conversely, those pointwise observations, displayed comparison rows, dyadic ledger rows, and finite bundle rows repack into the same handoff surface.*

The StreamName side contributes no host index equality, quotient data, completion data, metric-completeness row, Classical datum, or standard-bridge datum. RegSeqRat *regularity and the* Real$^{\uparrow}$ *seal classifier remain downstream obligations, while the DyadicRatCore ledger and displayed* hsame *rows are part of the visible finite handoff surface.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRegSeqRatPointwiseHandoffExhaustion`

Proof. Apply Definition 126.98. Its proof projects the handoff through Definition 126.79, then identifies the pointwise carrier and classifier rows by Definition 126.1, Definition 126.2, Definition 126.22, and Definition 126.23.

The same visible-row theorem uses Definition 126.97 to keep the displayed hsame comparisons and consumed DyadicRatCore ledger on the same finite window. Thus the listed rows exhaust the consumer-facing surface and repack into that surface.

Apply Definition 126.99. Its proof uses Definition 126.82 and Definition 126.88 to keep downstream regularity, the finite-window Real$^{\uparrow}$ seal, host-index equality, quotient data, completion data, metric-completeness rows, Classical data, standard-bridge rows, selected limits, and ambient Real$^{\uparrow}$ completeness outside the source handoff. □

Theorem 126.101 (StreamName RegSeqRat nested-window handoff)**.** *Let $K \subseteq J \subseteq L$ be certified finite windows of a public* StreamName$^{\uparrow}$ *rational stream package. For any* RegSeqRat *consumer, and for any finite-window* Real$^{\uparrow}$ *consumer, the source surface obtained by first restricting the handoff from L to J and then from J to K is the same source surface as the handoff obtained by restricting directly from L to K.*

The common source surface consists only of the pointwise RatStreamNameCarrier *and* RatStreamNameClassifier *observations at certified* UnaryHistory *indices, the finite* ProbeBundle *ledger, the* InBundle *membership rows, and the displayed* hsame *comparisons. It contains no* RegSeqRat *regularity datum,* Real$^{\uparrow}$ *seal datum, completion datum, quotient datum, or host index equality.*

Proof. First restrict the outer window. By Definition 126.79, the handoff from L to J exposes only the selected rational-stream point rows, the finite bundle ledger, the membership rows, and the displayed hsame comparisons. Applying the same theorem again to the certified subwindow $K \subseteq J$ projects the two-step handoff to that same kind of surface over K.

Now compare the direct route. Applying Definition 126.79 directly to $K \subseteq L$ gives a handoff surface whose visible rows are again exactly the certified pointwise carrier and classifier observations, the finite ProbeBundle ledger, the InBundle membership rows, and the displayed hsame comparisons over K.

Use Definition 126.88 first on the overlap J and then on the overlap K. The hypotheses are the same certified point rows and the same finite ledger rows inherited from L, so the two restriction routes cannot produce different StreamName source surfaces on either overlap.

Finally apply Definition 126.100. It collapses both restricted handoffs to the same pointwise RatStreamNameCarrier and RatStreamNameClassifier rows together with the same finite ledger. The exclusion clauses in that exhaustion theorem and in the finite-window handoff theorem keep regularity, seal, completion, quotient, and host-index data outside the common surface. □

Theorem 126.102 (StreamName RegSeqRat nested-window seal determinacy)**.** *Let $K \subseteq J \subseteq L$ be certified finite windows of a public* StreamName$^{\uparrow}$ *rational stream package. Suppose the* RegSeqRat *handoff consumes the same* DyadicRatCore *finite ledger along the direct restriction route from L to K and along the two-step restriction route from L to J and then from J to K. Then the induced finite-window* Real$^{\uparrow}$ *seal classifier rows agree on every certified index of K.*

The common seal row is determined only by the pointwise RatStreamNameCarrier *and* RatStreamNameClassifier *rows, the accepted* DyadicRatCore *ledger entries over K, the displayed* hsame *transports, the finite* Cont *routes, and the shared* Pkg *provenance. It does not use completion data, quotient representatives, host-index equality, or any* Real$^{\uparrow}$ *completeness datum.*

Proof. First compare the two restriction routes at the StreamName source level. By Definition 126.101, the direct route L to K and the two-step route through J expose the same pointwise source rows and the same finite ledger over K.

Next transport those rows to the seal side. Apply Definition 126.89 at each certified index of K. Since the carrier row, classifier row, hsame transport, Cont route, Pkg provenance, and DyadicRatCore ledger entry are the same on both routes, the corresponding Real$^{\uparrow}$ seal classifier row is the same at that index.

Finally use Definition 126.100. It says that the RegSeqRat consumer has no additional public handoff data beyond those pointwise rows and finite ledger entries. The exclusion clauses in the handoff and stability theorems keep completion, quotient, host-index, and Real$^{\uparrow}$-completeness data outside the determinacy claim, so the rowwise agreement over K is exactly the stated finite-window seal determinacy. □

Theorem 126.103 (StreamName RegSeqRat RealUp triple seal cover)**.** *Let $\mathcal{S}$ be an accepted finite* StreamName$^{\uparrow}$ *rational-window package, let $\mathcal{R}$ be the* RegSeqRat *pointwise seal package read from the same certified unary indices, and let $\mathcal{E}$ be the* Real$^{\uparrow}$ *sealing endpoint reached by the finite-window consumer. Then $\mathcal{S}$, $\mathcal{R}$, and $\mathcal{E}$ determine the same public read exactly when their unary observation rows, finite* Cont *ledger,* hsame *endpoint transports, and* Pkg *provenance rows agree.*

Equivalently, the three-way cover contains only the pointwise RatStreamNameCarrier *and* RatStreamNameClassifie *observations, the accepted* RegSeqRat *pointwise seal rows, the* Real$^{\uparrow}$ *endpoint seal row, the finite transport ledger, and the shared provenance package. It contains no quotient representative, completion modulus, host index equality, or additional regularity datum beyond those rows.*

Proof. First compare the $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}$ sides pointwise. By Definition 126.89, agreement of the unary observations, hsame transports, finite Cont rows, and Pkg provenance preserves the accepted seal row at each certified index.

Next paste the pointwise seals. Apply Definition 126.90 to the certified finite window. The pasted package has exactly the pointwise rows and the shared finite ledger, so it is independent of any extra quotient or completion representative.

Now exhaust the visible handoff. By Definition 126.100, every public row read by the RegSeqRat consumer is one of the displayed unary observation, transport, ledger, or provenance rows. Thus the RegSeqRat package contributes no additional public datum once those rows agree.

Finally use Definition 126.101. It identifies the finite-window route to the $\mathsf{Real}^{\uparrow}$ sealing endpoint with the same restricted source surface. Therefore the StreamName window package, the RegSeqRat pointwise seal package, and the RealUp endpoint seal determine one public read exactly in the stated agreement conditions, and the reverse direction reads the same four families of rows back into the three packages. □

Theorem 126.104 (StreamName RegSeqRat RealUp tail-selector factorization)**.** *Every accepted finite-window* $\mathsf{StreamName}^{\uparrow}$ *handoff whose* $\mathsf{RegSeqRat}$ *carrier supplies the scheduled-window projection and whose* $\mathsf{Real}^{\uparrow}$ *endpoint read uses finite-prefix exactness factors the tail-selector read through exactly three public rows: the* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier row, the* $\mathsf{RegSeqRat}$ *scheduled projection and readback row, and the* $\mathsf{Real}^{\uparrow}$ *finite-prefix classifier row.*

The factorization exports no quotient stream, selected limit, host equality, countable choice row, or ambient completeness row. All exported data are already contained in the certified finite $\mathsf{ProbeBundle}$ *ledger, the displayed* Cont *routes, the unary observation rows, the* hsame *transports, and the shared* Pkg *provenance.*

Proof. Start with the three-way cover of Definition 126.103. It identifies the accepted $\mathsf{StreamName}^{\uparrow}$ window, the pointwise $\mathsf{RegSeqRat}$ seal package, and the $\mathsf{Real}^{\uparrow}$ endpoint read on the same unary observations, finite transport ledger, endpoint transports, and provenance rows.

The first factor is the StreamName finite-window classifier. By Definition 126.86, the scheduled seal over the accepted window is exhausted by the visible StreamName carrier and classifier observations together with the finite ledger rows. Thus the tail-selector source read begins at the finite-window classifier rather than at a quotient stream or host-index equality.

The second factor is the RegSeqRat scheduled projection and readback row. Apply Definition 126.100: every public row consumed by the $\mathsf{RegSeqRat}$ carrier is already one of the certified pointwise rows, Cont routes, hsame transports, and Pkg provenance rows. The scheduled projection therefore reads back exactly the finite window selected by the StreamName classifier.

The third factor is the RealUp finite-prefix classifier. Use Definition 126.108 to compare all finite windows selected by the tail read. Since the overlaps are already compatible in the triple cover, the endpoint classifier depends only on the finite prefix ledger presented by the RegSeqRat readback row. This gives the claimed three-row factorization and excludes quotient, selected-limit, countable-choice, host-equality, and ambient-completeness exports. □

Theorem 126.105 (StreamName RegSeqRat tail-budget uniformity)**.** *Let a finite accepted* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}$ *handoff packet present StreamName finite observations through a common pointwise classifier, with matching* BHist *rows,* hsame *transports, finite* Cont *routes, shared* Pkg *provenance, and a displayed* $\mathsf{NameCert}$ *for the handoff surface. Suppose the* $\mathsf{RegSeqRat}$ *tail selector carries a dyadic budget row consumed by the finite-prefix* $\mathsf{Real}^{\uparrow}$ *endpoint. Then every later finite window accepted by the same StreamName pointwise classifier factors through the same tail-budget certificate.*

Equivalently, once the packet has fixed the StreamName finite observations, the RegSeqRat tail selector, and the RealUp budget consumer, enlarging the finite window changes only the visible window ledger. It does not export a new tail selector, budget witness, completion datum, quotient stream, host equality, or ambient regularity row outside the certified NameCert*,* Cont*,* hsame*,* BHist*, and* Pkg *surface.*

Proof. First apply Definition 126.104. The tail-selector read factors through the StreamName finite-window classifier, the RegSeqRat scheduled projection and readback row, and the RealUp finite-prefix classifier. Thus the budget row is already located on the displayed finite ledger rather than on a selected completion representative.

Next use Definition 126.102 for a later finite window accepted by the same pointwise StreamName classifier. The nested window has the same BHist source rows, hsame transport witnesses, finite Cont routes, and Pkg provenance on the overlap, so the RegSeqRat scheduled projection reads the same tail-selector certificate on the shared part.

Finally compare all later windows with Definition 126.108. The finite cover determinacy theorem pastes the overlapping StreamName, RegSeqRat, and RealUp rows into one cover-indexed source surface. Therefore each RealUp budget consumer sees the same dyadic tail-budget certificate, and no further completion, quotient, host-index, or off-ledger regularity datum can enter the handoff. □

Theorem 126.106 (StreamName RegSeqRat RealUp cover tail-budget finality)**.** *Let* $\{W_i\}_{i\in I}$ *be a finite public* $\mathsf{StreamName}^{\uparrow}$ *cover feeding the same* RegSeqRat *finite-window consumer and the same finite-window* $\mathsf{Real}^{\uparrow}$ *endpoint. Suppose every displayed pairwise overlap satisfies the nested-window handoff hypotheses, every nested pair satisfies the nested-window seal determinacy hypotheses, and every triple overlap is compatible in the triple seal cover. Then the cover forces a single tail-budget certificate for the* RegSeqRat *consumer, and every endpoint read factors through exactly the* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier row, the* RegSeqRat *scheduled projection and readback row, and the* $\mathsf{Real}^{\uparrow}$ *finite-prefix classifier row.*

The forced certificate is a finite-cover surface over the displayed NameCert*,* ProbeBundle*,* InBundle*,* BHist*,* Cont*,* hsame*, and* Pkg *rows. It contains no quotient stream data, selected limit, host index equality, countable choice row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First identify the source rows on pairwise overlaps. Apply Definition 126.101 to each displayed nested overlap in the finite cover. The direct and two-step restrictions expose the same StreamName classifier rows, unary observations, finite bundle ledger, membership rows, and hsame comparisons.

Next transport those source rows through the endpoint seal. Use Definition 126.102 on the same nested overlaps, and then apply Definition 126.103 on every displayed triple. The RegSeqRat seal rows and the RealUp endpoint rows are therefore read from the same finite transport, provenance, and pointwise observation surface throughout the cover.

Now factor each endpoint read. By Definition 126.104, every accepted read passes through exactly the StreamName finite-window classifier, the RegSeqRat scheduled projection and readback row, and the RealUp finite-prefix classifier row. The factorization clauses rule out quotient stream data, selected limits, host index equality, countable choice, and ambient Real completeness as exported rows.

Finally apply Definition 126.105 to the cover-indexed family of accepted windows. Since all overlaps have the same pointwise classifier, BHist rows, hsame transports, finite Cont routes, shared Pkg provenance, and displayed NameCert surface, the RegSeqRat tail selector carries one dyadic

budget certificate across the finite cover. Thus the endpoint reads are forced by the same finite-cover surface and by exactly the three classifier/projection rows named above. □

Theorem 126.107 (StreamName finite-section tail-window lock)**.** *Let Q be an accepted finite request section of the current L10* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose that Q exposes the same* $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row,* $\mathsf{RegSeqRat}^{\uparrow}$ *scheduled projection and readback row,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and StreamName tail-window coverage packet as a finite cover satisfying Definition 126.106. Then every* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing finite consumer of Q is locked to the same tail-budget certificate forced by that cover.*

Consequently each such consumer factors through exactly the $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *scheduled projection and readback row, and the* $\mathsf{Real}^{\uparrow}$ *finite-prefix classifier row. The lock exports no quotient stream, selected limit, host index equality, countable-choice row, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, or standard bridge row.*

Proof. First apply Definition 126.586 to the accepted section Q. The shared finite window, dyadic ledger, RegSeqRat readback, and RealUp seal identify Q with the same four-face finite route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 126.224 to every finite $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer whose source reads the displayed tail-window coverage packet. Each consumer is therefore read only through the packet rows already named by the finite window, the accepted $\mathsf{RegSeqRat}$ spine, the DyadicRatCore ledger, and the shared $\mathsf{Cont}/\mathsf{hsame}/\mathsf{Pkg}$ support.

Now use Definition 126.225. Since the section and the cover expose the same tail-window packet, the possible consumer source is unique on the displayed StreamName, RegSeqRat, DyadicRatCore, continuation, history, package, and ledger rows. There is no second source row from which a quotient representative, host index, completion object, or bridge datum could be read.

Finally invoke Definition 126.106. The finite cover has already forced one tail-budget certificate and one three-row factorization for endpoint reads. Transporting the accepted section Q through the same pullback and tail-window packet therefore locks every eligible consumer to that certificate and to exactly the StreamName classifier row, the RegSeqRat scheduled projection/readback row, and the RealUp finite-prefix classifier row. □

Theorem 126.108 (StreamName RegSeqRat finite-window cover determinacy)**.** *Let $\{W_i\}_{i\in I}$ be a finite public* $\mathsf{StreamName}^{\uparrow}$ *cover of rational windows feeding the same* $\mathsf{RegSeqRat}$ *finite-window consumer and the same finite-window* $\mathsf{Real}^{\uparrow}$ *handoff surface. Suppose every displayed pairwise overlap satisfies the overlap-source and nested-window determinacy hypotheses for the StreamName source rows, and suppose every three-way overlap is compatible in the triple seal cover. Then the induced* $\mathsf{RegSeqRat}$ *seal rows and finite-window* $\mathsf{Real}^{\uparrow}$ *handoff rows determine one cover-indexed source surface: the selected* $\mathsf{RatHistoryClassifier}$ *rows, the* $\mathsf{ProbeBundle}$ *ledger, the* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *observations, and the displayed* hsame *comparisons.*

The determined surface contains no completion datum, quotient datum, host index equality, RegSeqRat regularity claim outside the finite seal rows, or $\mathsf{Real}^{\uparrow}$ *seal classifier outside the displayed ledger boundary.*

Proof. Use Definition 126.87 and Definition 126.88 on each displayed pairwise overlap. They identify the source row, unary observation, bundle membership, and hsame comparison read by the two windows.

Induct over the finite cover. The empty and singleton cases are just the displayed window rows. In the step case, apply Definition 126.102 to paste the new window into the already determined finite surface along the pairwise overlap.

For compatibility of the pasted overlaps, use Definition 126.103. The triple cover keeps the StreamName, RegSeqRat, and RealUp reads on the same finite ledger, so no completion, quotient, host-index, external regularity, or off-ledger classifier row is introduced. □

Theorem 126.109 (StreamName RegSeqRat cover Real handoff descent)**.** *Let $\{W_i\}_{i\in I}$ be a finite public* $\mathsf{StreamName}^{\uparrow}$ *cover feeding one* $\mathsf{RegSeqRat}$ *finite-window consumer and one finite-window* $\mathsf{Real}^{\uparrow}$ *endpoint. Suppose that every displayed pairwise overlap satisfies the overlap-source hypotheses and the nested-window handoff hypotheses, that every nested pair satisfies seal determinacy, and that every displayed triple overlap satisfies the triple seal cover. Then the induced* $\mathsf{Real}^{\uparrow}$ *finite-window handoff descends to the single cover-indexed source surface determined by Definition 126.108.*

The visible rows are exactly the selected $\mathsf{RatHistoryClassifier}$ *rows, the* $\mathsf{ProbeBundle}$ *ledger, the* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *observations, displayed* hsame *comparisons,* $\mathsf{DyadicRatCore}$ *finite ledger rows, and the endpoint seal rows licensed by the triple cover. The descent contains no completion data, quotient representatives, host index equality, countable choice, ambient completeness, or off-ledger* $\mathsf{Real}^{\uparrow}$ *seal classifiers.*

Proof. First apply Definition 126.108 to the finite public cover. Its conclusion supplies a single cover-indexed StreamName source surface for the selected classifier rows, bundle ledger, membership rows, unary observations, and displayed hsame comparisons.

Next stabilize the endpoint-facing seal rows on nested overlaps. By Definition 126.102, two nested routes reading the same $\mathsf{DyadicRatCore}$ finite ledger induce the same finite-window $\mathsf{Real}^{\uparrow}$ seal classifier row on every certified subwindow.

Now compare triples. The compatibility hypothesis feeds Definition 126.103, so the StreamName source rows, the $\mathsf{RegSeqRat}$ finite ledger, and the $\mathsf{Real}^{\uparrow}$ endpoint seal rows read the same public package on each displayed three-way overlap.

Finally exhaust the consumer-visible surface with Definition 126.100. Every row seen by the $\mathsf{RegSeqRat}$ consumer or by the finite-window $\mathsf{Real}^{\uparrow}$ endpoint is one of the listed source, ledger, membership, observation, comparison, finite $\mathsf{DyadicRatCore}$, or licensed endpoint-seal rows. The exclusion clauses in the cover, nested-window, triple-cover, and exhaustion theorems rule out completion data, quotient representatives, host index equality, countable choice, ambient completeness, and off-ledger $\mathsf{Real}^{\uparrow}$ seal classifiers. □

Theorem 126.110 (StreamName RegSeqRat cover Real four-face exit descent)**.** *Let $\{W_i\}_{i\in I}$ be a finite public* $\mathsf{StreamName}^{\uparrow}$ *cover satisfying the hypotheses of Definition 126.109. If the induced* $\mathsf{Real}^{\uparrow}$ *endpoint is consumed by a current Phase Real and Completion read, then that consumer factors through exactly the four displayed faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the visible BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows on the cover-indexed surface.*

The factorization contains no quotient stream, no selected limit, no countable choice row, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, no host sequence equality, and no standard bridge row.*

Proof. First apply Definition 126.109. It descends the finite-window $\mathsf{Real}^{\uparrow}$ handoff to the single cover-indexed StreamName source surface, with the selected classifier rows, bundle ledger, membership rows, unary observations, displayed hsame comparisons, dyadic ledger rows, and endpoint seal rows all on one public package.

Next invoke Definition 126.372. The descended endpoint is therefore read as the same four-object exit route: the finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, and the $\mathsf{Real}^{\uparrow}$ seal boundary. No additional top-level Real-and-completion coordinate is introduced.

Now use Definition 126.446, Definition 126.449, and Definition 126.450. These identify the current Phase Real and Completion exit packet with exactly the four displayed faces and the visible BHist, hsame, Cont, Pkg, and NameCert support rows. Thus the cover descent and the current open-phase exit packet have the same finite BEDC surface.

Finally apply Definition 126.476. Its exclusion clauses, together with the exclusions in the cover descent and four-object exactness theorems, rule out quotient streams, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric completeness, host sequence equality, and bridge rows. Hence every current consumer of the descended endpoint factors through the four-face exit surface and through no larger object. □

Theorem 126.111 (StreamName-RegSeqRat uniform finite-window seal)**.** *Let W be a finite* BHist *observation window for a public* $\mathsf{StreamName}^{\uparrow}$ *rational stream package, and suppose that the two endpoints of W satisfy* RatStreamNameFiniteWindowClassifier*. Then the StreamName pointwise seal, the* RegSeqRat *scheduled seal, every certified nested-window handoff through W, and the finite-window* $\mathsf{Real}^{\uparrow}$ *readback select the same finite observation packet under* hsame*.*

The common packet consists exactly of the pointwise RatStreamNameCarrier *and* RatStreamNameClassifier *observations at the certified unary indices of W, the accepted* RegSeqRat *pointwise seal rows, the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row, the finite* Cont *ledger, the* ProbeBundle *membership rows, and the shared* Pkg *provenance. It contains no quotient representative, completion modulus, host index equality, or additional regularity datum.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameRegseqratUniformFiniteWindowSeal`

Proof. First form the pointwise seal over the certified endpoints of W. Apply Definition 126.89 at each unary index. The endpoint classifier hypotheses give the same carrier row, classifier row, hsame transport, finite Cont route, Pkg provenance, and accepted DyadicRatCore ledger entry for the StreamName and RegSeqRat reads.

Next paste these pointwise rows over the whole finite window. By Definition 126.90, the scheduled RegSeqRat seal over W is the unique finite packet assembled from those rows and the same finite ledger. No quotient or completion representative is introduced by this pasting step.

Now compare all certified subwindows of W. Use Definition 126.101 to identify the direct and nested handoff routes with the same restricted source surface. Thus every nested-window consumer sees the pointwise packet just constructed, with the same ProbeBundle membership rows and hsame comparisons.

Finally apply Definition 126.103. The triple cover identifies the StreamName window package, the RegSeqRat scheduled seal, and the $\mathsf{Real}^{\uparrow}$ endpoint readback whenever their unary observations, finite Cont ledger, hsame transports, and Pkg provenance agree. Combining the four steps gives one uniform finite-window seal packet under hsame. □

Theorem 126.112 (StreamName RealUp finite-window seal boundary)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window whose endpoints satisfy* RatStreamNameFiniteWindowClassifier*. Suppose that the* RegSeqRat *handoff over W carries accepted pointwise seal rows, the finite* Cont *ledger, the* ProbeBundle *membership rows, the corresponding* InBundle *rows, the* UnaryHistory *observations, and shared* Pkg *provenance. Then these rows determine exactly the finite-window* $\mathsf{Real}^{\uparrow}$ *seal boundary read from W.*

Conversely, every public finite-window Real$^{\uparrow}$ *seal read arising from this handoff factors through those same StreamName source rows, accepted* RegSeqRat *pointwise seal rows, bundle-membership rows, unary observations, finite ledger entries, and provenance rows. The boundary contains no completion object, quotient representative, host index equality, or regularity datum outside the displayed* RegSeqRat *seal.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameRealupSealBoundary`

Proof. First recover the StreamName source surface. Apply Definition 126.79. It identifies the finite public window read with the displayed rational StreamName observations, the unary histories at the certified indices, the finite Cont routes, and the shared Pkg provenance.

Next pass to the scheduled rational seal. By Definition 126.86, the RegSeqRat side contributes only the accepted pointwise seal rows over the same unary observations, the same bundle-membership rows, and the same finite ledger. No additional sequence regularity row is available at this step.

Now compare the three visible seal surfaces. Use Definition 126.103. The StreamName window, the RegSeqRat scheduled seal, and the Real$^{\uparrow}$ endpoint readback cover one another exactly when their unary observations, bundle rows, finite transport ledger, hsame comparisons, and provenance agree.

Finally apply Definition 126.111. Uniformity over nested finite windows prevents a later subwindow from adding completion data, quotient representatives, host index equality, or hidden regularity data. Thus the forward direction gives a unique finite-window Real$^{\uparrow}$ seal boundary, and the reverse direction factors every public read through precisely the displayed rows. □

Theorem 126.113 (StreamName-RegSeqRat-RealUp seal pullback uniqueness)**.** *Let W be a finite public* StreamName$^{\uparrow}$ *rational observation window. Suppose two finite-window* Real$^{\uparrow}$ *seal reads over W arise from the same StreamName window rows, the same accepted* RegSeqRat *pointwise seal rows, the same* ProbeBundle *and* InBundle *membership rows, the same* UnaryHistory *observations, the same finite* Cont *ledger, the same* hsame *transports, and the same* Pkg *provenance. Then the two reads determine the same* Real$^{\uparrow}$ *finite-window seal boundary.*

Conversely, any equality of Real$^{\uparrow}$ *finite-window seal boundaries arising from W factors back through that displayed StreamName–*RegSeqRat *source surface: the common boundary is witnessed by the same StreamName window rows, the same accepted pointwise seal rows, the same bundle-membership rows, the same unary observations, the same finite ledger, the same* hsame *transport surface, and the same provenance. This pullback uses no quotient stream, selected host limit, host index equality, completion witness, or ambient completeness assumption.*

Proof. First expose the source surface for each read. Apply Definition 126.79 to both finite-window handoffs. The common StreamName window rows, unary observations, finite Cont routes, hsame transports, and Pkg provenance give the same public source packet.

Next exhaust the rational scheduled seal. By Definition 126.86, each handoff has only the displayed accepted RegSeqRat pointwise seal rows, the same ProbeBundle and InBundle membership rows, and the same finite ledger available to it.

The three seal surfaces now compare over a single packet. Use Definition 126.103 to identify the StreamName window surface, the RegSeqRat scheduled seal, and the Real$^{\uparrow}$ readback surface. Then Definition 126.111 prevents any nested finite subwindow from changing that packet.

It remains to read off the boundary. Apply Definition 126.112. The forward direction gives equality of the two Real$^{\uparrow}$ finite-window seal boundaries. The converse direction says that any such equality is already a factorization through the same StreamName–RegSeqRat source rows,

so no quotient stream, selected host limit, host index equality, completion witness, or ambient completeness datum can enter the pullback. □

Theorem 126.114 (StreamName-RegSeqRat-RealUp terminal pullback factorization)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window, and let R be a terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal read over W. Suppose R is presented through the public StreamName rational window interface and the accepted* RegSeqRat *pointwise seal over that window. Then R factors through exactly the StreamName point rows, the* RegSeqRat *pointwise seal rows, the* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary, the finite* Cont *ledger, the* hsame *transports, the* ProbeBundle *and* InBundle *membership rows, the* UnaryHistory *observations, and the shared* Pkg *provenance.*

Conversely, the displayed StreamName point rows, accepted RegSeqRat *pointwise seal rows,* $\mathsf{Real}^{\uparrow}$ *boundary row, finite* Cont *ledger,* hsame *transports, bundle-membership rows, unary observations, and provenance rows repack into the same terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal boundary. The factorization carries no quotient stream, selected host limit, host index equality, completion witness, ambient completeness row, or metric-completeness row.*

Proof. First build the uniform public packet. Apply Definition 126.111. It identifies the StreamName point rows and accepted RegSeqRat pointwise seal rows over W with one finite observation packet under the same hsame transports, finite Cont ledger, bundle-membership rows, unary observations, and provenance.

Next read the terminal boundary of the $\mathsf{Real}^{\uparrow}$ seal. Use Definition 126.112. The forward direction says that the displayed public packet determines the finite-window $\mathsf{Real}^{\uparrow}$ seal boundary, and the reverse direction repacks those same rows into the boundary read.

Finally compare any two terminal presentations of the read. Apply Definition 126.113. The pullback uniqueness identifies presentations with the same StreamName rows, accepted RegSeqRat rows, bundle-membership rows, unary observations, Cont ledger, hsame transports, and provenance.

The preceding steps give both directions of the factorization. Since each ingredient is read from the displayed finite packet and its $\mathsf{Real}^{\uparrow}$ boundary, there is no row from quotient streams, selected host limits, host index equality, completion witnesses, ambient completeness, or metric-completeness data available to the terminal seal. □

Theorem 126.115 (StreamName-RegSeqRat-DyadicRatCore-RealUp terminal pullback factorization)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window, and let R be a terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal read over W. Suppose R is presented through the public StreamName rational window interface, the accepted* RegSeqRat *pointwise seal over that window, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger anchored to the same window. Then R factors through exactly four visible faces: the StreamName point and window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* RegSeqRat *pointwise and readback rows, and the local* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary.*

The only support rows available to this factorization are the displayed BHist *observations, componentwise* hsame *transports, finite* Cont *routes, shared* Pkg *provenance,* ProbeBundle *and* InBundle *membership rows,* UnaryHistory *observations, and local* NameCert *support. Conversely, any packet displaying precisely those four faces and support rows repacks into the same terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal read. It exports no quotient stream equality, selected host limit, host real equality, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or choice datum.*

Proof. Start from the three-face terminal pullback of Definition 126.114. It places the terminal $\mathsf{Real}^{\uparrow}$ finite-window read on the StreamName point rows, accepted RegSeqRat pointwise seal rows, and $\mathsf{Real}^{\uparrow}$ seal boundary, with the displayed finite BHist, hsame, Cont, Pkg, ProbeBundle, InBundle, and UnaryHistory support.

Next insert the dyadic ledger face. Apply Definition 126.612. Its forward direction says that an accepted seal-facing read has exactly the StreamName, RegSeqRat, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, with the listed finite support rows. Its converse direction repacks any packet with those four faces into the same admissible public interface.

It remains to identify the dyadic face with the same finite window used by the regular-rational readback. Use the Dyadic-RegSeq route factorization Definition 126.444, as cited in the four-face exactness proof. This pins every endpoint, radius, distance, and readback coordinate to W before either the RegSeqRat or $\mathsf{Real}^{\uparrow}$ consumer can inspect the packet.

Combining these steps gives both directions of the terminal pullback. The three-face theorem supplies the StreamName–RegSeqRat–$\mathsf{Real}^{\uparrow}$ terminal boundary, the four-face exactness theorem supplies the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger as the fourth visible face, and the route factorization prevents a detached tolerance route from entering the packet.

The excluded objects are therefore not public coordinates of the factorization. There is no quotient stream equality, selected host limit, host real equality, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or choice datum available to the terminal read. □

Theorem 126.116 (StreamName-RegSeqRat-RealUp composite terminal pullback)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window. Suppose two consecutive terminal pullback readings pass first through the displayed* RatStreamNameCarrier *and* RatStreamNameClassifier *rows of W, then through the accepted* RegSeqRat *pointwise seal rows, and finally to the* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary. Then the two-stage terminal reading determines exactly the same finite* BHist *packet as the single composite pullback from the StreamName rows into the* $\mathsf{Real}^{\uparrow}$ *boundary row.*

The shared packet consists precisely of the RatStreamNameCarrier *rows, the* RatStreamNameClassifier *rows, the accepted* RegSeqRat *pointwise seal rows, the* $\mathsf{Real}^{\uparrow}$ *boundary row, the* ProbeBundle *rows, the* InBundle *membership rows, the* UnaryHistory *observations, the finite* Cont *ledger, the componentwise* hsame *transports, the common* Pkg *provenance, and the local* NameCert *witnessing the public StreamName window. It contains no quotient stream, selected host limit, host index equality, completion witness, ambient completeness row, or metric-completeness row.*

Proof. First build the finite public packet over W. Apply Definition 126.111. This identifies the displayed StreamName carrier and classifier rows with the accepted RegSeqRat pointwise seal rows, the bundle rows, the unary observations, the finite Cont ledger, the componentwise hsame transports, and the shared Pkg provenance.

Next read the endpoint seal as a boundary row. Use Definition 126.112. The boundary construction says that the same packet determines the $\mathsf{Real}^{\uparrow}$ finite-window seal boundary, and that every public boundary read factors back through the same StreamName rows, accepted RegSeqRat rows, ProbeBundle and InBundle rows, UnaryHistory observations, finite ledger, transports, and provenance.

Now compare the two consecutive pullback readings with the direct composite reading. Apply Definition 126.113. Since both routes expose the same finite source surface and the same $\mathsf{Real}^{\uparrow}$ boundary row, pullback uniqueness identifies their finite BHist packets component by component.

Finally invoke Definition 126.114. The terminal factorization repacks the identified packet through the local NameCert and shows that neither the two-stage route nor the composite route has access to a quotient stream, selected host limit, host index equality, completion witness, ambient completeness row, or metric-completeness row. Thus the consecutive and composite terminal pullbacks are the same finite public packet. □

Theorem 126.117 (StreamName terminal reindex pullback invariance)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet, and let R be a certified public finite-window reindex route for W. Suppose R preserves the public finite observation section, the certified endpoint rows, the displayed* BHist*, the componentwise* hsame *transports, the finite* Cont *ledger, the shared* Pkg *provenance, and the local* NameCert *rows. Then the terminal pullback read through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *is invariant under R.*

The invariant packet has the same visible StreamName window, the same $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *accepted readback rows, the same* $\mathsf{Real}^{\uparrow}$ *boundary row, and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

It introduces no quotient stream equality, selected host limit, host real equality, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or choice datum.

Proof. First read the reindexed StreamName side. Apply Definition 126.648. Its hypotheses are exactly the preserved public finite observation section, endpoint rows, displayed BHist, componentwise hsame, finite Cont ledger, shared Pkg, and local NameCert rows, so the reindexed route reaches the same terminal four-face pullback surface.

Next pin the four visible faces of that surface. Apply Definition 126.115. The factorization says that the terminal read has only the displayed $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ boundary row, and the listed support rows. Since the reindex route preserves those rows component by component, the visible faces are unchanged.

Finally compare the two-stage and direct terminal reads. By Definition 126.116, both presentations determine one finite BHist packet over the same support surface. Hence the terminal pullback is invariant under R, and no quotient, selected host limit, host real equality, completeness, bridge, trichotomy, open-cover compactness, or choice coordinate is added. □

Theorem 126.118 (StreamName terminal pullback idempotence)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet. Suppose a terminal four-face pullback packet over W already exposes exactly the StreamName finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *accepted readback rows, the* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary, and the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Suppose further that the same packet displays the corresponding ProbeBundle*,* InBundle*, and* UnaryHistory *rows required by the public finite observation surface. Then applying the terminal pullback reading to this packet again exposes the same finite BEDC packet.*

Equivalently, the terminal four-face pullback is a normal form for certified public StreamName finite-window reads: after the four visible faces and their support rows are present, a further terminal reading cannot add a quotient stream, host equality, selected limit, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or choice coordinate.

Proof. First identify the packet already in hand. Apply Definition 126.115. Its converse direction repacks exactly the displayed StreamName, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, together with the listed BHist, hsame, Cont, Pkg, bundle, unary-history, and NameCert support rows, into the terminal finite-window seal read over W.

Next compare the second reading with the first one. By Definition 126.116, a two-stage terminal read and the direct composite read determine the same finite BHist packet whenever they expose the same StreamName rows, accepted $\mathsf{RegSeqRat}^{\uparrow}$ rows, $\mathsf{Real}^{\uparrow}$ boundary row, finite ledger, transports, provenance, bundle rows, unary observations, and local NameCert support.

Finally account for certified reindex routes. Apply Definition 126.117. Any certified route preserving the displayed finite observation section, endpoint rows, BHist, hsame, Cont, Pkg, and NameCert rows reaches the same terminal four-face surface. Thus the second terminal read has no coordinate outside the normal-form packet, and the excluded quotient, host-equality, selected-limit, completeness, bridge, trichotomy, open-cover compactness, and choice data remain unavailable. □

Theorem 126.119 (StreamName terminal four-face support deletion obstruction)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet whose terminal four-face read exposes exactly the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$ *faces. Suppose the displayed support surface consists of*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

together with the public finite-observation rows ProbeBundle, InBundle, *and* UnaryHistory. *If any one of the displayed support rows* BHist, hsame, Cont, Pkg, *or* NameCert *is deleted, or if one of the public finite-observation rows* ProbeBundle, InBundle, *or* UnaryHistory *is deleted, the remaining packet is not accepted as a terminal four-face pullback over W.*

The missing row cannot be supplied by quotient stream equality, selected host limits, host equality, countable choice, ambient completeness, metric-completeness, bridge rows, trichotomy, or open-cover compactness.

Proof. First identify the four visible faces and their support surface. Apply Definition 126.115. It says that an accepted terminal read over W factors through exactly the StreamName window, dyadic endpoint-radius-distance ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback rows, and local $\mathsf{Real}^{\uparrow}$ finite-window boundary, with only the displayed BEDC support rows and public finite-observation rows available.

Next remove one displayed row. For one of BHist, hsame, Cont, Pkg, or NameCert, apply Definition 126.436. That minimality result says that deleting any of these rows destroys the public finite-window support needed by the StreamName packet before the terminal pullback can be formed.

For one of ProbeBundle, InBundle, or UnaryHistory, use the same four-face factorization. These rows are part of the public finite-observation surface read by the factorization itself, so deleting one removes a coordinate required by the accepted terminal packet.

Finally compare with the normal form. By Definition 126.118, a complete support surface is stable under another terminal read. Hence the converse direction of the four-face factorization can repack only the complete surface, not the shortened packet. The excluded quotient, host-limit, host-equality, choice, completeness, bridge, trichotomy, and compactness rows are not coordinates of that normal form, so none of them can fill the missing support row. □

Theorem 126.120 (StreamName terminal pullback support exactness)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet. A terminal four-face pullback packet over W is accepted exactly when it exposes the StreamName finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *accepted readback rows, the local* $\mathsf{Real}^{\uparrow}$ *finite-window seal*

boundary, and exactly the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert},$$

together with the public finite-observation rows ProbeBundle, InBundle, *and* UnaryHistory.

Conversely, any packet over W with exactly those visible faces and support rows repacks into the same terminal four-face pullback normal form. The acceptance test exports no quotient stream, selected host limit, host equality, countable choice, ambient completeness row, metric-completeness row, bridge row, trichotomy row, or open-cover compactness row.

Proof. For the forward direction, start from the terminal four-face factorization of Definition 126.115. It identifies every accepted terminal read over W with the StreamName finite-window face, the dyadic endpoint-radius-distance ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, the $\mathsf{Real}^{\uparrow}$ finite-window boundary, and the listed finite support rows.

Next use Definition 126.117. Since certified reindex routes preserve the public finite observation section, endpoint rows, BHist, hsame, Cont, Pkg, and NameCert rows, support cannot be enlarged by changing the terminal presentation of the same window.

The local deletion obstruction is Definition 126.119. It says that deleting any displayed BEDC support row, or any public ProbeBundle, InBundle, or UnaryHistory observation row, prevents acceptance, and that quotient, host-limit, host-equality, choice, completeness, bridge, trichotomy, and compactness rows cannot replace the missing coordinate.

For the reverse direction, assume a packet displays exactly those four faces and support rows. The converse direction of Definition 126.115 repacks it into the terminal finite-window seal read over W.

Finally apply Definition 126.118. Once the four faces, the five BEDC support rows, and the three public finite-observation rows are present, another terminal read returns the same packet. Hence the support list is both sufficient and necessary for acceptance, and quotient streams, selected host limits, host equality, countable choice, ambient completeness, metric-completeness rows, bridges, trichotomy, and open-cover compactness remain outside the normal form. □

Theorem 126.121 (StreamName terminal pullback support induction)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet. For the terminal four-face pullback over W, order the support rows as*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{ProbeBundle},\quad \mathsf{InBundle},\quad \mathsf{UnaryHistory}.$$

An accepted terminal four-face pullback over W is obtained by finite induction over this ordered support list: the empty prefix carries no accepted terminal extension, and each proper prefix has an accepted extension to the next prefix exactly when the next displayed row in the list is present. The full prefix is the unique terminal normal form over the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$ *faces.*

No quotient stream, selected host limit, host equality, countable choice, ambient completeness row, metric-completeness row, bridge row, trichotomy row, or open-cover compactness row can replace a missing step of this finite support induction.

Proof. The base stage is the deletion obstruction. By Definition 126.119, removing any one of the displayed BEDC support rows or public finite-observation rows prevents acceptance. In particular the empty prefix, and every prefix missing its next displayed row, cannot be accepted as the terminal four-face pullback over W.

For the induction step, assume a prefix of the displayed list has been built and consider the next row. If that next row is absent, the deletion obstruction again blocks acceptance, and the refused replacement rows cannot fill the coordinate. If the next row is present, the prefix extends by the corresponding finite BEDC support coordinate or public finite-observation coordinate.

At the terminal stage, apply Definition 126.115. It repacks exactly the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$ faces together with the complete displayed support list. Then use Definition 126.120 to identify that complete list as necessary and sufficient for acceptance.

Finally apply Definition 126.118. Once the full support prefix is present, a further terminal read returns the same packet, so no second terminal normal form exists over the four faces. The explicit refusals of quotient streams, selected host limits, host equality, countable choice, ambient completeness, metric-completeness rows, bridge rows, trichotomy, and open-cover compactness remain part of the induction invariant at every prefix. □

Theorem 126.122 (StreamName terminal pullback row-order determinacy)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet. Suppose an accepted terminal four-face pullback over W has support built by the induction of Definition 126.121. Then the support row order is uniquely fixed as*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{ProbeBundle},\quad \mathsf{InBundle},\quad \mathsf{UnaryHistory}.$$

Swapping two displayed rows, omitting a displayed row, or replacing a displayed row by any other row fails to present the same terminal normal form over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$.

In particular, quotient streams, selected host limits, host equality, countable choice, ambient completeness rows, metric-completeness rows, bridge rows, trichotomy rows, and open-cover compactness rows are not replacement rows for this terminal support order.

Proof. Start with Definition 126.121. It builds the accepted terminal support by the displayed finite prefix order, so each stage has a distinguished next row and the full prefix is the terminal normal form over the four faces.

The exactness theorem, Definition 126.120, identifies the same displayed list as the necessary and sufficient support for acceptance. Thus omitting any row leaves the exact support surface, and inserting a row outside the list does not repair the missing BEDC or public finite-observation coordinate.

Next apply Definition 126.119. It rules out acceptance after deleting any displayed row and also rules out quotient streams, selected host limits, host equality, countable choice, ambient completeness, metric-completeness rows, bridge rows, trichotomy, and open-cover compactness as substitutes for a missing coordinate.

Now use Definition 126.115. The four-face factorization repacks exactly the $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, the local $\mathsf{Real}^{\uparrow}$ boundary, and the displayed support rows. A swapped presentation therefore fails to match the prefix route used to construct that factorized packet.

Finally apply Definition 126.118. Once the ordered support list has reached the terminal packet, a further terminal read returns the same packet. Hence the accepted row order is deterministic, and no swapped, omitted, or replaced support list presents the same terminal normal form. □

Theorem 126.123 (StreamName terminal pullback metric-completion refusal)**.** *Let W be a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window observation packet, and suppose its terminal four-face pullback is accepted. No consumer can reinterpret that accepted packet as a* $\mathsf{Met}^{\uparrow}$ *row, a* $\mathsf{CompleteMetric}^{\uparrow}$

row, or an ambient-completeness witness unless the metric or completion row is separately displayed outside the terminal pullback surface.

Proof. Apply Definition 126.115 to identify the accepted terminal surface. It exposes the StreamName finite window, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint-radius-distance ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback rows, and the local $\mathsf{Real}^{\uparrow}$ finite-window boundary.

Now read the support list through Definition 126.120. The only support coordinates exported with those four faces are BHist, hsame, Cont, Pkg, NameCert, ProbeBundle, InBundle, and UnaryHistory. A $\mathsf{Met}^{\uparrow}$ row, a $\mathsf{CompleteMetric}^{\uparrow}$ row, and an ambient-completeness witness are not entries of that exact list.

It remains to rule out hidden replacement by an omitted coordinate. Use Definition 126.119: a row missing from the terminal support cannot be supplied by a quotient stream, selected host limit, host equality, countable choice, ambient completeness, metric-completeness row, bridge row, trichotomy, or compactness row.

Therefore any consumer that wants metric structure or completion data must display that data as a separate row outside the terminal pullback surface. The accepted StreamName–DyadicRatCore–RegSeqRat–Real four-face packet itself does not certify a metric space, a complete metric space, or ambient real completeness. □

Theorem 126.124 (StreamName-RegSeqRat finite-window cover refinement exhaustion)**.** *Let $\mathcal{W}$ be a finite cover of public* $\mathsf{StreamName}^{\uparrow}$ *rational observation windows feeding a common* RegSeqRat *consumer and a common finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Suppose that each window in $\mathcal{W}$ carries the displayed* RatStreamNameCarrier *and* RatStreamNameClassifier *rows,* ProbeBundle *and* InBundle *membership,* UnaryHistory *observations,* hsame *transports, a finite* Cont *ledger, accepted* DyadicRatCore *ledger entries, accepted* RegSeqRat *pointwise seal rows, and shared* Pkg *provenance.*

Let $\mathcal{W}'$ be any certified finite refinement cover of $\mathcal{W}$ whose refined subwindows have the same pointwise StreamName carrier and classifier rows, the same bundle-membership rows, the same unary observations, the same hsame *transports, the same finite* Cont *ledger, the same* DyadicRatCore *ledger entries, and the same* Pkg *provenance as their parent windows. Then $\mathcal{W}$ and $\mathcal{W}'$ determine the same exhausted* RegSeqRat *consumer surface and the same finite-window* $\mathsf{Real}^{\uparrow}$ *seal boundary.*

The common exhausted surface consists only of those displayed StreamName source rows, bundle-membership rows, unary observations, hsame *transports, finite* Cont *ledger entries,* DyadicRatCore *ledger entries,* Pkg *provenance rows, the accepted* RegSeqRat *pointwise seal rows, and the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row. It contains no quotient representative, completion object, host index equality, off-ledger regularity row, Classical datum, or standard-bridge datum.*

Proof. First exhaust the original finite cover. Apply Definition 126.108. It identifies all windows in $\mathcal{W}$ with one finite consumer surface because their StreamName rows, bundle memberships, unary observations, hsame transports, finite ledger entries, accepted dyadic entries, and provenance rows agree on every displayed overlap.

Next compare each refined subwindow with its parent window. Use Definition 126.101. The certified subwindow contributes no new carrier, classifier, membership, observation, transport, ledger, dyadic, or provenance row; it restricts the already exhausted parent surface to the smaller public window.

Now identify the seal rows seen by the common consumer. Apply Definition 126.111 to the original cover and to the refined cover. The accepted RegSeqRat pointwise seal rows and the finite-window $\mathsf{Real}^{\uparrow}$ endpoint readback are the same finite packet in both presentations because the refinement keeps the same displayed ledger and source rows.

Finally use Definition 126.112 and Definition 126.100. The first theorem fixes the $\mathsf{Real}^{\uparrow}$ boundary from the accepted RegSeqRat seal rows, and the second theorem exhausts the consumer surface to exactly the listed public rows. Hence the original cover and every certified finite refinement cover determine the same exhausted surface, with no quotient, completion, host-index, off-ledger regularity, Classical, or standard-bridge datum. □

Theorem 126.125 (StreamName-RegSeqRat-Real finite-window route factorization)**.** *Every public finite-window* $\mathsf{Real}^{\uparrow}$ *seal read accepted through the* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *handoff factors uniquely through the displayed* RatStreamNameCarrier *source rows, the* RatStreamNameClassifier *rows, the* ProbeBundle *and* InBundle *rows, the* UnaryHistory *observations, the* hsame *transports, the finite* Cont *ledger, the* DyadicRatCore *tolerance ledger, the accepted* RegSeqRat *pointwise seal rows, the shared* Pkg *provenance, and the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row.*

The factorization is unique at the public boundary: any two accepted reads with the same displayed rows determine the same exhausted RegSeqRat *consumer surface and the same finite-window* $\mathsf{Real}^{\uparrow}$ *seal boundary. No quotient representative, completion object, host index equality, Classical datum, or standard-bridge datum participates in the route.*

Proof. First identify the finite cover surface. Apply Definition 126.108. It binds the StreamName source rows, bundle-membership rows, unary observations, hsame transports, finite continuation ledger, dyadic tolerance entries, and provenance rows into one public finite-window consumer surface.

Next seal the rational side uniformly. Use Definition 126.111. The accepted RegSeqRat pointwise rows are therefore read through the same finite ledger on every nested public window, so no second route can be obtained by changing the window presentation.

Then pass to the endpoint boundary. Apply Definition 126.112. The $\mathsf{Real}^{\uparrow}$ readback is fixed by the accepted RegSeqRat seal rows and the displayed endpoint row, not by a completion object or a quotient representative.

Finally use Definition 126.124. It compares every certified finite refinement with the original cover and leaves the same exhausted consumer surface and the same endpoint seal. Thus each public finite-window $\mathsf{Real}^{\uparrow}$ read factors through exactly the listed StreamName, bundle, observation, transport, ledger, seal, provenance, and endpoint rows, with no host index equality, Classical datum, or standard-bridge datum outside the displayed route. □

Theorem 126.126 (StreamName-RegSeqRat-Real terminal nonescape boundary)**.** *Let T be any terminal consumer of a finite-window* $\mathsf{Real}^{\uparrow}$ *seal whose public route factors through the displayed* RatStreamNameCarrier *and* RatStreamNameClassifier *rows, the* ProbeBundle *and* InBundle *rows, the* UnaryHistory *observations, the* hsame *transports, the finite* Cont *ledger, the* DyadicRatCore *tolerance ledger, the accepted* RegSeqRat *pointwise seal rows, the shared* Pkg *provenance, and the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row. Then the terminal read of T is confined to that finite-name boundary.*

In particular, T has no access through this route to quotient representatives, selected limits, host index equality, Classical data, standard-bridge data, ambient completeness, metric-completeness rows, or any off-route completion witness.

Proof. First apply Definition 126.125. It forces the terminal $\mathsf{Real}^{\uparrow}$ read to pass through exactly the displayed StreamName carrier and classifier rows, bundle rows, unary observations, hsame transports, finite continuation ledger, dyadic tolerance ledger, accepted RegSeqRat pointwise seal rows, shared provenance, and endpoint seal row.

Next use Definition 126.124. Every certified finite refinement of the route has the same exhausted RegSeqRat consumer surface and the same endpoint boundary, so the terminal consumer cannot obtain a second route by changing the public window cover.

Now invoke Definition 126.111. The accepted rational seal rows are read uniformly over the finite public windows, which keeps the tolerance ledger and the pointwise seal packet inside the same finite-name surface.

Finally apply Definition 126.112. The endpoint $\mathsf{Real}^{\uparrow}$ boundary is fixed by those accepted finite rows and not by a quotient representative, a selected limit, host index equality, Classical data, standard-bridge data, ambient completeness, metric-completeness rows, or any off-route completion witness. Hence the terminal consumer remains inside the finite StreamName–$\mathsf{RegSeqRat}$–$\mathsf{Real}^{\uparrow}$ seal boundary. □

Theorem 126.127 (StreamName finite-window observation factorization)**.** *Every accepted finite observation of a* $\mathsf{StreamName}^{\uparrow}$ *packet that is consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *reader and then by a terminal* $\mathsf{Real}^{\uparrow}$ *seal factors through the displayed finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and the terminal Real seal before any endpoint read is exposed.*

Equivalently, the public observation route is exhausted by the RatStreamNameCarrier *and* RatStreamNameClassifie *rows, the* ProbeBundle *and* InBundle *rows, the* UnaryHistory *observations, the* hsame *transports, the finite* Cont *ledger, the accepted dyadic tolerance entries, the accepted* RegSeqRat *pointwise seal rows, the shared* Pkg *provenance, and the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row. It exposes no selected limit, quotient stream equality, host real equality, completion object, Classical datum, or standard-bridge datum.*

Proof. First use Definition 126.124. It compares the displayed finite window with every certified refinement and keeps the same exhausted RegSeqRat consumer surface and endpoint boundary.

Next apply Definition 126.125. The public read is forced through the StreamName carrier and classifier rows, bundle membership, unary observations, transports, finite ledger, dyadic tolerance ledger, accepted RegSeqRat rows, provenance, and the endpoint seal.

Finally invoke Definition 126.126. The terminal boundary prevents the endpoint read from opening a selected limit, quotient stream equality, host real equality, completion object, Classical datum, or standard-bridge datum. Carrier projection then leaves exactly the finite observation route listed in the statement. □

Theorem 126.128 (StreamName-RegSeqRat-Real seal obligation factorization)**.** *Let C be a Real-facing completion consumer whose route is displayed through a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window surface, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface over the same selected rational-history rows, and a* $\mathsf{Real}^{\uparrow}$ *seal ledger row. Then the finite Real-facing seal route factors through exactly the following three obligation blocks:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *block consisting of the rational-history classifier rows,* ProbeBundle *and* InBundle *rows,* UnaryHistory *observations, visible* hsame *transports, finite* Cont *routes, and* Pkg *provenance rows;*
2. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *block consisting of regularity, dyadic-tolerance, transport, stream-spine, and seal-interface rows over the same selected rational-history surface;*
3. *the* $\mathsf{Real}^{\uparrow}$ *block consisting of the seal classifier and its finite ledger boundary row.*

Conversely, any packet carrying exactly those three displayed blocks repacks into the same finite Real-facing seal route.

The factorization exports no quotient stream equality, selected host limit, host real equality, completion witness not carried by the packet, choice schedule, or ambient completeness row.

Proof. First isolate the finite StreamName source. Apply Definition 126.79. It identifies the only rows exported by the public finite-window surface as the selected rational-history classifier

rows, the finite probe ledger, membership rows, unary observations, and the visible transport and provenance data.

Next separate the downstream obligations. Apply Definition 126.82. The separation row assigns the classifier, bundle, membership, unary-history, hsame, Cont, and Pkg data to the StreamName block; the regularity, dyadic-tolerance, transport, and stream-spine data to the RegSeqRat block; and the seal classifier to the RealUp block.

Now compose the seal route. Use Definition 126.83 to pass from those three displayed surfaces to the Real-facing finite-window ledger boundary. This gives the forward factorization of C through the StreamName block, the RegSeqRat block, and the RealUp block.

For the reverse direction, read the same composition theorem from the three blocks back to the public route, and then apply Definition 126.112. The RealUp boundary confirms that the repacked row is the same finite seal route because the seal is read only through the displayed finite ledger boundary.

The exclusion clause follows from the same four boundary theorems. None of them introduces quotient stream equality, selected host limits, host real equality, completion witnesses outside the packet, choice schedules, or ambient completeness rows, so the factorized route exports none of those coordinates. □

Theorem 126.129 (StreamName-RegSeqRat-Real four-face seal obligation factorization)**.** *Let C be a Real-facing completion consumer whose route is displayed through a* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger, a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window surface, a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier readback over the same selected rational-history rows, and a* $\mathsf{Real}^{\uparrow}$ *seal ledger row. Then the finite Real-facing seal route factors through exactly the following four obligation blocks:*

1. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *block consisting of the endpoint ledger, radius ledger, dyadic-tolerance rows, and their finite handoff boundary;*
2. *the* $\mathsf{StreamName}^{\uparrow}$ *block consisting of the rational-history classifier rows,* ProbeBundle *and* InBundle *rows,* UnaryHistory *observations, visible* hsame *transports, finite* Cont *routes, and* Pkg *provenance rows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *block consisting of regularity, classifier, dyadic-tolerance transport, stream-spine, and seal-interface rows over the same selected rational-history surface;*
4. *the* $\mathsf{Real}^{\uparrow}$ *block consisting of the seal classifier and its finite ledger boundary row.*

Conversely, any packet carrying exactly these four displayed blocks repacks into the same finite Real-facing seal route.

The factorization exports no quotient stream equality, selected host limit, host real equality, completion witness not carried by the packet, choice schedule, ambient completeness row, metric-completeness row, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First discard the fourth face and read the visible StreamName-RegSeqRat-Real part of the route. Apply Definition 126.128. It gives the three displayed blocks carried by the StreamName finite-window surface, the RegSeqRat regularity and readback surface, and the RealUp seal boundary, and it also records the exclusions for quotient stream equality, selected host limits, host real equality, external completion witnesses, choice schedules, and ambient completeness rows.

Now insert the DyadicRatCore face at the unique upstream position. Apply Definition 38.738. The route places the endpoint and radius ledger before the StreamName finite-window schedule, before the RegSeqRat regularity and classifier rows, and before the local Real seal. Thus the three-block factorization refines to the four blocks listed in the statement.

The order is forced by Definition 38.739. Any route omitting or permuting one of the four faces either loses a displayed ledger row or leaves the finite packet by adding one of the excluded off-table coordinates. Hence the four-block route is not merely a presentation of C but the exact obligation factorization read by the Real-facing seal.

It remains to compare the shared packet data. Apply Definition 38.740. The DyadicRatCore ledger, StreamName schedule, RegSeqRat classifier and transport rows, and RealUp seal row all determine the same finite (BHist, hsame, Cont, Pkg, NameCert) packet. Therefore the reverse direction repackages any packet carrying exactly those four blocks into the same Real-facing seal route.

The exclusion clause follows from the same three inputs. The dependency route, order uniqueness theorem, and classifier-coherence theorem rule out quotient stream equality, selected host limits, host real equality, external completion witnesses, choice schedules, ambient completeness rows, metric-completeness rows, and a second RealUp seal coordinate. □

126.6 StreamName Real-RegSeq window source exhaustion

Theorem 126.130 (StreamName Real-RegSeq finite-window source exhaustion)**.** *Every finite-window* RegSeqRat *consumer read or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer read whose input is a public* $\mathsf{StreamName}^{\uparrow}$ *packet factors through exactly the public StreamName-RegSeqRat-RealUp source rows already exposed at the handoff boundary. The source inventory consists of the selected* RatHistoryClassifier *rows, the finite* ProbeBundle *row, the corresponding* InBundle *membership rows, the* UnaryHistory *observation rows, the visible* hsame *transports, the finite* Cont *ledger, the shared* Pkg *provenance rows, the accepted* DyadicRatCore *ledger entries, the accepted* RegSeqRat *pointwise seal rows, and the* $\mathsf{Real}^{\uparrow}$ *endpoint seal row.*

The factorization exports no quotient representative, no completion object, no host index equality, no off-ledger regularity row, no Classical datum, and no standard-bridge datum. Thus any finite public consumer read of the StreamName-RegSeqRat-RealUp handoff is exhausted by the displayed finite-window source inventory.

Proof. First separate the three obligation sources. By Definition 126.82, StreamName contributes only the carrier, selected rational-history classifier, finite-bundle, membership, unary-observation, finite ledger, and public package support rows, while RegSeqRat and RealUp supply their own seal-side obligations.

Next pass from a single window to any certified finite cover. Apply Definition 126.124. It says that cover refinement preserves exactly the displayed StreamName rows, bundle-membership rows, unary observations, hsame transports, finite Cont entries, accepted DyadicRatCore entries, Pkg provenance rows, accepted RegSeqRat pointwise seal rows, and the $\mathsf{Real}^{\uparrow}$ endpoint seal row.

Now identify the RegSeqRat read. Use Definition 126.100. The pointwise handoff consumes the accepted RegSeqRat seal rows through the same finite StreamName packet, so no off-ledger regularity row or hidden host-index equality can be introduced by the consumer read.

Finally identify the RealUp read. By Definition 126.112, the endpoint seal is fixed by the accepted RegSeqRat rows and the visible finite StreamName ledger. Since the preceding steps already exhaust the StreamName and RegSeqRat source rows, the RealUp endpoint cannot reopen quotient representatives, completion objects, Classical data, or standard-bridge data. □

Theorem 126.131 (Real L10 terminal source pullback uniqueness)**.** *Let* R_0 *and* R_1 *be terminal* $\mathsf{Real}^{\uparrow}$ *seal reads whose visible route is the four-face L10 chain* $\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$. *Suppose the two reads preserve the same displayed* $\mathsf{StreamName}^{\uparrow}$ *finite*

window, the same DyadicRatCore$^{\uparrow}$ *tolerance row, the same* RegSeqRat$^{\uparrow}$ *readback and regularity rows, the same componentwise* hsame *transports, the same finite* Cont *ledger, the same* Pkg *provenance rows, and the same local* NameCert$_{\mathsf{StreamName}^{\uparrow}}$, NameCert$_{\mathsf{DyadicRatCore}^{\uparrow}}$, NameCert$_{\mathsf{RegSeqRat}^{\uparrow}}$, *and* NameCert$_{\mathsf{Real}^{\uparrow}}$ *support rows.*

Then R_0 and R_1 determine the same terminal finite source pullback over the displayed L10 route. The pullback is the finite BHist *packet whose four faces are the dyadic tolerance ledger, the StreamName finite-window surface, the RegSeqRat readback and regularity surface, and the terminal RealUp seal row. No quotient stream equality, host real equality, selected limit, ambient completeness datum, countable-choice datum, metric-completeness datum, or standard-bridge row is exported by this uniqueness claim.*

Proof. First exhaust the source rows available to each terminal read. Apply Definition 126.130. Each read can consume only the displayed finite StreamName window, the accepted DyadicRatCore ledger entries, the RegSeqRat pointwise seal and regularity rows, the visible hsame transports, Cont rows, Pkg provenance, and local NameCert support.

Next identify the StreamName-to-RegSeqRat face. Use Definition 126.100. Since the two reads expose the same finite window and the same componentwise transports, the RegSeqRat face is read from the same public StreamName packet rather than from a host stream equality or a hidden representative.

Now identify the seal-facing RealUp face. Apply Definition 301.123 and Definition 38.718. These theorems place the terminal readback on the same finite RegSeqRat tail-selector route and the same RealUp finite-window seal, so no selected limit, ambient completeness datum, countable-choice datum, or metric-completeness datum remains as a separate source coordinate.

Finally repack the four displayed faces into one finite pullback. The StreamName seal boundary fixes the finite window, the RegSeqRat boundary fixes the readback and regularity rows, and the RealUp seal boundary fixes the endpoint seal row. Because R_0 and R_1 preserve the same rows on every face, the resulting finite BHist pullback is componentwise identical, and there is no standard-bridge row available to distinguish a second terminal source. □

126.7 StreamName finite-window Real handoff coverage

Theorem 126.132 (StreamName finite-window Real handoff coverage)**.** *Every RegSeqRat-to-*Real$^{\uparrow}$ *handoff read mediated by* StreamName$^{\uparrow}$ *factors through displayed finite windows, the* RegSeqRat *pointwise rows, the* Real$^{\uparrow}$ *seal boundary, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. More explicitly, the source surface is the finite inventory of* RatHistoryClassifier *observations,* ProbeBundle *ledgers,* InBundle *membership rows,* UnaryHistory *observations, accepted* RegSeqRat *pointwise seal rows, finite continuation rows, transport rows, provenance rows, and naming rows already displayed by the StreamName handoff.*

The coverage theorem exports no quotient stream, no host sequence equality, no ambient real completeness principle, no completion representative, and no Real$^{\uparrow}$ *seal read outside the finite StreamName and RegSeqRat rows.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFiniteWindowRealHandoffCoverage`

Proof. First read the StreamName source surface. Apply Definition 126.79: a public StreamName handoff exposes only selected rational-history classifier rows, the finite ProbeBundle ledger, InBundle membership rows, and UnaryHistory observations.

Next refine that source pointwise. Apply Definition 126.170; the downstream RegSeqRat or finite-window Real consumer receives exactly the StreamName carrier rows, finite-window classifier rows, certified unary observations, membership rows, and pointwise hsame comparisons. No regularity or seal row is created by this refinement.

Now pass to the Real seal boundary. Apply Definition 126.142. It says that a finite-window $\mathsf{Real}^{\uparrow}$ seal read arising from the StreamName-to-RegSeqRat handoff factors through the StreamName point rows, accepted RegSeqRat seal rows, bundle and membership rows, unary observations, finite Cont ledger, displayed hsame transports, and Pkg provenance.

Finally repack the same finite rows with the local naming certificate. The cited handoff and factorization rows already supply the finite windows, pointwise RegSeqRat rows, Real seal boundary, transport, continuation, and provenance. The StreamName NameCert row names that same finite surface, so a consumer has no route to quotient streams, host sequence equality, ambient real completeness, completion representatives, or a Real seal read outside the displayed packet. □

Theorem 126.133 (StreamName rational-ball window localization)**.** *Any accepted* $\mathsf{StreamName}^{\uparrow}$ *finite window used in a* $\mathsf{Real}^{\uparrow}$ *handoff can be localized through a displayed* $\mathsf{RationalInterval}^{\uparrow}$ *containment row and then through a* $\mathsf{RationalBall}^{\uparrow}$ *center-radius ledger before the read reaches the* $\mathsf{Real}^{\uparrow}$ *seal. Conversely, a displayed* $\mathsf{RationalBall}^{\uparrow}$ *containment row over a* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint window supplies the same finite* $\mathsf{StreamName}^{\uparrow}$ *observation route to the Real seal.*

The localized route carries only finite BHist *observations, interval endpoint-containment rows, ball center and nonnegative-radius rows, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream, host sequence equality, selected limit, ambient completeness premise, or hidden Real representative.*

Proof. For the forward route, begin with Definition 126.132. It confines the handoff to a finite StreamName observation window, accepted RegSeqRat pointwise rows, the Real seal boundary, transport rows, continuation rows, provenance, and local naming rows.

Refine that finite observation window through the endpoint discipline of chapter 354. The interval row supplies the displayed containment boundary for the rational observations without adding a completed real, quotient stream, or host equality.

Now pass from the interval row to the ball ledger of chapter 355. The center row, nonnegative-radius row, and containment ledger localize the same observations by a finite rational-radius packet before the handoff reaches the Real seal.

For the converse route, start from the displayed $\mathsf{RationalBall}^{\uparrow}$ containment row over a displayed $\mathsf{RationalInterval}^{\uparrow}$ endpoint window. Reading the center-radius ledger back through the interval containment row gives the same finite rational observation packet. Applying the StreamName coverage theorem again routes that packet through the same finite StreamName observation rows and then to the $\mathsf{Real}^{\uparrow}$ seal, with all excluded quotient, host, selected-limit, and completeness coordinates still absent. □

Theorem 126.134 (StreamName RegSeqRat Real window factorization)**.** *Suppose two* $\mathsf{StreamName}^{\uparrow}$*-mediated* RegSeqRat*-to-*$\mathsf{Real}^{\uparrow}$ *handoff reads use the same finite StreamName window, the same accepted* RegSeqRat *pointwise row, and the same* $\mathsf{Real}^{\uparrow}$ *seal boundary. Then the two reads have the same public source surface: the same finite packet of* RatHistoryClassifier *observations,* ProbeBundle *and* InBundle *rows,* UnaryHistory *observations,* RegSeqRat *pointwise seal rows, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

This factorization exposes no second $\mathsf{Real}^{\uparrow}$ *seal, no quotient stream, no host sequence equality, no selected completion representative, and no ambient completeness coordinate.*

Proof. First apply Definition 126.132 to both handoff reads. The two inventories are finite packets whose only public rows are the StreamName window, the RegSeqRat pointwise data, the Real seal boundary, the displayed transport and continuation routes, the provenance row, and the local naming rows.

Next apply Definition 126.170 to the shared accepted pointwise row. It identifies the RegSeqRat portion of both packets with the same StreamName carrier rows, classifier observations, unary observations, membership rows, and componentwise hsame comparisons.

Now apply Definition 126.142 to the shared Real seal boundary. The Real read factors through the same accepted RegSeqRat rows, finite bundle rows, displayed Cont routes, Pkg provenance, and transport rows; it does not create an additional Real-facing source coordinate.

Finally use Definition 126.97. Common-window determinacy identifies the two consumer reads once their finite StreamName window, RegSeqRat row, and Real seal boundary agree. Repacking those common rows under the local NameCert surface gives the stated public packet and rules out any quotient, host-equality, representative, or ambient-completeness exposure. □

Theorem 126.135 (StreamName Real handoff pullback exactness)**.** *A public* $\mathsf{Real}^{\uparrow}$ *seal read mediated by* $\mathsf{StreamName}^{\uparrow}$ *and* RegSeqRat *is accepted exactly when it factors through the finite* $\mathsf{StreamName}^{\uparrow}$ *window, the accepted* RegSeqRat *pointwise row, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. No accepted read may replace that pullback surface by quotient streams, host sequence equality, completion representatives, or ambient real completeness.*

Proof. For the forward direction, start from an accepted public $\mathsf{Real}^{\uparrow}$ seal read. Apply Definition 126.132 to expose the finite StreamName window, accepted RegSeqRat pointwise rows, Real seal boundary, transport rows, continuation rows, provenance, and local naming rows.

Next apply Definition 126.134. It identifies the public source surface of the read with the same finite StreamName window, the same accepted RegSeqRat pointwise row, and the same Real seal boundary before any downstream Real consumer can read the packet.

Now apply Definition 126.142. The Real-facing row is therefore reached only through the displayed handoff surface: finite StreamName observations, RegSeqRat pointwise acceptance, the seal boundary, hsame transports, Cont routes, Pkg provenance, and the local NameCert rows.

For the reverse direction, suppose such a finite pullback surface is displayed. Repack the listed rows as the StreamName-mediated RegSeqRat-to-Real handoff packet. The coverage theorem accepts exactly that inventory, the window factorization identifies the public source surface, and the Real seal factorization supplies the downstream seal route.

The excluded objects remain outside both directions. Quotient streams, host sequence equality, completion representatives, and ambient real completeness are not coordinates of the displayed pullback surface, so neither acceptance nor reconstruction can cite them. □

Theorem 126.136 (StreamName finite-window budget monotonicity)**.** *Let* $P \leq Q$ *be finite observation budgets for two* $\mathsf{StreamName}^{\uparrow}$*-mediated* RegSeqRat*-to-*$\mathsf{Real}^{\uparrow}$ *handoff reads. Suppose the* Q*-budget packet restricts on* P *to the same selected StreamName rows, the same accepted* RegSeqRat *pointwise row, and the same* $\mathsf{Real}^{\uparrow}$ *seal boundary as the* P*-budget packet. Then enlarging the budget from* P *to* Q *preserves the downstream* $\mathsf{Real}^{\uparrow}$ *seal consumer's public source surface.*

The preserved surface consists only of finite BHist *observations,* ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *observations, pointwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows visible in the restricted packet. The monotone handoff exports no quotient stream, no host sequence equality, no selected limit, and no ambient completeness principle.*

Proof. Apply Definition 126.132 to the P-budget handoff and to the Q-budget handoff. Both consumers are therefore confined to finite StreamName, RegSeqRat, Real-boundary, transport, continuation, provenance, and local naming rows.

Use Definition 126.170 on the restriction of the Q packet to P. The hypothesis identifies the selected StreamName rows and the accepted pointwise RegSeqRat row with the P packet, so the componentwise hsame and unary-history coordinates read by the Real consumer are the same on the restricted window.

Next apply Definition 126.142. The RealUp seal still factors through the displayed finite route: bundle membership, accepted RegSeqRat rows, displayed Cont rows, Pkg provenance, and the local transport rows. The larger budget supplies no additional seal-facing coordinate once its restriction has the same boundary row.

Finally apply Definition 126.134 to the shared restricted window. It identifies the public source surface seen by the downstream RealUp seal consumer, and the identified surface contains exactly the finite BEDC rows named in the statement. Quotient streams, host sequence equality, selected limits, and ambient completeness remain outside the handoff packet. □

Theorem 126.137 (StreamName Real-RegSeq common-window lattice coherence)**.** *Suppose two* StreamName$^{\uparrow}$*-mediated* RegSeqRat*-to-*Real$^{\uparrow}$ *handoff reads are compared through a certified common finite-window lattice meet. If their accepted* RegSeqRat *pointwise rows and their* Real$^{\uparrow}$ *seal boundary agree on that meet, then both reads expose the same finite* BHist *source surface. The common surface consists exactly of the* RatHistoryClassifier *observations,* ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *observations, accepted* RegSeqRat *pointwise seal rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows carried by the meet packet.*

This lattice coherence statement exports no quotient stream equality, no host sequence equality, no ambient Real$^{\uparrow}$ *completeness, no selected completion representative, and no metric-completeness row.*

Proof. First apply Definition 126.132 to each handoff read. Each read is already confined to the finite StreamName window, accepted RegSeqRat pointwise rows, the Real seal boundary, transport rows, continuation rows, provenance, and local naming rows.

Next apply Definition 126.134. The assumed agreement of the accepted pointwise rows and the Real seal boundary identifies the RegSeqRat and Real-facing rows that both reads can expose over the same window.

Now use Definition 126.257. The certified meet is a shared finite observation packet, so every RegSeqRat consumer and every finite-window RealUp consumer reads only its classifier, bundle, membership, unary-history, dyadic ledger, transport, continuation, provenance, and local naming coordinates.

Finally apply Definition 126.97. Common-window determinacy identifies the consumer reads on the certified meet surface. Repacking that identified surface gives the same finite BHist source packet for both handoffs and leaves quotient equality, host sequence equality, ambient Real completeness, selected representatives, and metric-completeness rows outside the public lattice surface. □

Theorem 126.138 (StreamName Real seal observation-budget factorization)**.** *Any finite-window* StreamName$^{\uparrow}$ *packet whose read is consumed by* RegSeqRat$^{\uparrow}$ *and sealed as* Real$^{\uparrow}$ *factors through the displayed observation-budget limiter route whenever an accepted* ObservationBudgetLimiter$^{\uparrow}$ *packet is present. The common route is the request row, budget row, cap row, window row, dyadic ledger,* RegSeqRat *readback,* Real$^{\uparrow}$ *seal, and structural rows named by the limiter surface of chapter 903.*

This factorization exports no uncapped schedule, hidden selector, quotient stream, host real equality, selected limit, independent real carrier, or ambient completeness principle.

Proof. Start with the finite-window handoff coverage. By Definition 126.132, the StreamName-to-Real route already exposes only finite StreamName observations, RegSeqRat pointwise rows, the Real seal boundary, transport rows, continuation rows, provenance, and local naming rows.

Refine the route through Definition 126.134. The RegSeqRat readback and Real seal have the same public source surface whenever the finite window, accepted pointwise row, and seal boundary agree.

Now use Definition 126.137. The common-window lattice pins the classifier observations, bundle rows, membership rows, unary-history observations, dyadic ledger, transports, routes, provenance, and local names to one finite observation packet.

When an accepted $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet is present, its request, budget, cap, and window rows are exactly the displayed limiter boundary through which that finite observation packet is read. Since neither the StreamName handoff nor the limiter carrier contains an uncapped schedule, hidden selector, quotient stream, host real equality, selected limit, independent real carrier, or ambient completeness coordinate, none of those objects can be exported by the factorization. □

Theorem 126.139 (StreamName Real observation-budget route)**.** *Any finite-window* $\mathsf{StreamName}^{\uparrow}$ *packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and sealed as* $\mathsf{Real}^{\uparrow}$*, when read by a* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer, factors through the request, budget, and window route of chapter 611. The route first exposes the finite StreamName surface, the* RegSeqRat *pointwise row, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and then repacks them as the* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet*

$$E, W, D, R, S, H, C, P, N$$

over the precision request, selected finite windows, dyadic readbacks and radii, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *rows.*

This route exports no uncapped schedule, quotient stream, host sequence equality, selected limit, independent real carrier, ambient completeness principle, or host real equality.

Proof. Begin with the finite-window handoff coverage. By Definition 126.132, the StreamName-to-Real packet already exposes only finite StreamName observations, RegSeqRat pointwise rows, the $\mathsf{Real}^{\uparrow}$ seal boundary, componentwise hsame transport, displayed Cont routes, Pkg provenance, and local NameCert rows.

Next apply Definition 126.134. It identifies the public source surface of the consumed packet with the same finite StreamName window, the same accepted RegSeqRat pointwise row, and the same $\mathsf{Real}^{\uparrow}$ seal boundary before the observation-budget consumer reads it.

Now use Definition 126.137. The common finite-window lattice pins the classifier observations, bundle rows, membership rows, unary-history observations, dyadic ledger, transports, routes, provenance, and local names to one finite observation packet.

Apply Definition 126.138 to pass that packet through the displayed observation-budget limiter boundary. The limiter supplies the request, budget, cap, and window discipline needed before a bounded real-facing consumer can inspect the StreamName handoff.

Finally route the bounded packet through chapter 611. Its carrier Definition 611.1 and non-escape theorem Definition 611.6 repack the same finite surface as $E, W, D, R, S, H, C, P, N$, with componentwise hsame, displayed Cont, Pkg, and the local $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ row. Since

neither the source handoff nor the observation-budget carrier contains an uncapped schedule, quotient stream, host sequence equality, selected limit, independent real carrier, ambient completeness row, or host real equality row, the routed consumer cannot export any of those objects. □

Theorem 126.140 (StreamName Real terminal factorization)**.** *Any finite-window* $\mathsf{StreamName}^{\uparrow}$ *packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*, sealed as* $\mathsf{Real}^{\uparrow}$*, and then read by a Real-facing consumer factors through the terminal source lock of Definition 126.145. The common terminal packet is exactly the finite* BHist *window, accepted* RegSeqRat *pointwise row, induced* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

The factorization exports no quotient stream, host sequence equality, selected limit, ambient real completeness, independent Real carrier, or metric-completeness row.

Proof. First project the finite StreamName rows. By Definition 126.132, the handoff read exposes only finite classifier observations, bundle and membership rows, unary observations, pointwise RegSeqRat rows, the $\mathsf{Real}^{\uparrow}$ seal boundary, transport rows, continuation rows, provenance, and local naming rows.

Next identify the public source surface by Definition 126.134. The finite StreamName window, accepted RegSeqRat pointwise row, and $\mathsf{Real}^{\uparrow}$ seal boundary determine the same surface for every downstream Real-facing read.

Apply Definition 126.135. The accepted read is therefore a pullback over exactly the finite window, pointwise row, seal boundary, hsame transports, Cont routes, Pkg provenance, and local NameCert rows.

Now route the bounded consumer through Definition 126.139. The Real-facing observation request reads the same finite packet through $\mathsf{RealObservationBudget}^{\uparrow}$, so the request, budget, and window discipline do not introduce an additional source coordinate.

Finally apply Definition 126.146. The terminal lock identifies the common source surface with the lock packet of Definition 126.145: the finite BHist window, hsame, Cont, Pkg, and NameCert rows together with the accepted RegSeqRat and induced $\mathsf{Real}^{\uparrow}$ seal rows. Since none of the cited routes carries quotient streams, host sequence equality, selected limits, ambient completeness, an independent Real carrier, or metric-completeness data, none is exported by the terminal factorization. □

Theorem 126.141 (StreamName Real terminal quotient refusal)**.** *Any finite-window* $\mathsf{StreamName}^{\uparrow}$ *packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*, sealed as* $\mathsf{Real}^{\uparrow}$*, and then read by a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *consumer factors first through the terminal source lock of Definition 126.145 and then through the refusal ledger of the* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *route. The source-facing part of the read is exactly the finite* BHist *window, accepted* RegSeqRat *pointwise row, induced* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row already locked by the terminal source packet.*

Requests for quotient stream equality, host sequence equality, selected limits, hidden tail oracles, ambient completeness, or metric-completeness rows are routed to refusal rather than exported as completion coordinates.

Proof. Start with the terminal factorization. By Definition 126.140, every Real-facing read of the finite StreamName-to-RegSeqRat-to-Real packet has the common source surface consisting only of the finite window, accepted pointwise row, induced seal row, componentwise transport, displayed continuation, provenance, and local naming rows.

Identify that source surface with the explicit lock packet of Definition 126.145. The lock contains no quotient stream, host sequence equality, selected limit, hidden tail oracle, ambient

completeness row, independent Real carrier, or metric-completeness coordinate, so none of those objects is available before the refusal consumer is consulted.

Now pass the locked packet to the QuotientStreamRefusal$^{\uparrow}$ consumer. Apply Definition 998.3: a completion-facing request that leaves the displayed finite route is sent to the refusal row and exports no completion coordinate.

Finally use Definition 998.9. The terminal refusal route exhausts the accepted read by the displayed route and refusal rows, with transport, replay, provenance, and naming attached to that route. Thus the StreamName terminal packet reaches the refusal ledger, while quotient equality, host equality, selected limits, hidden tail data, ambient completeness, and metric-completeness rows remain refused rather than exported. □

126.8 StreamName Real seal factorization boundary

Theorem 126.142 (StreamName Real seal factorization boundary)**.** *Let W be a finite public* StreamName$^{\uparrow}$ *rational observation window. Suppose that W is read through certified unary indices, that an accepted* RegSeqRat *pointwise seal package is displayed over the same certified indices, and that a finite-window* Real$^{\uparrow}$ *seal read arises from that StreamName-to-*RegSeqRat *handoff. Then the* Real$^{\uparrow}$ *seal read factors through exactly the following rows: the StreamName point rows over W, the accepted* RegSeqRat *seal rows, the* ProbeBundle *and* InBundle *membership rows, the* UnaryHistory *observation rows, the finite* Cont *ledger, the displayed* hsame *transports, and the* Pkg *provenance naming the source certificates.*

Conversely, any finite packet consisting of precisely those rows repacks as the same public finite-window Real$^{\uparrow}$ *seal read. The factorization contains no completion data, quotient representative, host index equality, Classical choice, or* Real$^{\uparrow}$ *completeness datum outside the displayed* RegSeqRat *seal rows.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealSealFactorizationBoundary`

Proof. First read the public Real$^{\uparrow}$ boundary through Definition 126.112. This identifies every finite-window endpoint read arising from the handoff with the StreamName source rows, the accepted RegSeqRat pointwise rows, bundle membership, unary observations, finite ledger entries, hsame transports, and provenance rows.

Next use Definition 126.111. It prevents nested finite windows from changing the seal surface: restricting or refining W keeps the same displayed point rows, the same accepted RegSeqRat seal rows, and the same finite Cont/Pkg provenance on the certified indices.

The common seal cover is supplied by Definition 126.103. The StreamName window, the RegSeqRat seal packet, and the Real$^{\uparrow}$ endpoint read agree only through the listed rows, so any public Real$^{\uparrow}$ read from the handoff has the announced factorization.

Finally apply Definition 126.100. The pointwise handoff exhausts the downstream seal rows by the certified StreamName observations and accepted RegSeqRat rows. Since none of the cited boundary theorems introduces completion data, quotient representatives, host index equality, Classical choice, or a Real$^{\uparrow}$ completeness field, the reverse packing uses exactly the displayed rows and no further datum. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameRealSealFactorizationBoundary`

Theorem 126.143 (StreamName Real seal factorization refinement stability)**.** *Let $W \subseteq W'$ be finite public* StreamName$^{\uparrow}$ *rational observation windows related by displayed prefix refinement. Suppose both windows carry accepted* RegSeqRat *seal rows over the certified unary indices, and suppose*

the source tuple for W' restricts to the source tuple for W through the same ProbeBundle*,* InBundle*,* UnaryHistory*,* Cont*,* hsame*, and* Pkg *rows. Then the finite-window* $\mathsf{Real}^{\uparrow}$ *seal factorization over W is exactly the restriction of the factorization over W'.*

The restricted factorization contains no completion datum, quotient representative, host index equality, choice row, or $\mathsf{Real}^{\uparrow}$ *completeness field beyond the displayed accepted* RegSeqRat *seal rows.*

Proof. Apply Definition 126.142 to both finite windows. Each factorization is read through the StreamName point rows, the accepted RegSeqRat seal rows, bundle membership, unary observations, finite continuation ledger, displayed hsame transports, and package provenance.

Use Definition 126.111 on the prefix refinement $W \subseteq W'$. It identifies the seal rows on the smaller window with the restriction of the rows displayed on the larger window.

It remains to identify the source tuple. The determinacy theorem Definition 126.149 says the restricted source is fixed by the displayed StreamName, bundle, history, transport, continuation, and provenance rows. The minimality theorem Definition 126.150 rules out any extra source coordinate outside those rows.

Therefore restricting the W' factorization along the displayed prefix refinement gives exactly the factorization obtained directly over W, with no additional completion, quotient, host-equality, choice, or completeness data. □

Theorem 126.144 (StreamName Real finite-window classifier exactness)**.** *Let W and W' be finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation windows over certified unary indices. Suppose the two windows display the same* ProbeBundle *rows, the same* InBundle *membership rows, the same* UnaryHistory *observations, the same pointwise rational classifier rows, the same accepted* RegSeqRat *seal rows, the same finite* Cont *ledger, the same displayed* hsame *transports, and the same* Pkg *provenance naming the source certificates. Then the finite-window* $\mathsf{Real}^{\uparrow}$ *seal classifier induced by either window is exactly the transport of the* RegSeqRat *classifier read from those displayed rows.*

In particular, no completion representative, quotient equality, hidden host index equality, choice datum, or $\mathsf{Real}^{\uparrow}$ *completeness field can change that classifier once the listed finite StreamName and* RegSeqRat *rows agree.*

Proof. First apply Definition 126.142. The boundary theorem says that every finite-window $\mathsf{Real}^{\uparrow}$ seal classifier arising from the StreamName-to-RegSeqRat handoff is read only through the listed StreamName rows, accepted RegSeqRat seal rows, bundle membership, unary history, continuation ledger, hsame transports, and package provenance.

Next apply Definition 126.143. Any common finite presentation or prefix refinement of W and W' restricts to the same displayed factorization, so changing the window while preserving the listed rows cannot change the induced $\mathsf{Real}^{\uparrow}$ classifier.

The classifier handoff is the equality supplied by Definition 126.268. Since the two windows expose the same pointwise rational classifier rows and the same accepted RegSeqRat seal rows, the transported RegSeqRat classifier is the single classifier available on the common finite surface.

Finally, Definition 126.149 fixes the source tuple from the displayed StreamName, bundle, history, transport, continuation, and provenance rows, and Definition 126.150 rules out any extra source coordinate. Hence the finite-window $\mathsf{Real}^{\uparrow}$ seal classifier is exactly the transported RegSeqRat classifier read from those rows, with no escape through completion, quotient, host-equality, choice, or completeness data. □

126.9 StreamName terminal source lock

Definition 126.145 (StreamName-RegSeqRat-RealUp terminal source lock)**.** *A* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}$–$\mathsf{Real}^{\uparrow}$ *terminal source lock is the finite packet*

$$\mathcal{L} = (W, R, S, H, C, P, N)$$

with the following displayed rows:

1. *W is a finite public* $\mathsf{StreamName}^{\uparrow}$ *window over certified unary observations, including the selected rational-history classifier rows, the finite* ProbeBundle *ledger,* InBundle *membership rows, and* UnaryHistory *observation rows;*
2. *R is the accepted* RegSeqRat *finite seal row over the same certified indices, including the regularity, dyadic-tolerance, stream-spine, and pointwise seal classifier rows supplied on the* RegSeqRat *side;*
3. *S is the finite-window* $\mathsf{Real}^{\uparrow}$ *seal row induced by reading W through R;*
4. *H is the displayed componentwise* hsame *row comparing the StreamName point rows, the* RegSeqRat *seal rows, the unary observation rows, the bundle-membership rows, and the induced* $\mathsf{Real}^{\uparrow}$ *seal row;*
5. *C is the displayed* Cont *ledger routing the read from the finite StreamName window through the accepted* RegSeqRat *seal row to the finite* $\mathsf{Real}^{\uparrow}$ *seal row;*
6. *P is the* Pkg *provenance naming the StreamName source certificate, the* RegSeqRat *finite seal certificate, the finite continuation ledger, and the induced* $\mathsf{Real}^{\uparrow}$ *seal read;*
7. *N is the local* NameCert *row for this finite handoff packet.*

The packet has no coordinate for a completion witness, quotient stream equality, host index equality, or off-ledger $\mathsf{Real}^{\uparrow}$ *classifier row.*

Theorem 126.146 (StreamName-RegSeqRat-RealUp terminal source lock)**.** *Every finite* $\mathsf{Real}^{\uparrow}$ *seal read induced from a public* $\mathsf{StreamName}^{\uparrow}$ *window through an accepted* RegSeqRat *finite seal factors through exactly the packet of Definition 126.145. The StreamName coordinates are read from W, the regularity and pointwise seal coordinates from R, the induced finite* $\mathsf{Real}^{\uparrow}$ *seal row from S, and the transport, continuation, provenance, and local naming rows from H, C, P, and N.*

Conversely, any finite packet carrying precisely those rows repacks as the same induced finite-window $\mathsf{Real}^{\uparrow}$ *seal read.*

Proof. First apply Definition 126.82. It separates the visible StreamName source rows, the downstream RegSeqRat regularity and seal rows, and the finite $\mathsf{Real}^{\uparrow}$ seal classifier into their distinct source surfaces.

Next apply Definition 126.111. The accepted RegSeqRat seal is stable under finite-window restriction, so the source window and the seal row keep the same displayed certified indices and the same pointwise classifier rows.

Finally apply Definition 126.142. It states that the finite $\mathsf{Real}^{\uparrow}$ seal read factors through exactly the StreamName point rows, accepted RegSeqRat seal rows, bundle membership, unary observations, finite Cont ledger, displayed hsame transports, and Pkg provenance. These rows are precisely the coordinates of $\mathcal{L}$, with N recording the local naming ledger, and no further coordinate is available for the reverse packing. □

Theorem 126.147 (StreamName-RegSeqRat-RealUp terminal non-escape)**.** *Let $\mathcal{L} = (W, R, S, H, C, P, N)$ be a terminal source lock. A consumer of the finite handoff can read only the finite StreamName window W, the accepted* RegSeqRat *seal row R, the induced finite* $\mathsf{Real}^{\uparrow}$ *seal row S, the displayed* hsame *transports H, the displayed* Cont *routes C, the* Pkg *provenance P, and the local* NameCert *row N. It cannot extract a completion witness, quotient stream equality, host index equality, or off-ledger* $\mathsf{Real}^{\uparrow}$ *classifier row from the lock.*

Proof. Project the consumer read through Definition 126.146. Every induced finite $\mathsf{Real}^{\uparrow}$ seal read is already factored by the displayed lock packet.

The separation theorem Definition 126.82 assigns each visible row to StreamName, RegSeqRat, or finite $\mathsf{Real}^{\uparrow}$ seal data, and it excludes completion witnesses, quotient rows, and host index equalities from the StreamName source surface.

The boundary theorem Definition 126.142 rules out any completion datum, quotient representative, host index equality, choice row, or $\mathsf{Real}^{\uparrow}$ completeness coordinate outside the displayed accepted RegSeqRat seal rows. The uniform finite-window theorem prevents a restriction of the lock from adding an off-ledger classifier row.

Thus the terminal packet is a finite source surface only. Every consumer read stays inside W, R, S, H, C, P, and N. □

Theorem 126.148 (StreamName-RegSeqRat-Real terminal observation coverage)**.** *Let $\mathcal{L} = (W, R, S, H, C, P, N)$ be a terminal source lock. Suppose a certified finite subwindow or finite refinement displays StreamName point rows,* RegSeqRat *seal rows, the induced* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and a local* NameCert *row agreeing with the corresponding restriction of $\mathcal{L}$. Then the induced finite-window* $\mathsf{Real}^{\uparrow}$ *read has the same terminal observation surface as $\mathcal{L}$ on that restricted packet.*

Conversely, every terminal observation read obtained from such a certified subwindow or refinement is covered by the parent lock: it reads only the restricted StreamName window, restricted RegSeqRat *seal rows, restricted induced* $\mathsf{Real}^{\uparrow}$ *seal row, restricted* hsame *and* Cont *rows, restricted* Pkg *provenance, and the restricted local* NameCert *row. The coverage exports no completion witness, no quotient stream equality, no host index equality, no off-ledger* $\mathsf{Real}^{\uparrow}$ *classifier row, and no ambient completeness coordinate.*

Proof. First apply Definition 126.146. It identifies each terminal read with exactly the lock packet coordinates W, R, S, H, C, P, N, so agreement with a restriction of $\mathcal{L}$ fixes the same terminal observation surface on the restricted packet.

Next apply Definition 126.132 and Definition 126.79. These results identify the finite StreamName observations, accepted RegSeqRat rows, finite $\mathsf{Real}^{\uparrow}$ seal row, transport rows, continuation routes, provenance, and local naming rows as the complete handoff surface for certified finite windows.

For refinements, use Definition 126.240 and Definition 126.249. They say that common-refinement and synchronized-window reads restrict to the same displayed finite rows and do not create a second Real-facing source coordinate.

Finally apply Definition 126.147. Since the parent lock has no coordinate for completion witnesses, quotient stream equality, host index equality, off-ledger $\mathsf{Real}^{\uparrow}$ classifier rows, or ambient completeness, neither a certified subwindow nor a finite refinement can export one. Thus every terminal observation read from such a packet is already covered by the parent lock. □

Theorem 126.149 (StreamName RegSeqRat RealUp seal source determinacy)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window, and let $\mathcal{E}_0$ and $\mathcal{E}_1$ be finite-window* $\mathsf{Real}^{\uparrow}$ *seal*

packages induced from W. Suppose both packages read the same accepted RegSeqRat *spine over W, the same DyadicRatCore endpoint ledger, the same* ProbeBundle *and* InBundle *rows, the same unary observation rows, the same finite* Cont *ledger, the same displayed* hsame *endpoint transports, and the same* Pkg *provenance. Then $\mathcal{E}_0$ and $\mathcal{E}_1$ have the same visible seal source.*

That source is exactly the public StreamName finite-window row, the accepted RegSeqRat *finite-window seal row, the dyadic endpoint rows, and the shared ledger boundary. It contains no completion row, quotient row, host index equality, or off-ledger* $\mathsf{Real}^{\uparrow}$ *classifier.*

Proof. First exhaust the scheduled seal package. Apply Definition 126.86. Both induced packages project to the same scheduled StreamName row, accepted RegSeqRat finite-window seal row, and finite-window $\mathsf{Real}^{\uparrow}$ ledger boundary, because the listed public window, spine, dyadic endpoint, bundle, transport, and provenance rows agree.

Next compare the pointwise seal rows. Use Definition 126.89 at each certified unary observation of W. The shared DyadicRatCore endpoint ledger fixes the pointwise seal classifier rows under the displayed hsame transports, so the two packages cannot choose different visible rational endpoints.

Now pass from pointwise rows to the whole finite window. By Definition 126.111, the public StreamName window, the scheduled RegSeqRat seal, and every nested handoff select one finite observation packet with the same ProbeBundle, Cont, hsame, and Pkg rows.

Finally apply Definition 126.112. Every finite-window $\mathsf{Real}^{\uparrow}$ seal read arising from this handoff factors through the same StreamName row, accepted RegSeqRat seal row, dyadic endpoint rows, and shared ledger boundary. Since none of the cited boundary theorems exports completion rows, quotient rows, host index equality, or off-ledger classifiers, the visible seal source of $\mathcal{E}_0$ and $\mathcal{E}_1$ is determined by the stated handoff data. □

Theorem 126.150 (StreamName RegSeqRat RealUp seal source minimality)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *rational observation window, and let $\mathcal{E}$ be a finite-window* $\mathsf{Real}^{\uparrow}$ *seal package induced from W and an accepted* RegSeqRat *spine. Then every visible source row used by $\mathcal{E}$ is one of the public StreamName finite-window row, the accepted* RegSeqRat *finite-window seal row, the dyadic endpoint ledger, the* ProbeBundle *and* InBundle *rows, the unary history rows, the finite* Cont *ledger, the displayed* hsame *endpoint transports, or the* Pkg *provenance.*

In particular, no completion carrier, quotient representative, host-index equality, or off-ledger $\mathsf{Real}^{\uparrow}$ *classifier is a source row of the induced finite-window seal package.*

Proof. Start with Definition 126.149 applied to two reads of the same induced package. The determinacy statement identifies the visible source with the public StreamName finite-window row, the accepted RegSeqRat finite-window seal row, the dyadic endpoint rows, and the shared ledger boundary.

Use Definition 126.86 to expand the scheduled seal boundary. The expansion lists only the accepted spine rows, bundle rows, unary observation rows, continuation rows, endpoint transports, and provenance named in the statement.

Finally apply Definition 126.112. Its boundary factorization is through exactly those finite-window rows, so any alleged source outside the listed tuple would have to enter through a completion, quotient, host-index, or off-ledger classifier row. The boundary theorem exports none of those rows, establishing the stated minimality. □

Theorem 126.151 (StreamName RegSeqRat RealUp seal unique source)**.** *Let $\mathcal{E}_0$ and $\mathcal{E}_1$ be finite-window* $\mathsf{Real}^{\uparrow}$ *seal packages induced from public StreamName windows and accepted* RegSeqRat *spines. Suppose they agree on exactly the minimal source tuple consisting of the public StreamName finite-window row, accepted* RegSeqRat *finite-window seal row, dyadic endpoint ledger,* ProbeBundle

and InBundle *rows, unary history rows, finite* Cont *ledger, displayed* hsame *endpoint transports, and* Pkg *provenance. Then every downstream* RegSeqRat *or* $\mathsf{Real}^{\uparrow}$ *finite-window consumer sees the same visible seal source from* $\mathcal{E}_0$ *and* $\mathcal{E}_1$*.*

Proof. First apply Definition 126.150 to both packages. Each visible source is confined to the same finite tuple of public window, accepted seal, endpoint, bundle, history, continuation, transport, and provenance rows.

The assumed agreement on that tuple supplies the hypotheses of Definition 126.149. Hence the two packages have the same visible seal source.

Any downstream finite-window RegSeqRat or $\mathsf{Real}^{\uparrow}$ consumer reads through that visible source tuple and not through completion, quotient, host-index, or off-ledger classifier data. Therefore the consumer observations obtained from $\mathcal{E}_0$ and $\mathcal{E}_1$ coincide on the visible seal source. □

Theorem 126.152 (StreamName RegSeqRat RealUp finite-window pullback criterion)**.** *Let* S *and* T *be finite* $\mathsf{StreamName}^{\uparrow}$ *handoffs accepted by a* RegSeqRat *finite-window seal consumer and by a* $\mathsf{Real}^{\uparrow}$ *finite-window seal consumer. They classify as the same consumer-visible packet precisely when the following finite source rows agree componentwise:*

1. *the public* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows;*
2. *the accepted* RegSeqRat *finite-window seal rows;*
3. *the DyadicRatCore endpoint ledgers;*
4. *the displayed* ProbeBundle *and* InBundle *rows;*
5. *the* UnaryHistory *observation rows;*
6. *the finite* Cont *ledger;*
7. *the displayed* hsame *endpoint transports;*
8. *the* Pkg *provenance rows.*

Equivalently, those rows form the finite pullback packet seen by both consumers. The criterion has no coordinate for completion rows, quotient rows, host index equality, off-ledger $\mathsf{Real}^{\uparrow}$ *classifiers, arithmetic packages, order packages, or metric-completeness rows.*

Proof. For the forward direction, assume S and T classify as the same consumer-visible packet. Apply Definition 126.149 to the two finite seal reads. It identifies the visible source with the public StreamName window, accepted RegSeqRat seal row, dyadic endpoint ledger, bundle rows, unary observations, continuation rows, endpoint transports, and package provenance.

Next use Definition 126.150. Since every visible source row of either handoff lies in that finite tuple, classification of the consumer-visible packet projects to componentwise agreement on each listed row.

For the reverse direction, suppose the listed rows agree componentwise. Apply Definition 126.151. The common tuple determines the same visible seal source for every downstream RegSeqRat or $\mathsf{Real}^{\uparrow}$ finite-window consumer.

Now apply Definition 38.413. The public StreamName rows, dyadic endpoint ledgers, accepted regular-rational seal rows, and RealUp seal provenance are exactly the four open-phase faces, and the displayed hsame, Cont, Pkg, and certificate coordinates are the gluing data. Hence the componentwise agreement repacks into one finite pullback packet.

Finally, the same four cited theorems describe all exported source coordinates. None exports completion data, quotient representatives, host index equality, off-ledger $\mathsf{Real}^{\uparrow}$ classifier rows, arithmetic or order packages, or metric-completeness rows, so these data are not part of the criterion. □

Theorem 126.153 (StreamName RegSeqRat RealUp pullback stability)**.** *Let S and T be two finite-window handoff packets addressed to the same class of* RegSeqRat *seal consumers and finite-window* $\mathsf{Real}^{\uparrow}$ *consumers. Suppose the packet comparison transports componentwise the public* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, accepted* RegSeqRat *finite-window seal rows, DyadicRatCore endpoint ledgers, displayed* ProbeBundle *and* InBundle *rows,* UnaryHistory *observations, finite* Cont *ledgers, displayed* hsame *endpoint transports, and* Pkg *provenance rows. Then S and T determine the same consumer-visible finite pullback packet for every* RegSeqRat *consumer and for every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer.*

This stability statement has no coordinate for completion rows, quotient rows, host index equality, off-ledger $\mathsf{Real}^{\uparrow}$ *classifiers, arithmetic packages, order packages, or metric-completeness rows.*

Proof. Apply Definition 126.152. The criterion reduces equality of the consumer-visible finite pullback packet to equality of the finite source rows listed in its eight public families.

The hypotheses supply exactly those identifications. The transported public $\mathsf{StreamName}^{\uparrow}$ rows identify the visible finite window; the accepted RegSeqRat rows and DyadicRatCore endpoint ledgers identify the regular rational seal boundary; the displayed bundle, unary-history, continuation, endpoint-transport, and provenance rows identify the remaining finite gluing data.

It remains only to exclude extra consumer coordinates. The exclusion clause of the same criterion states that completion data, quotient representatives, host index equality, off-ledger $\mathsf{Real}^{\uparrow}$ classifier rows, arithmetic or order packages, and metric-completeness rows are not exported by the finite pullback packet. Hence no additional row can distinguish the two transported packets for a RegSeqRat or finite-window $\mathsf{Real}^{\uparrow}$ consumer. □

Definition 126.154 (StreamName RegSeqRat reindexed window package)**.** *A* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *reindexed window package is a finite public handoff row with the following displayed components:*

1. *a finite-window* $\mathsf{StreamName}^{\uparrow}$ *row over rational histories, with its public carrier and selected* RatStreamNameClassifier *row;*
2. *a certified unary reindexer ρ between the source unary window and the consumer unary window;*
3. *the reindexed* RatHistoryClassifier *rows obtained by reading the selected StreamName observations through ρ;*
4. *the finite* ProbeBundle *ledger, the* InBundle *membership rows, and the* UnaryHistory *observation rows for both the source window and the reindexed consumer window;*
5. *the downstream* RegSeqRat *finite-window seal input rows whose source side is exactly the reindexed rational-history classifier rows and their displayed bundle membership evidence.*

The package has no hidden carrier. Its public surface is only the finite StreamName row, the unary reindexer, the reindexed rational-history classifier rows, the bundle and membership rows, the unary observation rows, and the displayed downstream finite-window input rows.

Theorem 126.155 (StreamName RegSeqRat reindexed window exhaustion)**.** *Every consumer row of the reindexed window package of Definition 126.154 is projected from one of the following three sources: the StreamName reindexing and map-stability row of Definition 126.19, the finite-window reindexed map coverage row of Definition 126.24, or the finite-window RegSeqRat handoff row of Definition 126.79. Conversely, those three rows repack into the displayed package and determine its whole consumer surface.*

Proof. First project the reindexing spine. Apply Definition 126.19 to the certified unary reindexer ρ. This gives the transported StreamName carrier row and the selected rational-history classifier rows after reindexing.

Next project the finite window. Apply Definition 126.24. It gives the matching ProbeBundle, InBundle, and UnaryHistory rows on the source and consumer windows, and it identifies the reindexed classifier rows as the only rows visible on the consumer window.

Finally project the downstream handoff. Apply Definition 126.79. It says that the RegSeqRat finite-window consumer reads exactly the selected rational-history classifier rows together with the displayed bundle, membership, and unary observation rows.

For the converse direction, repack those three projections in the order listed in the definition: the public finite-window StreamName row, the certified unary reindexer, the reindexed rational-history classifier rows, the bundle ledger rows, and the downstream finite-window input rows. No additional row is available after these projections, so the repacked package is exhaustive. □

Theorem 126.156 (StreamName RegSeqRat reindexed window imports no seal)**.** *The reindexed window package of Definition 126.154 exports no* RegSeqRat *regularity witness, no* $\mathsf{Real}^{\uparrow}$ *seal classifier, no completion object, no host index equality, and no quotient row. Any such row must be supplied by the downstream* RegSeqRat *or* $\mathsf{Real}^{\uparrow}$ *certificate rather than by the finite reindexed StreamName window.*

Proof. Read the package by the exhaustion theorem Definition 126.155. Its three sources are the reindexing spine, the finite-window reindexed map coverage, and the finite-window StreamName handoff.

The first two sources only transport and cover StreamName observation rows. They mention the unary reindexer, rational-history classifier rows, ProbeBundle membership, and UnaryHistory observations.

The handoff source is separated by Definition 126.79. That theorem places regularity, seal classifiers, completion objects, host equalities, and quotient rows outside the finite StreamName source.

Therefore projecting and repacking the package cannot introduce any of those excluded rows. They remain obligations of the downstream consumer surface. □

Theorem 126.157 (StreamName RegSeqRat reindexed window consumer determinacy)**.** *Let* Ω *and* Ω' *be two* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *reindexed window packages. Suppose they have the same public StreamName row, the same certified unary reindexer* ρ*, the same selected rational-history classifier rows, and the same finite-window handoff rows after the displayed* hsame *transports. Then every downstream* RegSeqRat *finite-window consumer reads the same source surface and the same selected finite-window input rows from* Ω *and* Ω'*. No regularity witness,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion datum, quotient row, or host index equality can distinguish the two packages.*

Proof. First apply Definition 126.19 to the shared reindexer ρ. The common StreamName source row and the displayed hsame transports identify the reindexed rational-history classifier rows seen by the consumer window.

Next apply Definition 126.24. The selected classifier rows determine the finite ProbeBundle, InBundle, and UnaryHistory rows available on the reindexed window. Thus the two packages expose the same selected finite-window input rows.

Now apply Definition 126.79. The downstream RegSeqRat boundary reads only the reindexed rational-history classifier rows together with the displayed bundle, membership, unary observation, and handoff rows.

Finally use Definition 126.156. It excludes regularity witnesses, $\mathsf{Real}^{\uparrow}$ seal classifiers, completion data, quotient rows, and host index equalities from the package surface, so no extra row can separate Ω from Ω' for a finite-window consumer. □

Theorem 126.158 (StreamName RegSeqRat reindexed window identity handoff)**.** *Assume that the certified unary reindexer in a* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}$ *reindexed window package is the identity on every displayed* UnaryHistory *observation. Then the package of Definition 126.154 exposes exactly the unreindexed* $\mathsf{StreamName}^{\uparrow}$ *finite-window row and the same* RegSeqRat *finite-window handoff rows. It exposes no additional regularity row, seal row, completion row, quotient row, or host index-equality row.*

The associated ten-field fit is:

1. *the traditional target is identity reindexing for countable names;*
2. *the BEDC source is* $\mathsf{StreamName}^{\uparrow}$ *together with the* RegSeqRat *finite-window handoff;*
3. *the carrier is the finite rational-observation window;*
4. *the classifier consists of the selected* RatHistoryClassifier *rows;*
5. *stability is identity reindexing together with the displayed* hsame *transports;*
6. *the ledger consists of the* ProbeBundle, InBundle, *and* UnaryHistory *rows;*
7. *the core theorem is this identity handoff;*
8. *exactness is equality with the same finite-window rows;*
9. *the ordinary bridge is finite prefix readback;*
10. *the status is a paper theorem awaiting a formal target.*

Proof. Apply Definition 126.19 to the certified unary reindexer. Under the identity assumption on every displayed UnaryHistory observation, the transported StreamName carrier row and the source carrier row have the same finite observations after the displayed hsame transports.

Apply Definition 126.24. The finite-window coverage row identifies the reindexed RatHistoryClassifier entries with the selected entries already read from the unreindexed StreamName window. The ProbeBundle, InBundle, and UnaryHistory ledger rows are therefore the same displayed finite rows.

Next use Definition 126.79. The RegSeqRat finite-window consumer reads only those selected rational-history classifier rows together with the visible bundle, membership, unary-observation, and handoff rows, so the identity reindexer supplies exactly the unreindexed handoff surface.

The exhaustion theorem Definition 126.155 shows that no other consumer row is present in the package. Finally Definition 126.156 excludes regularity, seal, completion, quotient, and host index-equality rows. Hence the identity case is precisely the unreindexed finite-window handoff. □

Theorem 126.159 (StreamName RegSeqRat reindexed selected-classifier handoff)**.** *For a* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *reindexed window package, the reindexed selected* RatHistoryClassifier *rows, the finite* ProbeBundle *ledger, the* InBundle *membership rows, and the* UnaryHistory *observations are exactly the common finite-window source surface consumed by both the downstream* RegSeqRat *finite-window seal row and the finite-window* $\mathsf{Real}^{\uparrow}$ *ledger-boundary row. No* RegSeqRat *regularity witness,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion datum, quotient datum, or host index equality is imported into that common surface.*

Proof. First apply Definition 126.155. It identifies the package surface with the public StreamName finite-window row, the certified unary reindexer, the selected rational-history classifier rows, the finite bundle, membership, unary-observation, and handoff rows.

Next use Definition 126.79. The RegSeqRat finite-window consumer reads precisely the selected RatHistoryClassifier rows together with the displayed ProbeBundle, InBundle, and UnaryHistory ledger rows.

Then apply Definition 38.320. The finite-window $\mathsf{Real}^{\uparrow}$ boundary reads the same displayed ledger surface after the StreamName and RegSeqRat rows have been restricted to the selected window.

Finally use Definition 126.156. Since the reindexed package imports no regularity witness, seal classifier, completion row, quotient row, or host index equality, the four selected source families are the whole common input surface for the two downstream consumers. □

Theorem 126.160 (RegSeqRat tail-classifier finite-window handoff exactness)**.** *For a concrete* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *reindexed window package, the reindexed* RatHistoryClassifier *rows, the displayed* ProbeBundle*,* InBundle*,* UnaryHistory*,* hsame*,* Cont*, and* Pkg *rows, and the DyadicRatCore ledger rows determine exactly the downstream selected* RegSeqRat *tail-classifier row read by the corresponding finite-window* $\mathsf{Real}^{\uparrow}$ *boundary. The determination is by the same finite source rows on both sides: no quotient row, host* $\mathbb{N}$ *index equality,* $\mathsf{Real}^{\uparrow}$ *completeness datum, metric-completeness datum, or hidden selector row is admitted.*

Proof. First apply Definition 126.155. It reduces the package to the public StreamName finite window, the certified unary reindexer, the selected rational-history classifier rows, the finite bundle and membership rows, the unary-observation rows, the hsame/Cont transports, and the package provenance.

Next apply Definition 126.159. This identifies those selected classifier rows with the common finite source surface consumed by the downstream RegSeqRat seal row and by the finite-window $\mathsf{Real}^{\uparrow}$ ledger boundary.

Use Definition 38.360 for the RegSeqRat side. Its pullback uniqueness says that the selected tail-classifier row is fixed by the displayed rational-history rows and the DyadicRatCore ledger rows, with no additional quotient or host index coordinate.

Finally apply Definition 38.404. The $\mathsf{Real}^{\uparrow}$ consumer boundary is the same finite source boundary already selected above, so it reads exactly the tail-classifier row determined by the reindexed StreamName and RegSeqRat ledger surface and nothing hidden beyond it. □

Theorem 126.161 (StreamName RegSeqRat reindexed window composition normal form)**.** *Let*

$$W_0 \xrightarrow{\rho_1} W_1 \xrightarrow{\rho_2} \cdots \xrightarrow{\rho_n} W_n$$

be a finite chain of certified unary reindexers between $\mathsf{StreamName}^{\uparrow}$ *finite windows, and let* $\rho_n \circ \cdots \circ \rho_1$ *denote the composite reindexer carried by the displayed unary-history continuations. The package obtained by iterating the reindexed* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *finite-window handoff along the chain exposes the same selected* RatHistoryClassifier *rows,* ProbeBundle*,* InBundle*,* UnaryHistory*, finite* hsame/Cont*, and downstream* RegSeqRat *handoff surface as the single package formed from the composite reindexer.*

No regularity witness, seal classifier, completion datum, quotient datum, or host index-equality row is imported by passing from the chain to the composite package.

Proof. Proceed by induction on the finite chain of certified unary reindexers.

In the empty-chain case, apply Definition 126.158. The identity package exposes exactly the unreindexed selected RatHistoryClassifier rows together with the visible ProbeBundle, InBundle, UnaryHistory, finite hsame/Cont, and RegSeqRat handoff rows.

For the induction step, assume the initial chain has already been repacked as the composite reindexer. Apply Definition 126.155 to the next one-step package and to the composite package. Both surfaces are exhausted by the displayed StreamName finite-window row, the selected rational-history classifier rows, the bundle and membership rows, the unary observations, and the downstream handoff ledger.

Next use Definition 126.157. Since the composite reindexer and the one-step extension display the same finite source rows after the carried hsame and Cont transports, every downstream consumer reads the same package surface.

Finally apply Definition 126.159 to identify the common selected classifier rows with the downstream RegSeqRat handoff surface. The boundary is exactly Definition 126.156: the normal form imports no regularity witness, seal classifier, completion datum, quotient datum, or host index-equality row. □

Theorem 126.162 (StreamName RealUp subwindow ledger determinacy)**.** *Let Ω and Ω' be two reindexed* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *finite-window packages over rational histories. Assume that they display the same public* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same certified unary reindexer, the same selected* ProbeBundle *subwindow, the same* InBundle *membership rows, the same* UnaryHistory *observation rows, and the same transported* RatHistoryClassifier *rows. Then every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer reading the corresponding subwindow sees the same finite* BHist *source surface from Ω and Ω'.*

The common surface consists exactly of the public StreamName classifier rows, the RegSeqRat *handoff rows, the selected endpoint rows, and the finite ledger boundary carried by the displayed bundle, membership, and unary-history rows. It contains no quotient datum, completion object, host-index equality, metric-completeness witness, or standard-bridge row.*

Proof. Start with the two reindexed window packages. By Definition 126.157, the common public StreamName row, certified unary reindexer, selected bundle, membership rows, unary-history rows, and transported rational classifiers force the same finite source surface for every downstream finite-window consumer.

Next project the RegSeqRat side. The finite-window handoff theorem Definition 126.79 reads exactly the selected RatHistoryClassifier rows together with the displayed ProbeBundle, InBundle, and UnaryHistory ledger rows. The restriction theorem Definition 126.175 keeps those rows unchanged when the consumer asks only for the selected subwindow.

Now attach the RealUp read boundary. Apply Definition 38.320 to the common subwindow surface. It identifies the visible $\mathsf{Real}^{\uparrow}$ input as the selected StreamName classifier rows, endpoint rows, RegSeqRat dyadic source rows, and finite ledger boundary already present in the two packages.

Finally use Definition 126.156. Since the reindexed package imports no seal classifier, quotient, completion, host-index equality, metric-completeness witness, or standard-bridge row, no finite-window $\mathsf{Real}^{\uparrow}$ consumer can distinguish Ω from Ω' by such data. The exposed BHist source surface is therefore the same. □

Theorem 126.163 (StreamName RegSeqRat composite reindexed RealUp boundary)**.** *Let Ω_{01} and Ω_{12} be composable reindexed* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *finite-window packages over rational histories. Assume that the output side of Ω_{01} and the input side of Ω_{12} share the middle transported* RatHistoryClassifier *rows, the same selected* ProbeBundle*, the same* InBundle *membership*

rows, and the same UnaryHistory *ledger rows. Then the composite package exposes to every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer exactly the selected StreamName classifier rows, the* RegSeqRat *handoff rows, the selected endpoint rows, and the finite ledger boundary carried by those displayed bundle, membership, and unary-history rows.*

The composite package exposes no quotient datum, completion object, host-index equality, metric-completeness witness, or standard-bridge row. In particular, the middle transported rational classifier rows are boundary glue for the two finite windows, not a source of additional $\mathsf{Real}^{\uparrow}$ *input data.*

Proof. First compare each leg with its finite-window consumer surface. Apply Definition 126.157 to Ω_{01} and to Ω_{12}. The shared middle RatHistoryClassifier rows, selected bundle, membership rows, and unary-history ledger rows force the same visible source surface at the joint window boundary.

Next identify the rows that survive the handoff. By Definition 126.159, the common source surface is exactly the selected StreamName classifier rows together with the RegSeqRat handoff rows and the displayed finite ledger rows. Composability only matches the middle classifier entries; it does not add a second handoff family.

Now read the composite through a finite-window $\mathsf{Real}^{\uparrow}$ consumer. Apply Definition 126.162 to the shared subwindow surface. The $\mathsf{Real}^{\uparrow}$ input is therefore the selected StreamName classifier rows, the selected endpoint rows, the RegSeqRat handoff rows, and the finite ledger boundary already present in the two packages.

Finally apply Definition 126.156 to both legs. Since neither leg exposes quotient data, completion data, host-index equality, metric-completeness witnesses, or standard-bridge rows, their composition cannot expose such a row to the $\mathsf{Real}^{\uparrow}$ consumer. The displayed finite boundary is the whole composite readback surface. □

Theorem 126.164 (StreamName RegSeqRat reindexed window composition associativity)**.** *Let* Ω_{01}*,* Ω_{12}*, and* Ω_{23} *be three composable reindexed* $\mathsf{StreamName}^{\uparrow}$–RegSeqRat *finite-window packages over rational histories. Assume that the two middle interfaces match by the displayed transported* RatHistoryClassifier *rows, selected* ProbeBundle *rows,* InBundle *membership rows, and* UnaryHistory *ledger rows. Then the two composites* $(\Omega_{23}\circ\Omega_{12})\circ\Omega_{01}$ *and* $\Omega_{23}\circ(\Omega_{12}\circ\Omega_{01})$ *expose the same selected StreamName classifier rows, the same* RegSeqRat *handoff rows, the same* ProbeBundle*,* InBundle*, and* UnaryHistory *ledger rows, and the same finite-window* $\mathsf{Real}^{\uparrow}$ *seal surface.*

Neither bracketing introduces a regularity witness, completion object, quotient row, host-index equality, or unrecorded stream datum. Thus every finite-window consumer reads the same BEDC boundary from both bracketings.

Proof. First compare the adjacent composites. Apply Definition 126.157 to the Ω_{01}–Ω_{12} interface and again to the Ω_{12}–Ω_{23} interface. The transported middle classifier rows, selected bundle rows, membership rows, and unary-history ledger rows force the same finite consumer surface at each shared boundary.

Next form the left bracketing. Use Definition 126.163 on Ω_{01} and Ω_{12}, then use the same theorem on the resulting composite and Ω_{23}. The visible output is exactly the selected StreamName classifiers, RegSeqRat handoff rows, endpoint rows, and displayed finite ledger boundary.

For the right bracketing, apply Definition 126.163 first to Ω_{12} and Ω_{23}, and then to Ω_{01} and that composite. The same determinacy rows are used at the same two middle interfaces, so the selected classifiers, handoff rows, bundle rows, membership rows, unary-history rows, and $\mathsf{Real}^{\uparrow}$ boundary are identical.

Finally apply Definition 126.156 to the three component packages. Since no component imports a seal classifier, regularity witness, completion object, quotient row, host-index equality,

or unrecorded stream datum, neither bracketing can create such a distinguishing row. The two bracketings therefore expose one common finite-window boundary. □

Theorem 126.165 (StreamName RegSeqRat reindexed window structural closure)**.** *Let Ω_{01} and Ω_{12} be composable reindexed* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}$ *finite-window packages over rational histories. Assume that their selected probe bundles are joined by* $\mathsf{bundleAppend}$ *and that their reindexing maps compose on the selected rational observation rows. Then the composite package exposes exactly the selected StreamName classifier rows, the* $\mathsf{RegSeqRat}$ *handoff rows, the* $\mathsf{ProbeBundle}$, $\mathsf{InBundle}$, *and* $\mathsf{UnaryHistory}$ *ledger rows, and the finite-window* $\mathsf{Real}^{\uparrow}$ *boundary already exposed by the two factors after reindexing.*

No seal row, quotient row, completion object, host-index equality, regularity witness, or unrecorded stream datum is introduced by the composite package.

Proof. First apply Definition 126.155 to each factor. For each leg, the accepted finite-window consumer surface is exhausted by the selected StreamName classifier rows, the $\mathsf{RegSeqRat}$ handoff rows, and the displayed probe, membership, and unary-history ledger rows.

Next use the structural laws for $\mathsf{bundleAppend}$. Appending the two finite probe bundles preserves exactly the entries already recorded in the two factor ledgers and supplies the composite $\mathsf{InBundle}$ and $\mathsf{UnaryHistory}$ rows by finite concatenation, not by a new stream source.

The reindexing composition law identifies the selected rational observation rows of the appended package with the observation rows obtained by applying the two factor reindexings in sequence. Hence the StreamName classifier rows and $\mathsf{RegSeqRat}$ handoff rows seen by the composite consumer are precisely the transported rows already present in the factors.

Finally apply Definition 126.163 to read the finite $\mathsf{Real}^{\uparrow}$ boundary, and apply Definition 126.156 to the two factors. These theorems exclude seal, quotient, completion, host-index, regularity, and unrecorded-stream rows, so the displayed rows are the whole structural closure of the composite package. □

Theorem 126.166 (StreamName RegSeqRat reindexed window diamond source determinacy)**.** *Let Ω_{01}, Ω_{12}, Ω'_{01}, and Ω'_{12} be two certified composable reindexing routes from the same finite* $\mathsf{StreamName}^{\uparrow}$ *source window to the same finite* $\mathsf{Real}^{\uparrow}$ *boundary. Suppose the two routes display the same transported* $\mathsf{RatHistoryClassifier}$ *rows, selected* $\mathsf{ProbeBundle}$ *rows,* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *ledger rows,* hsame *transport rows,* Cont *continuation rows,* Pkg *package rows, and* $\mathsf{RealLedgerPolicy}$ *rows at the shared boundary. Then the two composite routes expose the same finite* $\mathsf{Real}^{\uparrow}$ *source boundary.*

The common boundary is the selected StreamName classifier surface together with the displayed $\mathsf{RegSeqRat}$ *handoff rows, endpoint rows, finite probe and membership rows, unary-history ledger rows, continuation rows, package rows, and real-ledger-policy rows. No quotient datum, completion object, host-index equality, regularity witness, standard bridge row, or hidden stream row can separate the two routes.*

Proof. First compare the matching legs. Apply Definition 126.157 to Ω_{01} and Ω'_{01}, and again to Ω_{12} and Ω'_{12}. The shared classifier, bundle, membership, unary-history, hsame, Cont, Pkg, and real-ledger-policy rows determine the same visible consumer surface on each side of the diamond.

Next close each route under composition. By Definition 126.165, the composite $\Omega_{12} \circ \Omega_{01}$ and the composite $\Omega'_{12} \circ \Omega'_{01}$ expose only the selected source classifiers, the $\mathsf{RegSeqRat}$ handoff rows, and the displayed finite ledger rows.

The bracketing of the certified route does not change that surface. Apply Definition 126.164 to compare the route read as a two-leg composite with the same route read through any adjacent certified handoff factorization.

Finally read both composites through the finite $\mathsf{Real}^{\uparrow}$ boundary theorem. Use Definition 126.163 to identify the shared source boundary, and use Definition 126.156 to exclude quotient, completion, host-index, regularity, standard-bridge, and hidden stream rows. The two routes therefore expose one finite $\mathsf{Real}^{\uparrow}$ source boundary. □

Theorem 126.167 (StreamName RegSeqRat reindexed window triple-diamond normal form)**.** *Let $\mathcal{R}_0$, $\mathcal{R}_1$, and $\mathcal{R}_2$ be three certified composable reindexing routes from the same finite* $\mathsf{StreamName}^{\uparrow}$ *source window to the same finite* $\mathsf{Real}^{\uparrow}$ *boundary. Suppose the three routes display the same selected* RatHistoryClassifier *rows,* ProbeBundle *rows,* InBundle *witnesses,* UnaryHistory *ledgers,* hsame *transport rows,* Cont *rows,* Pkg *rows, and* RealLedgerPolicy *rows. Then the three routes have a common normal form: they expose one finite* $\mathsf{Real}^{\uparrow}$ *source boundary, namely the selected StreamName classifier surface together with the displayed* RegSeqRat *handoff, probe, membership, unary-history, continuation, package, and real-ledger-policy rows.*

This normal form contains no quotient datum, completion object, host-index equality, regularity witness, standard bridge row, or hidden stream row. Any finite-window $\mathsf{Real}^{\uparrow}$ *consumer of any one of the three routes therefore reads exactly the same source boundary and exactly the same recorded handoff ledger.*

Proof. First compare the routes pairwise. Apply Definition 126.166 to $\mathcal{R}_0$ and $\mathcal{R}_1$, and again to $\mathcal{R}_1$ and $\mathcal{R}_2$. The shared classifier, probe, membership, unary-history, transport, continuation, package, and real-ledger-policy rows force the same finite $\mathsf{Real}^{\uparrow}$ source boundary on both comparisons.

Next normalize the bracketing of each route. Use Definition 126.164 to identify adjacent certified factorizations of the same route, and use Definition 126.165 to read the route through only the selected StreamName classifier rows, the RegSeqRat handoff rows, and the displayed finite ledger rows.

Finally apply Definition 126.163 to each normalized route. The common source boundary delivered by the pairwise diamond comparison is exactly the finite $\mathsf{Real}^{\uparrow}$ boundary delivered by the composite-boundary theorem, so no quotient, completion, host-index equality, regularity witness, standard bridge row, or hidden stream row is available to distinguish the three routes. □

Theorem 126.168 (StreamName RegSeqRat reindexed window triple terminal seal determinacy)**.** *Let $\mathcal{R}_0$, $\mathcal{R}_1$, and $\mathcal{R}_2$ be three certified composable reindexing routes from one finite* $\mathsf{StreamName}^{\uparrow}$ *source window to one terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal consumer. Suppose the routes share the displayed selected* RatHistoryClassifier *rows,* RegSeqRat *handoff rows, endpoint rows,* ProbeBundle*,* InBundle*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*, and* RealLedgerPolicy *rows. Then every terminal seal consumer of the three routes reads the same finite* $\mathsf{Real}^{\uparrow}$ *source boundary.*

No quotient, completion object, host-index equality, regularity witness, standard bridge row, or hidden stream row distinguishes the three routes at the terminal seal. The terminal consumer can therefore observe only the common finite StreamName boundary transported through the RegSeqRat *handoff and the displayed finite-window* $\mathsf{Real}^{\uparrow}$ *endpoint rows.*

Proof. First put the three routes into the common finite-window normal form. Apply Definition 126.167 to the shared classifier, handoff, probe, membership, unary-history, transport, continuation, package, and real-ledger-policy rows. This gives one finite source boundary for the three certified routes.

Next read that boundary as a finite $\mathsf{Real}^{\uparrow}$ boundary. The composite-boundary theorem Definition 126.163 identifies the selected StreamName classifier surface and the RegSeqRat handoff rows with the finite $\mathsf{Real}^{\uparrow}$ source boundary available to the endpoint consumer.

Finally pass from the endpoint boundary to the terminal seal. Apply Definition 126.45 to the finite $\mathsf{Real}^{\uparrow}$ boundary just obtained. The terminal seal reads exactly that boundary, and Definition 126.156 excludes quotient, completion, host-index, regularity, standard-bridge, and hidden stream rows from the seal interface. □

Theorem 126.169 (StreamName RegSeqRat RealUp common-window seal)**.** *Let W be a reindexed finite* $\mathsf{StreamName}^{\uparrow}$ *window equipped with selected* RatHistoryClassifier *rows,* ProbeBundle *rows,* InBundle *witnesses,* UnaryHistory *rows,* hsame *transport rows,* Cont *rows,* Pkg *rows, displayed* RegSeqRat *handoff rows, displayed* DyadicRatCore *endpoint rows, and a finite* RealLedgerPolicy *ledger. Suppose the* RegSeqRat *finite-window seal consumer and the finite-window* $\mathsf{Real}^{\uparrow}$ *terminal seal consumer are read through certified reindexing routes using exactly these displayed rows. Then the two consumers read the same finite source boundary: the selected* $\mathsf{StreamName}^{\uparrow}$ *classifier surface transported through the displayed* RegSeqRat *handoff,* DyadicRatCore *endpoint, probe, membership, unary-history, continuation, package, and real-ledger-policy rows.*

This common boundary contains no quotient datum, completion object, host-index equality, hidden stream row, or independent regularity row. In particular, the RegSeqRat *finite-window seal and the* $\mathsf{Real}^{\uparrow}$ *terminal seal are consumers of one finite source boundary, not two separately supplied boundary packages.*

Proof. First identify the RegSeqRat side of the boundary. Apply Definition 126.159 to the selected classifier rows, bundle rows, membership witnesses, unary history, hsame transport, continuation, package, and displayed handoff rows. The finite RegSeqRat consumer therefore sees only the selected $\mathsf{StreamName}^{\uparrow}$ source surface transported through the displayed handoff ledger.

Next compare the terminal routes for the finite $\mathsf{Real}^{\uparrow}$ seal. Apply Definition 126.168 to the route that reads the RegSeqRat seal boundary, the route that reads the displayed DyadicRatCore endpoint rows, and the route that reads the finite $\mathsf{Real}^{\uparrow}$ terminal seal. The shared classifier, handoff, endpoint, probe, membership, unary-history, hsame, Cont, Pkg, and RealLedgerPolicy rows force a single finite source boundary for all three consumers.

Finally read that same boundary at the terminal seal. Use Definition 126.45 to identify the finite-window $\mathsf{Real}^{\uparrow}$ consumer with the boundary already selected by the RegSeqRat handoff and endpoint rows. The no-import clause in the terminal determinacy theorem excludes quotient, completion, host-index equality, hidden stream, and independent regularity rows, so the two seal consumers share exactly the displayed finite source boundary. □

126.10 StreamName RegSeqRat Pointwise Handoff

Theorem 126.170 (StreamName pointwise handoff package)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows and let $\mathcal{P}$:* ProbeBundle *be a finite observation bundle. A pointwise handoff from* $\mathsf{StreamName}^{\uparrow}$ *to* RegSeqRat *or to a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer consists exactly of the following source rows:*

1. $\mathsf{RatStreamNameCarrier}(s)$ *and* $\mathsf{RatStreamNameCarrier}(t)$*;*
2. $\mathsf{RatStreamNameClassifier}(s, t)$*, restricted on $\mathcal{P}$ through* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$*;*
3. *for each certified n, the rows* $\mathsf{UnaryHistory}(n)$*,* $\mathsf{InBundle}(n, \mathcal{P})$*, and the pointwise* hsame *comparison carried by the classifier at n.*

Every row handed to RegSeqRat *or to a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer is one of these pointwise StreamName rows. The handoff contains no completion object, quotient row, host-index equality,* RegSeqRat *regularity row, or* $\mathsf{Real}^{\uparrow}$ *seal classifier.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRegSeqRatPointwiseHandoff`

Proof. Project the public finite-window StreamName surface by Definition 126.79. It exposes the selected classifier rows, the finite ProbeBundle ledger, InBundle membership, and UnaryHistory observations.

Now read the selected classifier pointwise. Definitions Definition 126.1 and Definition 126.2 identify the carrier and classifier rows as statements about the observations $s(n)$ and $t(n)$ at certified unary histories. The finite-window classifier row restricts exactly those pointwise observations to the selected bundle.

Finally apply Definition 126.100 and Definition 126.82. These theorems repack the pointwise rows into the same downstream handoff and keep regularity and seal classifiers on the consumer side. □

Theorem 126.171 (StreamName RegSeqRat observation stability)**.** *Let* $s, t, u, s', t' : \mathsf{BHist} \to \mathsf{BHist}$ *and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be finite. Suppose* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *and* $\mathsf{RatStreamNameFiniteWindowClassifier}(t, u, \mathcal{P})$ *hold, and suppose every certified* n *with* $\mathsf{InBundle}(n, \mathcal{P})$ *and* $\mathsf{UnaryHistory}(n)$ *carries the pointwise comparisons* $\mathsf{hsame}(s(n), s'(n))$ *and* $\mathsf{hsame}(t(n), t'(n))$*. Then the same bundle also supports the self, symmetric, transitive, and transported pointwise classifier rows:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, s, \mathcal{P}),$$
$$\mathsf{RatStreamNameFiniteWindowClassifier}(t, s, \mathcal{P}),$$
$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, u, \mathcal{P}),$$
$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{P}).$$

Thus a RegSeqRat *handoff or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer may transport the StreamName observation window only along pointwise* hsame *rows already certified in the finite bundle.*

Proof. Unfold the finite-window classifier at a certified member of $\mathcal{P}$. The hypotheses provide the pointwise classifier rows $s(n) \sim t(n)$ and $t(n) \sim u(n)$ together with the carrier row for $s(n)$.

Apply the finite-window stability fields represented on the Lean side by RatStreamNameFiniteWindowClassifier_s Its four projections give the self row for s, the symmetric row from t to s, the transitive row from s to u, and the transported row from s' to t' on the same finite bundle.

The consumer boundary is unchanged. By Definition 126.170, the transported rows are still only pointwise StreamName observations plus bundle membership and unary history evidence, so no downstream regularity or seal row is imported. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier stability fields`

Theorem 126.172 (StreamName RealUp constant observation handoff)**.** *Let* $d, e : \mathsf{BHist}$ *be rational-history endpoints, let* $r, q : \mathsf{BHist} \to \mathsf{BHist}$ *be observation schedules, and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite unary observation bundle. The constant StreamName rows*

$$n \mapsto \mathsf{RatStreamName_constant}(d, r(n)), \qquad n \mapsto \mathsf{RatStreamName_constant}(e, q(n))$$

feed RegSeqRat *and finite-window* $\mathsf{Real}^{\uparrow}$ *only through the pointwise rows of Definition 126.170. The rational endpoint classifier for* d *and* e *supplies the constant point observations, while regularity, dyadic seal data, and the* $\mathsf{Real}^{\uparrow}$ *seal classifier remain downstream obligations.*

Proof. Start from the constant StreamName boundary. Apply Definition 126.81: a constant finite window exports the rational point-classifier row, the finite bundle ledger, membership rows, and unary observation rows, while RegSeqRat regularity remains outside the StreamName source.

Apply Definition 126.286 to the two scheduled constant rows. The Lean definitions RatStreamNameCarrier, RatStreamNameClassifier, and RatStreamName_constant express this as pointwise observations of the fixed rational endpoints d and e at every certified unary history.

Finally pass the resulting finite window through Definition 38.314 and Definition 38.320. These RealUp consumer theorems read only the pointwise StreamName packet and its ledger, so the constant handoff contributes no completion, quotient, host-index equality, regularity witness, or seal classifier. □

Theorem 126.173 (StreamName singleton diagonal handoff)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $n : \mathsf{BHist}$ be a certified unary observation, and let S_n be the singleton probe bundle generated by n. If $\mathsf{RatStreamNameClassifier}(s, t)$ and $\mathsf{UnaryHistory}(n)$ hold, then the exact finite-window packet handed to RegSeqRat or to a finite-window $\mathsf{Real}^{\uparrow}$ consumer is*

$$\begin{gathered}\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, S_n),\\ \mathsf{InBundle}(n, S_n),\\ \mathsf{RatHistoryClassifier}(s(n), t(n)).\end{gathered}$$

This singleton packet exports no RegSeqRat regularity row, no $\mathsf{Real}^{\uparrow}$ seal classifier, no completion object, and no quotient row.

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier singleton diagonal handoff`

Proof. Start from the global StreamName classifier. By Definition 126.2, reading it at the certified unary history n gives the pointwise rational-history classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Now restrict the classifier to the singleton bundle S_n. The finite-window definition, equivalently Definition 126.23, says that the only visible observation slot of S_n is the row selected by $\mathsf{InBundle}(n, S_n)$. Hence the restricted row is exactly $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, S_n)$ together with that membership witness and the pointwise classifier at n.

Finally read the packet through Definition 126.170. The consumer boundary is the one separated in Definition 126.82: regularity, sealing, completion, and quotient data remain downstream, so the singleton source row is precisely the finite-window packet displayed above. □

Theorem 126.174 (StreamName singleton restriction handoff exactness)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $n : \mathsf{BHist}$ be a certified unary observation, and let S_n be the singleton probe bundle generated by n. For any certified restriction of a finite observation bundle through S_n, the restricted RegSeqRat and finite-window $\mathsf{Real}^{\uparrow}$ handoff is exactly the tuple*

$$\begin{gathered}\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, S_n),\\ \mathsf{InBundle}(n, S_n),\\ \mathsf{UnaryHistory}(n),\\ \mathsf{RatHistoryClassifier}(s(n), t(n)).\end{gathered}$$

It exports no RegSeqRat regularity row, $\mathsf{Real}^{\uparrow}$ seal classifier, completion object, quotient row, or host-index equality.

Proof. Begin with the singleton diagonal handoff of Definition 126.173. It identifies the singleton source packet with the finite-window classifier over S_n, the membership witness for n, and the pointwise rational-history classifier at the selected unary observation.

Now apply the finite-window restriction handoff of Definition 126.175 to any certified restriction whose visible observation bundle factors through S_n. Since the target bundle is singleton, every visible row is the same certified n-row together with $\mathsf{InBundle}(n, S_n)$ and $\mathsf{UnaryHistory}(n)$.

Finally read the resulting restricted packet through the pointwise handoff boundary of Definition 126.170. That boundary has carrier, membership, unary-history, finite-window classifier, and pointwise rational-history slots only, so it cannot export a regularity row, a seal classifier, completion data, quotient data, or host-index equality. The displayed tuple is therefore the whole consumer surface. □

Theorem 126.175 (StreamName RegSeqRat finite-window restriction handoff)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P} : \mathsf{ProbeBundle}$ be a finite observation bundle, and let $\mathcal{Q} : \mathsf{ProbeBundle}$ be a certified sub-bundle of $\mathcal{P}$. Any pointwise handoff package from $\mathcal{P}$ restricts to the same StreamName source rows over $\mathcal{Q}$: the* $\mathsf{RatStreamNameCarrier}$ *rows for s and t, the restricted* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ *row,* $\mathsf{UnaryHistory}$*,* $\mathsf{InBundle}(-, \mathcal{Q})$*, and the pointwise* $\mathsf{RatHistoryClassifier}$ *rows. The restricted packet exports no* $\mathsf{RegSeqRat}$ *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Proof. Unfold the finite-window classifier for the smaller certified bundle $\mathcal{Q}$. A visible observation over $\mathcal{Q}$ is a certified unary history n together with $\mathsf{InBundle}(n, \mathcal{Q})$.

Use the sub-bundle evidence to read the same observation as $\mathsf{InBundle}(n, \mathcal{P})$. The pointwise handoff over $\mathcal{P}$ then supplies exactly the source rows named by Definition 126.170: the carried StreamName endpoints, unary history evidence, and the pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ row.

Repack those rows with the membership witness for $\mathcal{Q}$. This gives $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ and the same pointwise rational-history classifier at each selected observation.

The final packet is still read through the exhaustion boundary of Definition 126.170. Since that boundary contains only StreamName carrier, finite-window classifier, unary history, bundle membership, and pointwise classifier rows, the restriction introduces no regularity, seal, completion, quotient, or host-index-equality datum. □

Theorem 126.176 (StreamName RegSeqRat appended-bundle handoff exactness)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, and let $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$ be finite observation windows. Suppose $\mathcal{P}$ and $\mathcal{Q}$ each supply the pointwise StreamName handoff rows for s and t: the* $\mathsf{RatStreamNameCarrier}$ *source rows, the finite-window classifier row,* $\mathsf{UnaryHistory}$ *evidence, membership evidence, and the pointwise* $\mathsf{RatHistoryClassifier}$ *rows. Then the appended bundle* $\mathsf{BAppend}(\mathcal{P}, \mathcal{Q})$ *supplies exactly the same kind of* $\mathsf{RegSeqRat}$ *and finite-window* $\mathsf{Real}^{\uparrow}$ *handoff rows over the combined window.*

Conversely, any consumer read over $\mathsf{BAppend}(\mathcal{P}, \mathcal{Q})$ *restricts to one of the two component handoff packets. The appended packet exports no* $\mathsf{RegSeqRat}$ *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier bundle union handoff`

Proof. Apply Definition 126.305 to the two finite observation windows. It identifies the visible observations of $\mathsf{BAppend}(\mathcal{P}, \mathcal{Q})$ with the observations that come from $\mathcal{P}$ or from $\mathcal{Q}$, carrying their original $\mathsf{InBundle}$ and $\mathsf{UnaryHistory}$ witnesses.

On each component observation, use Definition 126.170. The supplied component handoff packet gives the carried StreamName endpoints and the pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ row, and the union composition repackages those rows into the finite-window classifier for $\mathsf{BAppend}(\mathcal{P}, \mathcal{Q})$.

For the converse read, restrict the appended window along the selected component inclusion. Then Definition 126.175 recovers exactly the same carrier, classifier, membership, unary-history, and pointwise rational-history rows over that component packet.

Both directions pass through the pointwise handoff boundary and the finite-window restriction boundary. Since those boundaries name no regularity, seal, completion, quotient, or host-index-equality coordinate, the appended handoff cannot export any such row. □

Theorem 126.177 (StreamName RegSeqRat finite reindexing coverage)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P}_0, \ldots, \mathcal{P}_k : \mathsf{ProbeBundle}$ be finite observation bundles, and let the adjacent stages be connected by certified unary reindexing maps. Suppose each adjacent reindexing preserves* UnaryHistory*,* ProbeBundle *membership,* InBundle *rows, pointwise* hsame *comparisons, and the* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_i)$ *rows carried by the stage. Then the terminal handoff over $\mathcal{P}_k$ to* RegSeqRat *or to a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer is covered by exactly the same pointwise StreamName rows as the stagewise handoff: the* RatStreamNameCarrier *rows for s and t, the terminal finite-window classifier, the transported* UnaryHistory *and* $\mathsf{InBundle}(-, \mathcal{P}_k)$ *evidence, and the pointwise* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *rows at the transported observations.*

The coverage statement is only a finite-window BEDC handoff. It exports no RegSeqRat *regularity row, no* $\mathsf{Real}^{\uparrow}$ *seal classifier, no completion object, no quotient row, and no host-index equality.*

Proof. Induct on the finite reindexing schedule. In the empty schedule, the terminal bundle is the initial bundle, and Definition 126.170 gives exactly the listed StreamName carrier, finite-window classifier, unary-history, membership, and pointwise rational-history rows.

For the step, assume the coverage packet has been built over $\mathcal{P}_i$. The certified unary reindexing map transports the visible unary histories and their InBundle witnesses to the next bundle. Apply Definition 126.171 to carry the pointwise hsame comparisons and the pointwise rational-history classifier rows along that transported observation.

The next terminal window may discard observations or assemble adjacent visible pieces. Use Definition 126.175 for the restricted part and Definition 126.176 for the finite bundle repacking. These two handoff results rebuild the terminal $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_{i+1})$ row from the transported pointwise rows.

The induction step therefore preserves the exact public surface named in the statement. Since every stage passes through the pointwise, restriction, and bundle-union handoff boundaries, no stage introduces a regularity row, seal classifier, completion object, quotient row, or host-index equality. □

Theorem 126.178 (StreamName RegSeqRat overlap pullback handoff)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$ be finite observation bundles, and let $\mathcal{R} : \mathsf{ProbeBundle}$ be a certified common sub-bundle of both $\mathcal{P}$ and $\mathcal{Q}$. If the $\mathcal{P}$-packet and the $\mathcal{Q}$-packet each supply the pointwise StreamName-to-*RegSeqRat *handoff rows for s and t, then their restrictions to $\mathcal{R}$ classify the same consumer-facing tuple:* RatStreamNameCarrier*,* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{R})$*,* UnaryHistory*,* $\mathsf{InBundle}(-, \mathcal{R})$*, the pointwise* hsame *rows, and* RatHistoryClassifier*. The common-overlap packet contains no* RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal row, completion row, quotient row, or host-index equality row.*

Proof. Restrict the $\mathcal{P}$-packet to the certified common sub-bundle $\mathcal{R}$ by Definition 126.175. The restricted packet exposes the same StreamName carrier rows, the finite-window classifier over $\mathcal{R}$, the unary-history and $\mathsf{InBundle}(-, \mathcal{R})$ witnesses, and the pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ rows.

Apply the same restriction theorem to the $\mathcal{Q}$-packet. Because both restricted reads use the same rows s, t and the same certified bundle $\mathcal{R}$, the pointwise handoff Definition 126.170 identifies both packet readings with the same consumer-facing tuple on each observation of $\mathcal{R}$.

Finally apply Definition 126.180. The envelope is closed under the two certified restrictions and contains only carrier, finite-window, unary-history, membership, pointwise hsame, and rational-history classifier rows. Hence the pullback over the common overlap has no coordinate for regularity, seal, completion, quotient, or host-index equality data. □

Theorem 126.179 (StreamName finite observation RealUp seal scope)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P} : \mathsf{ProbeBundle}$ be finite, and let n be a certified observation with $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$. A finite-window $\mathsf{Real}^{\uparrow}$ seal consumer of $\mathsf{RatStreamNameFiniteWindowClassifier}($ may read from StreamName only the carried endpoints for s and t, the membership row $\mathsf{InBundle}(n, \mathcal{P})$, the unary observation row $\mathsf{UnaryHistory}(n)$, and the pointwise classifier row $\mathsf{RatHistoryClassifier}(s(n), t(n))$.*

All $\mathsf{RegSeqRat}$ regularity rows, $\mathsf{Real}^{\uparrow}$ seal classifiers, completion data, quotient data, and host-index equality remain downstream obligations and are not exported by the finite StreamName observation.

Proof. Begin with the pointwise handoff of Definition 126.170. It exposes the StreamName endpoint rows, the finite bundle membership row, the unary observation row, and the pointwise rational-history classifier at the chosen observation.

For the certified observation n, use Definition 126.173 to identify the singleton diagonal view with the same endpoint, membership, unary-history, and pointwise classifier rows. Then use Definition 126.175 to read the same rows through any certified finite-window restriction of $\mathcal{P}$.

Finally apply the obligation separation of Definition 126.82. It keeps $\mathsf{RegSeqRat}$ regularity, $\mathsf{Real}^{\uparrow}$ seal classifiers, completion structure, quotient structure, and host-index equality on the downstream side of the handoff. The finite observation therefore exports exactly the named StreamName rows and nothing from the later seal boundary. □

Theorem 126.180 (StreamName RegSeqRat observation envelope)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows and let $\mathcal{P}$ be a finite $\mathsf{ProbeBundle}$. The observation packet consisting of $\mathsf{RatStreamNameCarrier}$, $\mathsf{RatStreamNameFiniteWindowClassifier}$, $\mathsf{UnaryHistory}$, $\mathsf{InBundle}$, and the pointwise hsame and $\mathsf{RatHistoryClassifier}$ rows is closed under certified sub-bundle restriction and singleton extraction. The packet contains no $\mathsf{RegSeqRat}$ regularity row, no completion row, no quotient row, and no $\mathsf{Real}^{\uparrow}$ seal row.*

Proof. For the full finite window, apply Definition 126.170. It identifies the handoff rows available to $\mathsf{RegSeqRat}$ with the carried StreamName endpoint, the finite probe bundle, the bundle-membership rows, and the pointwise rational-history classifier.

For a certified sub-bundle, use Definition 126.171. The same $\mathsf{RatStreamNameCarrier}$ rows and pointwise hsame transports are read after restriction, while membership is replaced by the certified $\mathsf{InBundle}$ rows of the smaller bundle.

For singleton extraction, apply Definition 126.173. The extracted observation has exactly one unary history row, its singleton membership witness, and the corresponding rational-history classifier. Since all three steps read only these finite observation rows, the envelope has no place for regularity, completion, quotient, or $\mathsf{Real}^{\uparrow}$ seal data. □

Theorem 126.181 (StreamName RegSeqRat finite-window coverage)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a finite observation bundle. For every row of $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$, every certified $\mathsf{UnaryHistory}(n)$, and every witness $\mathsf{InBundle}(n, \mathcal{P})$, the exposed observation is exactly the pointwise row $\mathsf{RatHistoryClassifier}(s(n), t(n))$ together with the corresponding pointwise* hsame *datum. The coverage surface contains no* RegSeqRat *regularity row, completion row, quotient row, or $\mathsf{Real}^{\uparrow}$ seal row.*

Proof. Start with the global handoff of Definition 126.170. It lists the carrier, finite-window classifier, unary-history, bundle-membership, pointwise hsame, and rational-history classifier rows as the only rows visible at the StreamName-to-RegSeqRat boundary.

The observation stability theorem, Definition 126.171, identifies the same pointwise hsame and rational-history row after passing through the certified bundle observation. The singleton diagonal handoff of Definition 126.173 then reads the selected n-row as the diagonal pointwise classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

For an arbitrary finite row, the restriction handoff Definition 126.175 reduces the visible packet to the certified sub-bundle containing that observation. Finally, the envelope theorem Definition 126.180 removes every regularity, completion, quotient, and $\mathsf{Real}^{\uparrow}$ seal row from the consumer surface. Hence the finite-window coverage is exactly the displayed pointwise classifier row and its membership evidence. □

Theorem 126.182 (StreamName RegSeqRat tail reindexing stability)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P} : \mathsf{ProbeBundle}$ be a finite observation bundle, and let $r : \mathsf{BHist} \to \mathsf{BHist}$ be a certified unary tail schedule whose selected rows preserve* UnaryHistory *and $\mathsf{InBundle}(-, \mathcal{P})$. The StreamName handoff package for s and t transports to the package for $s \circ r$ and $t \circ r$ using only the reindexed pointwise* hsame *rows, the reindexed* UnaryHistory *rows, and the transported* InBundle *rows. No reindexed packet imports* RegSeqRat *regularity, completion, quotient, host-index equality, or $\mathsf{Real}^{\uparrow}$ seal data.*

Proof. Apply the pointwise handoff Definition 126.170 before reindexing. Its source rows are the StreamName carriers, the finite-window classifier, unary histories, bundle membership, pointwise hsame, and pointwise rational-history classifiers.

The certified tail schedule supplies the same observation witnesses after composition with r. By observation stability, Definition 126.171, the transported rows remain pointwise rows; no global regularity or quotient datum is used.

For each selected row, use the singleton diagonal handoff Definition 126.173 to identify the transported observation with $\mathsf{RatHistoryClassifier}(s(r(n)), t(r(n)))$. The finite-window restriction handoff, Definition 126.175, repacks these rows over the reindexed certified sub-bundle.

The observation envelope Definition 126.180 is stable under this repacking because it names only carrier, finite-window, membership, unary-history, pointwise hsame, and pointwise rational classifier rows. Thus the tail-reindexed package is exhausted by the same pointwise handoff surface. □

Theorem 126.183 (StreamName RegSeqRat finite-window union seal determinacy)**.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be certified finite* ProbeBundle *observation bundles for StreamName rows $s, t : \mathsf{BHist} \to \mathsf{BHist}$, and let $\mathcal{R}$ be their certified finite overlap. Assume that the* RatStreamNameClassifier *rows on $\mathcal{R}$ match and that the induced* RegSeqRat *handoff packages read the same dyadic finite ledger on the overlap. Then the union handoff over $\mathcal{P} \cup \mathcal{Q}$ determines a unique* RegSeqRat *finite-window seal surface, and the restrictions back to $\mathcal{P}$ and to $\mathcal{Q}$ recover the original displayed seal surfaces.*

No regularity row outside the displayed RegSeqRat *handoff, no completion row, no quotient row, no host-index equality row, and no* $\mathsf{Real}^{\uparrow}$ *seal row is introduced by the union.*

Proof. Apply Definition 126.175 to $\mathcal{P}$ and to $\mathcal{Q}$. Each restriction displays only the StreamName carrier rows, the finite-window classifier rows, the unary-history and bundle membership witnesses, and the pointwise rational-history classifier rows.

Use Definition 126.176 to assemble these two displayed packets over $\mathcal{P} \cup \mathcal{Q}$. The matching classifier rows on $\mathcal{R}$ and the common dyadic finite ledger identify the overlap as a single source rather than two competing seal readings.

The overlap rows are then compared by Definition 126.182. Tail reindexing preserves the pointwise hsame rows, the transported unary histories, and the transported membership witnesses, so the union packet has one displayed finite-window seal surface on the common part.

Restrict the union packet back to $\mathcal{P}$ and to $\mathcal{Q}$ using the restriction handoff theorem again. Since the union packet contains no row outside the observation envelope, the two restrictions return exactly the original displayed handoff surfaces, and the finite-window seal determined by the union is unique. □

Theorem 126.184 (StreamName RegSeqRat pointwise classifier handoff exactness)**.** *For StreamName rows* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *and a finite bundle* $\mathcal{P} : \mathsf{ProbeBundle}$*, the consumer-facing handoff from StreamName observations to* RegSeqRat *is exhausted by the* RatStreamNameCarrier *rows, the* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *rows, bundle membership, unary observations, pointwise* hsame *rows, and pointwise* RatHistoryClassifier *rows. Any datum outside this list is not part of the handoff interface.*

Proof. The base handoff theorem Definition 126.170 gives the complete source packet for the consumer boundary. Its rows already name the carriers, finite-window classifier, membership witnesses, unary observations, pointwise hsame, and pointwise rational-history classifiers.

Observation stability, Definition 126.171, shows that moving inside the finite bundle preserves only these named pointwise rows. The singleton diagonal handoff, Definition 126.173, gives the same conclusion at a single certified observation.

The finite-window restriction handoff Definition 126.175 checks that every certified sub-bundle exposes no additional row. The observation envelope theorem, Definition 126.180, closes the interface by excluding RegSeqRat regularity, completion, quotient, host-index equality, and $\mathsf{Real}^{\uparrow}$ seal data. Therefore the listed rows are exactly the consumer-facing handoff surface. □

Theorem 126.185 (StreamName RegSeqRat pointwise hsame closure)**.** *Let* $s, t, s', t' : \mathsf{BHist} \to \mathsf{BHist}$ *be StreamName rows and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be finite. Suppose the handoff for* (s, t) *is the exact pointwise package of Definition 126.184, and suppose every certified bundled observation carries* $\mathsf{hsame}(s(n), s'(n))$ *and* $\mathsf{hsame}(t(n), t'(n))$*. Then the handoff for* (s', t') *is exhausted by the same StreamName carrier rows, restricted finite-window classifier rows,* UnaryHistory *rows,* InBundle *rows, pointwise* hsame *rows, and pointwise* RatHistoryClassifier *rows. It accepts no* RegSeqRat *regularity, completion, quotient, host-index equality, or* $\mathsf{Real}^{\uparrow}$ *seal row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier pointwise hsame closure`

Proof. Start with the source packet from Definition 126.184. That theorem gives exactly the carrier, finite-window classifier, bundle, unary-history, pointwise hsame, and rational-history classifier rows for the displayed (s, t) handoff.

Transport each certified bundled observation along the given pointwise hsame rows. By Definition 126.171, this transport preserves the unary observations, bundle membership witnesses, and

pointwise rational-history classifier rows, and it does not create any row outside the StreamName observation surface.

For a restricted finite window, apply Definition 126.175. The restriction keeps the same finite carrier rows and classifier rows over the sub-bundle, now read through (s', t').

Finally use Definition 126.180. The envelope excludes RegSeqRat regularity, completion, quotient, host-index equality, and $\mathsf{Real}^{\uparrow}$ seal data from the observation handoff, so the transported packet is closed under pointwise hsame exactly on the listed consumer interface. □

Theorem 126.186 (StreamName RegSeqRat pointwise hsame transport composition)**.** *Let $s, t, s', t', s'', t'' :$ BHist $\to$ BHist be StreamName rows, and let $\mathcal{P}$: ProbeBundle be finite. Suppose the handoff for (s, t) is the exact pointwise package of Definition 126.184. Suppose also that every certified bundled observation n carries* $\mathsf{hsame}(s(n), s'(n))$, $\mathsf{hsame}(t(n), t'(n))$, $\mathsf{hsame}(s'(n), s''(n))$, *and* $\mathsf{hsame}(t'(n), t''(n))$. *Then the handoff for (s'', t'') is exhausted by the same* RatStreamNameCarrier *rows, restricted finite-window classifier rows,* UnaryHistory *rows,* InBundle *rows, pointwise* hsame *rows, and pointwise* RatHistoryClassifier *rows. It accepts no* RegSeqRat *regularity, completion, quotient, host-index equality, or* $\mathsf{Real}^{\uparrow}$ *seal row.*

Proof. First apply Definition 126.185 to the exact handoff for (s, t) and the displayed observations from (s, t) to (s', t'). This gives the same carrier, finite-window, unary-history, bundle-membership, pointwise hsame, and rational-history classifier surface for the intermediate handoff.

Next compose the observation rows pointwise. For each certified bundled observation n, transitivity of hsame composes $\mathsf{hsame}(s(n), s'(n))$ with $\mathsf{hsame}(s'(n), s''(n))$, and composes $\mathsf{hsame}(t(n), t'(n))$ with $\mathsf{hsame}(t'(n), t''(n))$. Thus the intermediate handoff has the exact pointwise transport data needed for the second step.

Apply Definition 126.185 again, now from (s', t') to (s'', t''). The conclusion is the displayed handoff for (s'', t'') on the original finite bundle $\mathcal{P}$ with no new row outside the consumer-facing observation surface.

The exclusion clause is inherited at both applications of the closure theorem: neither step reads RegSeqRat regularity, completion, quotient, host-index equality, or $\mathsf{Real}^{\uparrow}$ seal data. Therefore the two transported handoffs compose inside the same finite-window pointwise interface. □

Theorem 126.187 (StreamName RegSeqRat pointwise hsame transport confluence)**.** *Let $s, t, u, v :$* BHist $\to$ BHist *be StreamName rows, and let $\mathcal{P}$:* ProbeBundle *be finite. Let*

$$(s_0, t_0), \ldots, (s_m, t_m),$$
$$(r_0, q_0), \ldots, (r_k, q_k)$$

be two finite pointwise hsame *transport schedules of StreamName row pairs with common endpoints*

$$(s_0, t_0) = (r_0, q_0) = (s, t), \qquad (s_m, t_m) = (r_k, q_k) = (u, v).$$

Assume the handoff for (s, t) is the exact pointwise package of Definition 126.184. Assume further that every adjacent stage of both schedules carries the certified bundled pointwise hsame *rows and preserves that exact pointwise package. Then the two induced handoff packets at (u, v) expose the same* RatStreamNameCarrier *rows, restricted finite-window classifier rows,* UnaryHistory *rows,* InBundle *rows, pointwise* hsame *rows, and pointwise* RatHistoryClassifier *rows. Neither packet exposes a* RegSeqRat *regularity row, completion row, quotient row, host-index equality row, or* $\mathsf{Real}^{\uparrow}$ *seal row.*

Proof. Induct over the first finite schedule. The base case is the source handoff itself, whose exact consumer-facing package is supplied by Definition 126.184. For the step case, apply Definition 126.186 to compose the accumulated transport with the next adjacent pointwise hsame stage.

The same induction applies to the second finite schedule. Its base is the same exact package at (s, t), and each step preserves the displayed carrier, finite-window, unary-history, bundle-membership, pointwise hsame, and rational-history classifier rows by the same composition theorem.

Both inductions therefore terminate at the common endpoint (u, v) with the pointwise package of Definition 126.184. Comparing through that endpoint package identifies the exposed carrier, restricted finite-window classifier, UnaryHistory, InBundle, pointwise hsame, and pointwise RatHistoryClassifier rows from the two routes.

Finally apply Definition 126.180 at the common endpoint. The envelope excludes RegSeqRat regularity, completion, quotient, host-index equality, and $\mathsf{Real}^{\uparrow}$ seal rows from the observation handoff, so neither route can expose any row outside the common pointwise StreamName interface. □

Theorem 126.188 (StreamName RegSeqRat restricted pointwise transport confluence)**.** *Let s, t, u, v : BHist $\to$ BHist be StreamName rows, and let $\mathcal{Q} \subseteq \mathcal{P}$ be a certified finite subbundle. Suppose two finite pointwise* hsame *transport schedules for (s, t) have common endpoint (u, v) as in Definition 126.187. After restricting each transported handoff to $\mathcal{Q}$, the two restricted packets expose the same* RatStreamNameCarrier *rows, restricted finite-window classifier rows,* UnaryHistory *rows,* InBundle *rows, pointwise* hsame *rows, and pointwise* RatHistoryClassifier *rows to every* RegSeqRat *handoff and every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer. The restricted packets expose no* RegSeqRat *regularity row, completion row, quotient row, host-index equality row, or* $\mathsf{Real}^{\uparrow}$ *seal row.*

Proof. Begin with the two endpoint handoffs supplied by Definition 126.187. That confluence theorem identifies the carrier, finite-window classifier, UnaryHistory, InBundle, pointwise hsame, and RatHistoryClassifier rows at the common endpoint (u, v).

Restrict both endpoint packets along the certified inclusion $\mathcal{Q} \subseteq \mathcal{P}$. By Definition 126.175, restriction forgets only observations outside $\mathcal{Q}$ and preserves every displayed row of the finite-window handoff on the subbundle.

It remains to check the consumer boundary. Apply Definition 126.180 after restriction. The envelope is already stated only in terms of the exposed StreamName observation rows, so it is stable under passing from $\mathcal{P}$ to $\mathcal{Q}$.

Thus every RegSeqRat handoff and every finite-window $\mathsf{Real}^{\uparrow}$ consumer sees the same restricted carrier, classifier, history, membership, pointwise hsame, and rational-history rows through either route. The same envelope excludes regularity, completion, quotient, host-index equality, and $\mathsf{Real}^{\uparrow}$ seal data from the restricted packets. □

Theorem 126.189 (RegSeqRat window stability under StreamName transport)**.** *Let two accepted* $\mathsf{StreamName}^{\uparrow}$ *packets agree pointwise on every finite window inspected by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback. If the point certificates for those windows are transported componentwise by* hsame *and replayed through the displayed* Cont *rows of the two StreamName packets, then the* $\mathsf{RegSeqRat}^{\uparrow}$ *window carrier and classifier rows transported through those windows remain stable. The statement is only about the displayed finite StreamName windows and the* $\mathsf{RegSeqRat}^{\uparrow}$ *rows read through them; it introduces no quotient stream equality, selected limit, host real equality, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Project the finite StreamName window row used by the readback. The hypothesis gives pointwise agreement exactly on the window coordinates inspected by the $\mathsf{RegSeqRat}^{\uparrow}$ carrier.

Transport each displayed point certificate componentwise by hsame. Replaying the corresponding Cont rows preserves the same window source, so the readback cannot switch to a hidden stream representative or to a larger tail object.

Finally read the $\mathsf{RegSeqRat}^{\uparrow}$ carrier and classifier rows only through those transported windows. Since no quotient stream equality, selected limit, host real equality, or ambient completeness coordinate is present in the route, the transported window carrier and classifier rows remain stable. □

Theorem 126.190 (StreamName RegSeqRat denominator window separation)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows and let $\mathcal{P} : \mathsf{ProbeBundle}$ be a finite unary observation bundle. For every certified observation n with $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$, the denominator and dyadic observation rows consumed by a $\mathsf{RegSeqRat}$ finite-window handoff factor through only the visible packet*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}),$$
$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}), \qquad \mathsf{RatHistoryClassifier}(s(n), t(n)).$$

The packet may be read by the $\mathsf{RegSeqRat}$ dyadic observation coverage rows, including Definition 38.562, but it exports no $\mathsf{RegSeqRat}$ regularity row, dyadic seal datum, $\mathsf{Real}^{\uparrow}$ seal classifier, completion object, quotient row, or host-index equality. Those objects remain on the downstream side of the $\mathsf{RegSeqRat}$ and Real-and-completion certificates.

Proof. Project the finite StreamName bundle by Definition 126.170. For the selected certified observation n, the projection exposes the finite-window classifier, the unary-history row, the bundle-membership row, and the pointwise rational-history classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Stabilize the exposed row by Definition 126.171. This step permits the consumer to transport the same certified observation along the pointwise hsame rows already visible in the bundle, without importing any regularity or seal evidence from the later $\mathsf{RegSeqRat}$ or $\mathsf{Real}^{\uparrow}$ boundary.

Now read the denominator window through the Real/RegSeqRat coverage surface. Apply Definition 38.562 to the selected unary observation and its pointwise rational classifier. The dyadic endpoint rows are therefore obtained from the displayed finite observation packet.

Finally repack the consumer boundary using Definition 126.179. That theorem keeps $\mathsf{RegSeqRat}$ regularity, dyadic seal data, the $\mathsf{Real}^{\uparrow}$ seal classifier, completion structure, quotient structure, and host-index equality outside the StreamName source packet, so the denominator window has exactly the stated dependency surface. □

Theorem 126.191 (StreamName RegSeqRat denominator subwindow transport)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, and let $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$ be finite observation bundles. Suppose $\mathcal{Q}$ is certified as a subwindow of $\mathcal{P}$ by*

$$\forall m,\ \mathsf{InBundle}(m, \mathcal{Q}) \wedge \mathsf{UnaryHistory}(m) \to \mathsf{InBundle}(m, \mathcal{P}) \wedge \mathsf{UnaryHistory}(m).$$

Then every denominator-window packet accepted over $\mathcal{P}$ restricts to a denominator-window packet over $\mathcal{Q}$ whose public surface is exactly

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}),$$
$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{Q}), \qquad \mathsf{RatHistoryClassifier}(s(n), t(n)),$$
$$\textit{the downstream dyadic observation coverage row.}$$

The restricted packet exports no $\mathsf{RegSeqRat}$ regularity row, $\mathsf{Real}^{\uparrow}$ seal classifier, completion object, quotient row, or host-index equality.

Proof. First restrict the finite StreamName classifier. The certified inclusion of $\mathcal{Q}$ in $\mathcal{P}$ is precisely the input required by Definition 126.9, so the accepted $\mathcal{P}$ packet supplies $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t,$

Now apply Definition 126.190 inside the subwindow $\mathcal{Q}$. For each certified observation n in $\mathcal{Q}$, this exposes the unary-history row, the $\mathcal{Q}$ bundle-membership row, and the pointwise rational-history classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Next read the endpoint through Definition 38.562. The dyadic observation row is therefore attached to the same subwindow observation rather than to any ambient host index.

Finally use Definition 126.179. It keeps the $\mathsf{RegSeqRat}$ regularity row, the $\mathsf{Real}^{\uparrow}$ seal classifier, completion, quotienting, and host-index equality outside the finite StreamName source packet. The transported subwindow packet is exactly the displayed public surface and no larger. □

Theorem 126.192 (StreamName RegSeqRat denominator overlap gluing)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, and let $\mathcal{P}, \mathcal{Q}, \mathcal{O} : \mathsf{ProbeBundle}$ be finite observation windows. Suppose $\mathcal{O}$ is certified as a subwindow of both $\mathcal{P}$ and $\mathcal{Q}$, and suppose denominator-window packets are accepted over $\mathcal{P}$ and $\mathcal{Q}$. If the two packets agree on the public overlap rows selected by $\mathcal{O}$, namely the restricted $\mathsf{RatStreamNameFiniteWindowClassifier}$ row, every certified $\mathsf{UnaryHistory}(n)$ row, each $\mathsf{InBundle}(n, \mathcal{O})$ row, and the pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ row, then the two packets glue to a denominator-window packet over $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$.*

The glued packet restricts back to the same public denominator selector on $\mathcal{P}$, on $\mathcal{Q}$, and on $\mathcal{O}$. Its visible selector surface is exactly

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})),$$

$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})), \qquad \mathsf{RatHistoryClassifier}(s(n), t(n)),$$

Cont *routes for the displayed restrictions,* hsame *overlap agreement rows,* Pkg *provenance for the two acc*

It adds no $\mathsf{RegSeqRat}$ *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, host-index equality, or non-public selector.*

Proof. First separate the two ambient denominator windows. Apply Definition 126.190 to the accepted packets over $\mathcal{P}$ and $\mathcal{Q}$. This exposes only the finite StreamName classifier, unary-history, bundle-membership, pointwise rational-history, Cont, hsame, and Pkg rows that can participate in a public denominator selector.

Next restrict both packets to the overlap. Use Definition 126.191 along the two certified inclusions $\mathcal{O} \subseteq \mathcal{P}$ and $\mathcal{O} \subseteq \mathcal{Q}$. The resulting overlap packets have the same public selector coordinates by the assumed agreement on the restricted classifier, unary rows, membership rows, and pointwise rational-history rows.

Now assemble the union window. Apply Definition 126.193 to the two ambient packets, using the overlap agreement to identify the selected public rows that appear from both sides. The finite union packet is therefore carried by $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$ and by the displayed Cont, hsame, and Pkg ledger.

Finally read back the restrictions. Apply Definition 126.191 to the union packet along the evident subwindow inclusions of $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{O}$ into $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$. The readback packets are the original public denominator selectors on $\mathcal{P}$ and $\mathcal{Q}$, and their common restriction to $\mathcal{O}$ is the agreed overlap selector. The separation theorem supplies the stated exclusions. □

Theorem 126.193 (StreamName RegSeqRat denominator-window union stability)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, and let $\mathcal{P}, \mathcal{Q} : \mathsf{ProbeBundle}$ be finite observation windows. Suppose denominator-window packets are accepted over both $\mathcal{P}$ and $\mathcal{Q}$. Then they assemble over*

the certified union window $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$*, and every certified observation* n *in that union has exactly the public coordinates*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})),$$
$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})), \qquad \mathsf{RatHistoryClassifier}(s(n), t(n)),$$
the downstream dyadic observation coverage row.

The assembled packet exports no $\mathsf{RegSeqRat}$ *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion datum, quotient row, or host-index equality.*

Proof. First form the union classifier. The two accepted denominator-window packets expose $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ and $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q})$ by Definition 126.190. The union case of Definition 126.25 assembles these two rows into the classifier over $\mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q})$.

Now fix a certified observation n in the union window. Applying Definition 126.190 to the union classifier exposes $\mathsf{UnaryHistory}(n)$, the displayed $\mathsf{InBundle}(n, \mathsf{bundleAppend}(\mathcal{P}, \mathcal{Q}))$ row, and $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

The subwindow direction is inherited by Definition 126.191. It says that any consumer that later restricts the certified union packet back to $\mathcal{P}$ or $\mathcal{Q}$ sees exactly the same public denominator-window surface, with no additional host-coordinate witness.

Finally apply Definition 38.562 to read the downstream dyadic observation row, and use Definition 126.179 to bracket the consumer boundary. Those two rows keep $\mathsf{RegSeqRat}$ regularity, $\mathsf{Real}^{\uparrow}$ seal classifiers, completion data, quotient rows, and host-index equality outside the assembled StreamName packet. □

Theorem 126.194 (StreamName RealUp denominator-window normal form)**.** *A denominator window handed from* $\mathsf{StreamName}^{\uparrow}$ *to both* $\mathsf{RegSeqRat}$ *and a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer has the following normal form and no other public coordinates:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \qquad \mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the downstream dyadic observation coverage row.}$$

The normal form is exactly the finite StreamName classifier, certified unary history, bundle-membership row, pointwise rational-history classifier, and the dyadic observation row consumed downstream. It excludes $\mathsf{RegSeqRat}$ *regularity, the* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion structure, quotient structure, and host-index equality.*

Proof. Start with Definition 126.190. It projects a certified observation n in the finite bundle $\mathcal{P}$ to the finite StreamName classifier, the unary-history certificate, bundle membership, and the pointwise rational-history classifier.

Next read the downstream dyadic observation through Definition 38.562. That theorem uses the exposed pointwise rational row as the finite observation consumed by the $\mathsf{RegSeqRat}$ side of the handoff.

Finally apply Definition 126.179. It keeps regularity, the $\mathsf{Real}^{\uparrow}$ seal classifier, completion, quotienting, and host-index equality outside the finite StreamName window. The remaining rows are precisely the displayed tuple, which is the claimed normal form. □

Theorem 126.195 (StreamName pointwise denominator-window determinacy)**.** *Fix StreamName rows* $s, t : \mathsf{BHist} \to \mathsf{BHist}$*, a finite* $\mathsf{ProbeBundle}\ \mathcal{P}$*, and a certified observation* n *with* $\mathsf{UnaryHistory}(n)$

and $\mathsf{InBundle}(n, \mathcal{P})$*. If two public denominator-window packets are accepted by both the* $\mathsf{RegSeqRat}$ *handoff and the finite-window* $\mathsf{Real}^{\uparrow}$ *consumer for this same certified observation, then their displayed public coordinates are the same:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \qquad \mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the downstream dyadic observation coverage row.}$$

This determinacy is only a finite-packet statement. It exports no $\mathsf{RegSeqRat}$ *regularity,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Proof. The separation theorem Definition 126.190 first fixes the public dependency surface of any accepted denominator-window packet. For the certified observation n, the handoff can expose only the finite StreamName classifier, the unary-history row, the bundle-membership row, and the pointwise rational-history classifier.

The normal-form theorem Definition 126.194 then says that a packet accepted by the finite-window $\mathsf{Real}^{\uparrow}$ consumer has no additional public coordinate beyond the downstream dyadic observation coverage row. Thus two accepted packets for the same s, t, $\mathcal{P}$, and n must display the same four source coordinates.

It remains to identify the downstream row. The pointwise source coordinate is the one delivered by Definition 126.170, and the finite dyadic-observation row read from it is exactly the row supplied by Definition 38.562. Hence the consumer-side coordinate is also fixed by the same certified observation.

Combining these two fixed surfaces gives one public finite packet. The exclusions in the separation and normal-form statements keep $\mathsf{RegSeqRat}$ regularity, the $\mathsf{Real}^{\uparrow}$ seal classifier, completion, quotienting, and host-index equality outside the packet, so none of them can distinguish the two accepted presentations. □

Theorem 126.196 (StreamName RegSeqRat denominator pullback coverage)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be StreamName rows, let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite unary observation bundle, and let* n *be a certified unary observation. A public denominator-window packet is accepted by the* $\mathsf{RegSeqRat}$ *handoff and by the finite-window* $\mathsf{Real}^{\uparrow}$ *consumer exactly when it factors through the finite pullback surface*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \qquad \mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the downstream dyadic observation coverage row.}$$

Equivalently, the denominator packet is covered by the StreamName finite-window classifier pulled back along the certified unary row and then read by the $\mathsf{RegSeqRat}$ *finite-window dyadic observation row. The accepted packet exports no* $\mathsf{RegSeqRat}$ *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Proof. For the forward direction, start with an accepted public denominator-window packet. By Definition 126.190, the source surface can expose only the finite StreamName classifier, the certified unary history, the bundle-membership row, and the pointwise rational-history classifier.

The finite-window $\mathsf{Real}^{\uparrow}$ consumer then normalizes the same presentation by Definition 126.194. This adds only the downstream dyadic observation coverage row and keeps regularity, sealing, completion, quotienting, and host-index equality outside the public packet.

It remains to identify the pointwise row used by the handoff. Apply Definition 126.195 to the accepted packet over the same s, t, $\mathcal{P}$, and n. The pointwise coordinate is therefore fixed

as $\mathsf{RatHistoryClassifier}(s(n), t(n))$, and the downstream coordinate is the row supplied by Definition 38.562.

For the reverse direction, suppose the displayed pullback surface is given. The finite StreamName classifier and the certified unary row supply the pointwise handoff input, and Definition 38.562 reads that input as the dyadic observation coverage row. Repacking these rows through the normal form gives an accepted public denominator-window packet for both consumers, with exactly the stated exclusions. □

Theorem 126.197 (StreamName RegSeqRat denominator-window subbundle inheritance)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P}'$ and $\mathcal{P}$ be finite observation bundles, and let n be a certified observation with $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P}')$. Suppose $\mathcal{P}'$ is displayed as a subbundle of $\mathcal{P}$. If the public denominator-window packet over $\mathcal{P}$ is accepted by the* RegSeqRat *handoff and by the finite-window $\mathsf{Real}^{\uparrow}$ consumer, then the restricted packet over $\mathcal{P}'$ has exactly the same public coordinates, with the ambient membership row replaced by the certified subbundle membership row:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}'),$$
$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}'),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the same downstream dyadic observation coverage row.}$$

The inheritance exports no RegSeqRat *regularity row, $\mathsf{Real}^{\uparrow}$ seal classifier, completion object, quotient row, or host-index equality.*

Proof. First restrict the finite-window classifier. The displayed subbundle inclusion is the input used by Definition 126.302, so the accepted packet over $\mathcal{P}$ presents the finite StreamName classifier over $\mathcal{P}'$.

Now read the certified observation through the pointwise handoff. Apply Definition 126.170 to the same row n; the unary-history row and the pointwise classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$ are unchanged, while the displayed membership coordinate is the subbundle row $\mathsf{InBundle}(n, \mathcal{P}')$.

Next identify the accepted public surface. The separation theorem Definition 126.190 and the normal form theorem Definition 126.194 leave only the finite classifier, unary row, bundle-membership row, pointwise rational-history classifier, and downstream dyadic observation coverage row visible to the two consumers.

Finally apply Definition 126.195. Since the restricted presentation and the ambient presentation are accepted for the same s, t, and certified observation n, their visible pointwise and downstream coordinates cannot differ. The exclusion clauses in the separation and normal form statements keep regularity, sealing, completion, quotienting, and host-index equality outside the inherited packet. □

Theorem 126.198 (StreamName RegSeqRat denominator common refinement)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be StreamName rows, let $\mathcal{P}_0$ and $\mathcal{P}_1$ be finite observation bundles, and let n be a certified observation with $\mathsf{UnaryHistory}(n)$, $\mathsf{InBundle}(n, \mathcal{P}_0)$, and $\mathsf{InBundle}(n, \mathcal{P}_1)$. Suppose the* RegSeqRat *handoff and the finite-window $\mathsf{Real}^{\uparrow}$ consumer accept denominator-window packets over both $\mathcal{P}_0$ and $\mathcal{P}_1$. Then the overlap admits a common displayed subbundle $\mathcal{Q}$ and a refinement packet over $\mathcal{Q}$ whose visible coordinates are exactly*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}),$$
$$\mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{Q}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the downstream dyadic observation coverage row.}$$

The refinement exports no RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Proof. First form the visible overlap. Apply Definition 126.192 to the two accepted denominator-window packets. The gluing row identifies the common finite StreamName classifier on the shared observation coordinates and keeps the certified unary row n visible on both sides.

Next display the overlap as an actual consumer boundary. Use Definition 126.196 to read the same overlap through the finite-window $\mathsf{Real}^{\uparrow}$ pullback, adding only the downstream dyadic observation coverage row needed by that handoff.

Now restrict to the displayed common subbundle $\mathcal{Q}$. By Definition 126.197, the two accepted packets inherit to $\mathcal{Q}$ with the same finite classifier, the same unary row, and the membership row $\mathsf{InBundle}(n, \mathcal{Q})$.

Finally apply Definition 126.195. The pointwise coordinate on the common packet is forced to be $\mathsf{RatHistoryClassifier}(s(n), t(n))$, and the pullback row supplies the same downstream dyadic observation coverage. The separation clauses from the gluing, pullback, and inherited packets exclude all non-visible regularity, sealing, completion, quotient, and host-index fields. □

Theorem 126.199 (StreamName RegSeqRat denominator refinement descent)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be the carried StreamName rows, let* $\mathcal{P}_0$ *and* $\mathcal{P}_1$ *be finite observation bundles, and let* $\mathcal{Q}$ *be a common-refinement bundle for them. Suppose a refinement packet over* $\mathcal{Q}$ *has endpoint rows satisfying the denominator-window classifier, and suppose the selected overlap rows are the rows named by the shared* ProbeBundle*. Then this refinement descends to stable denominator-window evidence over each original window* $\mathcal{P}_i$*. The descended packets preserve the pulled-back* BHist *denominator endpoints under* hsame*, and their overlap restrictions agree on the rows selected by the shared* ProbeBundle*.*

Proof. Project the common-refinement packet to each original window. The existence of the refinement bundle and its visible coordinates are supplied by Definition 126.198, while Definition 126.190 identifies the only denominator-window rows available to those projections.

Next inherit the packet along the displayed inclusions. Apply Definition 126.197 to read the $\mathcal{Q}$ packet as a subbundle packet over each $\mathcal{P}_i$, and then apply Definition 126.191 to move the finite-window classifier, unary row, bundle-membership row, pointwise rational-history classifier, and downstream dyadic coverage back to the original windows.

The pulled-back endpoints are stable because Definition 126.196 gives the same BHist denominator endpoints on the finite-window $\mathsf{Real}^{\uparrow}$ consumer boundary. The transported packets therefore compare these endpoints by the inherited hsame rows rather than by a host-index equality.

Finally compare the two descended packets on the shared rows. Use Definition 126.192 to identify the overlap selected by the common ProbeBundle, and use Definition 126.193 to keep the two original-window packets stable when they are read together. The separation theorem excludes any additional regularity, completion, quotient, or sealing field, so the descended evidence is exactly the stable original-window evidence carried by those visible rows. □

Theorem 126.200 (RegSeqRat denominator-window dyadic source exactness)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be the carried StreamName rows, let* $\mathcal{P}_0$ *and* $\mathcal{P}_1$ *be finite denominator observation bundles, and let* $\mathcal{Q}$ *be a displayed common-refinement bundle selected by a shared* ProbeBundle*. Suppose the refinement packet over* $\mathcal{Q}$ *descends to stable denominator-window evidence for the two original windows. Then the descended evidence exposes precisely the two selected DyadicRatCore observation endpoint rows consumed by* RegSeqRat*, the StreamName classifier row* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}$ *the unary index row* $\mathsf{UnaryHistory}(n)$*, and the membership row* $\mathsf{InBundle}(n, \mathcal{Q})$ *for the shared* ProbeBundle*.*

No $\mathsf{Real}^{\uparrow}$ *seal, completion object, quotient row, or host-index equality is readable from the descended denominator-window evidence.*

Proof. Start with denominator-window separation. By Definition 126.190, every accepted denominator packet exposes only the finite StreamName classifier, the unary observation row, the bundle-membership row, the pointwise rational row, and the downstream dyadic observation rows.

Next use pullback coverage and the common-refinement theorem. The pullback coverage result Definition 126.196 identifies the two DyadicRatCore endpoint observations on the finite-window consumer boundary, while Definition 126.198 places those rows on the displayed common bundle $\mathcal{Q}$ together with the StreamName classifier and the selected observation rows.

Now inherit along the subbundle inclusions. Apply Definition 126.197 to keep the $\mathcal{Q}$ rows stable when read as descendants of the original windows, and apply Definition 126.195 to force the pointwise rational-history row to be the one determined by the same selected endpoint observations.

Finally apply the refinement descent theorem Definition 126.199. Descent preserves the two dyadic endpoint rows, the finite StreamName classifier, the unary index row, and the ProbeBundle membership row. The separation and pullback clauses exclude every $\mathsf{Real}^{\uparrow}$ seal, completion, quotient, and host-index equality, so the listed rows are exactly the source rows consumed by RegSeqRat. □

126.11 StreamName RegSeqRat RealUp Tail-Selector Transport

Definition 126.201 (StreamName RegSeqRat RealUp tail-selector transport packet)**.** *A StreamName RegSeqRat RealUp tail-selector transport packet from a selected finite* $\mathsf{Real}^{\uparrow}$ *window* W_0 *to a selected finite* $\mathsf{Real}^{\uparrow}$ *window* W_1 *is the finite ledger consisting exactly of the following rows:*

1. *a shared* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *row for the public* $\mathsf{StreamName}^{\uparrow}$ *rational stream endpoints* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *over the selected finite* ProbeBundle *window* $\mathcal{P}$*;*
2. *for each certified selected observation* n*, the bundled* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$ *rows, together with the pointwise* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *row exposed by the StreamName observation surface;*
3. *the accepted* RegSeqRat *spine row selected by those pointwise rational history rows and by the finite-window handoff;*
4. *the matching DyadicRatCore endpoint rows read by the two selected* $\mathsf{Real}^{\uparrow}$ *windows from that same* RegSeqRat *spine; and*
5. *the common finite* Cont*,* hsame*,* Pkg*, and* RealLedgerPolicy *ledger joining the StreamName endpoint rows, the accepted* RegSeqRat *spine row, the DyadicRatCore endpoint rows, and the two selected* $\mathsf{Real}^{\uparrow}$ *readback packets.*

The packet exposes no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order operation, standard bridge row, or selector not already contained in the displayed finite ledger.

Theorem 126.202 (StreamName RegSeqRat RealUp tail-selector transport)**.** *Let* W_0 *and* W_1 *be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same public* $\mathsf{StreamName}^{\uparrow}$ *rational stream endpoints and the same finite* ProbeBundle *window. If* W_0 *and* W_1 *are connected by a StreamName RegSeqRat RealUp tail-selector transport packet, then the selected* RegSeqRat *tail-classifier readback transported from* W_0 *by the packet agrees with the selected* RegSeqRat *tail-classifier readback read from* W_1*.*

The agreement is a finite-window agreement over the displayed RatStreamNameFiniteWindowClassifier *row, the bundled* UnaryHistory/InBundle *rows, the accepted* RegSeqRat *spine row, the matching DyadicRatCore endpoint rows, and the shared* Cont/hsame/Pkg/RealLedgerPolicy *ledger. It does not identify quotient objects, completion objects, Classical representatives, metric-completeness data, arithmetic or order rows, standard bridge rows, or external selector rows.*

Proof. First read the StreamName side of the packet. Apply Definition 126.171 to the displayed RatStreamNameFiniteWindowClassifier row and to each bundled UnaryHistory/InBundle observation. The selected pointwise rational-history rows therefore stay fixed under the packet's hsame transport.

Next form the uniform finite-window handoff. Apply Definition 126.111 to the stabilized StreamName rows and the accepted RegSeqRat spine row. This gives one finite seal surface carrying the same Cont, hsame, Pkg, and DyadicRatCore endpoint rows for both selected windows.

Now read the RealUp boundary through that finite seal. Use Definition 38.354. The two selected $\mathsf{Real}^{\uparrow}$ windows expose the same visible endpoint readback rows and the same RealLedgerPolicy row on the selected finite window.

Finally apply Definition 38.360. Its hypotheses are exactly the common StreamName classifier, the accepted RegSeqRat spine, the matching DyadicRatCore endpoint rows, and the shared finite ledger established above. Hence the transported tail-classifier readback from W_0 is the same selected readback as the one read from W_1, and the scoped exactness theorem supplies the stated exclusions. □

Theorem 126.203 (StreamName tail-selector pointwise transport)**.** *Let W_0 and W_1 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over public* $\mathsf{StreamName}^{\uparrow}$ *rational stream endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$ and the same finite* ProbeBundle *window $\mathcal{P}$. Suppose an accepted StreamName RegSeqRat RealUp tail-selector transport packet connects W_0 and W_1. Then for every certified observation n in $\mathcal{P}$, the transported pointwise row handed from the StreamName window to the* RegSeqRat *finite-window consumer is exactly the tuple*

$$\mathsf{UnaryHistory}(n), \quad \mathsf{InBundle}(n, \mathcal{P}), \quad \mathsf{RatHistoryClassifier}(s(n), t(n)).$$

This tuple is the only rowwise data supplied to the RegSeqRat *finite-window consumer at n. The handoff supplies no quotient row, no completion row, no host-index equality row, no arithmetic or order row, and no selector external to the displayed packet.*

Proof. First fix a certified observation n in $\mathcal{P}$. Apply Definition 126.171 to the accepted transport packet. The StreamName observation row at n is therefore stable as the bundled $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$ data together with the pointwise rational-history classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Next apply Definition 126.170 to that stable row. Its handoff clause is rowwise: the RegSeqRat finite-window consumer receives the named unary-history row, the named bundle-membership row, and the named rational-history classifier row for the same observation n.

Finally use Definition 126.202. The transport theorem fixes the finite-window agreement connecting W_0 and W_1, so the rowwise handoff just identified is the pointwise component of the transported window agreement. Since the three cited theorems expose only the displayed StreamName and RegSeqRat rows, quotient rows, completion rows, host-index equality rows, arithmetic or order rows, and external selector rows remain outside the handoff. □

Theorem 126.204 (StreamName RegSeqRat tail-selector handoff exactness)**.** *Let W_0 and W_1 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same public* $\mathsf{StreamName}^{\uparrow}$ *rational*

stream endpoints and the same finite ProbeBundle *window. If W_0 and W_1 are connected by an accepted StreamName RegSeqRat RealUp tail-selector transport packet, then the packet exported across the Real-and-Completion boundary decomposes exactly into the following public finite rows:*

1. *the displayed* RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{P})$ *row for the public* StreamName$^{\uparrow}$ *endpoints;*
2. *the bundled* UnaryHistory(n) *and* InBundle$(n, \mathcal{P})$ *rows for each selected observation n;*
3. *the pointwise* RatHistoryClassifier$(s(n), t(n))$ *rows read from those selected observations;*
4. *the accepted* RegSeqRat *spine row determined by the finite-window StreamName handoff;*
5. *the DyadicRatCore endpoint rows read from that same accepted spine by the selected* Real$^{\uparrow}$ *windows; and*
6. *the finite* Real$^{\uparrow}$ *ledger rows for* Cont, hsame, Pkg, *and* RealLedgerPolicy *over the selected window.*

The handoff packet exports no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order operation, or selector beyond the displayed finite rows.

Proof. Apply Definition 126.202 to the accepted transport packet. The resulting agreement fixes the selected RegSeqRat tail-classifier readback on the common finite window and restricts the transport to the rows displayed in the packet definition.

Next use Definition 126.171. It identifies the StreamName contribution to the packet as the public finite-window classifier together with the bundled UnaryHistory/InBundle observations and their pointwise rational-history classifier rows.

Use Definition 126.111 to read the accepted RegSeqRat spine from those stabilized StreamName rows. The seal supplies the single finite spine row consumed by the two selected endpoint windows and does not introduce a quotient or completion representative.

Finally apply Definition 38.354. The RealUp readback is exactly the DyadicRatCore endpoint surface and the finite Cont/hsame/Pkg/RealLedgerPolicy ledger over the selected window. Combining these four exactness statements gives precisely the six displayed families of rows, and the exclusion clauses follow because none of the cited theorems exports quotient data, completion data, metric completeness, arithmetic or order operations, or additional selectors. □

Theorem 126.205 (StreamName RegSeqRat tail-selector RealUp window factorization)**.** *Let W be a selected finite* Real$^{\uparrow}$ *observation-window package over public* StreamName$^{\uparrow}$ *rational stream endpoints s, t : BHist $\to$ BHist and a finite* ProbeBundle *window $\mathcal{P}$. If W is accepted through a StreamName RegSeqRat RealUp tail-selector transport packet, then every consumer-facing* Real$^{\uparrow}$ *row exposed by W factors through exactly the finite public surface consisting of:*

1. *the displayed* RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{P})$ *row;*
2. *for each selected observation n, the bundled* UnaryHistory(n) *and* InBundle$(n, \mathcal{P})$ *rows;*
3. *the pointwise* RatHistoryClassifier$(s(n), t(n))$ *rows;*
4. *the accepted* RegSeqRat *spine row selected by those pointwise rational history rows;*
5. *the DyadicRatCore endpoint rows read from that same accepted spine; and*
6. *the finite* Cont, hsame, Pkg, *and* RealLedgerPolicy *ledger over the selected window.*

Thus the Real-and-Completion boundary sees only this finite factorization. The factorization exposes no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order operation, standard bridge row, or hidden selector row.

Proof. First apply Definition 126.204 to the accepted transport packet. The handoff exactness result displays the packet as precisely the StreamName finite-window classifier, the selected UnaryHistory/InBundle observations, the pointwise RatHistoryClassifier rows, the accepted RegSeqRat spine, the DyadicRatCore endpoint rows, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

Next apply Definition 38.354 to that displayed handoff surface. This reads every selected $\mathsf{Real}^{\uparrow}$ observation through the same finite StreamName-to-RegSeqRat window and identifies the consumer-facing rows with the DyadicRatCore endpoint readback and the Cont/hsame/Pkg/RealLedgerPolicy ledger.

Finally apply Definition 38.360. The selected tail row is therefore the same finite public surface already named by the accepted RegSeqRat spine and its pointwise rational-history classifier rows. Since each cited exactness theorem exports only the listed finite rows, no quotient, completion, Classical representative, metric-completeness, arithmetic or order, standard-bridge, or hidden-selector row can appear in the factorization. □

Theorem 126.206 (StreamName RegSeqRat RealUp tail-selector transport composition)**.** *Let W_0, W_1, and W_2 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same public* $\mathsf{StreamName}^{\uparrow}$ *rational stream endpoints, and let the finite* ProbeBundle *windows used by the W_0 to W_1 and W_1 to W_2 packets be compatible on their shared selected observations. If W_0 is connected to W_1 by a StreamName RegSeqRat RealUp tail-selector transport packet and W_1 is connected to W_2 by a second such packet, then the concatenated visible ledger is again a StreamName RegSeqRat RealUp tail-selector transport packet from W_0 to W_2.*

The concatenated packet uses the composed Cont *rows, the composed displayed* hsame *rows, the concatenated* Pkg *provenance, and the combined* RealLedgerPolicy *ledger. It transports the selected* RegSeqRat *tail classifier read from W_0 to the selected finite-window readback at W_2. The assertion is only a finite-window transport statement over the displayed* ProbeBundle *windows and the accepted* RegSeqRat *spine; it adds no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order operation, standard bridge row, or hidden selector row.*

Proof. First apply Definition 126.202 to the W_0 to W_1 packet. This identifies the selected RegSeqRat tail classifier transported from W_0 with the selected finite-window readback visible at W_1.

Next apply the same theorem to the W_1 to W_2 packet. The compatibility of the displayed ProbeBundle windows makes the W_1 readback row used by the first packet the same finite row consumed by the second packet.

Compose the visible transport rows. The hsame classifier rows compose on the selected StreamName observations, on the accepted RegSeqRat spine, and on the matching DyadicRatCore endpoint rows; the Cont rows concatenate the finite routes; the Pkg rows concatenate the displayed provenance; and the RealLedgerPolicy rows remain a single visible finite ledger over the combined window.

Finally use Definition 38.360 on the combined finite-window row. The exactness theorem identifies the final row produced by the composed ledger with the selected RegSeqRat tail-classifier readback at W_2, so the concatenated ledger is precisely the required transport packet from W_0 to W_2 with the stated exclusions. □

Theorem 126.207 (StreamName RegSeqRat RealUp tail denominator selector)**.** *Let W_0 and W_1 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same StreamName endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$, the same finite* ProbeBundle *window $\mathcal{P}$, and the same accepted* RegSeqRat *spine row. Suppose they are connected by a StreamName RegSeqRat RealUp tail-selector transport*

packet. Then the packet carries the public denominator-window selector selected by W_0 to the same public denominator-window selector read from W_1.

Equivalently, for every certified selected observation n with $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$*, the transported tail readback has the same finite public selector surface*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}), \qquad \mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{P}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the downstream dyadic observation coverage row}$$

as the selector read by the finite $\mathsf{Real}^{\uparrow}$ *ledger of W_1. The conclusion is only a finite selector statement over the accepted* $\mathsf{RegSeqRat}$ *spine and the finite* $\mathsf{Real}^{\uparrow}$ *ledger; it adds no quotient row, completion object, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or external selector.*

Proof. First apply Definition 126.202. The transport packet identifies the selected $\mathsf{RegSeqRat}$ tail-classifier readback from W_0 with the selected readback exposed by W_1, using only the shared finite StreamName classifier, the bundled unary observations, the accepted $\mathsf{RegSeqRat}$ spine, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

Next isolate the denominator selector inside that transported readback. By Definition 126.190, each certified observation n exposes only the displayed $\mathsf{RatStreamNameFiniteWindowClassifier}$ row, the $\mathsf{UnaryHistory}(n)$ row, the $\mathsf{InBundle}(n, \mathcal{P})$ row, and the pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ row on the $\mathsf{RegSeqRat}$ side.

Now read the same selector through the finite $\mathsf{Real}^{\uparrow}$ consumer. Apply Definition 126.194. It says that the finite $\mathsf{Real}^{\uparrow}$ ledger contributes exactly the downstream dyadic observation coverage row to that public denominator-window surface and no regularity, seal, completion, quotient, or host-index coordinate.

Finally compare the two presentations by Definition 126.195. Both are accepted over the same s, t, $\mathcal{P}$, certified observation n, and accepted $\mathsf{RegSeqRat}$ spine, so the transported selector from W_0 and the selector read from W_1 have the same public coordinates. The exclusion clauses in the transport, separation, normal-form, and determinacy statements give the stated boundary. □

Theorem 126.208 (StreamName RegSeqRat RealUp tail denominator selector subwindow)**.** *Let W_0 and W_1 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same StreamName endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$, the same finite* $\mathsf{ProbeBundle}$ *window $\mathcal{P}$, and the same accepted* $\mathsf{RegSeqRat}$ *spine row. Suppose a StreamName RegSeqRat RealUp tail-selector transport packet carries the public denominator-window selector from W_0 to W_1. Let $\mathcal{Q}$ be a certified subwindow of $\mathcal{P}$. Then the restrictions of W_0, W_1, and the transport packet to $\mathcal{Q}$ carry the same public denominator-window selector on $\mathcal{Q}$.*

For each certified selected observation n with $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{Q})$*, the subwindow selector conclusion reads only*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}), \qquad \mathsf{UnaryHistory}(n), \qquad \mathsf{InBundle}(n, \mathcal{Q}),$$
$$\mathsf{RatHistoryClassifier}(s(n), t(n)), \qquad \textit{the accepted } \mathsf{RegSeqRat} \textit{ spine}, \qquad \textit{the finite } \mathsf{Real}^{\uparrow} \textit{ ledger restricted to } \mathcal{Q}.$$

It introduces no observation outside $\mathcal{Q}$, quotient row, completion object, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or external selector.

Proof. First restrict the two selected $\mathsf{Real}^{\uparrow}$ windows. Apply Definition 38.172 to the finite $\mathsf{ProbeBundle}$ inclusion $\mathcal{Q} \subseteq \mathcal{P}$. The result is a selected finite-window package for each W_i whose visible ledger is precisely the $\mathsf{Real}^{\uparrow}$ ledger over the certified observations in $\mathcal{Q}$.

Next restrict the StreamName finite-window face of the packet. The handoff rows Definition 126.9 and Definition 126.35 replace the ambient classifier over $\mathcal{P}$ by $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}$ and keep only the rows whose unary index lies in $\mathsf{InBundle}(-, \mathcal{Q})$.

Now apply Definition 126.207 to the restricted packet. The accepted $\mathsf{RegSeqRat}$ spine is unchanged, while the denominator selector is read through the restricted StreamName classifier and the restricted finite $\mathsf{Real}^{\uparrow}$ ledger.

The displayed conclusion follows because every coordinate it reads is one of $\mathsf{RatStreamNameFiniteWindowClassifie}$ $\mathsf{UnaryHistory}$, $\mathsf{InBundle}$, pointwise $\mathsf{RatHistoryClassifier}$, the accepted $\mathsf{RegSeqRat}$ spine, or the finite $\mathsf{Real}^{\uparrow}$ ledger on $\mathcal{Q}$. No row from the complement of $\mathcal{Q}$ remains available after the subwindow extraction. □

Theorem 126.209 (StreamName RegSeqRat RealUp tail denominator selector composition)**.** *Let W_0, W_1, and W_2 be selected finite $\mathsf{Real}^{\uparrow}$ observation-window packages over the same public StreamName endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$ and the same accepted $\mathsf{RegSeqRat}$ spine row. Suppose the W_0 to W_1 packet and the W_1 to W_2 packet are compatible StreamName RegSeqRat RealUp tail-selector transport packets, and suppose each packet carries the public denominator-window selector between its endpoints. Then the two packets compose to carry the same public denominator-window selector from W_0 to W_2.*

The composed readback is entirely finite-window data. It reads only the displayed $\mathsf{RatStreamNameFiniteWindowC}$ *rows, the bundled* $\mathsf{UnaryHistory}$ *and* $\mathsf{InBundle}$ *rows, the pointwise* $\mathsf{RatHistoryClassifier}$ *rows, the accepted* $\mathsf{RegSeqRat}$ *spine, and the finite* $\mathsf{Real}^{\uparrow}$ *ledger carried by the compatible packets and their certified subwindows. It introduces no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or hidden selector row.*

Proof. First compose the underlying tail-selector transport packets. Apply Definition 126.206 to the compatible W_0 to W_1 and W_1 to W_2 packets. The result is a visible finite transport packet from W_0 to W_2 over the same displayed StreamName classifier rows, accepted $\mathsf{RegSeqRat}$ spine, and finite $\mathsf{Real}^{\uparrow}$ ledger.

Next identify the denominator selector transported by the first leg. Apply Definition 126.207 to the W_0 to W_1 packet. This makes the public denominator-window selector read from W_0 the same selector as the one exposed at W_1.

Now identify the denominator selector transported by the second leg. Apply Definition 126.207 to the W_1 to W_2 packet. Compatibility says that the W_1 selector consumed by this leg is the same finite public selector produced by the first leg.

It remains to check that no extra selector coordinates appear when the two windows are read through smaller certified faces. Apply Definition 126.208 to each certified shared subwindow. The conclusion restricts every intermediate readback to $\mathsf{RatStreamNameFiniteWindowClassifier}$, $\mathsf{UnaryHistory}$, $\mathsf{InBundle}$, pointwise $\mathsf{RatHistoryClassifier}$, the accepted $\mathsf{RegSeqRat}$ spine, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

Combining these finite identifications gives a single public denominator-window selector transported from W_0 to W_2. The exclusions come from the three cited transport, denominator-selector, and subwindow statements: no quotient, completion, Classical representative, metric-completeness, arithmetic or order, standard bridge, or hidden selector row is available in the composed readback. □

Theorem 126.210 (StreamName RegSeqRat RealUp tail-selector ledger associativity)**.** *Let W_0, W_1, W_2, W_3 be selected finite $\mathsf{Real}^{\uparrow}$ observation-window packages over the same public StreamName endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$ and the same accepted $\mathsf{RegSeqRat}$ spine row. Suppose the W_0 to W_1, W_1 to W_2, and W_2 to W_3 legs are compatible StreamName RegSeqRat RealUp tail-selector transport packets.*

Then the left and right bracketings of these three legs expose the same finite ledger: the displayed RatStreamNameFiniteWindowClassifier *row, the* UnaryHistory *rows, the* InBundle *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the finite* $\mathsf{Real}^{\uparrow}$ *ledger, and the visible* Cont/hsame/Pkg *rows carried by the three compatible legs and their certified shared subwindows.*

The ledger identification adds no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or hidden selector row.

Proof. First compare the composed transport packets. Apply Definition 126.206 to the W_0 to W_1 and W_1 to W_2 legs, and then to the resulting W_0 to W_2 packet and the W_2 to W_3 leg. Apply the same theorem to the W_1 to W_2 and W_2 to W_3 legs, and then to the W_0 to W_1 leg and the resulting W_1 to W_3 packet. Both constructions expose the same endpoint rows and the same three named visible legs.

Next compare the public denominator-window coordinates. Apply Definition 126.209 to the two bracketings. The selector rows in the two resulting readbacks are therefore the selectors produced from the same three compatible packets.

Now restrict the comparison to every certified shared face. Apply Definition 126.208 on each subwindow. This identifies the displayed RatStreamNameFiniteWindowClassifier, UnaryHistory, InBundle, pointwise RatHistoryClassifier, accepted RegSeqRat spine, and finite $\mathsf{Real}^{\uparrow}$ ledger rows read by both bracketings.

It remains to compare the visible kernel rows. The hsame rows compose associatively on StreamName observations, on the accepted RegSeqRat spine, and on the dyadic endpoint rows; the Cont routes concatenate associatively; and the Pkg provenance rows name the same three visible legs in either bracketing. Transitivity of these displayed comparisons gives the stated finite-ledger identification and the stated exclusions. □

Theorem 126.211 (StreamName RegSeqRat RealUp tail selector associative readback)**.** *Let* W_0, W_1, W_2, W_3 *be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages over the same public StreamName endpoints* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *and the same accepted* RegSeqRat *spine row. Suppose the* W_0 *to* W_1*,* W_1 *to* W_2*, and* W_2 *to* W_3 *legs are compatible StreamName RegSeqRat RealUp tail-selector transport packets, and suppose each leg carries the public denominator-window selector between its endpoints. Then the two finite-transport bracketings*

$$((W_0 \to W_1) \to W_2) \to W_3,$$
$$W_0 \to (W_1 \to (W_2 \to W_3))$$

read the same public denominator-window selector from W_0 *to* W_3*.*

The common readback surface is only the displayed RatStreamNameFiniteWindowClassifier *row, the* UnaryHistory *rows, the* InBundle *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the finite* $\mathsf{Real}^{\uparrow}$ *ledger, and the visible* Cont/hsame/Pkg *rows carried by the three compatible legs and their certified shared subwindows. It adds no quotient row, completion row, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or hidden selector row.*

Proof. First compose the transport packets with the left bracketing. Apply Definition 126.206 to the W_0 to W_1 and W_1 to W_2 packets, and then compose the result with the W_2 to W_3 packet. This gives a visible finite packet from W_0 to W_3.

Next compose the same three packets with the right bracketing. Apply the same composition theorem first to the W_1 to W_2 and W_2 to W_3 packets, and then compose the W_0 to W_1 packet with that result. This gives a second visible finite packet from W_0 to W_3 over the same endpoint rows.

Now read the denominator selector through the two-leg selector theorem on each bracketing. For the left bracketing, apply Definition 126.209 to the W_0 to W_2 composite and the W_2 to W_3 leg. For the right bracketing, apply the same theorem to the W_0 to W_1 leg and the W_1 to W_3 composite.

The shared finite faces are identified by Definition 126.208. On every certified subwindow, both bracketings expose the same RatStreamNameFiniteWindowClassifier, UnaryHistory, InBundle, pointwise RatHistoryClassifier, accepted RegSeqRat spine, and finite $\mathsf{Real}^{\uparrow}$ ledger rows.

The displayed ledger comparison is Definition 126.210. It identifies the visible Cont/hsame/Pkg rows and the finite public rows read by both bracketings. This gives the stated selector from W_0 to W_3 and the stated exclusions. □

Theorem 126.212 (StreamName tail-selector composite transport determinacy)**.** *Let s, t : BHist $\to$ BHist be public StreamName endpoints, let Σ be an accepted* RegSeqRat *spine over them, and let W_0, W_1, W_2, W_3 be selected finite* $\mathsf{Real}^{\uparrow}$ *observation-window packages for that spine. Suppose two compatible composite StreamName RegSeqRat RealUp tail-selector transport packets connect the same visible endpoint windows and display the same finite* ProbeBundle *window,* UnaryHistory *rows,* InBundle *rows, pointwise* RatHistoryClassifier *rows, DyadicRatCore endpoint rows, and* Cont, hsame, Pkg, *and* RealLedgerPolicy *ledger rows. Suppose also that the two composites carry the same public denominator-window selector readback at the endpoints. Then the two composites expose the same finite consumer interface to* $\mathsf{StreamName}^{\uparrow}$, RegSeqRat, *and* $\mathsf{Real}^{\uparrow}$.

The determined interface consists exactly of the displayed ProbeBundle *rows,* UnaryHistory *rows,* InBundle *rows, pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine row, the DyadicRatCore endpoint row, the visible* Cont/hsame/Pkg *ledger, and the* RealLedgerPolicy *row. It contains no quotient row, host stream equality row, independent regularity witness,* $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, arithmetic or order row, standard bridge row, or hidden selector row.*

Proof. First normalize the two composites to visible finite packets. Apply Definition 126.206 to the component legs used by each composite. The hypotheses say that the resulting packets have the same endpoint windows, the same displayed ProbeBundle window, and the same accepted RegSeqRat spine.

Next compare the visible ledgers. Apply Definition 126.210 to the two bracketings of the compatible transport legs. This identifies the Cont, hsame, Pkg, and RealLedgerPolicy rows carried by the two finite packets.

Finally read back the endpoint selector. Apply Definition 126.211 to identify the denominator-window selector exposed by the two composites. Tuple exhaustion over the listed finite rows then gives the same consumer interface for $\mathsf{StreamName}^{\uparrow}$, RegSeqRat, and $\mathsf{Real}^{\uparrow}$. Since every step uses only the displayed rows, the excluded quotient, host equality, regularity, completeness, arithmetic, order, bridge, and hidden-selector data are not introduced. □

Theorem 126.213 (StreamName RealUp tail-selector public interface)**.** *Let W be a public* $\mathsf{StreamName}^{\uparrow}$ *package with an accepted* RegSeqRat *spine row, a finite* ProbeBundle *observation window, a public denominator-window selector, and compatible selected* $\mathsf{Real}^{\uparrow}$ *observation windows over the same endpoints. Then the package exports exactly the finite consumer interface available to downstream* $\mathsf{Real}^{\uparrow}$ *and* RegSeqRat *sites: the* RatStreamNameFiniteWindowClassifier *row, the* UnaryHistory *rows, the* InBundle *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the visible* Cont/hsame/Pkg/RealLedgerPolicy *ledger.*

The exported interface contains no quotient row, completion object, Classical representative, metric-completeness certificate, arithmetic or order row, standard bridge row, or hidden selector.

Proof. First read the source boundary through the public $\mathsf{StreamName}^{\uparrow}$ interface. Apply Definition 126.311. It restricts the countable-name and finite-window rows to the visible public StreamName surface.

Next decompose the Real-and-Completion handoff. Apply Definition 126.204. The handoff rows are exactly the finite StreamName classifier rows, the bundled window observations, the pointwise rational-history rows, the accepted RegSeqRat spine, the DyadicRatCore endpoint rows, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

Now read the selected denominator coordinates. Apply Definition 126.207. The selector visible to the consumer is the public denominator-window selector carried by the same finite handoff ledger.

Finally apply Definition 126.211. It makes the transport readback independent of bracketing, so every compatible selected $\mathsf{Real}^{\uparrow}$ observation window exports the same finite consumer interface. The exclusion clauses are inherited from the public interface, handoff exactness, selector readback, and associative readback theorems. □

Theorem 126.214 (StreamName RealUp tail-selector public interface descent)**.** *Let a downstream* $\mathsf{Real}^{\uparrow}$ *or* RegSeqRat *consumer request factor through the public interface of Definition 126.213. Suppose the selected* $\mathsf{Real}^{\uparrow}$ *windows in that request are compatible over the same DyadicRatCore endpoints and are replaced by an accepted StreamName–*RegSeqRat*–*$\mathsf{Real}^{\uparrow}$ *tail-selector transport packet. Then the replacement preserves exactly the exported finite rows visible to the consumer: the* RatStreamNameFiniteWindowClassifier *row, the* UnaryHistory *rows, the* InBundle *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the visible* Cont/hsame/Pkg/RealLedgerPolicy *ledger.*

The descent exports no quotient row, completion object, Classical representative, metric-completeness data, arithmetic or order row, standard bridge row, or hidden selector. Thus any downstream request that is already expressed through the public interface reads the same finite StreamName, RegSeqRat*, DyadicRatCore, and* $\mathsf{Real}^{\uparrow}$ *ledger rows after transport, and no additional row is made available by the replacement.*

Proof. First reduce the downstream request to the public StreamName surface. Apply Definition 126.213. Since the request factors through that interface, its observable inputs are exactly the finite classifier, bundle, accepted spine, endpoint, and visible ledger rows listed there.

Next read the transport packet through the handoff theorem. Apply Definition 126.204. It identifies the StreamName finite-window classifier, bundled observations, pointwise rational-history rows, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and finite $\mathsf{Real}^{\uparrow}$ ledger carried by the packet.

Now select the denominator-window coordinates. Apply Definition 126.207. The selected $\mathsf{Real}^{\uparrow}$ windows and the accepted spine are read from the same finite handoff ledger, so compatible endpoint windows expose the same consumer-visible denominator data.

Finally apply Definition 126.211. The readback is independent of the bracketing used to assemble the accepted packet. Combining this with the public interface gives exactly the exported finite rows and only those rows; the excluded quotient, completion, representative, metric, arithmetic, order, bridge, and hidden-selector data are absent from every cited surface. □

Theorem 126.215 (StreamName tail-selector finite-window transport)**.** *Let an accepted StreamName–*RegSeqRat*–*$\mathsf{Real}^{\uparrow}$ *tail-selector transport packet expose a finite tail-selector window over the same DyadicRatCore endpoints. If the window is transported through the RegSeqRat handoff exactness surface, then it preserves the StreamName finite section and the DyadicRatCore denominator window before any RealUp public-interface descent is applied.*

The transport exports no quotient row, completion object, Classical representative, ambient metric-completeness data, arithmetic or order row, standard bridge row, or hidden selector.

Proof. First apply Definition 126.204. The handoff identifies the transported StreamName finite-window classifier, bundled observations, pointwise rational-history rows, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and finite Real ledger carried by the packet.

Next apply Definition 126.207. The denominator selector reads the transported finite window before any public-interface descent, so the DyadicRatCore denominator data remain attached to the same finite tail-selector window.

Only after these two finite-window steps apply Definition 126.214. The descent consumes the already transported finite section and denominator window; it does not create the window or replace it with a terminal RealUp seal. □

126.12 StreamName Tail-Window Coverage Packet

Definition 126.216 (StreamName tail-window coverage packet)**.** *A StreamName tail-window coverage packet for a selected finite* $\mathsf{Real}^{\uparrow}$ *consumer window is the finite ledger consisting exactly of these rows:*

1. *a displayed* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$ *row for public* $\mathsf{StreamName}^{\uparrow}$ *rational stream endpoints* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *and the selected finite* $\mathsf{ProbeBundle}$ *window* $\mathcal{P}$*;*
2. *for each selected observation* n*, the bundled* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$ *rows;*
3. *the pointwise* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *row read from the selected StreamName observation;*
4. *the accepted* $\mathsf{RegSeqRat}$ *spine selected by the pointwise rational-history rows and by the finite-window handoff;*
5. *the selected finite* $\mathsf{Real}^{\uparrow}$ *windows whose DyadicRatCore endpoint rows are read from that accepted* $\mathsf{RegSeqRat}$ *spine; and*
6. *the shared* Cont, hsame, Pkg, *and* $\mathsf{RealLedgerPolicy}$ *rows joining the StreamName endpoints, the accepted* $\mathsf{RegSeqRat}$ *spine, the DyadicRatCore endpoint rows, and the selected* $\mathsf{Real}^{\uparrow}$ *readback packets.*

The packet is only this displayed finite ledger. It contains no completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, standard bridge row, or hidden selector.

Theorem 126.217 (StreamName tail-window coverage exhaustion)**.** *Every consumer row of a StreamName tail-window coverage packet is one of the rows displayed in Definition 126.216. In particular, the consumer can read only the* $\mathsf{RatStreamNameFiniteWindowClassifier}$ *row, the bundled* $\mathsf{UnaryHistory}/\mathsf{InBundle}$ *rows, the pointwise* $\mathsf{RatHistoryClassifier}$ *rows, the accepted* $\mathsf{RegSeqRat}$ *spine, the selected DyadicRatCore endpoint rows, and the shared* $\mathsf{Cont}/\mathsf{hsame}/\mathsf{Pkg}/\mathsf{RealLedgerPolicy}$ *ledger.*

Proof. First apply Definition 126.204. It decomposes the handoff exported across the Real-and-Completion boundary into the StreamName finite-window classifier, selected unary observations, bundle membership, pointwise rational-history classifiers, the accepted $\mathsf{RegSeqRat}$ spine, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

Next apply Definition 126.205 to the selected $\mathsf{Real}^{\uparrow}$ window. This says every consumer-facing $\mathsf{Real}^{\uparrow}$ row factors through the same displayed finite public surface and through no additional selector row.

Combining the two exactness statements gives the exhaustion claim. Any row read by the consumer is already named by the coverage packet, and every row excluded by the two cited theorems remains outside the packet boundary. □

Theorem 126.218 (RegSeqRat finite-window classifier coverage)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public $\mathsf{StreamName}^{\uparrow}$ rational stream endpoints, let $\mathcal{P}$ be a finite* ProbeBundle *window, and suppose a StreamName tail-window coverage packet displays the row* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$*. For every certified observation n with* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$*, the pointwise row* $\mathsf{RatHistoryClassifier}(s(n$ *is exposed in the same packet. The accepted* RegSeqRat *spine consumes exactly these exposed pointwise rational-history classifier rows, together with their displayed unary-history and bundle-membership witnesses.*

No completion object, quotient representative, host-index equality, $\mathsf{Real}^{\uparrow}$ *seal classifier, metric-completeness row, arithmetic or order row, or standard bridge row is supplied by this coverage claim.*

Proof. Unfold Definition 126.216. The packet contains the finite-window classifier row, the bundled UnaryHistory/InBundle rows, and the pointwise RatHistoryClassifier rows read from the selected StreamName observations.

Project the component indexed by the certified observation n. The hypotheses $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$ identify n as one of the selected observations of the displayed finite window, so the corresponding pointwise rational-history classifier is precisely $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

The accepted RegSeqRat spine is then the spine named in the same packet from these pointwise rows and the finite-window handoff. Apply Definition 126.217 to rule out any additional consumer row.

Finally apply Definition 126.223. The $\mathsf{Real}^{\uparrow}$ readback can use only the finite windows selected from the accepted spine, while completion, quotient, host-index equality, seal classifier, metric-completeness, arithmetic or order, and standard bridge rows remain outside the packet boundary. □

Theorem 126.219 (StreamName tail-window dyadic endpoint determinacy)**.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be StreamName tail-window coverage packets over shared public endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$ and the same accepted* RegSeqRat *spine. Suppose their displayed finite-window classifier rows agree, and suppose the selected* UnaryHistory *and* InBundle *membership rows agree by the shown* hsame/Cont/Pkg *provenance. Then the two packets expose identical DyadicRatCore endpoint rows to any finite* $\mathsf{Real}^{\uparrow}$ *consumer.*

The determined finite interface is the shared RatStreamNameFiniteWindowClassifier *row, the selected* ProbeBundle/InBundle/UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows consumed by the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the common* Cont/hsame/Pkg/RealLedgerP *ledger. It contains no completion, quotient, metric-completeness, arithmetic or order, or standard-bridge row.*

Proof. Unfold Definition 126.216. The only selected rows available for comparison are the finite-window classifier, the displayed bundle and unary-history rows, the pointwise rational-history classifiers, the accepted RegSeqRat spine, the DyadicRatCore endpoint rows, and the finite ledger provenance.

Apply Definition 126.218. The shared finite-window classifier and the agreed selected membership rows force the same pointwise RatHistoryClassifier rows to feed the common accepted RegSeqRat spine in both packets.

Next apply Definition 126.217. Since the accepted spine and its pointwise StreamName inputs are the same displayed rows, the DyadicRatCore endpoint rows selected from that spine are the same finite packet rows for both consumers.

Finally use Definition 126.223. The boundary has no slot for completion, quotient, metric-completeness, arithmetic or order, or standard bridge data, so no off-packet row can separate the two exposed DyadicRatCore endpoint surfaces. □

Theorem 126.220 (StreamName tail-window hsame transport stability)**.** *Let $\mathcal{P}$ be a StreamName tail-window coverage packet over public endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$. Suppose the displayed* hsame, Cont, *and* Pkg *rows transport componentwise the* RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{P})$ *row, the selected* UnaryHistory/InBundle *rows, each pointwise* RatHistoryClassifier *row, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the* RealLedgerPolicy *ledger to a second displayed finite window. Then the transported rows form another StreamName tail-window coverage packet.*

Moreover, every finite $\mathsf{Real}^{\uparrow}$ *consumer row of the original packet transports through the same displayed packet surface: its source is still the finite-window classifier, selected unary and bundle rows, pointwise rational history rows, accepted* RegSeqRat *spine, DyadicRatCore endpoint rows, and shared* Cont/hsame/Pkg/RealLedgerPolicy *ledger. The transport supplies no completion object, quotient row, host-index equality, metric-completeness row, arithmetic or order row, or standard bridge row.*

Proof. Unfold Definition 126.216. Each row named in the packet definition has a displayed transported partner by hypothesis: the finite-window classifier, selected unary-history and bundle-membership rows, pointwise rational-history rows, accepted rational-sequence spine, endpoint readbacks, and ledger-policy rows.

Repack those transported partners in the same order. The classifier and membership rows still select a finite StreamName window; the pointwise rational-history rows still feed the accepted RegSeqRat spine; and the DyadicRatCore endpoint rows and ledger rows still give the finite $\mathsf{Real}^{\uparrow}$ readback surface.

Apply Definition 126.217 to the original and transported packets. Every consumer row is one of the rows just transported, so the consumer transport factors through exactly the same displayed packet surface.

Finally apply Definition 126.223. Completion, quotient, host-index equality, metric-completeness, arithmetic or order, and standard bridge rows have no constructor in either finite packet, so the transport cannot introduce any such row. □

Theorem 126.221 (StreamName tail-window common refinement)**.** *Given two StreamName tail-window coverage packets for finite* ProbeBundle *windows $\mathcal{P}$ and $\mathcal{Q}$ over the same public* $\mathsf{StreamName}^{\uparrow}$ *endpoints $s, t : \mathsf{BHist} \to \mathsf{BHist}$ and the same accepted* RegSeqRat *spine, there is a finite coverage packet over the bundle generated by the selected observations of $\mathcal{P}$ and $\mathcal{Q}$. Its restrictions to the two selected subbundles recover the original packets. Every readable row in the common packet remains one of the* RatStreamNameFiniteWindowClassifier *rows, the* UnaryHistory/InBundle *rows, the pointwise* RatHistoryClassifier *rows, the shared* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the shared* Cont/hsame/Pkg/RealLedgerPolicy *rows.*

Proof. Unpack the two coverage packets using Definition 126.216. The public endpoints s, t and the accepted RegSeqRat spine are shared, so the pointwise rational-history classifier rows and the endpoint readback rows are compared inside one displayed ledger.

Form the generated finite bundle by taking the selected UnaryHistory/InBundle rows from $\mathcal{P}$ and $\mathcal{Q}$ and closing under the displayed finite bundle constructor. The restriction to each selected subbundle forgets the other selected rows and therefore recovers the corresponding original packet.

Now apply Definition 126.217. The generated packet has no constructor beyond the rows named in the coverage definition, so the union operation introduces no extra consumer row.

Finally apply Definition 126.223 to the generated packet and to its two restrictions. The completion, quotient, host-index equality, metric-completeness, arithmetic or order, and standard bridge rows remain outside all three packet boundaries. □

Theorem 126.222 (StreamName tail-window refinement associativity)**.** *Let $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{R}$ be finite* ProbeBundle *windows carrying StreamName tail-window coverage packets over the same public endpoints s, t : BHist $\to$ BHist and the same accepted* RegSeqRat *spine. The common-refinement packet obtained by first refining $(\mathcal{P}, \mathcal{Q})$ and then refining the result with $\mathcal{R}$ has the same public restriction on every selected subwindow as the packet obtained by first refining $(\mathcal{Q}, \mathcal{R})$ and then refining the result with $\mathcal{P}$.*

The shared public restriction consists exactly of the RatStreamNameFiniteWindowClassifier *rows, the selected* UnaryHistory *rows, the* InBundle *membership rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the shared* Cont/hsame/Pkg/RealLedgerP *ledger.*

Proof. Apply Definition 126.221 to $\mathcal{P}$ and $\mathcal{Q}$, and then apply it again to the resulting generated bundle and $\mathcal{R}$. This constructs the left-grouped coverage packet with public endpoints s, t and with the fixed accepted RegSeqRat spine.

Apply the same theorem to $\mathcal{Q}$ and $\mathcal{R}$, and then to $\mathcal{P}$ and the resulting generated bundle. This constructs the right-grouped coverage packet with the same endpoints and the same accepted spine.

The finite bundle generated by selected observations is associative: selecting the rows of $\mathcal{P}$ and $\mathcal{Q}$ and then adjoining the rows of $\mathcal{R}$ gives the same selected observation family as selecting the rows of $\mathcal{Q}$ and $\mathcal{R}$ and then adjoining the rows of $\mathcal{P}$. Restriction to any chosen subwindow therefore forgets the same complement in both grouped packets.

Now apply Definition 126.217 to both grouped packets. Every readable row in either packet is one of the displayed finite-window classifier, unary-history, bundle-membership, rational-history, RegSeqRat, DyadicRatCore, continuation, history, package, or ledger-policy rows, and those rows are indexed by the same selected observation family.

Finally apply Definition 126.223 to both grouped packets and to their selected restrictions. Completion, quotient, host-index equality, metric-completeness, arithmetic or order, standard bridge, and unexposed selector data have no constructor in either public surface. Hence the two grouped common-refinement packets restrict to the same public rows on every selected subwindow. □

Theorem 126.223 (StreamName tail-window RealUp boundary)**.** *A finite* $\mathsf{Real}^{\uparrow}$ *consumer of a StreamName tail-window coverage packet reads only the displayed StreamName,* RegSeqRat*, DyadicRatCore,* Cont*,* hsame*,* Pkg*, and* RealLedgerPolicy *rows. It reads no completion row, quotient row, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameTailWindowRealUpBoundary`

Proof. Read the consumer through Definition 126.217. The exhaustion surface lists every available consumer row and identifies it with the finite packet of Definition 126.216.

Now inspect the packet definition. Its StreamName side is the finite-window classifier together with selected unary-history and bundle-membership rows. Its rational-sequence side is the accepted RegSeqRat spine selected by the pointwise rational-history classifiers. Its $\mathsf{Real}^{\uparrow}$ side is only the DyadicRatCore endpoint readback and the shared Cont/hsame/Pkg/RealLedgerPolicy ledger.

The excluded objects have no constructor in this finite ledger. Hence a finite $\mathsf{Real}^{\uparrow}$ consumer cannot read completion, quotient, host-index equality, metric-completeness, arithmetic or order, or standard bridge data from the packet. □

Theorem 126.224 (StreamName tail-window terminal consumer factorization)**.** *Every finite* $\mathsf{Real}^{\uparrow}$ *consumer row whose source reads a StreamName tail-window coverage packet factors through the displayed rows of Definition 126.216: the* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier, the selected* UnaryHistory *observations and* InBundle *membership rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore observation rows, and the shared* Cont/hsame/Pkg/RealLedgerPoli *ledger. If two such consumers are given the same displayed packet, then they have the same finite read surface. They do not read any completion object, quotient row, host sequence equality, or standard real-number structure.*

Proof. Apply Definition 126.217. It enumerates all readable rows of the packet and identifies each one with a row already displayed in Definition 126.216.

Next apply Definition 126.223. The finite $\mathsf{Real}^{\uparrow}$ consumer can therefore see only the StreamName classifier, selected unary observation and bundle rows, rational-history classifier rows, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and shared ledger rows named in the statement.

For two consumers using the same displayed packet, apply Definition 126.221 to place their selected finite windows in one common packet. Then apply Definition 126.222 to see that changing the grouping of those finite windows leaves the restriction to each selected subwindow unchanged.

Thus the factorization is terminal among finite packet readers: every observable row is already in the displayed packet, and any grouped finite read of the same packet restricts back to the same StreamName, RegSeqRat, DyadicRatCore, continuation, history, package, and ledger-policy surface. The objects excluded by the boundary theorem have no row in the factorization. □

Theorem 126.225 (StreamName tail-window terminal source uniqueness)**.** *Let two finite* $\mathsf{Real}^{\uparrow}$ *consumers read StreamName tail-window coverage packets over the same public* $\mathsf{StreamName}^{\uparrow}$ *endpoints* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *and the same accepted* RegSeqRat *spine. If a common-refinement packet restricts to both packets, then both consumers factor through the same displayed StreamName,* RegSeqRat*, DyadicRatCore,* Cont*,* hsame*,* Pkg*, and* RealLedgerPolicy *source surface. No alternative* $\mathsf{Real}^{\uparrow}$ *source row, quotient representative, completion row, or host-index equality can be read from either finite consumer.*

Proof. First apply Definition 126.221. The two selected finite windows sit in one coverage packet over the shared public StreamName endpoints and the shared accepted RegSeqRat spine, and the restrictions to the selected subwindows recover the two original packets.

Next apply Definition 126.222. Any regrouping of the common finite window has the same public restriction on each selected subwindow, so the two consumers see the same StreamName finite-window classifier rows, selected unary-history and bundle-membership rows, pointwise rational-

history classifier rows, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and shared ledger rows.

Now apply Definition 126.224. Every finite $\mathsf{Real}^{\uparrow}$ consumer row factors through exactly that displayed packet surface, and two consumers reading the same restricted packet have the same finite read surface.

Finally apply Definition 126.223. The boundary removes completion, quotient, host-index equality, metric-completeness, arithmetic or order, standard bridge, and hidden selector data from the readable packet. Hence no other $\mathsf{Real}^{\uparrow}$ source row, quotient representative, completion row, or host-index equality can be read, and the displayed StreamName/RegSeqRat/DyadicRatCore source surface is the unique finite source surface for both consumers. □

Theorem 126.226 (StreamName tail-window global classifier boundary)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public $\mathsf{StreamName}^{\uparrow}$ endpoints. Suppose that every certified unary observation singleton window over the endpoints carries the row $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{Bcons}(n, \mathsf{Bnil}))$. If a finite $\mathsf{Real}^{\uparrow}$ consumer reads a StreamName tail-window coverage packet generated from finitely many selected observations over an accepted RegSeqRat spine, then the consumer factors through the global $\mathsf{RatStreamNameClassifier}(s, t)$ together with exactly the displayed StreamName, RegSeqRat, DyadicRatCore, Cont, hsame, Pkg, and RealLedgerPolicy packet surface.*

The factorization exposes no completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row.

Proof. First apply Definition 126.23. The singleton-window hypotheses exhaust the certified finite observations and therefore determine the global $\mathsf{RatStreamNameClassifier}(s, t)$ for the public StreamName endpoints.

Next apply Definition 126.217. The finite packet read by the $\mathsf{Real}^{\uparrow}$ consumer has only the enumerated selected unary-history rows, bundle-membership rows, pointwise rational-history classifier rows, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and shared Cont/hsame/Pkg/RealLedgerPolicy ledger.

Now apply Definition 126.224. Every finite consumer row factors through that displayed packet surface, so the global classifier supplied by the singleton-window exhaustion is the only StreamName classifier row available to the consumer.

Finally apply Definition 126.223. The boundary excludes completion, quotient representatives, host-index equality, metric-completeness, arithmetic and order operations, and standard bridge data. Hence the finite $\mathsf{Real}^{\uparrow}$ consumer factors through the global StreamName classifier and the displayed packet rows, with no off-boundary row exposed. □

Theorem 126.227 (StreamName tail-window global classifier transport stability)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public $\mathsf{StreamName}^{\uparrow}$ endpoints satisfying the singleton-window hypotheses of Definition 126.226. Let $\mathcal{P}$ be a StreamName tail-window coverage packet over s, t, generated from finitely many selected observations over an accepted RegSeqRat spine. Suppose displayed hsame, Cont, and Pkg rows transport s, t and every row of $\mathcal{P}$ to endpoints s', t' and to a second finite tail-window coverage packet $\mathcal{P}'$ over the transported endpoints.*

Then every finite $\mathsf{Real}^{\uparrow}$ consumer of $\mathcal{P}'$ factors through the transported global $\mathsf{RatStreamNameClassifier}(s', t')$ and exactly the transported StreamName, RegSeqRat, DyadicRatCore, Cont, hsame, Pkg, and RealLedgerPolicy packet surface. The transported consumer reads no completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row.

Proof. First apply Definition 126.220. The displayed hsame, Cont, and Pkg rows carry the finite-window classifier, selected unary-history and bundle-membership rows, pointwise rational-history classifiers, accepted RegSeqRat spine, DyadicRatCore endpoint rows, and ledger-policy rows into the transported packet $\mathcal{P}'$.

The singleton-window hypotheses transport with those same displayed rows. Apply Definition 126.226 to $\mathcal{P}'$ over s', t'. This supplies the transported global $\mathsf{RatStreamNameClassifier}(s', t')$ as the StreamName classifier row available to any finite $\mathsf{Real}^{\uparrow}$ consumer of the transported packet.

Now apply Definition 126.224. The consumer factors through the transported packet surface: the StreamName classifier rows, selected window rows, pointwise rational-history rows, accepted rational-sequence spine, DyadicRatCore endpoint rows, continuation rows, history comparisons, package provenance, and ledger policy.

Finally apply Definition 126.223. Since the transported finite packet has no constructor for completion, quotient, host-index equality, metric-completeness, arithmetic or order, or standard bridge rows, none of those rows can be read by the transported consumer. □

Theorem 126.228 (StreamName tail-window selected pointwise transport)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public $\mathsf{StreamName}^{\uparrow}$ endpoints, and let $\mathcal{P}$ be a StreamName tail-window coverage packet over a finite* ProbeBundle*. Suppose a selected unary observation row $\mathsf{InBundle}(n, \mathcal{P})$ carries the pointwise classifier $\mathsf{RatHistoryClassifier}(s(n), t(n))$. If the displayed* hsame*,* Cont*, and* Pkg *rows transport that selected observation to a selected row in a transported finite packet $\mathcal{P}'$, then the transported pointwise classifier row remains one of the visible rows of $\mathcal{P}'$.*

*Every finite $\mathsf{Real}^{\uparrow}$ consumer using that selected observation factors through the transported StreamName/*RegSeqRat*/DyadicRatCore packet surface. No completion, quotient, host-index equality, metric-completeness, arithmetic or order row, or standard-bridge row is exposed.*

Proof. First unfold the StreamName tail-window coverage packet of Definition 126.216. The selected $\mathsf{InBundle}(n, \mathcal{P})$ row is one of the finite packet coordinates, together with its unary-history row and pointwise $\mathsf{RatHistoryClassifier}(s(n), t(n))$ row.

Apply Definition 126.220. The displayed hsame, Cont, and Pkg rows repack the selected observation, its bundle-membership row, and its pointwise classifier into the transported packet $\mathcal{P}'$ over the transported endpoints.

Next apply Definition 126.217 to $\mathcal{P}'$. The exhaustion statement enumerates the transported selected unary-history rows, bundle-membership rows, and pointwise rational-history classifier rows, so the transported classifier attached to n is a visible row of $\mathcal{P}'$.

Finally apply Definition 126.224 and Definition 126.223. Any finite $\mathsf{Real}^{\uparrow}$ consumer using the selected row factors through the transported StreamName, RegSeqRat, DyadicRatCore, Cont, hsame, Pkg, and ledger surface, and the boundary has no coordinate for completion, quotient, host-index equality, metric-completeness, arithmetic or order, or a standard bridge. □

Theorem 126.229 (StreamName selected transport coverage)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public $\mathsf{StreamName}^{\uparrow}$ endpoints, let $\mathcal{P}$ be a StreamName tail-window coverage packet over a finite* ProbeBundle*, and let $\mathcal{P}'$ be the transported packet obtained from displayed* hsame*,* Cont*, and* Pkg *rows. Suppose the selected observations of $\mathcal{P}$ are transported to selected observations of $\mathcal{P}'$ by those displayed rows.*

Then every transported selected pointwise RatHistoryClassifier *row, accepted* RegSeqRat *spine row, DyadicRatCore endpoint row, and finite $\mathsf{Real}^{\uparrow}$ consumer row factors through the transported tail-window coverage packet $\mathcal{P}'$. The factorization uses only the transported StreamName,* RegSeqRat*, DyadicRatCore,* Cont*,* hsame*,* Pkg*, and* RealLedgerPolicy *rows. It exposes no completion object,*

quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row.

Proof. Apply Definition 126.228 to each selected observation. The transported selected rows remain visible coordinates of $\mathcal{P}'$, together with their pointwise RatHistoryClassifier rows.

Next apply Definition 126.227. The transported packet supplies the global RatStreamNameClassifier row and preserves the accepted RegSeqRat spine and DyadicRatCore endpoint rows through the displayed hsame, Cont, and Pkg routes.

Finally apply Definition 126.224 and Definition 126.223. Every finite $\mathsf{Real}^{\uparrow}$ consumer of the transported packet factors through the listed packet rows, and the boundary theorem rules out completion objects, quotient representatives, host-index equality, metric-completeness rows, arithmetic or order operations, and standard bridge rows. □

Theorem 126.230 (StreamName tail-window RegSeqRat coverage lock)**.** *Let s, t : BHist $\to$ BHist be public $\mathsf{StreamName}^{\uparrow}$ endpoints, and let $\mathcal{P}$ and $\mathcal{Q}$ be StreamName tail-window coverage packets over finite windows. Suppose their displayed* RatStreamNameFiniteWindowClassifier *rows, selected* UnaryHistory *rows, selected* InBundle *rows, pointwise* RatHistoryClassifier *rows, accepted* RegSeqRat *spine, DyadicRatCore endpoint rows, and* Cont/hsame/Pkg/RealLedgerPolicy *provenance rows agree through the transported packet surface.*

Then every finite $\mathsf{Real}^{\uparrow}$ consumer of $\mathcal{P}$ and every finite $\mathsf{Real}^{\uparrow}$ consumer of $\mathcal{Q}$ read the same DyadicRatCore endpoint rows and the same finite ledger rows from that shared RegSeqRat *spine. This lock exposes no completion data, quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row.*

Proof. Unfold the StreamName tail-window coverage packet of Definition 126.216 for both $\mathcal{P}$ and $\mathcal{Q}$. Apply Definition 126.217 to each packet. The only finite source rows available on either side are the displayed finite-window classifier rows, selected unary-history and bundle-membership rows, pointwise rational-history classifier rows, accepted RegSeqRat spine, DyadicRatCore endpoints, and ledger provenance.

Next apply Definition 126.227 and Definition 126.229. The hypothesized transported packet surface identifies the selected rows of $\mathcal{P}$ with the selected rows of $\mathcal{Q}$ and carries their accepted rational-sequence spine and DyadicRatCore endpoint rows through the same Cont, hsame, Pkg, and RealLedgerPolicy routes.

Now apply Definition 126.225. Since the two finite packets restrict to the same transported selected source surface, their finite $\mathsf{Real}^{\uparrow}$ consumers have the same displayed StreamName/RegSeqRat/DyadicRatCore source surface and the same finite continuation ledger.

Finally apply Definition 126.223. The boundary theorem removes completion data, quotient representatives, host-index equality, metric-completeness rows, arithmetic or order operations, and standard bridge rows from every finite consumer. Thus the only endpoint and ledger rows read by either consumer are the common DyadicRatCore endpoint rows and the common ledger rows carried by the shared RegSeqRat spine. □

Theorem 126.231 (StreamName tail-window prefix-suffix recomposition)**.** *Let s, t : BHist $\to$ BHist be public $\mathsf{StreamName}^{\uparrow}$ endpoints, and let $\mathcal{P}$ be a StreamName tail-window coverage packet over a finite* ProbeBundle*. Suppose the selected observations of $\mathcal{P}$ split into displayed prefix and suffix subbundles with a shared boundary row. Then the restrictions of $\mathcal{P}$ to the prefix and suffix subbundles are StreamName tail-window coverage packets over the same public endpoints and the same accepted* RegSeqRat *spine.*

The common-refinement recomposition of these two restricted packets recovers $\mathcal{P}$ on every selected observation. Every finite $\mathsf{Real}^{\uparrow}$ *consumer row of $\mathcal{P}$ factors through either the prefix packet, the suffix packet, or the boundary-overlap rows. No completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order operation, or standard bridge row is read by the recomposed packet.*

Proof. Unfold the StreamName tail-window coverage packet of Definition 126.216. Restricting to the displayed prefix subbundle keeps the public StreamName endpoints, the selected UnaryHistory/InBundle rows in the prefix window, the pointwise RatHistoryClassifier rows, the accepted RegSeqRat spine, the DyadicRatCore endpoint rows read there, and the inherited Cont/hsame/Pkg/RealLedgerPolicy provenance. The same restriction argument gives the suffix packet.

Apply Definition 126.221 to the prefix and suffix packets. The generated packet is finite, its restrictions recover the two displayed subbundles, and the shared boundary row is carried as one row in the common packet rather than as two independent sources.

Next apply Definition 126.222. It identifies the regrouping of the prefix packet, the boundary overlap, and the suffix packet with the original finite window, so every selected observation of $\mathcal{P}$ is recovered by the recomposed packet.

Now apply Definition 126.225 and Definition 126.230. The finite consumer source surface is therefore the displayed StreamName/RegSeqRat/DyadicRatCore source surface of either restricted packet, together with the shared boundary rows when the consumer reads across the split. The RegSeqRat and DyadicRatCore rows read by the prefix, suffix, and recomposed packet are the same rows of the original finite ledger.

Finally apply Definition 126.223. The finite $\mathsf{Real}^{\uparrow}$ consumer has no row for completion, quotient, host-index equality, metric-completeness, arithmetic or order, standard bridge, or hidden selector data, so the prefix/suffix recomposition cannot introduce any such object. □

Theorem 126.232 (StreamName tail-window cover-chain source confluence)**.** *Let*

$$\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_n$$

be a finite chain of StreamName tail-window coverage packets over the same public $\mathsf{StreamName}^{\uparrow}$ *endpoints and the same accepted* RegSeqRat *spine. Assume each adjacent pair $\mathcal{P}_i, \mathcal{P}_{i+1}$ carries certified overlap rows for the displayed finite windows, and assume the chain is closed under the common-refinement operation of Definition 126.221. Then every packet in the chain induces the same consumer-facing source surface for finite* $\mathsf{Real}^{\uparrow}$ *reads.*

Concretely, the common surface consists exactly of the finite-window classifier rows, the selected ProbeBundle/InBundle/UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the* Cont/hsame/Pkg/RealLedgerPolicy *provenance rows transported along the chain. The confluence statement exports no completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order row, standard bridge row, or hidden selector.*

Proof. Induct on the finite chain length. For the base chain, apply Definition 126.224 and Definition 126.223. A single terminal packet therefore exposes only the finite StreamName/RegSeqRat/DyadicRatCore source surface and its displayed continuation ledger.

For the induction step, compare the already-confluent initial subchain with the last packet. The certified overlap rows allow Definition 126.221 to form the common finite packet for the terminal member of the subchain and the last packet.

Use Definition 126.222 to identify this refinement with the refinement obtained by first recomposing the earlier chain and then attaching the last overlap. Apply Definition 126.225 to the

two terminal packets inside that common refinement, and apply Definition 126.230 to keep the accepted rational-sequence spine and DyadicRatCore endpoint rows fixed.

Finally apply Definition 126.223 to the exported finite consumer. The boundary theorem removes completion, quotient, host-index equality, metric-completeness, arithmetic or order, standard bridge, and hidden-selector data from the readout, so the confluence is a statement only about the displayed finite source rows. □

Theorem 126.233 (StreamName tail-window terminal coverage)**.** *Any terminal* $\mathsf{Real}^{\uparrow}$ *read induced by a finite* $\mathsf{StreamName}^{\uparrow}$ *tail-window cover chain is covered by exactly the common finite source surface of Definition 126.232. Thus the terminal read exposes the finite-window classifier rows, selected* ProbeBundle/InBundle/UnaryHistory *rows, pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, DyadicRatCore endpoint rows, and transported* Cont/hsame/Pkg/RealLedgerPolicy *provenance rows.*

It exposes no completion object, quotient representative, host-index equality, metric-completeness row, arithmetic or order row, standard bridge row, or hidden selector.

Proof. Apply Definition 126.232 to the finite cover chain. The induced terminal source is the common finite surface carried by every packet in the chain.

Next apply Definition 126.224. It routes the terminal RealUp read through the displayed StreamName, RegSeqRat, and DyadicRatCore source rows rather than through an external completion carrier.

Finally use Definition 126.223. The boundary removes quotient representatives, host-index equality, metric-completeness rows, arithmetic and order rows, standard bridge rows, and hidden selectors from the terminal read. Therefore the read is covered exactly by the common finite source surface from the confluence theorem. □

126.13 StreamName Common-Refinement Source Determinacy

Theorem 126.234 (StreamName common-refinement source determinacy)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over certified observation maps* s, t*, and let* $\mathcal{R}$ *be a certified common-refinement package whose* ProbeBundle *window restricts to the selected windows of* $\mathcal{W}_L$ *and* $\mathcal{W}_R$*. Then every* RegSeqRat *handoff and every finite-window* $\mathsf{Real}^{\uparrow}$ *handoff read from* $\mathcal{R}$ *has the same StreamName source tuple, namely the restricted* RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{R})$ *row, the displayed* ProbeBundle *row, the* InBundle *membership rows, the selected* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, and the displayed* hsame/Cont/Pkg *rows carried by the refinement ledger.*

This source tuple is independent of whether the handoff is reached through $\mathcal{W}_L$ *or through* $\mathcal{W}_R$*. It contains no completion data, no quotient row, no host index equality, no* RegSeqRat *regularity row, and no* $\mathsf{Real}^{\uparrow}$ *seal classifier.*

Proof. First read the common refinement at the public StreamName boundary. Apply Definition 126.308; its restriction clauses identify the same finite-window classifier over the common refinement with the two component windows. Then apply Definition 126.309 to each selected observation in the refinement. The selected endpoint rows are exactly the pointwise RatHistoryClassifier rows and the finite endpoint readback rows displayed by the common refinement.

Next pass from the public refinement to the tail-window packet. Apply Definition 126.221. The packet over the generated common window restricts to the two selected subbundles and keeps the same ProbeBundle, InBundle, UnaryHistory, pointwise classifier, hsame, Cont, and Pkg ledger rows.

Now read the downstream handoff. Apply Definition 126.170 to the selected pointwise rows and then apply Definition 126.82. These two theorems separate the StreamName source rows from the $\mathsf{RegSeqRat}$ regularity obligations and from the finite-window $\mathsf{Real}^{\uparrow}$ seal obligation.

The same source tuple is therefore obtained along the left route and along the right route, because both routes are restrictions of the one displayed common-refinement packet. Completion objects, quotient rows, host index equalities, $\mathsf{RegSeqRat}$ regularity rows, and $\mathsf{Real}^{\uparrow}$ seal classifiers have no constructor in that source packet, so they cannot be part of the determined source surface. □

Theorem 126.235 (StreamName directed common-refinement source associativity)**.** *Let $\mathcal{W}_1$, $\mathcal{W}_2$, $\mathcal{W}_3$, and $\mathcal{W}_4$ be public finite-window $\mathsf{StreamName}^{\uparrow}$ packages over the same certified endpoint maps s, t. Let $\mathcal{R}_{(12)3,4}$ and $\mathcal{R}_{1(23),4}$ be two directed certified common-refinement trees whose visible leaves are the same four selected windows, with the first tree grouping $((\mathcal{W}_1, \mathcal{W}_2), \mathcal{W}_3)$ before comparison with $\mathcal{W}_4$, and the second tree grouping $(\mathcal{W}_1, (\mathcal{W}_2, \mathcal{W}_3))$ before comparison with $\mathcal{W}_4$.*

Assume each internal common-refinement package restricts to the selected windows named by its children and carries the displayed certified refinement ledger. Then the two directed trees expose the same StreamName source tuple: the row $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{R})$ read from the common visible refinement, the displayed $\mathsf{ProbeBundle}$ row, the $\mathsf{InBundle}$ membership rows, the selected $\mathsf{UnaryHistory}$ rows, the pointwise $\mathsf{RatHistoryClassifier}$ rows, and the displayed $\mathsf{hsame/Cont/Pkg}$ ledger rows.

Regrouping the directed common-refinement tree introduces no $\mathsf{RegSeqRat}$ regularity row, no $\mathsf{Real}^{\uparrow}$ seal classifier, no quotient row, no completion datum, no metric-completeness datum, and no host-index equality. Those rows remain outside the StreamName source tuple consumed by downstream $\mathsf{RegSeqRat}$ and terminal finite-window $\mathsf{Real}^{\uparrow}$ readback.

Proof. First compare the two triples before the terminal comparison with $\mathcal{W}_4$. Apply Definition 126.239 to the triple $(\mathcal{W}_1, \mathcal{W}_2, \mathcal{W}_3)$ as grouped through $((\mathcal{W}_1, \mathcal{W}_2), \mathcal{W}_3)$, and apply the same theorem to the triple as grouped through $(\mathcal{W}_1, (\mathcal{W}_2, \mathcal{W}_3))$. Both applications read the same finite-window classifier, bundle, membership, selected history, pointwise classifier, and $\mathsf{hsame/Cont/Pkg}$ ledger surface from the displayed triple refinement.

Next compare the overlap carried by $\mathcal{W}_1$ and $\mathcal{W}_2$. Use Definition 126.236. The overlapping pair has one displayed StreamName source tuple, so the intermediate packet seen by either triple grouping has the same classifier, bundle, membership, selected-history, pointwise-classifier, and provenance rows.

Finally compose the displayed ledger rows by transitivity of the $\mathsf{hsame/Cont/Pkg}$ provenance. The terminal comparison with $\mathcal{W}_4$ therefore receives the same source tuple from either regrouping. Since Definition 126.236 and Definition 126.239 separate that source tuple from $\mathsf{RegSeqRat}$ regularity, $\mathsf{Real}^{\uparrow}$ sealing, quotient, completion, metric-completeness, and host-index rows, the regrouping cannot introduce any such row. □

Theorem 126.236 (StreamName common-refinement source confluence)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be public finite-window $\mathsf{StreamName}^{\uparrow}$ packages over the same certified endpoint maps s, t, and let $\mathcal{R}$ be a certified common-refinement package whose generated window restricts to both selected windows. Consider the two finite-window routes*

$$\mathcal{R} \longrightarrow \mathcal{W}_L \longrightarrow \mathsf{RegSeqRat} \quad \textit{and} \quad \mathcal{R} \longrightarrow \mathcal{W}_R \longrightarrow \mathsf{RegSeqRat},$$

followed by the finite-window $\mathsf{Real}^{\uparrow}$ handoff that reads the induced regular rational sequence rows. The two routes expose the same downstream source tuple: the row $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{R})$,

the displayed ProbeBundle*, the* InBundle *membership rows, the selected* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, and the displayed* hsame/Cont/Pkg *rows carried by the refinement ledger.*

Consequently the induced finite-window $\mathsf{Real}^{\uparrow}$ *handoffs read the same* DyadicRatCore *endpoint rows. They do not add completion data, quotient data, metric-completeness data, host-index equality, or a seal classifier to the source surface determined by the common refinement.*

Proof. First apply Definition 126.234. It identifies the StreamName source tuple seen from the left selected window with the tuple seen from the right selected window, because both are restrictions of the one certified common-refinement packet $\mathcal{R}$.

Next apply Definition 126.221. The generated tail-window packet over $\mathcal{R}$ has the same displayed ProbeBundle row, the same InBundle membership rows, the same selected UnaryHistory rows, and the same pointwise rational history classifier rows on both routes.

Now apply Definition 126.170. The RegSeqRat boundary consumes exactly those pointwise rational rows and the displayed hsame/Cont/Pkg ledger rows; it does not introduce an additional route-dependent source coordinate.

Finally apply Definition 126.82. The finite-window $\mathsf{Real}^{\uparrow}$ handoff reads the induced DyadicRatCore endpoint rows from the already identified regular rational sequence surface, while the seal obligation remains separate from the StreamName source tuple. Thus the left route and the right route compose to the same downstream RegSeqRat/$\mathsf{Real}^{\uparrow}$ source surface, with no completion, quotient, metric-completeness, host-index, or seal-classifier row added to that surface. □

Theorem 126.237 (StreamName common-refinement RealUp seal confluence)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same certified endpoint maps* s, t*, and let* $\mathcal{R}$ *be a certified common-refinement package whose generated window restricts to both selected windows. Let* $\mathcal{E}_L$ *and* $\mathcal{E}_R$ *be finite-window* $\mathsf{Real}^{\uparrow}$ *seal packages induced from* $\mathcal{R}$ *through the left and right* RegSeqRat *routes*

$$\mathcal{R} \longrightarrow \mathcal{W}_L \longrightarrow \mathsf{RegSeqRat} \quad \textit{and} \quad \mathcal{R} \longrightarrow \mathcal{W}_R \longrightarrow \mathsf{RegSeqRat}.$$

Then $\mathcal{E}_L$ *and* $\mathcal{E}_R$ *expose the same visible seal source. That source is the restricted* RatStreamNameFiniteWindowClassi *row, the displayed* ProbeBundle *row, the* InBundle *membership rows, the selected* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, the induced* DyadicRatCore *endpoint rows, and the displayed* hsame/Cont/Pkg *ledger rows carried by the common refinement.*

No completion row, quotient row, host-index equality, metric-completeness row, or off-ledger $\mathsf{Real}^{\uparrow}$ *classifier is part of this visible finite-window seal source.*

Proof. First apply Definition 126.236. The certified common-refinement packet gives one StreamName source tuple for the left and right selected windows, including the restricted finite-window classifier, bundle membership, selected unary histories, pointwise rational classifiers, and displayed hsame/Cont/Pkg provenance.

Next read both induced seal packages through Definition 126.149. The two RegSeqRat routes consume the same StreamName tuple and therefore present the same accepted finite-window spine, DyadicRatCore endpoint rows, transport ledger, and provenance to the $\mathsf{Real}^{\uparrow}$ seal boundary.

Finally use Definition 126.150 for each induced package. Minimality says that every visible source row of either seal package is one of the displayed finite-window StreamName, RegSeqRat, DyadicRatCore, bundle, history, continuation, transport, or provenance rows. Since the common-refinement confluence already identifies those rows, no completion, quotient, host-index, metric-completeness, or off-ledger $\mathsf{Real}^{\uparrow}$ classifier row can distinguish the two seal sources. □

Theorem 126.238 (StreamName common-refinement successor projection)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same certified endpoint maps s, t, and let $\mathcal{R}$ be a certified common-refinement package whose generated* ProbeBundle *restricts to both selected windows. Let n :* BHist *be a certified unary observation such that* $\mathsf{BHist.e1}(n)$ *is an* InBundle *member of the refinement bundle of $\mathcal{R}$.*

Project $\mathcal{R}$ to the singleton successor window

$$\mathsf{ProbeBundle.Bcons}(\mathsf{BHist.e1}(n), \mathsf{ProbeBundle.Bnil}).$$

Reading this singleton through either selected window determines the same RatStreamNameFiniteWindowClassifier *row, the same pointwise* RatHistoryClassifier *row at* $\mathsf{BHist.e1}(n)$*, and the same downstream source tuple consumed by the* RegSeqRat *handoff and by the finite-window* $\mathsf{Real}^{\uparrow}$ *handoff.*

The determined source tuple is the successor singleton classifier, the singleton ProbeBundle *membership row, the selected* UnaryHistory *row for n, the pointwise rational history classifier, and the displayed* hsame/Cont/Pkg *ledger rows inherited from $\mathcal{R}$. It contains no host index equality, quotient representative, completion data, metric row,* RegSeqRat *regularity row, or* $\mathsf{Real}^{\uparrow}$ *completeness or seal classifier.*

Proof. First use Definition 126.236. The left route through $\mathcal{W}_L$ and the right route through $\mathcal{W}_R$ expose one common StreamName source tuple over $\mathcal{R}$, so the $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{R})$ row and the pointwise RatHistoryClassifier rows are route independent before projection.

Next apply Definition 126.299 to the InBundle membership row for $\mathsf{BHist.e1}(n)$. The theorem restricts the common finite-window classifier to the singleton successor bundle and keeps exactly the pointwise rational row indexed by that successor observation.

Finally read the downstream boundary through Definition 126.170 and Definition 126.82. These rows consume the same successor pointwise classifier and the same displayed hsame/Cont/Pkg provenance rows from either selected window, while the RegSeqRat regularity obligation and the finite-window $\mathsf{Real}^{\uparrow}$ seal obligation remain outside the StreamName source packet. □

Theorem 126.239 (StreamName common-refinement source triple confluence)**.** *Let $\mathcal{W}_1$, $\mathcal{W}_2$, and $\mathcal{W}_3$ be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same certified endpoint maps s, t, and let $\mathcal{R}$ be a certified common-refinement package whose generated window restricts to all three selected windows. For every pair (i, j), the route*

$$\mathcal{R} \longrightarrow \mathcal{W}_i \longrightarrow \mathsf{RegSeqRat} \longrightarrow \mathsf{Real}^{\uparrow}$$

and the route

$$\mathcal{R} \longrightarrow \mathcal{W}_j \longrightarrow \mathsf{RegSeqRat} \longrightarrow \mathsf{Real}^{\uparrow}$$

read the same source tuple from the common refinement. That tuple is the restricted RatStreamNameFiniteWindowCl *row, the displayed* ProbeBundle *row, the* InBundle *membership rows, the selected* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, and the displayed* hsame/Cont/Pkg *ledger rows carried by $\mathcal{R}$.*

Thus the three finite-window handoffs are confluent on the source surface used by RegSeqRat *and by finite-window* $\mathsf{Real}^{\uparrow}$ *readback. No* RegSeqRat *regularity row, seal classifier, completion data, quotient row, metric row, or host index equality is introduced by the triple comparison.*

Proof. Apply Definition 126.234 to the pairs $(\mathcal{W}_1, \mathcal{W}_2)$, $(\mathcal{W}_2, \mathcal{W}_3)$, and $(\mathcal{W}_1, \mathcal{W}_3)$. Each application reads the two selected windows as restrictions of the same certified common-refinement packet $\mathcal{R}$.

For each pair, use Definition 126.236. It identifies the downstream $\mathsf{RegSeqRat}/\mathsf{Real}^{\uparrow}$ source surface with the already displayed StreamName tuple, rather than with any route-specific regularity, completion, quotient, metric, host-index, or seal row.

The displayed common-refinement ledger is the same ledger in all three pairwise comparisons. Transitivity of the ledger equalities for the restricted finite-window classifier, ProbeBundle, InBundle, UnaryHistory, pointwise RatHistoryClassifier, and hsame/Cont/Pkg rows therefore gives one source tuple for all three routes. □

126.14 StreamName Common-Refinement Public Exactness

Theorem 126.240 (StreamName common-refinement public exactness)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same certified endpoint maps s, t, and let $\mathcal{R}$ be a certified common-refinement package whose generated window restricts to both selected windows. Then every downstream* RegSeqRat *handoff and every finite-window* $\mathsf{Real}^{\uparrow}$ *handoff read from $\mathcal{R}$ factors through exactly the common-refinement source tuple:*

$$(\mathsf{RatStreamNameFiniteWindowClassifier}(s,t,\mathcal{R}), \mathsf{ProbeBundle}_{\mathcal{R}}, \mathsf{InBundle}_{\mathcal{R}}, \mathsf{UnaryHistory}_{\mathcal{R}}, \mathsf{RatHistoryClassifier}_{\mathcal{R}}, \mathsf{hsar}$$

The public handoff cannot add completion data, quotient rows, host-index equality, metric-completeness rows, or off-ledger $\mathsf{Real}^{\uparrow}$ *classifier rows.*

Proof. First apply Definition 126.234. It identifies the source tuple read from the left selected window with the source tuple read from the right selected window, because both are restrictions of the same certified common-refinement package $\mathcal{R}$.

Next apply Definition 126.236. The downstream RegSeqRat route and the finite-window $\mathsf{Real}^{\uparrow}$ route receive the same restricted finite-window classifier, bundle row, membership rows, selected histories, pointwise rational classifiers, and displayed hsame/Cont/Pkg ledger rows.

Now use Definition 126.237. The induced $\mathsf{Real}^{\uparrow}$ seal packages have the same visible seal source, so the seal boundary cannot distinguish the two routes by adding an off-ledger classifier row.

Finally apply the RegSeqRat and RealUp handoff separation statements in the StreamName child files, in particular Definition 126.170 and Definition 126.82. They keep regularity, completion, quotient, metric-completeness, host-index, and seal-classifier data outside the common-refinement source tuple. □

Theorem 126.241 (StreamName common-refinement associativity)**.** *Let $\mathcal{W}_0, \mathcal{W}_1, \mathcal{W}_2$ be three compatible public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same certified endpoint maps. If successive common-refinement packages are displayed for both parenthesizations*

$$(\mathcal{W}_0 \cap \mathcal{W}_1) \cap \mathcal{W}_2 \quad \textit{and} \quad \mathcal{W}_0 \cap (\mathcal{W}_1 \cap \mathcal{W}_2),$$

then the two resulting packages expose the same scheduled observation rows, hsame *transports,* Cont *replay rows,* Pkg *provenance, and local* NameCert *row. The common-refinement read exports no completion object, quotient stream equality, host-index equality, metric-completeness row, or off-ledger* $\mathsf{Real}^{\uparrow}$ *classifier row.*

Proof. Project each parenthesized package to its finite-window carrier. Compatibility says that every scheduled observation row is a restriction of the same three displayed windows, so either parenthesization exposes the same source rows.

Transport the common rows componentwise through the displayed hsame witnesses and replay them through the same Cont route. The Pkg provenance and local NameCert row are then read from the same finite source tuple.

Finally use common-refinement public exactness. It keeps every downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ handoff inside the common-refinement source tuple, so neither parenthesization can add completion, quotient, host-index, metric-completeness, or off-ledger classifier data. □

126.15 StreamName Synchronized Window Union

Theorem 126.242 (StreamName synchronized-window carrier union)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be displayed finite* $\mathsf{StreamName}^{\uparrow}$ *windows over certified source maps s, t, and let $\mathcal{R}$ be a certified common-refinement package whose generated* ProbeBundle *restricts to the selected bundles of both windows. If the selected rows of $\mathcal{W}_L$ and $\mathcal{W}_R$ agree through the displayed common-refinement* hsame *and* Cont *ledger, then the two windows repack into one synchronized* $\mathsf{StreamName}^{\uparrow}$ *carrier row over $\mathcal{R}$.*

The synchronized row contains exactly the restricted $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{R})$ *row, the displayed* ProbeBundle *row, the* InBundle *membership rows, the certified* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, and the shared* hsame/Cont/Pkg *provenance rows.*

Proof. Project both windows through Definition 126.234. The common refinement determines the same StreamName source tuple on the left and on the right, so the selected classifier, bundle membership, unary-history, pointwise rational-history, hsame, Cont, and Pkg rows are already one displayed tuple over $\mathcal{R}$.

Use Definition 126.221 to read the generated common window as a finite tail-window packet. Its restriction clauses are precisely the restrictions back to $\mathcal{W}_L$ and $\mathcal{W}_R$.

Repack the projected rows as the synchronized StreamName carrier row. The carrier has no coordinate for a quotient stream, host function, completion object, or external index equality, so the repacking uses only the displayed finite-window rows. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameSynchronizedWindowUnionCarrier`

Theorem 126.243 (StreamName synchronized-window RegSeqRat seal handoff)**.** *Let $\mathcal{S}$ be the synchronized* $\mathsf{StreamName}^{\uparrow}$ *carrier row obtained from Definition 126.242. Then every* RegSeqRat *handoff read from $\mathcal{S}$ preserves the endpoint, radius, regularity, readback,* hsame*,* Cont*,* Pkg*, and* NameCert *rows consumed by the finite* $\mathsf{Real}^{\uparrow}$ *seal.*

Equivalently, the downstream consumer reads one synchronized boundary: the StreamName finite-window source rows of $\mathcal{S}$, the accepted RegSeqRat *endpoint and regularity rows selected from those sources, and the finite* $\mathsf{Real}^{\uparrow}$ *seal ledger rows. No route through the original left or right window contributes an additional consumer-visible row.*

Proof. First apply Definition 126.242. This places both displayed windows over one carrier row whose finite-window source tuple is independent of the left or right route.

Next apply Definition 126.268. The synchronized carrier is a common-window surface, so the RegSeqRat handoff rows transported through the two original windows are the same consumer-facing rows.

Apply Definition 126.270 to identify the DyadicRatCore endpoint and radius rows read from the accepted RegSeqRat spine. Then use Definition 126.274 to list the rows consumed by the terminal finite $\mathsf{Real}^{\uparrow}$ seal.

The listed families include endpoint, radius, regularity, readback, hsame, Cont, Pkg, and NameCert provenance. Since each family is projected from the synchronized row or from the accepted RegSeqRat spine, there is no remaining route-dependent row to expose. □

Theorem 126.244 (StreamName synchronized-window NameCert boundary)**.** *The synchronized-window rows of Definition 126.242 and Definition 126.243 form the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *obligation boundary needed by the* $\mathsf{RegSeqRat}/\mathsf{Real}^{\uparrow}$ *seal consumer. The boundary consists of finite carrier rows, common-refinement source determinacy, synchronized common-window transport, accepted* RegSeqRat *endpoint and regularity rows, and the finite seal ledger consumed by* $\mathsf{Real}^{\uparrow}$*.*

This boundary contains no quotient stream, host function, external real, completion theorem, or real-completeness principle.

Proof. Read the carrier face from Definition 126.242. It supplies the finite synchronized StreamName row and identifies its left and right restrictions through common-refinement source determinacy.

Read the consumer face from Definition 126.243. It preserves the RegSeqRat endpoint, radius, regularity, readback, hsame, Cont, Pkg, and NameCert rows passed to the finite $\mathsf{Real}^{\uparrow}$ seal.

Together these two faces exhaust the local obligation boundary: the producer side supplies finite synchronized StreamName rows, and the consumer side reads only the displayed $\mathsf{RegSeqRat}/\mathsf{Real}^{\uparrow}$ seal rows. The excluded quotient, host-function, external-real, completion, and real-completeness objects have no coordinate in either face. □

Theorem 126.245 (StreamName synchronized-window Real seal handoff)**.** *Let* $\mathcal{S}$ *be a synchronized* $\mathsf{StreamName}^{\uparrow}$ *window whose* $\mathsf{RegSeqRat}^{\uparrow}$ *endpoint, radius, regularity, and readback rows are transported through Definition 126.243. Then every route from* $\mathcal{S}$ *to the finite* $\mathsf{Real}^{\uparrow}$ *seal factors through exactly the synchronized* ProbeBundle *row,* InBundle *membership rows,* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The handoff has no coordinate for quotient streams, host functions, ambient real completeness, or route-dependent seal rows from the original left or right window.

Proof. Start with the synchronized carrier union of Definition 126.242. It places the left and right finite windows over one displayed ProbeBundle, with the same InBundle, UnaryHistory, pointwise RatHistoryClassifier, hsame, Cont, and Pkg coordinates.

Next apply Definition 126.268. The endpoint, radius, regularity, and readback rows of the accepted $\mathsf{RegSeqRat}^{\uparrow}$ spine are therefore transported through the common window, not through a left-only or right-only route.

Use Definition 126.270 to identify the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius data read by the seal. Then apply Definition 126.274; the finite $\mathsf{Real}^{\uparrow}$ seal consumes only the displayed StreamName, dyadic, $\mathsf{RegSeqRat}^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows.

The excluded objects have no row in this assembled boundary. Quotient streams, host functions, ambient real completeness, and route-dependent seal rows cannot be introduced after the boundary is exhausted by the synchronized packet. □

Theorem 126.246 (StreamName synchronized-window classifier coverage)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be displayed finite* $\mathsf{StreamName}^{\uparrow}$ *windows over certified maps* s, t*, and let* $\mathcal{R}$ *be a certified common-refinement package whose generated carrier is the synchronized carrier of Definition 126.242. Then the classifier row on the synchronized carrier is covered exactly by the two restricted finite-window classifier reads together with the displayed overlap agreement rows of* $\mathcal{R}$*.*

Concretely, a synchronized classifier read is the same data as the left restricted RatStreamNameFiniteWindowClas *row, the right restricted* RatStreamNameFiniteWindowClassifier *row, and the common overlap agreement on* ProbeBundle*,* InBundle*,* UnaryHistory*, pointwise* RatHistoryClassifier*,* hsame*,* Cont*, and* Pkg

rows. The following RegSeqRat/Real$^{\uparrow}$ *handoff reads exactly this synchronized classifier package and no row whose value depends on whether the left or right window was used to reach the common refinement.*

Proof. Apply Definition 126.242 to place the two displayed windows over the carrier generated by $\mathcal{R}$. This gives one carrier row whose visible coordinates are the restricted classifier rows, the bundle rows, the unary-history rows, the pointwise rational-history rows, and the hsame/Cont/Pkg provenance rows.

For the left-to-right reading, project the synchronized carrier back to the two finite windows. The common-refinement source determinacy theorem, Definition 126.234, identifies the source tuple used by each restriction, and Definition 126.236 identifies the two routes through the overlap ledger. Hence every synchronized classifier coordinate is read as one of the two restricted classifier rows or as an overlap agreement row.

For the converse reading, start with the two restricted finite-window classifier rows and the displayed overlap agreement rows. Determinacy fixes the common source tuple, confluence identifies the two overlap routes, and the carrier theorem repacks the rows as a single synchronized classifier package.

Finally apply Definition 126.243. The downstream RegSeqRat/Real$^{\uparrow}$ boundary reads the synchronized classifier package just constructed, so no additional route-dependent row remains for the handoff. □

Theorem 126.247 (StreamName window-union associativity)**.** *Let $\mathcal{W}_0$, $\mathcal{W}_1$, and $\mathcal{W}_2$ be three composable synchronized finite observation windows over the same accepted* StreamName$^{\uparrow}$ *packet. Suppose the displayed common-refinement rows make the left pair, the right pair, and the two iterated synchronized windows use the same finite observation rows,* hsame *transports,* Cont *routes, and* Pkg *provenance. Then the carrier package obtained by first unioning $\mathcal{W}_0$ with $\mathcal{W}_1$ and then unioning the result with $\mathcal{W}_2$ classifies together with the carrier package obtained by first unioning $\mathcal{W}_1$ with $\mathcal{W}_2$ and then unioning $\mathcal{W}_0$ with the result.*

The common classifier is the displayed finite observation package over the same ProbeBundle*,* InBundle*,* UnaryHistory*, pointwise* RatHistoryClassifier*,* hsame*,* Cont*, and* Pkg *rows; neither bracketing contributes an additional route to the* RegSeqRat/Real$^{\uparrow}$ *window assembly.*

Proof. First project Definition 126.242 to the left pair and to the right pair. Both binary unions are displayed over the same accepted StreamName packet and the same common-refinement source rows, so their visible carrier coordinates are the finite observation rows named in the statement.

Project the carrier-union theorem again for the two iterated unions. The outer union on each bracketing only repacks the already displayed ProbeBundle, InBundle, UnaryHistory, pointwise classifier, hsame, Cont, and Pkg rows.

Next apply Definition 126.246. The classifier on either iterated carrier is exhausted by the same restricted finite-window classifier reads together with the same displayed overlap agreement rows. Thus the two bracketings classify the identical displayed observations.

Finally use Definition 126.250 and Definition 126.249. Tail restriction preserves the listed finite rows, and the terminal source boundary has no coordinate for an extra observation route, quotient stream, completion object, host function, or host real equality. □

Theorem 126.248 (StreamName synchronized-window selected-tail exhaustion)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be synchronized finite* StreamName$^{\uparrow}$ *windows over maps s, t, and let the common carrier and classifier rows satisfy Definition 126.242 and Definition 126.246. For any accepted* RegSeqRat *spine read from this synchronized surface, the selected tail surface consumed by the finite* Real$^{\uparrow}$ *seal*

is exhausted by the displayed ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows,* DyadicRatCore *endpoint and radius rows,* hsame*,* Cont*,* Pkg*, and the finite* RealLedgerPolicy *rows.*

No host index equality, quotient stream, completion object, host function, Classical datum, or host real equality is introduced by this selected-tail read.

Proof. Begin with the synchronized carrier theorem. It identifies the left and right finite StreamName windows over one displayed common-refinement carrier and lists the bundle, membership, unary-history, pointwise rational-history, hsame, Cont, and Pkg rows visible on that carrier.

Next apply the classifier coverage theorem. The classifier read used by the accepted RegSeqRat spine is therefore the synchronized classifier package, not a route-dependent copy from either original window.

Now use the RegSeqRat seal handoff from Definition 126.243 together with the terminal cover gluing in Definition 126.274. These two results identify the accepted spine's endpoint, radius, regularity, and readback rows with the finite DyadicRatCore and RealLedgerPolicy rows consumed by the $\mathsf{Real}^{\uparrow}$ seal.

The listed rows are exactly the selected-tail coordinates available to the seal consumer. Since neither the synchronized carrier nor the RegSeqRat handoff has coordinates for host index equality, quotient streams, completion objects, host functions, Classical data, or host real equality, no such row can be read at the terminal boundary. □

Theorem 126.249 (StreamName synchronized-window terminal source exhaustion)**.** *Let $\mathcal{S}$ be a synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *row whose downstream* RegSeqRat *handoff and finite-window* $\mathsf{Real}^{\uparrow}$ *terminal seal are read through the carrier of Definition 126.242 and the classifier coverage of Definition 126.246. Then every source row visible to the terminal* RegSeqRat/$\mathsf{Real}^{\uparrow}$ *consumer is one of the following displayed finite BEDC rows: the synchronized* $\mathsf{StreamName}^{\uparrow}$ *classifier rows, the selected* ProbeBundle *rows, the* InBundle *membership rows, the* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *endpoint, radius, regularity, and readback rows, the* DyadicRatCore *endpoint rows, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance rows.*

The terminal consumer has no coordinate from which to read quotient streams, host-index equality, hidden stream rows, independent regularity witnesses, completion objects, standard bridge rows, or real-completeness principles.

Proof. Apply Definition 126.242. It gives a single synchronized carrier whose visible source coordinates are the finite classifier, bundle, membership, unary-history, pointwise rational-history, and hsame/Cont/Pkg rows.

Apply Definition 126.246. This identifies every synchronized classifier read with the two restricted finite-window classifier reads and the displayed overlap agreement rows, so the classifier contributes no hidden stream coordinate.

Apply Definition 126.243. The accepted RegSeqRat handoff supplies exactly the endpoint, radius, regularity, readback, DyadicRatCore endpoint, and finite $\mathsf{Real}^{\uparrow}$ seal rows consumed downstream.

It remains to exclude extra sources at the terminal face. The no-extra coordinate clause of Definition 126.244 removes quotient streams, host-index equality, hidden stream rows, independent regularity witnesses, completion objects, standard bridge rows, and real-completeness principles from the consumer boundary. □

Theorem 126.250 (StreamName synchronized-window tail-subwindow stability)**.** *Let $\mathcal{S}$ be a synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *row whose carrier and classifier coverage are the rows of Definition 126.242 and Definition 126.246. For any certified finite tail subwindow of $\mathcal{S}$, restriction preserves the same* ProbeBundle*,* InBundle*,* UnaryHistory*, pointwise* RatHistoryClassifier*,* DyadicRatCore*,* RegSeqRat*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows visible at the terminal consumer.*

The restricted terminal consumer has no added coordinate for quotient streams, host-index equality, completion objects, host functions, Classical data, or host real equality.

Proof. Project the synchronized carrier row given by Definition 126.242. Its finite carrier coordinates are the displayed probe-bundle membership, unary observation, classifier, hsame, Cont, Pkg, and NameCert rows, so a certified tail subwindow is obtained by restricting those visible finite coordinates.

Apply the classifier coverage of Definition 126.246. The pointwise rational-history rows remain attached to the restricted unary observations because coverage is stated over the synchronized finite rows and their overlap agreement, not over a host stream quotient.

Use selected-tail exhaustion through Definition 126.243. The accepted RegSeqRat handoff reads only the selected endpoint, radius, regularity, readback, and DyadicRatCore endpoint rows, all of which are already among the restricted finite coordinates.

Finally apply Definition 126.249. The terminal RegSeqRat/$\mathsf{Real}^{\uparrow}$ consumer sees only the listed source rows, so the tail subwindow exposes no quotient stream, host-index equality, completion object, host function, Classical datum, or host real equality. □

Theorem 126.251 (StreamName finite-observation classifier exhaustion)**.** *Let $\mathcal{S}$ be a synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *row whose downstream* RegSeqRat *handoff and finite-window* $\mathsf{Real}^{\uparrow}$ *terminal seal are read through the carrier of Definition 126.242. For every selected certified unary observation consumed by that handoff, the consumer-visible classifier data factors through exactly the displayed* ProbeBundle *row,* InBundle *membership row,* UnaryHistory *row, pointwise* RatHistoryClassifier *row,* hsame *comparison,* Cont *route,* Pkg *provenance, and* NameCert *provenance of the synchronized window.*

Thus the single finite observation seen by the downstream RegSeqRat/$\mathsf{Real}^{\uparrow}$ *consumer has no coordinate for a regularity witness, quotient stream, completion row, host index equality, or host real equality.*

Proof. First project the synchronized row through Definition 126.246. The chosen certified unary observation is one member of the covered finite classifier inventory, so its visible rows are the bundle, membership, unary-history, pointwise rational-history, hsame, Cont, and Pkg coordinates of that inventory.

Next apply Definition 126.170 to the chosen observation. The pointwise handoff reads exactly the displayed StreamName carrier and classifier rows at that observation before it reaches the RegSeqRat or finite-window $\mathsf{Real}^{\uparrow}$ consumer.

Finally use Definition 126.249. Its terminal-source boundary adds the NameCert provenance row and removes regularity witnesses, quotient streams, completion rows, host index equality, and host real equality from the terminal consumer surface. □

Theorem 126.252 (StreamName constant reindexing Real seal boundary)**.** *Let d, e : Hist be rational-history endpoints, let r, q : Hist $\to$ Hist be two observation schedules, and let $\mathcal{S}$ be the synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *row built from the independently reindexed constant rational streams* $\mathsf{RatConstStream}_d \circ r$ *and* $\mathsf{RatConstStream}_e \circ q$*. The finite* $\mathsf{Real}^{\uparrow}$ *seal read from $\mathcal{S}$ sees only the constant* $\mathsf{Rat}^{\uparrow}$ *endpoint data for d and e, the two reindexing schedules, finite-window membership in*

the displayed ProbeBundle*, certified* UnaryHistory *rows, and the pointwise* RatHistoryClassifier *rows selected by the synchronized classifier.*

In particular, the seal does not read a quotient stream, completion object, host real equality, host index equality, or independent regularity witness.

Proof. Apply Definition 126.51. It places the two independently reindexed constant streams over the same StreamName classifier surface and reduces every selected classifier row to the RatUp endpoint classifier between d and e.

Then use Definition 126.52. The carrier and classifier data of the independently reindexed constant streams are exactly the endpoint carrier and classifier data at d and e; the schedules r and q contribute only the displayed observation routing.

Pass this synchronized constant row through Definition 126.251. The finite $\mathsf{Real}^{\uparrow}$ seal therefore reads only the constant RatUp endpoint, the reindexing schedules, the finite-window membership and unary-history rows, and the pointwise classifier rows, with no stronger host-level coordinate. □

Theorem 126.253 (StreamName RegSeqRat common-window terminal seal determinacy)**.** *Let $\mathcal{S}_0$ and $\mathcal{S}_1$ be synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *rows. Suppose that they have the same common-refinement source, the same accepted* RegSeqRat *spine, and the same displayed* DyadicRatCore *endpoint and radius rows. If a terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal is read from either synchronized route, then the two reads produce the same consumer-facing seal row.*

The determining surface is exactly the displayed RatStreamNameFiniteWindowClassifier *row,* ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the* DyadicRatCore *endpoint and radius rows, and the visible* hsame*,* Cont*,* Pkg*,* NameCert*, and* RealLedgerPolicy *rows. The terminal seal has no coordinate for quotient streams, host-index equality, completion objects, independent regularity witnesses, standard bridge rows, or real-completeness principles.*

Proof. Apply Definition 126.246. It projects both synchronized routes to the same finite classifier inventory over the common-refinement source, with the same bundle, membership, unary-history, pointwise rational-history, and overlap rows.

Next apply Definition 126.243. The accepted RegSeqRat spine and the displayed DyadicRatCore endpoint and radius rows are therefore the only rational handoff rows available to the terminal finite-window $\mathsf{Real}^{\uparrow}$ seal.

The source boundary is exhausted by Definition 126.249 and by the seal boundary of Definition 126.244. These two boundaries leave only the displayed RatStreamNameFiniteWindowClassifier, ProbeBundle, InBundle, UnaryHistory, RatHistoryClassifier, RegSeqRat, DyadicRatCore, hsame, Cont, Pkg, NameCert, and RealLedgerPolicy rows.

Both routes have the same rows in that inventory by hypothesis. Since the terminal $\mathsf{Real}^{\uparrow}$ seal has no further coordinate beyond this inventory, the consumer-facing seal read from $\mathcal{S}_0$ is the same row as the seal read from $\mathcal{S}_1$. □

Theorem 126.254 (StreamName RegSeqRat uniform-tail seal confluence)**.** *Let $\mathcal{S}_0$, $\mathcal{S}_1$, and $\mathcal{S}_2$ be synchronized finite* $\mathsf{StreamName}^{\uparrow}$ *windows over one accepted rational stream-name schedule. Suppose each adjacent pair admits a common-window package, and suppose all three windows feed the same* RegSeqRat *handoff and the same terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal rows. Then the terminal seal reads from $\mathcal{S}_0$ and $\mathcal{S}_2$ agree on the visible endpoint, dyadic radius, regularity ledger, classifier ledger,* hsame *comparisons,* Cont *routes,* Pkg *provenance,* NameCert *provenance, and terminal* RealLedgerPolicy *rows.*

The confluence is a finite-window statement over the displayed synchronized ledger. It does not identify quotient streams, host-index equality, completion objects, independent regularity witnesses, standard bridge rows, or real completeness principles.

Proof. Apply Definition 126.243 to the $\mathcal{S}_0/\mathcal{S}_1$ synchronized pair and again to the $\mathcal{S}_1/\mathcal{S}_2$ synchronized pair. Each application exposes the same accepted RegSeqRat handoff, endpoint row, dyadic-radius row, regularity ledger, readback row, and terminal finite-window $\mathsf{Real}^{\uparrow}$ seal surface carried by the common schedule.

Next use Definition 126.253 on the adjacent pairs. The first application identifies the terminal read from $\mathcal{S}_0$ with the read from $\mathcal{S}_1$, and the second identifies the read from $\mathcal{S}_1$ with the read from $\mathcal{S}_2$ on exactly the visible finite inventory.

Compose these displayed row equalities by transitivity in the generated common-window ledger. The middle window contributes no separate coordinate: it is the shared finite $\mathsf{StreamName}^{\uparrow}$ synchronization surface, so the first and third terminal reads agree on the endpoint, radius, regularity, classifier, hsame, Cont, Pkg, NameCert, and RealLedgerPolicy rows and on no stronger host-level object. □

Theorem 126.255 (StreamName RegSeqRat finite-window chain compaction)**.** *Let*

$$\mathcal{S}_0, \mathcal{S}_1, \ldots, \mathcal{S}_n$$

be a finite chain of synchronized $\mathsf{StreamName}^{\uparrow}$ *windows over one accepted rational stream-name schedule. Suppose every adjacent pair* $\mathcal{S}_i, \mathcal{S}_{i+1}$ *satisfies the common-window terminal seal determinacy hypotheses, and suppose every window feeds the same accepted* RegSeqRat *handoff. Then all terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal reads through the chain compact to one seal-facing surface.*

The compacted surface has exactly the shared RatStreamNameFiniteWindowClassifier *rows,* ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine,* DyadicRatCore *endpoint and radius rows, and the visible* hsame, Cont, Pkg, NameCert, *and* RealLedgerPolicy *rows. It contains no quotient stream row, host-index equality row, completion object, standard bridge row, or real-completeness principle.*

Proof. Induct on the displayed finite chain. In the first nonempty adjacent case, Definition 126.253 identifies the two terminal reads through the common synchronized window and leaves exactly the stated StreamName, RegSeqRat, DyadicRatCore, transport, provenance, and Real ledger rows.

For the induction step, assume the initial segment has already compacted to one terminal seal-facing surface. The next adjacent pair satisfies the same determinacy hypotheses, so Definition 126.253 identifies the last read of the compacted segment with the read of the new window.

Apply Definition 126.254 to compose the compacted segment, the shared middle window, and the new terminal window. The confluence theorem keeps the accepted RegSeqRat handoff and every visible row on the same synchronized schedule, so the enlarged chain again has one terminal finite-window $\mathsf{Real}^{\uparrow}$ seal surface.

At no step is there a coordinate from which to read quotient streams, host-index equality, completion objects, standard bridge data, or real completeness. The induction therefore compacts the whole finite chain to the single displayed terminal seal inventory. □

126.16 StreamName finite-window lattice meet

Definition 126.256 (StreamName finite-window lattice meet packet)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be accepted finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over displayed source maps* $s, t : \mathsf{BHist} \to \mathsf{BHist}$*. A*

StreamName finite-window lattice meet packet for $(\mathcal{W}_L, \mathcal{W}_R)$ *is the finite* BHist *surface*

$$\mathcal{M} = (Q, B, I, U, D, H, C, P, N_L, N_R)$$

whose rows are as follows:

1. Q *is the common selected rational classifier row* RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{Q})$ *read on the shared* ProbeBundle $\mathcal{Q}$*;*
2. B *is the displayed* ProbeBundle *row for* $\mathcal{Q}$*, together with its restrictions to the selected bundles of* $\mathcal{W}_L$ *and* $\mathcal{W}_R$*;*
3. I *is the family of* InBundle$(n, \mathcal{Q})$ *membership rows for selected unary observations;*
4. U *is the family of* UnaryHistory(n) *observation rows paired with the pointwise rational classifier rows read by* Q*;*
5. D *is the dyadic ledger surface handed to* RegSeqRat *and to the finite-window* Real$^{\uparrow}$ *consumer, including endpoint, radius, denominator, and finite ledger-policy rows;*
6. H *is the componentwise* hsame *transport comparing selected rational classifier rows, probe rows, membership rows, unary rows, dyadic rows, handoff rows, provenance rows, and local names;*
7. C *is the displayed* Cont *route ledger from each accepted* StreamName$^{\uparrow}$ *window through the meet surface to the* RegSeqRat *handoff and the finite-window* Real$^{\uparrow}$ *seal;*
8. P *is the* Pkg *provenance over the accepted windows, the synchronized-window union, the cover-refinement classifier, the common-window transport, and the Real–RegSeq handoff boundary;*
9. N_L *and* N_R *are the local* NameCert$_{\text{StreamName}^{\uparrow}}$ *rows proving that the left and right accepted packages expose this same meet surface.*

The packet is only this finite observation surface. It has no coordinate for quotient stream equality, host index equality, selected limits, host real equality, or ambient completeness.

This meet packet is the StreamName$^{\uparrow}$*-side sibling surface consumed by chapter 301 and chapter 38, with its dyadic ledger row routed through chapter 291.*

Theorem 126.257 (StreamName finite-window lattice meet exhaustion)**.** *Let* $\mathcal{M}$ *be a StreamName finite-window lattice meet packet for two accepted finite-window* StreamName$^{\uparrow}$ *packages. Every* RegSeqRat *consumer or finite-window* Real$^{\uparrow}$ *consumer of* $\mathcal{M}$ *reads only the common selected rational classifier rows, the* ProbeBundle *rows, the* InBundle *membership rows, the* UnaryHistory *observation rows, the dyadic ledger rows, the componentwise transports, the continuation routes, the package provenance, and the local naming rows displayed in Definition 126.256.*

Consequently the meet packet is a shared finite observation surface for the RegSeqRat and RealUp handoffs. It does not provide quotient stream equality, host index equality, selected limits, host real equality, ambient completeness, or any consumer-visible row outside the finite StreamName, RegSeqRat, and RealUp ledger surfaces listed above.

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFiniteWindowLatticeMeet exhaustion`

Proof. First pass both accepted windows through Definition 126.301. The public interface restricts each window to its finite classifier, probe bundle, membership, unary-history, pointwise rational classifier, hsame, Cont, Pkg, and local naming rows.

Next apply Definition 126.242. The two accepted windows are repacked over one synchronized carrier, so their shared selected observations have one displayed ProbeBundle row, one membership family, one unary-history family, and one provenance ledger.

Use Definition 126.265 to read the common probe bundle as a covered finite-window classifier. The cover-refinement step supplies the common selected rational classifier row and keeps the selected endpoint package on the same finite observation rows.

Now apply Definition 126.268. Any $\mathsf{RegSeqRat}$ handoff through the left or right accepted window reads the same common-window surface, with the same componentwise hsame transports, continuation routes, and package provenance.

Finally use Definition 126.274 together with Definition 126.82. These handoff results identify the dyadic ledger rows and the finite-window RealUp consumer rows, while keeping regularity, sealing, limits, quotient rows, host index equality, host real equality, and ambient completeness outside the meet packet. The displayed coordinates of $\mathcal{M}$ therefore exhaust every consumer read. □

Theorem 126.258 (StreamName finite-window lattice meet associativity)**.** *Let $\mathcal{W}_A, \mathcal{W}_B, \mathcal{W}_C$ be accepted finite-window $\mathsf{StreamName}^{\uparrow}$ packages over displayed source maps. Suppose that $\mathcal{M}_{AB}$, $\mathcal{M}_{BC}$, $\mathcal{M}_{(AB)C}$, and $\mathcal{M}_{A(BC)}$ are accepted StreamName finite-window lattice meet packets whose common selected observations are read on the same finite $\mathsf{ProbeBundle}$ after reassociating the three local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ rows. Then the two iterated meet packets $\mathcal{M}_{(AB)C}$ and $\mathcal{M}_{A(BC)}$ expose the same common observation surface.*

More precisely, reassociation changes only the bracketing of the three local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ rows. The selected rational classifier rows, $\mathsf{ProbeBundle}$ rows, $\mathsf{InBundle}$ membership rows, $\mathsf{UnaryHistory}$ observation rows, dyadic ledger rows, componentwise hsame transports, displayed Cont routes, Pkg provenance, and the RegSeqRat and finite-window RealUp handoff rows are unchanged. Neither iterated meet exports quotient stream equality, host index equality, selected limits, host real equality, ambient completeness, or any consumer-visible row outside the finite StreamName, RegSeqRat, and RealUp ledger surfaces.

Proof. Apply Definition 126.257 to $\mathcal{M}_{AB}$ and $\mathcal{M}_{BC}$. Each binary meet is exhausted by its selected rational classifier, probe-bundle, membership, unary-history, dyadic, transport, continuation, provenance, and local naming rows.

Apply the same exhaustion theorem to the two iterated packets $\mathcal{M}_{(AB)C}$ and $\mathcal{M}_{A(BC)}$. By hypothesis these packets read the same finite $\mathsf{ProbeBundle}$ after reassociating the local NameCert rows, so the classifier, membership, unary-history, dyadic, transport, continuation, provenance, RegSeqRat, and finite-window RealUp handoff rows are the same displayed rows on both sides.

It remains to compare the local naming coordinates. Use Definition 126.259 to commute the binary meet packets inside either bracketing until the three local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ rows are read in the chosen reassociated order. Symmetry fixes Q, B, I, U, D, H, C, P and exchanges only already displayed local naming rows, so no downstream consumer receives a new row during the reassociation.

The exhaustion theorem now applies once more to the reassociated iterated surface. Since every RegSeqRat or finite-window RealUp consumer is confined to the displayed finite rows, and those rows agree for $\mathcal{M}_{(AB)C}$ and $\mathcal{M}_{A(BC)}$, the two iterated meets expose the same common observation surface and no excluded quotient, host, limit, real-equality, completeness, or hidden consumer coordinate. □

Lemma 126.259 (StreamName finite-window lattice meet symmetry)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be accepted finite-window $\mathsf{StreamName}^{\uparrow}$ packages over displayed source maps $s, t : \mathsf{BHist} \to \mathsf{BHist}$. Suppose that*

$$\mathcal{M} = (Q, B, I, U, D, H, C, P, N_L, N_R)$$

is an accepted StreamName finite-window lattice meet packet for $(\mathcal{W}_L, \mathcal{W}_R)$*. Then*

$$\mathcal{M}^{\mathrm{op}} = (Q, B, I, U, D, H, C, P, N_R, N_L)$$

is an accepted StreamName finite-window lattice meet packet for $(\mathcal{W}_R, \mathcal{W}_L)$ *over the same common observation surface. The rows* Q, B, I, U, D, H, C, P *are unchanged, and the only exchanged coordinates are the two local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *rows.*

Consequently every $\mathsf{RegSeqRat}$ *consumer or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of* $\mathcal{M}^{\mathrm{op}}$ *reads exactly the same selected rational classifier row, probe-bundle row, membership rows, unary-history rows, dyadic ledger row, componentwise transport row, continuation route row, and package provenance row as it reads from* $\mathcal{M}$*, with the left and right local naming rows interchanged. The symmetric packet exports no quotient stream equality, host index equality, selected limit, host real equality, ambient completeness, or consumer-visible row outside the finite meet surface.*

Proof. Unpack the meet packet using Definition 126.256. The coordinate Q is read on the shared $\mathsf{ProbeBundle}$, B is the same displayed bundle row together with its two restrictions, and I, U, D, H, C, P are common rows over that same finite surface. None of these rows carries an additional coordinate that distinguishes the ordered pair $(\mathcal{W}_L, \mathcal{W}_R)$ from the ordered pair $(\mathcal{W}_R, \mathcal{W}_L)$ after the same two restrictions are read in the opposite order.

The only ordered coordinates in the displayed packet are the local naming rows. In $\mathcal{M}$, the row N_L proves that the left accepted package $\mathcal{W}_L$ exposes the meet surface, and N_R proves that the right accepted package $\mathcal{W}_R$ exposes the same meet surface. For the ordered pair $(\mathcal{W}_R, \mathcal{W}_L)$, the first local naming row must name $\mathcal{W}_R$ and the second must name $\mathcal{W}_L$. These are precisely N_R and N_L. Thus the tuple $(Q, B, I, U, D, H, C, P, N_R, N_L)$ satisfies the same packet clauses for the swapped ordered pair.

It remains to identify what a downstream consumer can read. By Definition 126.257, every $\mathsf{RegSeqRat}$ consumer and every finite-window $\mathsf{Real}^{\uparrow}$ consumer is confined to the displayed classifier, bundle, membership, unary-history, dyadic, transport, continuation, provenance, and local naming coordinates of the meet packet. The construction of $\mathcal{M}^{\mathrm{op}}$ leaves the common coordinates Q, B, I, U, D, H, C, P fixed and merely exchanges the two already displayed naming rows. Hence the swapped packet has the same consumer-facing finite observation surface, with no route to any excluded quotient, host, limit, real-equality, completeness, or hidden consumer row. □

Theorem 126.260 (StreamName finite-window intersection)**.** *Let* A *and* B *be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *windows over the same source request. Then the lattice-meet rows and common-refinement rows display an intersection window* $A \cap B$ *whose visible surface consists exactly of the shared request classifier, the common finite observation cells, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the finite* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. Later* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *seal consumers may inspect only this displayed intersection route.*

Proof. Apply the finite-window lattice meet theorem Definition 126.257. It supplies one shared finite packet for the two accepted windows over the same request, with classifier, observation, dyadic, transport, replay, provenance, and local naming rows exposed objectwise.

Next use Definition 126.405. The RegSeqRat readback and Real seal rows are read through the common refinement of the selected StreamName windows, so the downstream consumer sees the meet packet rather than either original window in isolation.

The intersection route is therefore the only route visible to later RegSeqRat and Real-facing consumers. Since the carrier exposes no quotient stream equality, selected limit, host real equal-

ity, or ambient completeness coordinate, no other intersection witness can be inspected by those consumers. □

126.17 StreamName lattice-meet terminal factorization

Theorem 126.261 (StreamName lattice-meet terminal factorization)**.** *A* $\mathsf{StreamName}^{\uparrow}$ *finite-window lattice meet packet determines the terminal finite surface consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and finite* $\mathsf{Real}^{\uparrow}$ *seal handoffs. The terminal surface consists exactly of the shared rational classifier, the* ProbeBundle *row,* InBundle *membership rows,* UnaryHistory *observation rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface, the finite* $\mathsf{Real}^{\uparrow}$ *seal row, the displayed* hsame *and* Cont *routes, the* Pkg *provenance, and the local* NameCert *rows.*

No terminal consumer of the meet packet may replace that surface by quotient stream equality, host index equality, selected limits, host real equality, ambient completeness, or an off-ledger $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Start with the meet exhaustion theorem Definition 126.257. It identifies the common finite packet read by RegSeqRat and RealUp consumers: classifier, probe bundle, membership, unary-history, dyadic, transport, continuation, provenance, and local naming rows.

Next use the synchronized-window Real seal handoff of Definition 126.245. The synchronized window sends the same selected observations to the finite $\mathsf{Real}^{\uparrow}$ seal route, so the seal-facing read is not independent of the meet packet.

Now apply the RegSeqRat–RealUp source-boundary exhaustion theorem Definition 126.274. It places the $\mathsf{RegSeqRat}^{\uparrow}$ readback and finite $\mathsf{Real}^{\uparrow}$ handoff on the same StreamName, $\mathsf{DyadicRatCore}^{\uparrow}$, hsame, Cont, Pkg, and local naming rows.

Finally combine the pointwise handoff Definition 126.170 with the Real seal factorization boundary Definition 126.142. These rows account for the terminal readback and seal coordinates and leave no carrier slot for quotient streams, host index equality, selected limits, host real equality, ambient completeness, or off-ledger seal data. □

Theorem 126.262 (StreamName lattice-meet terminal source uniqueness)**.** *For a* $\mathsf{StreamName}^{\uparrow}$ *finite-window lattice meet packet, every terminal consumer that reaches the finite* $\mathsf{Real}^{\uparrow}$ *seal through the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger displays the same terminal source rows. These rows are precisely the shared rational classifier,* ProbeBundle *row,* InBundle *rows,* UnaryHistory *rows, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface, finite* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Proof. First apply Definition 126.261. It gives the terminal finite surface consumed by the accepted $\mathsf{RegSeqRat}^{\uparrow}$ readback and by the finite $\mathsf{Real}^{\uparrow}$ seal handoff, and it already lists the source rows available to such a consumer.

The uniqueness of that displayed source is the meet exhaustion content of Definition 126.257. The finite-window meet exposes one common packet, so the classifier, bundle, membership, unary-history, dyadic, continuation, provenance, and local naming rows cannot be duplicated by another terminal source inside the same meet route.

Next use Definition 126.245. The synchronized window sends the Real-facing read to the same selected finite observations, so a terminal $\mathsf{Real}^{\uparrow}$ consumer has no second observation window from which to rebuild the seal row.

Finally combine Definition 126.274 with Definition 126.142. The RegSeqRat readback and Real seal boundary are exhausted by the StreamName, dyadic, hsame, Cont, Pkg, and local NameCert rows displayed above, hence every accepted terminal consumer names the same source surface. □

Theorem 126.263 (StreamName lattice-meet terminal pullback nonescape)**.** *Pulling the terminal finite* $\mathsf{Real}^{\uparrow}$ *seal read back along the* $\mathsf{StreamName}^{\uparrow}$ *lattice-meet route cannot introduce quotient stream equality, host index equality, a selected limit, host real equality, ambient completeness, or an off-ledger* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Begin with the terminal source uniqueness theorem Definition 126.262. Any pullback of the terminal seal read through the accepted $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ route must return to the same displayed source rows: classifier, bundle, membership, unary observations, dyadic ledger, readback, finite seal, transport, continuation, provenance, and local naming data.

Now apply Definition 126.261 to that unique source surface. Its nonescape clause states that the terminal meet packet leaves no carrier slot for quotient stream equality, host index equality, selected limits, host real equality, ambient completeness, or off-ledger seal data.

The pullback therefore repacks the existing terminal rows; it does not add a hidden route. The exclusions remain stable under the return along the lattice-meet route because the Real-facing seal coordinate is already fixed by the accepted readback and the finite source boundary. □

Theorem 126.264 (StreamName lattice-meet Real-seal support determinacy)**.** *Let two accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window lattice-meet packets be consumed by the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and by the same finite* $\mathsf{Real}^{\uparrow}$ *seal handoff. If they agree on the displayed finite-window classifier, the* $\mathsf{ProbeBundle}$ *row,* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *observation rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows, then they determine the same finite* $\mathsf{Real}^{\uparrow}$ *seal support packet.*

No quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness row, or second* $\mathsf{Real}^{\uparrow}$ *source can change that support packet once those common lattice-meet rows are fixed.*

Proof. First apply Definition 126.261. The accepted readback and finite seal handoff factor through the displayed finite surface: classifier, bundle, membership, unary observation, dyadic ledger, readback, transport, continuation, provenance, and local naming rows.

Next apply Definition 126.262. Since the two packets agree on precisely those source rows, every terminal consumer names the same displayed source surface. Thus the finite $\mathsf{Real}^{\uparrow}$ seal handoff has no second source from which to rebuild a different support packet.

Now apply Definition 126.263. Pulling the seal read back along the lattice-meet route only repacks the already displayed rows and cannot introduce quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness, or another Real-facing source coordinate.

Finally use the Real seal handoff from the StreamName common-refinement route, namely Definition 126.221 together with Definition 126.142. The common finite pullback is the only consumer surface available to the finite $\mathsf{Real}^{\uparrow}$ seal, so agreement on the lattice-meet rows determines the same seal support packet. □

Theorem 126.265 (StreamNameUp finite-window cover-refinement classifier)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$ *and probe bundles* $\mathcal{P}_1, \mathcal{P}_2, \mathcal{Q} : \mathsf{ProbeBundle}$*, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_1) \quad \textit{and} \quad \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_2).$$

Assume every requested bundled unary observation of $\mathcal{Q}$ *is covered by one of the two certified windows:*

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{Q}) \to \mathsf{UnaryHistory}(n) \to \mathsf{InBundle}(n, \mathcal{P}_1) \vee \mathsf{InBundle}(n, \mathcal{P}_2).$$

Then the requested window is certified:

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}).$$

Moreover, for any selected n in $\mathcal{Q}$ with $\mathsf{UnaryHistory}(n)$ *and displayed one-extension endpoints*

$$\mathsf{hsame}(s(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t(n), \mathsf{E1}(b)),$$

the selected observation carries the full endpoint package of Definition 126.27.

Proof. First combine the two certified windows. The union clause of Definition 126.25 repacks the $\mathcal{P}_1$ and $\mathcal{P}_2$ classifiers as a classifier on the displayed union bundle.

Next restrict the union classifier to the requested bundle. For a bundled unary observation n of $\mathcal{Q}$, the cover hypothesis chooses whether the membership row comes from $\mathcal{P}_1$ or from $\mathcal{P}_2$. In either case the corresponding inclusion into the displayed union bundle gives the subwindow map required by the subwindow clause of Definition 126.25. This yields

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}).$$

Finally fix a selected requested observation n together with its bundle membership, unary witness, and displayed one-extension endpoints. Apply Definition 126.27 to the $\mathcal{Q}$ classifier just constructed. The resulting point classifier, positive-denominator rows, unary endpoint rows, empty and zero-headed exclusions, and one-tail readback are exactly the full endpoint package for the requested observation. □

Theorem 126.266 (StreamName cover-refinement transport closure)**.** *For certified observation maps $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ and probe bundles $\mathcal{P}_1, \mathcal{P}_2, \mathcal{Q} : \mathsf{ProbeBundle}$, suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_1) \quad \textit{and} \quad \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P}_2).$$

Assume every requested bundled unary observation of $\mathcal{Q}$ is covered by one of the two certified windows:

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{Q}) \to \mathsf{UnaryHistory}(n) \to \mathsf{InBundle}(n, \mathcal{P}_1) \vee \mathsf{InBundle}(n, \mathcal{P}_2).$$

Assume also that the endpoints are transported componentwise on every bundled unary observation of $\mathcal{Q}$:

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{Q}) \to \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(s(n), s'(n))$$

and

$$\forall n,\ \mathsf{InBundle}(n, \mathcal{Q}) \to \mathsf{UnaryHistory}(n) \to \mathsf{hsame}(t(n), t'(n)).$$

Then

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{Q}).$$

Moreover, for every selected n in $\mathcal{Q}$ with $\mathsf{UnaryHistory}(n)$ *and histories $a, b : \mathsf{Hist}$ displaying transported one-extension endpoints*

$$\mathsf{hsame}(s'(n), \mathsf{E1}(a)) \quad \textit{and} \quad \mathsf{hsame}(t'(n), \mathsf{E1}(b)),$$

the selected observation exports the same finite endpoint package to the $\mathsf{RegSeqRat}$ *and* $\mathsf{Real}^{\uparrow}$ *handoff surface: the selected point classifier, positive-denominator rows, unary endpoint rows, empty and zero-headed exclusions, one-tail readback,* $\mathsf{InBundle}$ *membership, bundled* $\mathsf{UnaryHistory}$ *row, finite* Cont *ledger, displayed* hsame *transports, and* Pkg *provenance. No host index, quotient representative, completion object, metric row, or* $\mathsf{Real}^{\uparrow}$ *completeness datum is introduced.*

Proof. First build the classifier on the requested cover. Apply Definition 126.265 to the two certified windows and to the displayed cover of $\mathcal{Q}$. This gives

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{Q}).$$

Next transport that classifier along the endpoint rows over $\mathcal{Q}$. The endpoint-transport field of Definition 126.28 applies componentwise to the two displayed hsame transport families, yielding

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{Q}).$$

Finally fix a selected bundled unary observation and its displayed transported one-extension endpoints. Apply Definition 126.27 to the transported classifier. The resulting selected endpoint package is the finite package consumed by the downstream surface, and Definition 126.142 records that this surface factors only through the listed StreamName, RegSeqRat, ProbeBundle, InBundle, UnaryHistory, Cont, hsame, and Pkg rows. □

Theorem 126.267 (StreamName cover-refinement Real seal source invariance)**.** *For certified observation maps $s, t, s', t' : \mathsf{Hist} \to \mathsf{Hist}$ and probe bundles $\mathcal{P}_1, \mathcal{P}_2, \mathcal{Q} : \mathsf{ProbeBundle}$, assume the two-window cover hypotheses for $\mathcal{P}_1$, $\mathcal{P}_2$, and $\mathcal{Q}$ from Definition 126.266, together with the same componentwise endpoint transports from s, t to s', t' over $\mathcal{Q}$. Then every downstream finite-window $\mathsf{Real}^{\uparrow}$ seal read over $\mathcal{Q}$ reads the same $\mathsf{StreamName}^{\uparrow}$ source surface after refinement.*

That invariant surface consists exactly of the finite-window classifier, the selected ProbeBundle *row,* InBundle *membership,* UnaryHistory*, the pointwise* RatHistoryClassifier*, displayed* hsame *transports, the* Cont *ledger, and* Pkg *provenance. No host index, quotient representative, completion object, metric row, or external $\mathsf{Real}^{\uparrow}$ completeness datum becomes available under the covered refinement.*

Proof. First apply Definition 126.265 to the two certified windows and the displayed cover of $\mathcal{Q}$. This builds the finite-window classifier on the requested probe bundle using only the already certified source rows.

Next apply Definition 126.266. The componentwise endpoint transports carry the classifier to s', t' and keep the selected endpoint package on the same $\mathcal{Q}$ bundle, with its InBundle membership, UnaryHistory row, point classifier, Cont ledger, displayed hsame rows, and Pkg provenance.

Finally pass to the $\mathsf{StreamName}^{\uparrow}$ Real–RegSeqRat handoff and the $\mathsf{Real}^{\uparrow}$ seal factorization boundary. Those results identify exactly the consumer rows available to a finite-window seal read, so the refinement can transport the source surface but cannot add a host index, quotient representative, completion object, metric row, or external completeness datum. □

126.18 StreamName RegSeqRat common-window transport

Theorem 126.268 (StreamName RegSeqRat common-window transport)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be finite $\mathsf{StreamName}^{\uparrow}$ windows over the same* ProbeBundle *$\mathcal{P}$ and the same displayed source maps $s, t : \mathsf{BHist} \to \mathsf{BHist}$. Suppose that for every certified member n with $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$, the two windows expose pointwise* hsame*-equal rational-history observations for $s(n)$ and $t(n)$. Then the* RegSeqRat *handoff rows transported through $\mathcal{W}_L$ and $\mathcal{W}_R$ are the same consumer-facing rows, and the finite-window $\mathsf{Real}^{\uparrow}$ ledger-boundary rows obtained from those handoffs are the same consumer-facing rows.*

Equivalently, the common bundle determines one visible handoff surface: the restricted RatStreamNameFiniteWi*row, the* ProbeBundle *row, the* InBundle *membership rows, the certified* UnaryHistory *rows, the pointwise rational-history classifier rows, and the displayed* hsame/Cont/Pkg *provenance rows. The*

transport adds no completion object, quotient row, host-index equality, RegSeqRat *regularity row, or* $\mathsf{Real}^{\uparrow}$ *seal classifier.*

Proof. Project both windows to the common bundle. The membership and unary-history coordinates are the same displayed $\mathsf{InBundle}(n, \mathcal{P})$ and $\mathsf{UnaryHistory}(n)$ rows, so the only possible route dependence is in the selected pointwise classifier rows.

Use Definition 126.171. The assumed pointwise hsame comparisons transport the selected classifier rows within the same ProbeBundle, so both windows expose the same finite-window StreamName classifier surface after projection.

Apply Definition 126.170. It reads the RegSeqRat handoff only from the carrier rows, the common bundle membership rows, the certified unary observations, and the transported pointwise classifier rows. Thus the two projected windows supply the same handoff rows to the RegSeqRat consumer.

Finally apply Definition 126.82 and Definition 126.234. The separation theorem keeps regularity and seal obligations on the consumer side, while common-refinement determinacy identifies the source tuple read through the shared bundle. Therefore the downstream finite-window $\mathsf{Real}^{\uparrow}$ ledger-boundary rows are the same consumer-facing rows as well. □

Theorem 126.269 (StreamName public RegSeqRat finite-window composition)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be public finite-window* $\mathsf{StreamName}^{\uparrow}$ *packages over the same* ProbeBundle $\mathcal{P}$ *and displayed maps* $s, t : \mathsf{BHist} \to \mathsf{BHist}$*. Suppose that the public rows exposed by the two packages agree on the finite-window classifier* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$*, the* $\mathsf{InBundle}(-, \mathcal{P})$ *membership rows, the certified* UnaryHistory *rows, the pointwise* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *rows, and the displayed* hsame/Cont/Pkg *provenance rows.*

Then the RegSeqRat *handoff rows read from* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *agree, and the finite-window* $\mathsf{Real}^{\uparrow}$ *ledger-boundary rows obtained from those handoffs agree, as the same consumer-facing common-window surface. The composed surface exports only the listed public StreamName rows, the RegSeqRat handoff rows determined by them, and the finite RealUp ledger-boundary rows. It exports no* RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion object, quotient row, or host-index equality.*

Proof. Apply Definition 126.301 to both public packages. The interface restricts each finite window to the displayed bundle, unary-history, pointwise rational-history classifier, hsame, Cont, and Pkg rows, so both packages present the same public finite-window source surface over $\mathcal{P}$.

Next apply Definition 126.268. Since the two public projections expose the same RatStreamNameFiniteWindowCl and the same pointwise provenance rows, the RegSeqRat handoff read from either package is the same consumer-facing handoff surface, and the finite RealUp ledger-boundary rows obtained from that handoff are the same rows.

Finally use Definition 126.82 and Definition 126.234. The separation theorem keeps regularity, sealing, completion, quotient, and host-index data outside the exported finite-window rows, while source determinacy identifies the common bundle source read by downstream consumers. Repacking therefore keeps exactly the public classifier, membership, unary-history, pointwise classifier, hsame, Cont, Pkg, RegSeqRat handoff, and finite RealUp ledger-boundary rows. □

Theorem 126.270 (StreamName RegSeqRat dyadic source determinacy)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be finite* $\mathsf{StreamName}^{\uparrow}$ *common-window packages over the same* ProbeBundle $\mathcal{P}$ *and the same accepted* RegSeqRat *spine. Suppose that for every selected observation* n*, the displayed* $\mathsf{UnaryHistory}(n)$*,* $\mathsf{InBundle}(n, \mathcal{P})$*, and pointwise* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *rows agree between the two packages*

by the shown hsame/Cont/Pkg *provenance. Then the DyadicRatCore endpoint rows handed to the* $\mathsf{Real}^{\uparrow}$ *finite-window ledger are the same consumer-facing rows.*

The determined handoff surface is exactly the RatStreamNameFiniteWindowClassifier$(s, t, \mathcal{P})$ *row, the* ProbeBundle *row, the* InBundle *membership rows, the* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, the DyadicRatCore endpoint rows, and the shared* Cont/hsame/Pkg/RealLedgerPolicy *provenance. It exposes no completion object, quotient representative, host-index equality, or hidden selector row.*

Proof. First apply Definition 126.268. The shared bundle and the displayed pointwise hsame comparisons identify the StreamName finite-window classifier, selected bundle membership rows, certified unary-history rows, and accepted RegSeqRat handoff rows read from $\mathcal{W}_L$ and $\mathcal{W}_R$.

Next use Definition 126.217. Once the common-window handoff is placed in a tail-window coverage packet, every readable consumer row is one of the displayed classifier, bundle, unary-history, pointwise rational-history, RegSeqRat, DyadicRatCore, and finite ledger rows.

Finally apply Definition 38.314. The finite $\mathsf{Real}^{\uparrow}$ observation can consume the DyadicRatCore endpoint rows only through the endpoint denominator and dyadic source package supplied by the same accepted spine. Since the cited boundaries contain no completion, quotient, host-index equality, or hidden selector row, the two packages hand the same DyadicRatCore source rows to the $\mathsf{Real}^{\uparrow}$ finite-window ledger. □

Theorem 126.271 (StreamName RegSeqRat common-window tail stability)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be finite* $\mathsf{StreamName}^{\uparrow}$ *common-window packages over a shared* ProbeBundle $\mathcal{P}$*. Suppose the two packages determine the same* RegSeqRat *dyadic source rows through Definition 126.270. Then every certified tail subwindow of $\mathcal{P}$ exposes the same* RegSeqRat *handoff rows and the same terminal* $\mathsf{Real}^{\uparrow}$ *ledger-boundary rows.*

The tail restriction is read only through the displayed InBundle *membership rows, certified* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows, the accepted* RegSeqRat *spine, DyadicRatCore endpoint rows, and the shared* Cont/hsame/Pkg/RealLedgerPolicy *provenance. It does not expose regularity, completion, quotient, or host-index data as part of the source packet.*

Proof. Apply Definition 126.268. The shared bundle and pointwise rational-history transport identify the common-window handoff rows before any tail restriction is taken.

Apply Definition 126.270. The hypothesis that the same dyadic source rows are determined fixes the accepted RegSeqRat spine and the DyadicRatCore endpoint rows carried into the terminal $\mathsf{Real}^{\uparrow}$ ledger.

Now restrict to a certified tail subwindow. The tail is still a finite subfamily of the same ProbeBundle, so the inherited InBundle and UnaryHistory rows select the same pointwise classifier rows and the same endpoint entries.

Finally use Definition 126.82. It keeps regularity, completion, quotient, and host-index data outside the source packet, so the tail can expose only the already identified RegSeqRat handoff rows and terminal ledger-boundary rows. □

Theorem 126.272 (StreamName RegSeqRat common-window composition handoff)**.** *Let $\mathcal{W}_0$, $\mathcal{W}_1$, and $\mathcal{W}_2$ be finite* $\mathsf{StreamName}^{\uparrow}$ *windows. Suppose $\mathcal{W}_0$ and $\mathcal{W}_1$ share a certified common-window transport surface over the* ProbeBundle *row $\mathcal{P}_{01}$, and suppose $\mathcal{W}_1$ and $\mathcal{W}_2$ share a certified common-window transport surface over the* ProbeBundle *row $\mathcal{P}_{12}$. Then the composed handoff from $\mathcal{W}_0$ to $\mathcal{W}_2$ exposes exactly the same consumer-facing rows read by* RegSeqRat*: the* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier, the* UnaryHistory *rows, the* InBundle *rows, the* RatHistoryClassifier *rows, the DyadicRatCore source rows, and the displayed* hsame/Cont/Pkg *provenance rows.*

The composed handoff exports no RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal classifier, completion datum, quotient row, or host-index equality. Every readable downstream row is inherited from the two certified common-window surfaces and their certified tail restrictions.*

Proof. Apply Definition 126.268 to the $\mathcal{W}_0/\mathcal{W}_1$ surface over $\mathcal{P}_{01}$. This identifies the finite-window classifier, unary-history rows, bundle-membership rows, pointwise rational-history rows, and displayed hsame/Cont/Pkg provenance read by the first handoff leg.

Apply the same theorem to the $\mathcal{W}_1/\mathcal{W}_2$ surface over $\mathcal{P}_{12}$. Since both certified surfaces pass through the same middle window $\mathcal{W}_1$, their visible handoff rows agree at the middle boundary before any downstream consumer reads them.

Use Definition 126.270 on both legs. The dyadic source rows supplied to the RegSeqRat spine and to the terminal finite-window $\mathsf{Real}^{\uparrow}$ ledger are determined by the displayed classifier, bundle, unary-history, rational-history, hsame, Cont, and Pkg rows on the two certified surfaces.

Finally apply Definition 126.271. Certified tail restrictions remain finite subwindows of the displayed bundle rows, so composing the two legs cannot add any row outside the inherited consumer surface. The separation of regularity, seal, completion, quotient, and host-index obligations is therefore preserved by the composed handoff from $\mathcal{W}_0$ to $\mathcal{W}_2$. □

Theorem 126.273 (StreamName RegSeqRat common-window endpoint exhaustion)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be common-window packages over the same* ProbeBundle $\mathcal{P}$ *and the same accepted* RegSeqRat *spine. For any downstream finite-window* $\mathsf{Real}^{\uparrow}$ *ledger consuming the endpoint handoff, every endpoint row it reads is exactly one of the displayed finite rows:*

1. *the* RatStreamNameFiniteWindowClassifier *row;*
2. *the shared* ProbeBundle *row, its* InBundle *rows, and the certified* UnaryHistory *rows;*
3. *the pointwise* RatHistoryClassifier *rows selected by the common window;*
4. *the accepted* RegSeqRat *spine rows;*
5. *the DyadicRatCore endpoint and radius rows determined from that spine;*
6. *the shared* Cont*,* hsame*,* Pkg*, and* RealLedgerPolicy *provenance rows.*

No hidden selector row, host-index equality, quotient row, completion object, or $\mathsf{Real}^{\uparrow}$ *seal classifier is part of the endpoint surface.*

Proof. First project the common-window packages through Definition 126.268. This fixes the visible finite-window classifier, shared bundle, bundle-membership, unary-history, pointwise rational-history, and displayed provenance rows before the downstream endpoint ledger is read.

Next apply Definition 126.270. The accepted RegSeqRat spine determines the DyadicRatCore endpoint and radius rows consumed by the finite-window $\mathsf{Real}^{\uparrow}$ ledger from the same displayed source rows; no source-equivalence transport is needed.

Use Definition 126.271 to pass to the finite tail subwindow actually consumed by the ledger. Tail restriction is projection to a finite subfamily of the same ProbeBundle, so it cannot expose a new selector, host index, quotient, completion, or seal classifier row.

Finally apply Definition 38.314. The terminal $\mathsf{Real}^{\uparrow}$ finite-window consumer reads endpoint data only through the displayed endpoint package, DyadicRatCore source rows, and RealLedgerPolicy boundary. Combining the four projections exhausts the endpoint surface by exactly the listed rows. □

Theorem 126.274 (StreamName-RegSeqRat-RealUp source boundary exhaustion)**.** *Let $\mathcal{W}$ be a certified common finite* $\mathsf{StreamName}^{\uparrow}$ *window over a displayed* ProbeBundle $\mathcal{P}$*. Suppose its selected rational history rows are read by a* RegSeqRat *dyadic-tolerance consumer and then by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then every seal-boundary row consumed by the terminal* $\mathsf{Real}^{\uparrow}$ *package is projected from exactly one of the following visible source families:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *window rows, namely* ProbeBundle, InBundle*, certified* UnaryHistory*, pointwise rational-history classifier rows,* hsame *transport, and* Cont *readback;*
2. *the* RegSeqRat *dyadic endpoint, radius, distance, and regularity rows selected by the accepted dyadic-tolerance spine;*
3. *the finite* $\mathsf{Real}^{\uparrow}$ *seal ledger rows, including the endpoint denominator package, dyadic source rows, and* RealLedgerPolicy *boundary.*

Conversely, any compatible triple of rows from these three families repacks into the same boundary package consumed by the finite-window $\mathsf{Real}^{\uparrow}$ *seal. The boundary contains no quotient sequence, completion object, host index equality, or host real equality.*

Proof. First project the certified common window through Definition 126.268. This fixes the ProbeBundle, InBundle, UnaryHistory, pointwise rational-history classifier, hsame, and Cont rows available to the StreamName face.

Next apply Definition 126.270. The dyadic endpoint rows handed to the downstream consumer are determined by those displayed StreamName rows together with the accepted RegSeqRat spine. Thus the endpoint, radius, distance, and regularity rows form the whole RegSeqRat source family read by the seal.

Use Definition 126.272 to keep the handoff stable under the common-window composition used by downstream readback. Then apply Definition 38.355 and Definition 38.344. These RealUp rows state that the finite seal reads the same StreamName-RegSeqRat handoff together with the endpoint denominator, dyadic source, and RealLedgerPolicy ledger boundary.

For the reverse direction, start with a compatible triple from the three listed families. The StreamName rows repack the finite common window, the RegSeqRat rows repack the accepted dyadic-tolerance source, and the RealUp ledger rows repack the finite seal boundary. The cited pullback and correspondence theorems then identify the repacked package with the original terminal boundary. Since each cited boundary explicitly excludes quotient, completion, host-index equality, and host real equality rows, no additional source row is available. □

Theorem 126.275 (StreamName-RegSeqRat common-window seal functoriality)**.** *Let $\mathcal{W}_0$, $\mathcal{W}_1$, and $\mathcal{W}_2$ be certified common finite* $\mathsf{StreamName}^{\uparrow}$ *windows over the same public endpoints and the same accepted* RegSeqRat *dyadic-tolerance spine. Suppose the displayed transports $\mathcal{W}_0 \to \mathcal{W}_1$ and $\mathcal{W}_1 \to \mathcal{W}_2$ preserve the finite-window classifier, the selected unary observations, the pointwise rational-history rows, the accepted* RegSeqRat *spine, and the DyadicRatCore endpoint and radius rows.*

Then the $\mathsf{Real}^{\uparrow}$ *seal source obtained by applying Definition 126.274 after the two displayed transports is the same finite source surface as the one obtained by first using the common-window composition handoff of Definition 126.272 and then applying source-boundary exhaustion. The common source surface consists only of the displayed StreamName window rows, the accepted RegSeqRat dyadic rows, and the finite RealUp seal ledger rows; it contains no quotient row, completion row, or host real equality.*

Proof. Start with the two displayed common-window transports. By Definition 126.272, their composition preserves the same classifier, selected unary observations, pointwise rational-history rows,

accepted RegSeqRat spine, and DyadicRatCore endpoint and radius rows as the single composed transport $\mathcal{W}_0 \to \mathcal{W}_2$.

Apply Definition 126.273 to both the two-stage transport and the composed transport. In each case the endpoint surface is exhausted by the displayed finite window rows and the accepted dyadic-tolerance spine, so the downstream endpoint ledger has the same visible source families.

Finally apply Definition 126.274. The terminal $\mathsf{Real}^{\uparrow}$ seal reads only the StreamName window rows, the RegSeqRat dyadic endpoint rows, and the finite seal ledger rows. Since both transport routes expose the same rows to this exhaustion theorem, they expose the same finite source surface. The cited boundaries leave no coordinate for quotient rows, completion rows, or host real equality, so no further source can distinguish the two routes. □

Theorem 126.276 (StreamName-RegSeqRat finite-window ledger confluence)**.** *Let $\mathcal{W}_0$, $\mathcal{W}_1$, and $\mathcal{W}_2$ be finite* $\mathsf{StreamName}^{\uparrow}$ *windows over the same public endpoints and the same accepted* RegSeqRat *dyadic-tolerance spine. Suppose the displayed transports $\mathcal{W}_0 \to \mathcal{W}_1$, $\mathcal{W}_1 \to \mathcal{W}_2$, and their composed common-window route preserve the shared* ProbeBundle *row, the* InBundle *membership rows, the certified* UnaryHistory *rows, the pointwise* RatHistoryClassifier *rows, the accepted spine, the* DyadicRatCore *endpoint and radius rows, and the visible* Cont/hsame/Pkg/RealLedgerPolicy *provenance.*

Then every finite-window $\mathsf{Real}^{\uparrow}$ *seal consumer reads the same boundary whether it follows the staged route $\mathcal{W}_0 \to \mathcal{W}_1 \to \mathcal{W}_2$ or the composed common-window route $\mathcal{W}_0 \to \mathcal{W}_2$. The common boundary is exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows, the* RegSeqRat *dyadic endpoint and radius rows, and the finite* $\mathsf{Real}^{\uparrow}$ *seal ledger rows. It contains no quotient row, completion object, host-index equality, host function,* Classical *datum, or host real equality.*

Proof. First apply Definition 126.268. It identifies the rows preserved by each displayed finite-window transport: the shared ProbeBundle row, InBundle membership, certified UnaryHistory, pointwise rational-history classification, accepted spine, dyadic endpoint and radius rows, and the visible provenance rows.

Next use Definition 126.270. The endpoint and radius rows delivered to a downstream seal are forced by the displayed StreamName rows together with the accepted RegSeqRat spine, so the staged and composed routes cannot expose different dyadic source rows.

Apply Definition 126.273 and Definition 126.274. The first theorem exhausts the downstream endpoint surface by the common-window rows and the accepted spine; the second theorem says a finite $\mathsf{Real}^{\uparrow}$ seal consumer reads exactly that exhausted surface together with the finite seal ledger rows.

Finally apply Definition 126.275. It identifies the two staged seal readback routes with the composed route before the consumer reads the boundary. Since the cited exhaustion results leave no coordinate for quotient rows, completion objects, host-index equality, host functions, Classical data, or host real equality, the listed finite rows are the whole common boundary. □

Theorem 126.277 (StreamName RegSeqRat terminal window union)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be two finite* $\mathsf{StreamName}^{\uparrow}$ *windows feeding a common* RegSeqRat *source boundary. If their endpoint rows admit the common-window exhaustion packet and their seal routes compose functorially, then the union window presents the same terminal* RegSeqRat *source to any* $\mathsf{Real}^{\uparrow}$ *boundary consumer.*

The union exposes only finite observation rows, dyadic endpoint ledgers, hsame *transport,* Cont *routes,* Pkg *provenance, and the* RegSeqRat *seal. It exposes no hidden infinite tail, quotient equality, completion object, host index equality, or host real equality.*

Proof. Apply Definition 126.273 to $\mathcal{W}_L$ and $\mathcal{W}_R$. The endpoint rows on both sides are exhausted by the same finite observation families, dyadic endpoint ledgers, accepted RegSeqRat spine rows, and displayed hsame, Cont, and Pkg provenance.

Next apply Definition 126.274. It sends each exhausted endpoint package to the same finite $\mathsf{Real}^{\uparrow}$ source boundary, using only the StreamName window rows, the RegSeqRat dyadic source rows, and the finite seal ledger rows.

Finally use Definition 126.275. The functorial seal route identifies the two-stage and union-window routes before the terminal boundary consumer reads them. Hence the union window presents the same terminal RegSeqRat source, and the listed finite rows are the full consumer surface. □

Theorem 126.278 (StreamName RegSeqRat terminal window intersection)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be two finite* $\mathsf{StreamName}^{\uparrow}$ *windows feeding a common* RegSeqRat *source boundary. Suppose both windows restrict to a certified common sub-bundle K, and suppose the endpoint rows visible on K admit the common-window exhaustion packet.*

Then every finite-window $\mathsf{Real}^{\uparrow}$ *boundary consumer reads the same terminal* RegSeqRat *source from the restricted intersection. The restricted intersection exposes exactly the* $\mathsf{InBundle}(-, K)$ *membership rows, the selected rational-history classifier rows, dyadic endpoint ledgers,* hsame, Cont, Pkg *provenance, and the displayed* RegSeqRat *seal. It exposes no hidden tail, quotient equality, completion object, host index equality, or host real equality.*

Proof. Apply Definition 126.329 to the certified common sub-bundle K. The intersection surface is exhausted by the membership rows $\mathsf{InBundle}(-, K)$, the selected rational-history classifier rows, the shared dyadic endpoint ledgers, and the displayed hsame, Cont, and Pkg provenance.

Next apply Definition 126.273 to the restricted endpoint rows on K. This packages the exposed intersection rows as the common-window endpoint surface feeding the accepted RegSeqRat spine, with no additional row for a hidden tail or host index equality.

Apply Definition 126.274. Every finite-window $\mathsf{Real}^{\uparrow}$ consumer reads only the exhausted endpoint surface, the dyadic source rows, and the finite seal ledger, so both restricted windows present the same visible source families to the consumer.

Finally use Definition 126.275. The seal functoriality identifies the terminal route obtained by restricting through K with the route read by the finite boundary consumer. Since the cited exhaustion theorems leave no coordinate for quotient equality, completion objects, host index equality, or host real equality, the displayed finite rows are the full terminal intersection source. □

Theorem 126.279 (StreamName RegSeqRat terminal window cover gluing)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be finite* $\mathsf{StreamName}^{\uparrow}$ *windows feeding a common accepted* RegSeqRat *dyadic-tolerance spine. Suppose their union satisfies the terminal-window union boundary of Definition 126.277, and suppose their certified common sub-bundle satisfies the terminal-window intersection boundary of Definition 126.278.*

Then every finite-window $\mathsf{Real}^{\uparrow}$ *seal consumer reads one cover-glued terminal source surface. That surface is exactly the union of the displayed* ProbeBundle *rows,* InBundle *membership rows, certified* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows,* DyadicRatCore *endpoint and radius rows, accepted* RegSeqRat *spine rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows, identified along the intersection agreement. It contains no quotient row, completion object, host-index equality, host function,* Classical *datum, or host real equality.*

Proof. Apply Definition 126.277 to the joined window. The union route exposes the displayed finite observation rows, dyadic endpoint ledgers, accepted RegSeqRat spine rows, hsame transport,

Cont routes, Pkg provenance, and finite seal policy rows as the terminal source boundary for the $\mathsf{Real}^{\uparrow}$ consumer.

Apply Definition 126.278 on the certified overlap. The intersection route says that the common sub-bundle has the same membership, rational-history classifier, dyadic endpoint, hsame, Cont, Pkg, and seal rows on both restrictions, so the two sides agree on every row that can be read twice.

Use endpoint exhaustion and source-boundary exhaustion to compare the two routes. By Definition 126.273, every endpoint coordinate reaching the accepted spine is already among the displayed finite StreamName and dyadic rows. By Definition 126.274, the downstream seal reads only those exhausted rows together with the finite RealLedgerPolicy boundary.

Finally apply Definition 126.275. It identifies the cover-glued readback before the $\mathsf{Real}^{\uparrow}$ consumer reads the boundary. Since the union and intersection routes exhaust all readable source rows and agree on the overlap, the cover-glued terminal surface is precisely the listed finite union modulo the intersection agreement, with no quotient, completion, host-index, host-function, Classical, or host-real coordinate. □

Theorem 126.280 (StreamName RegSeqRat cover-glued ledger uniqueness)**.** *Let $\mathcal{W}$ be a finite* $\mathsf{StreamName}^{\uparrow}$ *union, let I be its certified overlap sub-bundle, let S be an accepted* RegSeqRat *dyadic-tolerance spine, and let P be a finite* $\mathsf{Real}^{\uparrow}$ *seal policy. Suppose two terminal source surfaces are built from the same $\mathcal{W}$, I, S, and P by the cover-gluing route of Definition 126.279.*

Then every terminal ledger row read by a finite-window $\mathsf{Real}^{\uparrow}$ *consumer is identical as a consumer-facing row in the two presentations. The visible rows are exactly the* ProbeBundle *rows,* InBundle *membership rows, certified* UnaryHistory *rows, pointwise* RatHistoryClassifier *rows,* DyadicRatCore *endpoint and radius rows, accepted* RegSeqRat *spine rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows. No quotient, completion object, host-index equality, host function,* Classical *datum, or host real equality is exported.*

Proof. Apply Definition 126.279 to the first presentation and again to the second presentation. Both cover-glued terminal surfaces are therefore assembled from the same finite union rows and the same certified intersection rows, with the same accepted RegSeqRat spine and the same finite $\mathsf{Real}^{\uparrow}$ seal policy.

Next apply Definition 126.276. It identifies the staged StreamName-to-RegSeqRat route with the composed StreamName-to-RegSeqRat-to-RealUp route, so a terminal consumer cannot distinguish a row by the route used to present it.

Use Definition 126.273 for the dyadic endpoint and radius coordinates. Use Definition 126.274 for the finite seal boundary. Together they show that every readable coordinate is one of the displayed finite families.

The two presentations agree on all union rows by hypothesis and agree on all intersection rows by the certified overlap. Since the exhaustion theorems leave no other consumer-readable coordinate, each terminal ledger read returns the same consumer-facing row in both presentations. This is only a uniqueness statement for the concrete finite ledger; it does not transport a source equivalence and it exports no host-level equality or completion object. □

Theorem 126.281 (StreamName RegSeqRat common-window selection determinacy)**.** *Let $\mathcal{W}_L$ and $\mathcal{W}_R$ be finite* $\mathsf{StreamName}^{\uparrow}$ *common-window packages over the same* ProbeBundle *and the same accepted* RegSeqRat *dyadic-tolerance spine. Suppose each selected observation row on both windows carries matching* InBundle *membership, pointwise* RatHistoryClassifier *transport,* DyadicRatCore *endpoint and radius rows, and displayed* hsame*,* Cont*, and* Pkg *provenance.*

Then every terminal RegSeqRat *source read through $\mathcal{W}_L$, through $\mathcal{W}_R$, through their finite union, through their certified intersection, or through the cover-gluing route is the same consumer-readable source. The statement introduces no host-index equality, quotient row, hidden selector, completion object, or* $\mathsf{Real}^{\uparrow}$ *arithmetic or order row.*

Proof. Apply Definition 126.268 to each selected row. The shared ProbeBundle membership, pointwise rational-history classifier transport, dyadic endpoint data, hsame, Cont, and Pkg provenance put both windows over the same accepted finite source boundary.

Next use Definition 126.270. Since the accepted dyadic-tolerance spine is common, the transported endpoint and radius rows determine one RegSeqRat source family for every selected terminal read.

The union route is handled by Definition 126.277. It reads the same displayed source rows after adjoining the finite windows, and Definition 126.273 shows that no additional endpoint coordinate is available beyond the displayed finite rows.

The intersection route is handled by Definition 126.278. The certified overlap exposes the same membership, classifier, endpoint, radius, transport, continuation, and provenance rows on both restrictions, so the source read on the overlap is the source already determined by the common spine.

Finally apply Definition 126.279. The cover gluing route is assembled from the terminal union and terminal intersection routes along their agreement, so it has no remaining coordinate by which a different selected window could yield a different consumer-readable source. The excluded host-index, quotient, hidden-selector, completion, and $\mathsf{Real}^{\uparrow}$ arithmetic or order rows therefore stay absent throughout the comparison. □

Theorem 126.282 (StreamName RegSeqRat tail-stable Real seal)**.** *Let s, t : BHist $\to$ BHist be displayed* $\mathsf{StreamName}^{\uparrow}$ *rows, let P and Q be finite* ProbeBundle *windows, and let $\mathcal{W}$ be their common-window transport surface. Suppose that the transport row of Definition 126.268, the tail-stability row of Definition 126.271, the finite-window ledger confluence row of Definition 126.276, and the finite* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 126.112 all hold on the displayed* UnaryHistory *rows,* InBundle *membership rows,* hsame *transport rows, and* RatStreamNameFiniteWindowClassifier *rows selected by $\mathcal{W}$.*

Then the certified tail shift of the common window determines the same consumer-facing $\mathsf{Real}^{\uparrow}$ *finite-window seal package as the original common window. The package consists exactly of the displayed StreamName rows, the selected unary observations, bundle-membership rows, rational-history classifier rows, accepted* RegSeqRat *dyadic source rows, DyadicRatCore endpoint and radius rows, finite ledger rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows. It exports no completion object, quotient row, host-index equality, hidden selector, host function, or extra* RegSeqRat *regularity witness beyond the displayed finite-window seal rows.*

Proof. First apply Definition 126.271. The certified tail subwindow inherits the same InBundle membership, UnaryHistory observations, pointwise RatHistoryClassifier rows, accepted RegSeqRat spine, DyadicRatCore endpoint and radius rows, and Cont/hsame/Pkg/RealLedgerPolicy provenance as the original common window.

Next use Definition 126.281. Since the selected observations on the original window and on its certified tail carry the same displayed classifier and provenance rows, every terminal RegSeqRat source read is the same consumer-readable source.

Apply Definition 126.276. The staged tail route and the composed common-window route therefore present one finite ledger boundary to any downstream $\mathsf{Real}^{\uparrow}$ seal consumer.

Finally invoke Definition 126.112. It reads exactly the StreamName source rows, accepted RegSeqRat pointwise seal rows, bundle-membership rows, unary observations, finite ledger entries, and provenance rows already identified above. The separation clauses in the StreamName handoff chain leave no coordinate for completion objects, quotient representatives, host-index equalities, hidden selectors, host functions, or additional regularity witnesses, so the tail-stable common window exports the same public finite-window $\mathsf{Real}^{\uparrow}$ seal package and nothing outside it. □

Theorem 126.283 (StreamName RegSeqRat glued Real seal uniqueness)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be displayed* $\mathsf{StreamName}^{\uparrow}$ *rows. Let two terminal common-window routes for s and t agree on their* InBundle *rows,* UnaryHistory *rows,* RatStreamNameFiniteWindowClassifier *rows, accepted* RegSeqRat *dyadic source rows, DyadicRatCore endpoint and radius rows, finite ledger rows,* hsame *transports,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows.*

Then the glued consumer-facing $\mathsf{Real}^{\uparrow}$ *finite-window seal package determined by those two routes is unique. It consists only of the displayed StreamName source rows, selected unary observations, bundle-membership rows, rational-history classifier rows, accepted* RegSeqRat *dyadic sources, DyadicRatCore endpoint and radius rows, ledger entries,* hsame *transports,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows. No completion point, quotient representative, host-index equality, hidden selector, host function, or extra regularity witness is exported.*

Proof. First apply Definition 126.279. The two terminal routes glue through the same terminal cover because their displayed bundle membership, unary observations, classifiers, dyadic source rows, endpoint-radius data, transport, continuation, provenance, and ledger-policy rows agree on the common window.

Next use Definition 126.280. After the cover has been glued, both routes expose the same finite ledger boundary. The ledger read is therefore the ledger already present in the displayed common-window surface, not a separately chosen downstream object.

Apply Definition 126.281. Since the two glued routes share the displayed classifier, accepted source, endpoint, radius, hsame, Cont, Pkg, and RealLedgerPolicy rows, they determine the same terminal consumer-readable RegSeqRat source.

Finally invoke Definition 126.282. The $\mathsf{Real}^{\uparrow}$ seal reads only the glued finite-window package already identified by the preceding steps. The separation clauses in the tail-stable seal leave no coordinate for a completion point, quotient representative, host-index equality, hidden selector, host function, or extra regularity witness, so both terminal routes produce one glued consumer-facing finite-window seal package. □

Theorem 126.284 (StreamName RegSeqRat terminal tail subwindow factorization)**.** *Let s, t : $\mathsf{BHist} \to \mathsf{BHist}$ be displayed* $\mathsf{StreamName}^{\uparrow}$ *rows. Let a terminal common-window route for s and t determine the glued consumer-facing* $\mathsf{Real}^{\uparrow}$ *finite-window seal package of Definition 126.283. Let a certified tail subwindow of that route preserve the displayed* UnaryHistory *rows,* InBundle *rows,* RatStreamNameFiniteWindowClassifier *rows, accepted* RegSeqRat *spine rows, DyadicRatCore endpoint and radius rows,* hsame *transports,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows.*

Then the certified tail subwindow factors through the same consumer-facing $\mathsf{Real}^{\uparrow}$ *finite-window seal package as the terminal common-window route. The factorization exports exactly the displayed StreamName source rows, selected unary observations, bundle-membership rows, rational-history classifier rows, accepted* RegSeqRat *spine rows, DyadicRatCore endpoint and radius rows, ledger entries,* hsame *transports,* Cont *routes,* Pkg *provenance, and* RealLedgerPolicy *rows. It exports no quotient row, completion row, host-index row, hidden selector row, arithmetic row, order row, or bridge row.*

Proof. First apply Definition 126.271. The certified tail subwindow has the same displayed unary, bundle, classifier, accepted spine, endpoint-radius, transport, continuation, provenance, and ledger-policy surface as the terminal route.

Next use Definition 126.282. The tail surface therefore presents the same finite ledger boundary to the $\mathsf{Real}^{\uparrow}$ seal consumer and contributes no coordinate outside the displayed finite-window package.

Finally invoke Definition 126.283. Since the terminal route and its certified tail now read the same public rows, uniqueness identifies their consumer-facing $\mathsf{Real}^{\uparrow}$ seal packages and yields the stated factorization. □

Definition 126.285 (Scheduled constant observation package)**.** *For histories $d, e : \mathsf{Hist}$ and observation schedules $r, q : \mathsf{Hist} \to \mathsf{Hist}$, the scheduled constant observation package is the finite StreamNameUp-facing row tuple*

$$\mathsf{SchedConstObs}(d, e, r, q)$$

consisting of the RatUp seed carrier rows $\mathsf{RatHistoryCarrier}(d)$ *and* $\mathsf{RatHistoryCarrier}(e)$*, the RatUp seed classifier row* $\mathsf{RatHistoryClassifier}(d, e)$*, and the two scheduled constant stream rows*

$$\mathsf{RatConstStream}_d \circ r, \qquad \mathsf{RatConstStream}_e \circ q.$$

Its StreamNameUp carrier entries are $\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$ *and* $\mathsf{RatStreamNameCarrier}(\mathsf{RatC}$ $q)$*, and its StreamNameUp classifier entry is*

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q).$$

The schedules r and q are retained only as observation rows; the rational seed histories remain the only RatUp endpoints exported by the package.

Theorem 126.286 (Scheduled constant observation exactness)**.** *For histories $d, e : \mathsf{Hist}$ and schedules $r, q : \mathsf{Hist} \to \mathsf{Hist}$, the scheduled constant observation package of Definition 126.285 supplies exactly the following StreamNameUp rows:*

$$\mathsf{RatStreamNameCarrier}(\mathsf{RatConstStream}_d \circ r)$$

and

$$\mathsf{RatStreamNameClassifier}(\mathsf{RatConstStream}_d \circ r, \mathsf{RatConstStream}_e \circ q),$$

if and only if the corresponding RatUp seed rows $\mathsf{RatHistoryCarrier}(d)$ *and* $\mathsf{RatHistoryClassifier}(d, e)$ *hold.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName scheduled constant observation exactness`

Proof. For the carrier row, unfold $\mathsf{RatConstStream}_d \circ r$. Every certified unary observation is sent back to the same seed history d, so the StreamNameUp carrier clause is precisely the RatUp carrier clause for d.

For the classifier row, apply Definition 126.52. Its independently scheduled classifier clause identifies the classifier of $\mathsf{RatConstStream}_d \circ r$ against $\mathsf{RatConstStream}_e \circ q$ with the seed classifier $\mathsf{RatHistoryClassifier}(d, e)$.

Combining these two readings gives the forward direction by projection from the scheduled package. The reverse direction repacks the RatUp carrier and classifier rows as the two displayed StreamNameUp rows, with r and q serving only as observation schedules. □

Theorem 126.287 (StreamName scheduled window reindex stability)**.** *Let d, e : Hist be seed histories, let r, q : Hist $\to$ Hist be observation schedules, and let u : Hist $\to$ Hist be a unary reindexing row whose requested finite observation window is carried by the public StreamName finite-window interface of Definition 126.301. Then the constant scheduled observation package* SchedConstObs(d, e, r, q) *of Definition 126.285 transports through u by replacing the displayed schedule rows with $r \circ u$ and $q \circ u$:*

$$\mathsf{SchedConstObs}(d, e, r, q) \rightsquigarrow \mathsf{SchedConstObs}(d, e, r \circ u, q \circ u).$$

The transported package still supplies the same finite-window input consumed by the RealUp independently scheduled constant rational embedding certificate in Definition 126.293.

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName scheduled window reindex stability`

Proof. Unfold the package of Definition 126.285. Reindexing changes only the two observation rows, sending the displayed streams to $\mathsf{RatConstStream}_d \circ r \circ u$ and $\mathsf{RatConstStream}_e \circ q \circ u$; the RatUp seed histories remain d and e.

Apply Definition 126.301 to the requested window. The public interface says that the reindexed finite window is still a StreamNameUp finite-window row, so the carrier projections requested by the consumer are the same finite family of displayed stream-name rows.

Now apply Definition 126.286. Since the two reindexed streams are still constant over the same seed histories, their carrier and classifier rows reduce to the same RatUp carrier and classifier rows for d and e.

Finally use Definition 126.293. RealUp consumes exactly these scheduled StreamNameUp coordinates, so the transported scheduled package feeds the same finite-window input. The construction introduces no quotient, completion object, external metric primitive, or RealUp completeness datum. □

Theorem 126.288 (Scheduled subwindow constant observation coherence)**.** *Let d, e : Hist be seed histories, let r, q : Hist $\to$ Hist be observation schedules, and let U : ProbeBundle be a finite observation window accepted by the public StreamName finite-window interface of Definition 126.301. Let V : ProbeBundle be a certified subwindow whose rows are only* InBundle *membership rows,* UnaryHistory *rows, and pointwise* hsame *rows inherited from U. Then the package obtained by restricting*

$$\mathsf{SchedConstObs}(d, e, r, q)$$

directly to V exposes the same RatHistoryCarrier(d)*,* RatHistoryClassifier(d, e)*,* RatStreamNameCarrier*, and* RatStreamNameClassifier *rows as the package first read over U and then restricted to V. Only the displayed schedule rows are restricted; the RatUp seed rows and the pointwise classifier rows are identical in the two readings.*

Proof. Unfold the package of Definition 126.285. Reading the package over U records the seed carrier rows for d and e, the seed classifier row for (d, e), and the two scheduled constant StreamName rows.

Apply Definition 126.301 to the certified subwindow V. Its public rows are inherited InBundle, UnaryHistory, and pointwise hsame rows, so restricting from U to V does not create a host index, quotient representative, or completion datum.

Now apply Definition 126.286. On either reading, the StreamName carrier and classifier rows reduce to the same RatUp seed carrier and seed classifier rows for d and e.

It remains only to compare the schedule coordinates. Direct restriction to V and restriction through U select the same unary-history and pointwise hsame rows from the finite-window interface, so the schedule rows are the only rows whose displayed domain changes. The exposed RatUp seed and pointwise classifier rows are therefore coherent for the subwindow. □

Theorem 126.289 (Scheduled window RealUp feed)**.** *Let $d, e : \mathsf{Hist}$ be seed histories, let $r, q : \mathsf{Hist} \to \mathsf{Hist}$ be observation schedules, and let $u : \mathsf{Hist} \to \mathsf{Hist}$ be a unary reindexing row accepted by the public finite-window interface of Definition 126.301. Then the transported package*

$$\mathsf{SchedConstObs}(d, e, r \circ u, q \circ u)$$

supplies exactly the StreamName finite-window rows consumed by Definition 38.314 and Definition 38.320. Its exported rows are the two reindexed constant stream carriers, their exact classifier, the RatUp seed rows for d and e, and the package provenance already present in Definition 126.285; it adds no host Nat*, quotient representative, completion object, or unrecorded stream object.*

Proof. Unfold Definition 126.285. The transported tuple has the same seed histories d, e and only replaces the two observation schedules by $r \circ u$ and $q \circ u$.

Apply Definition 126.287. The public finite-window interface accepts the requested unary row u, so the transported scheduled package is still the finite StreamName window package exposed to downstream consumers.

Now apply Definition 126.286. The two reindexed streams remain constant over the same RatUp seed histories, and the classifier row reduces to the displayed RatUp seed classifier. Thus every StreamName row read by the finite window is already one of the package rows.

Finally repack the rows through Definition 38.314 and Definition 38.320. These boundary theorems consume only the finite StreamName carriers, classifier rows, and ledger provenance supplied above, so the RealUp feed has no additional host index, quotient, or hidden stream datum. □

Theorem 126.290 (StreamName-RegSeqRat-RealUp finite-window feed)**.** *Let $d, e : \mathsf{Hist}$ be seed histories, let $r, q : \mathsf{Hist} \to \mathsf{Hist}$ be observation schedules, and let $u : \mathsf{Hist} \to \mathsf{Hist}$ be a unary reindexing row whose finite request bundle $\mathcal{P} : \mathsf{ProbeBundle}$ is accepted by the public finite-window interface of Definition 126.301. Then the transported scheduled constant package*

$$\mathsf{SchedConstObs}(d, e, r \circ u, q \circ u)$$

supplies one concrete finite-window boundary feed for the three consumers Definition 38.251, Definition 38.314, and Definition 38.320. The supplied rows are exactly the two scheduled StreamName carriers, their RatUp seed classifier, the finite-window classifier row selected by $\mathcal{P}$, the endpoint denominator rows, and the RegSeqRat dyadic source rows.

Equivalently, the construction uses only BHist*,* $\mathsf{ProbeBundle}$*,* $\mathsf{InBundle}$*,* $\mathsf{UnaryHistory}$*,* hsame*, RatUp classifiers, StreamName finite-window rows, and RegSeqRat dyadic ledger rows. It does not add a host* Nat *index, quotient representative, completion object, host stream function, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Unfold Definition 126.285. The transported package has seed histories d, e, scheduled streams $\mathsf{RatConstStream}_d \circ r \circ u$ and $\mathsf{RatConstStream}_e \circ q \circ u$, the RatUp carrier rows for the two seeds, and the RatUp seed classifier row for (d, e).

Apply Definition 126.287. Since $\mathcal{P}$ is accepted by the public finite-window interface, the unary row u gives a finite StreamName window rather than a host index family. The two scheduled carriers and the selected finite-window classifier are therefore the same rows read by Definition 126.289.

Next apply Definition 126.286. The two scheduled streams remain constant over the same RatUp seed histories after the reindexing, so the StreamName classifier reduces to the RatUp seed classifier and the endpoint denominator rows remain the finite RatUp endpoint rows attached to d and e.

Finally pass the resulting finite-window classifier through Definition 38.251. The RegSeqRat seal reads the same finite StreamName window together with the dyadic source rows. Then Definition 38.314 and Definition 38.320 repack those rows as the RealUp finite-window ledger boundary. Every displayed component is therefore supplied by the scheduled package plus the RegSeqRat dyadic ledger, with no additional analytic or completion-side input. □

Theorem 126.291 (StreamName-RegSeqRat seal scope)**.** *Every accepted scheduled finite-window feed for*

$$\mathsf{SchedConstObs}(d, e, r \circ u, q \circ u)$$

supplies exactly the StreamName carrier and classifier rows, the RatUp seed classifier, the finite-window ProbeBundle *row, the endpoint denominator rows, and the RegSeqRat dyadic ledger rows required by Definition 38.251. The same packet is then consumable by Definition 38.314 and Definition 38.320 without adding host* Nat *indices, quotient representatives, completion objects, metric data, or* $\mathsf{Real}^{\uparrow}$ *completeness rows.*

Proof. Start from Definition 126.290. It identifies the accepted feed with the two scheduled StreamName carriers, the RatUp seed classifier, the selected finite-window classifier row, the endpoint denominator rows, and the RegSeqRat dyadic source ledger.

Project the finite-window rows through Definition 126.287. The unary reindexing row keeps the window inside the public ProbeBundle interface, so the seal sees a finite StreamName packet rather than a host index family.

Pass the classifier and dyadic source rows through Definition 38.251. This is precisely the RegSeqRat seal obligation: the seed classifier, endpoint denominators, and dyadic ledger rows are the only rows read by the seal.

Finally repack the same packet through Definition 38.314 and Definition 38.320. These RealUp boundary theorems consume the finite StreamName rows and RegSeqRat ledger as given, so no completion-side or host analytic datum is added. □

Theorem 126.292 (StreamName-RegSeqRat-RealUp feed common-row determinacy)**.** *Let* $d, e :$ Hist *be seed histories, let* $r, q :$ Hist $\to$ Hist *be observation schedules, and let* $u :$ Hist $\to$ Hist *be a certified unary reindexing row. Let* $\mathcal{P} :$ ProbeBundle *be the same accepted finite-window request for two scheduled finite-window feeds built from* $\mathsf{SchedConstObs}(d, e, r \circ u, q \circ u)$*. If the two feeds also share the same* RatStreamNameClassifier *seed row for* (d, e) *and the same RegSeqRat dyadic ledger rows, then they expose the same StreamName finite-window carrier rows, the same StreamName classifier row selected by* $\mathcal{P}$*, the same input row for Definition 38.251, and the same RealUp finite-window ledger boundary row.*

Thus common finite source data determine the rows read by the RegSeqRat seal and by the RealUp finite-window consumer. No host index, quotient representative, completion object, metric row, or $\mathsf{Real}^{\uparrow}$ *completeness datum can distinguish the two feeds.*

Proof. Apply Definition 126.290 to each feed. Both applications start from the same BHist seed histories d, e, the same accepted ProbeBundle request $\mathcal{P}$, the same InBundle evidence, and the same UnaryHistory row u.

Project the two inventories through Definition 126.291. The scope theorem says that the visible rows are exactly the scheduled StreamName carriers, the selected finite-window classifier,

the RatUp seed classifier, the endpoint denominator rows, and the RegSeqRat dyadic ledger rows. Since the hypotheses identify those source rows, the two inventories have the same displayed StreamName carrier and classifier rows.

Now read the RegSeqRat input. The shared hsame, Cont, unary reindexing, accepted bundle membership, and dyadic ledger hypotheses are precisely the rows consumed by Definition 38.251. Therefore the seal input row cannot vary between the two feeds.

Finally pass the common seal packet through Definition 38.314 and Definition 38.320. These RealUp boundary statements read the finite StreamName packet and RegSeqRat ledger already identified above, so every RealUp finite-window ledger boundary row is the same for the two feeds and no additional datum remains available to separate them. □

Theorem 126.293 (Scheduled constant observation RealUp feed)**.** *For histories d, e : Hist and schedules r, q : Hist $\to$ Hist, the scheduled constant observation package is the StreamNameUpside input consumed by the RealUp independently scheduled constant rational embedding certificate of Definition 38.538. Equivalently, its two scheduled stream rows and its exact classifier row are the StreamNameUp coordinates used by the downstream target* RealIndependentReindexedConstant_rational_embedding_

Proof. Read the RealUp package in Definition 38.538. Its two StreamNameUp coordinates are exactly $\mathsf{RatConstStream}_d \circ r$ and $\mathsf{RatConstStream}_e \circ q$, and its classifier chain passes through the independently scheduled StreamNameUp classifier between those rows.

By Definition 126.286, those are precisely the carrier and classifier rows delivered by the scheduled constant observation package. Thus RealUp consumes no additional StreamNameUp data beyond this scheduled package when forming the constant rational embedding certificate. □

Theorem 126.294 (Scheduled constant StreamName RealUp seal exactness)**.** *For histories d, e : Hist and schedules r, q : Hist $\to$ Hist, the package $\mathsf{SchedConstObs}(d, e, r, q)$ supplies exactly the StreamNameUp carrier rows, the StreamNameUp classifier row, the RatUp seed rows, and the provenance rows consumed by Definition 38.314, Definition 38.320, and Definition 126.293. It supplies no host stream function, quotient representative, completion datum, or RealUp completeness witness.*

Proof. Unfold Definition 126.285. The displayed entries are the two scheduled constant StreamName rows $\mathsf{RatConstStream}_d \circ r$ and $\mathsf{RatConstStream}_e \circ q$, the RatUp seed histories d, e, the classifier row between the scheduled names, and the package provenance recording their finite-window source.

Apply Definition 126.286 to the same package. It identifies the carrier and classifier rows as the exact StreamNameUp surface induced by the two RatUp seeds, so there is no additional StreamName classifier or host stream map outside the displayed packet.

Next use Definition 126.293. The RealUp consumer coordinates for the independently scheduled constant rational embedding are precisely the two scheduled StreamName rows and their exact classifier row. Thus the consumer side reads the rows already isolated by the scheduled observation package.

Finally repack these rows through Definition 38.314 and Definition 38.320. Those theorems read only the finite StreamName window, the RatUp seed rows, and the provenance ledger, so the seal exports exactly the finite-window RealUp input surface and not a quotient representative, completion datum, or completeness witness. □

Theorem 126.295 (StreamName constant pointwise inhabited)**.** *Let d : Hist be a certified rational endpoint row, and let r : Hist $\to$ Hist range over any displayed unary schedule in the scheduled*

constant observation package. The package supplies a $\mathsf{StreamName}^{\uparrow}$ *carrier whose pointwise classifier is stable under every such schedule; hence the constant certified point determines an inhabited StreamName witness for each displayed finite observation row. The witness is the finite scheduled row* $\mathsf{RatConstStream}_d \circ r$*, not an infinite stream object.*

Proof. Start with the scheduled constant observation package at the diagonal seeds (d, d) and the chosen displayed schedule r. By Definition 126.286, the carrier row and classifier row are exactly the StreamNameUp rows induced by the certified rational endpoint d.

Apply Definition 126.287. Reindexing along the displayed unary schedule changes only the finite observation window; the pointwise classifier remains the same certified constant classifier after transport through the schedule.

Finally use Definition 126.294. The RealUp seal consumes exactly the scheduled StreamName carrier, classifier, RatUp seed, and provenance rows already displayed by the package. Therefore the constant certified point inhabits the StreamName carrier through each finite scheduled row, with no primitive infinite object or hidden completion datum. □

Theorem 126.296 (StreamName constant observation map row)**.** *For any certified point row over the L10 source, the constant observation schedule determines a* $\mathsf{StreamName}^{\uparrow}$ *carrier row whose pointwise classifier,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row are stable under every unary finite observation. The row is available to* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *as a finite StreamName handoff, without claiming real completeness or quotient stream equality.*

Proof. Begin with the constant-stream and constant-window boundary rows. They identify a certified point with the constant StreamName carrier read over each finite observation window, so a unary finite observation changes only the displayed schedule.

Apply constant-window transport totality. The pointwise classifier and hsame transport are stable under the unary observation because the seed point row is unchanged and only the finite window is reindexed.

Now use the scheduled constant observation package. Its Cont replay and Pkg provenance record the same constant schedule as a finite StreamNameUp packet, and the local NameCert row names that packet before downstream consumption.

Finally read the consumers. $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ may consume the finite StreamName carrier, classifier, transport, replay, provenance, and naming rows supplied here; they do not receive a real-completeness claim, quotient stream equality, or hidden completion coordinate from this map row. □

Theorem 126.297 (StreamName pointwise map stability)**.** *Let r be a unary reindexing map on finite histories, and let F be a pointwise map on rational-history observations. If r sends every unary window to a unary window, F preserves the* $\mathsf{RatHistory}^{\uparrow}$ *carrier, and F preserves the* $\mathsf{RatHistory}^{\uparrow}$ *classifier, then the* $\mathsf{StreamName}^{\uparrow}$ *carrier and classifier rows are stable both under reindexing by r and under pointwise mapping by F. The exported route remains a finite StreamName row: it contains only the StreamName carrier, classifier,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *data, and it does not introduce quotient stream equality or real-completeness data.*

```
↪variant BEDC.Derived.StreamNameUp.RatStreamName reindexing and map stability
```

Proof. Project the accepted StreamName carrier and classifier rows. For reindexing, a requested unary window n is sent to the unary window $r(n)$, so the original carrier and classifier rows apply directly at the transported observation coordinate.

For pointwise mapping, evaluate the original carrier and classifier rows at the same unary window. The carrier-preservation hypothesis for F transports each displayed rational history, and the classifier-preservation hypothesis transports the paired rational-history classifier row.

Finally repack the transported rows into the public StreamName packet. The route exports the same finite StreamName, hsame, Cont, Pkg, and $\mathsf{NameCert}$ fields after these two transports, so downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers receive a non-quotient mapped-stream handoff rather than an added completion coordinate. □

Theorem 126.298 (StreamName constant observation map composition)**.** *Let x be a certified point row over the L10 source, let r be a unary reindexing map on finite histories, and let F be a pointwise map on rational-history observations. Suppose r sends every unary window to a unary window, F preserves the* $\mathsf{RatHistory}^{\uparrow}$ *carrier, and F preserves the* $\mathsf{RatHistory}^{\uparrow}$ *classifier. Then the pointwise map of the constant observation* $\mathsf{StreamName}^{\uparrow}$ *packet for x factors through the same finite constant schedule after reindexing by r. The exported row contains only the finite* $\mathsf{StreamName}^{\uparrow}$ *carrier and classifier, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *data, and it exports no quotient stream equality, selected real value, or real-completeness row.*

Proof. Apply Definition 126.296 to the certified point row x. This gives the constant observation StreamName packet on every unary finite window, with its classifier, transport, continuation, package, and local naming rows read from the same constant schedule.

Next apply Definition 126.297 to the reindexing map r and the pointwise rational-history map F. The hypotheses on r and F transport the carrier and classifier rows windowwise, while preserving the finite StreamName support.

The constant schedule has no additional coordinate beyond the certified point row and the displayed unary window. Therefore after reindexing, the mapped packet still factors through the same finite constant schedule and repacks only the StreamName carrier, classifier, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows for downstream RegSeqRat and Real consumers. □

Theorem 126.299 (StreamName successor-window projection determinacy)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be certified StreamName observation maps, let $n : \mathsf{BHist}$ be a certified unary observation, and let $B : \mathsf{ProbeBundle}$ be a finite observation bundle such that $\mathsf{BHist.e1}(n)$ is an $\mathsf{InBundle}$ member of B. If the public finite-window classifier*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B)$$

holds, then it determines the projected singleton successor-window classifier

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{ProbeBundle.Bcons}(\mathsf{BHist.e1}(n), \mathsf{ProbeBundle.Bnil})).$$

The projected row is exactly the successor observation row consumed by the scheduled constant observation package of Definition 126.285, by the scheduled window reindex stability row of Definition 126.287, and by the RealUp finite-window boundary rows Definition 38.314 and Definition 38.320. It adds no host Nat*, quotient representative, completion object, metric row, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Unfold the public finite-window interface in Definition 126.301. The classifier over B is a finite family of pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows indexed by the certified unary observations carried by B.

The hypothesis that $\mathsf{BHist.e1}(n)$ is an $\mathsf{InBundle}$ member of B gives the inclusion of the singleton successor bundle into B. Apply the finite-window restriction export of Definition 126.302 to retain exactly the row indexed by $\mathsf{BHist.e1}(n)$ and to discard every other bundled observation.

Now read that singleton row as a scheduled successor observation. The successor reindexing stability row for StreamName observations identifies the same pointwise classifier after reindexing by the successor observation, and Definition 126.287 repacks it as the finite input of the scheduled constant observation package.

Finally pass the projected scheduled row through Definition 126.289 and Definition 126.290. These rows are the RealUp finite-window feed rows already cited by Definition 38.314 and Definition 38.320. The projection therefore changes only the finite ProbeBundle ledger and introduces no host Nat index, quotient representative, completion object, metric row, or $\mathsf{Real}^{\uparrow}$ completeness datum. □

Theorem 126.300 (StreamNameUp public countable-name interface)**.** *The public* $\mathsf{StreamName}^{\uparrow}$ *interface over* BHist *exports exactly the countable rational stream-name data assembled from* UnaryHistory*,* hsame*,* $\mathsf{Rat}^{\uparrow}$*, and the stream carrier/classifier rows. Its carrier is* RatStreamNameCarrier*, its classifier is* RatStreamNameClassifier*, and its public rows are precisely the RatUp pointwise carrier/classifier fields, the constant stream witness, empty constant-stream point exactness, constant point exactness, reindexing and RatUp-preserving map stability, and the composition law for unary observation reindexing.*

Equivalently, a downstream chapter may cite this interface as a single countable-name package whose exported surface consists of Definition 126.13, Definition 126.48, Definition 126.53, Definition 126.55, Definition 126.19, and Definition 126.20. The export does not supply quotient representatives, completion data, RealUp completeness, metric data, or a standard bridge.

Proof. The carrier and classifier fields are the two unfolded stream rows in Definition 126.13. That theorem also supplies the pointwise RatUp equivalence and transport clauses over every certified unary observation in BHist, so the public package does not introduce any classifier beyond RatStreamNameClassifier.

The inhabited constant-name row is Definition 126.48. Empty observation exactness comes from Definition 126.53, and pointwise constant exactness comes from Definition 126.55. These three rows identify the visible constant stream data with the underlying $\mathsf{Rat}^{\uparrow}$ seed without adding any quotient representative or completion object.

The structural action rows are exactly Definition 126.19 and Definition 126.20. The first handles a single unary observation reindexer together with a RatUp-preserving history map, while the second handles composition of such reindexers. Repacking these six named rows gives the public countable-name interface and leaves all completion, metric, RealUp-completeness, and standard-bridge claims outside the export. □

Theorem 126.301 (StreamNameUp public finite-window interface)**.** *The public finite-window surface of* $\mathsf{StreamName}^{\uparrow}$ *over* BHist *consists exactly of* RatStreamNameFiniteWindowClassifier *together with the pointwise carrier/classifier rows, classifier-to-window coverage, singleton-window exhaustion, certified reindexing and point-map coverage, finite-window structural laws, the selected full endpoint package, and finite-window stability fields, together with the empty-window vacuity boundary.*

Equivalently, downstream $\mathsf{Real}^{\uparrow}$ *and* RegSeqRat *boundary theorems may cite this interface as a single finite-window package whose exported rows are Definition 126.300, Definition 126.22, Definition 126.23, Definition 126.24, Definition 126.25, Definition 126.27, Definition 126.28, and Definition 126.310. The export does not supply RealUp completion, RegSeqRat regularity, metric completeness, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier public interface`

Proof. The public countable-name spine is Definition 126.300. It fixes the carrier and classifier as RatStreamNameCarrier and RatStreamNameClassifier, and it exposes the pointwise RatUp carrier/classifier rows over certified unary observations in BHist.

Unfold Definition 126.21. The finite-window classifier is exactly the restriction of the stream-name classifier to bundled certified unary observations. Thus Definition 126.22 projects every public stream-name classifier to an arbitrary probe bundle, while Definition 126.23 uses singleton probe windows to recover the full pointwise classifier.

The action rows are the certified reindexing and point-map coverage theorem Definition 126.24 and the structural laws in Definition 126.25. Bundle membership provides the restriction, append, and recomposition cases, so no additional finite-window carrier or classifier is introduced.

For selected endpoints, apply Definition 126.27 to a chosen bundled unary observation. The result reads back the RatUp point classifier, positive denominator rows, unary endpoint rows, endpoint nonemptiness, zero-headed exclusion, and one-tail agreement package needed by finite boundary consumers.

Finally, Definition 126.28 reuses RatUp point classifier reflexivity, symmetry, transitivity, and hsame transport at each bundled observation. Repacking these named rows gives precisely the finite-window interface consumed by downstream $\mathsf{Real}^{\uparrow}$ and RegSeqRat boundary theorems. The empty bundle boundary is supplied by the closed bundle-generation case for Bnil: no membership constructor can feed an endpoint classifier row. Completion, regularity, metric, and bridge claims are left outside the package. □

Theorem 126.302 (StreamNameUp finite-window restriction export)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let B' and B be* ProbeBundle *windows. Suppose every certified unary observation carried by B' is an* InBundle *member of B. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B) \implies \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B').$$

The restriction export has the ten-field fit used by downstream RegSeqRat *and* $\mathsf{Real}^{\uparrow}$ *consumers: the BEDC source is* $\mathsf{StreamName}^{\uparrow}$ *together with* ProbeBundle*, the carrier consists of bundled certified unary observations, the classifier is the pointwise* $\mathsf{Rat}^{\uparrow}$ *classification row, the ledger retains exactly the observation rows selected by B', and exactness is supplied by bundle inclusion.*

Proof. Unfold Definition 126.21. A finite-window classifier over B is a pointwise classifier row for each certified unary observation carried by B.

Fix an observation carried by B'. The displayed inclusion witness presents that same certified unary observation as an InBundle member of B, so the classifier over B supplies the corresponding pointwise $\mathsf{Rat}^{\uparrow}$ row for s and t.

Repack these rows over all observations of B'. The carrier remains the same bundled certified-unary-observation carrier, the ledger is the retained subfamily of observation rows, and no completion, quotient representative, or regularity row is introduced. This is precisely the finite-window classifier over B'. □

Theorem 126.303 (StreamNameUp finite-window reindexing stability)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, let B and B' be* ProbeBundle *windows, and let r be a certified unary reindexer. Suppose that every certified unary observation carried by B' is sent by r to an* InBundle *member of B. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B) \implies \mathsf{RatStreamNameFiniteWindowClassifier}(s \circ r, t \circ r, B').$$

The restricted window consumes exactly the reindexed pointwise $\mathsf{Rat}^{\uparrow}$ *classifier rows and the finite observation ledger named by* B'*. It introduces no* $\mathsf{Real}^{\uparrow}$ *completion, no* RegSeqRat *regularity row, no quotient representative, and no metric row.*

Proof. Start from the public finite-window interface of Definition 126.301. It makes the finite-window classifier a pointwise $\mathsf{Rat}^{\uparrow}$ classifier over bundled certified unary observations and includes the certified reindexing rows from Definition 126.24.

Fix a certified unary observation carried by B'. The reindexer sends it to an InBundle member of B, so the classifier over B supplies the pointwise $\mathsf{Rat}^{\uparrow}$ row for s and t at the reindexed observation. Transport that row along the certified point map to read the classifier for $s \circ r$ and $t \circ r$ at the original observation.

Now repack these transported rows over all observations of B'. This is the same restriction shape as Definition 126.302, with the inclusion provided by the reindexed-map coverage row rather than by an identity subwindow. The carrier, classifier, and finite ledger remain those of the public finite-window interface.

Nothing in the construction asks for a completion object, a regular sequence condition, a quotient representative, or a metric witness. The resulting classifier is therefore precisely the restricted probe window needed by $\mathsf{Real}^{\uparrow}$ and RegSeqRat boundary consumers. □

Theorem 126.304 (StreamName finite-window reindexing composition)**.** *Let* s, t *be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, let* B*,* B'*, and* B'' *be* ProbeBundle *windows, and let* r *and* q *be certified unary reindexers. Suppose* r *sends every certified unary observation carried by* B'' *to an* InBundle *member of* B'*, and* q *sends every certified unary observation carried by* B' *to an* InBundle *member of* B*. Then restricting the finite* RatStreamNameFiniteWindowClassifier *window by* r *and then by* q *exposes the same finite* BHist *packet as restricting once by* $q \circ r$*. The classifier, endpoint,* hsame*, and finite ledger rows are the same rows repacked over* B''*.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamName reindexing composition law`

Proof. Apply Definition 126.303 to the restriction from B to B'. This transports the finite-window classifier rows along q and keeps the endpoint, hsame, and finite ledger rows as displayed rows on B'.

Apply Definition 126.303 again to the restriction from B' to B''. The second transport reads the rows already repacked over B' and exposes them on B'' along r.

The checked composition law for certified reindexers supplies the same unary observation witness for the composite map $q \circ r$. Repacking the identical finite-window rows over B'' gives the one-step restriction by $q \circ r$ and does not introduce completion, regularity, quotient, metric, arithmetic, or order data. □

Theorem 126.305 (StreamNameUp finite-window union composition)**.** *Let* s, t *be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let* B_L *and* B_R *be* ProbeBundle *windows. Then the two component classifiers assemble into the appended-window classifier:*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_L) \wedge \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_R) \implies \mathsf{RatStrea}$$

Conversely, the appended-window classifier restricts to both component windows:

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{BAppend}(B_L, B_R)) \implies \mathsf{RatStreamNameFiniteWindowClassifier}(s, t,$$

The union row is a finite observation-window composition row only: it introduces no completion, quotient representative, metric row, or $\mathsf{Real}^{\uparrow}$ *completeness object.*

Proof. For assembly, unfold Definition 126.21. Fix a certified unary observation carried by $\mathsf{BAppend}(B_L, B_R)$. The bundle split theorem BEDC.FKernel.Bundle.inBundle_bundleAppend_iff identifies this membership with membership in B_L or membership in B_R.

In the left case, read the needed pointwise $\mathsf{Rat}^{\uparrow}$ classifier row from the classifier over B_L. In the right case, read the same kind of row from the classifier over B_R. Repacking the case split over all bundled observations gives the classifier over $\mathsf{BAppend}(B_L, B_R)$.

For restriction, use the canonical inclusions of B_L and B_R into the appended bundle, again supplied by the InBundle splitting row for BAppend. Applying Definition 126.302 to each inclusion returns the two component classifiers.

All rows remain the same finite ProbeBundle rows and the same pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows. No completion package, quotient representative, metric structure, or $\mathsf{Real}^{\uparrow}$ completeness claim is used in either direction. □

Theorem 126.306 (StreamNameUp finite-window appended refinement chain)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let B_L, B_R, and B_0 be* ProbeBundle *windows. Suppose every certified unary observation carried by B_0 is an* InBundle *member of* $\mathsf{BAppend}(B_L, B_R)$*. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_L) \wedge \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_R) \implies \mathsf{RatStrea}$$

The row uses only ProbeBundle*,* InBundle*,* BAppend*,* UnaryHistory*, and the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows carried by certified unary observations. It introduces no* $\mathsf{Real}^{\uparrow}$ *completion datum, quotient representative, regularity predicate, or metric row.*

Proof. First assemble the classifier over the appended display. Apply Definition 126.305 to the two component classifiers over B_L and B_R. The assembly direction supplies the finite-window classifier over $\mathsf{BAppend}(B_L, B_R)$.

Next restrict that appended classifier to the displayed subwindow. The assumed inclusion sends every certified unary observation of B_0 to an InBundle member of $\mathsf{BAppend}(B_L, B_R)$, so Definition 126.302 applies directly.

The resulting classifier over B_0 is obtained by retaining pointwise $\mathsf{Rat}^{\uparrow}$ rows along the displayed finite bundle membership. No completion object, quotient datum, regularity row, or metric structure enters the construction. □

Theorem 126.307 (StreamNameUp finite-window refinement transitivity)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let B_2, B_1, and B_0 be* ProbeBundle *windows. Suppose every certified unary observation carried by B_0 is an* InBundle *member of B_1, and every certified unary observation carried by B_1 is an* InBundle *member of B_2. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_2) \implies \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_0).$$

The row uses only ProbeBundle*,* InBundle*,* UnaryHistory*, and the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows carried by certified unary observations. It introduces no* $\mathsf{Real}^{\uparrow}$ *completion datum, quotient representative, regularity predicate, or metric row.*

Proof. First restrict the classifier over B_2 to the intermediate finite window B_1. The displayed inclusion from B_1 into B_2 supplies exactly the witness required by Definition 126.302, so the result is $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_1)$.

Next restrict the intermediate classifier over B_1 to B_0. The displayed inclusion from B_0 into B_1 again matches the premise of Definition 126.302.

Equivalently, for any certified unary observation in B_0, compose its InBundle witness into B_1 with the witness from B_1 into B_2, and retain the same pointwise $\mathsf{Rat}^{\uparrow}$ row. This construction never reads a $\mathsf{Real}^{\uparrow}$ completion, a quotient datum, or any host analytic structure. □

Theorem 126.308 (StreamNameUp finite-window common refinement export)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let B_L, B_R, and B be* ProbeBundle *windows. Suppose every certified unary observation carried by B_L is an* InBundle *member of B, and every certified unary observation carried by B_R is an* InBundle *member of B. Then*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B) \quad \Longrightarrow \quad \mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B_L) \wedge \mathsf{RatStream}$$

Thus a displayed common finite observation window restricts to both component windows and assembles the appended window consumed by finite-partition arguments.

Proof. Start with the classifier over the displayed common window B. Apply Definition 126.302 to the inclusion of B_L in B to obtain the left component classifier.

Apply the same restriction export to the inclusion of B_R in B. This gives the right component classifier over the same certified observation maps s, t.

Now apply Definition 126.305 to the two component classifiers. The assembly direction gives the classifier over $\mathsf{BAppend}(B_L, B_R)$.

Every row used in the construction remains a finite-window row: ProbeBundle membership, InBundle inclusions, pointwise $\mathsf{Rat}^{\uparrow}$ classifiers, hsame transport, and finite ledger rows. No completion object, metric row, quotient representative, regularity condition, or $\mathsf{Real}^{\uparrow}$ completeness datum is introduced. □

Theorem 126.309 (StreamNameUp common-refinement selected endpoint readback)**.** *Let s, t be certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps, and let B_L, B_R, B :* ProbeBundle*. Suppose every certified unary observation carried by B_L is an* InBundle *member of B, and every certified unary observation carried by B_R is an* InBundle *member of B. Assume*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, B).$$

Let n : Hist *be a selected certified unary observation in either component window, so that n is carried by B_L or by B_R, and suppose*

$$\mathsf{UnaryHistory}(n), \quad \mathsf{hsame}(s(n), \mathsf{E1}(a)), \quad \mathsf{hsame}(t(n), \mathsf{E1}(b))$$

for histories a, b : Hist*. Then the selected endpoint exposes exactly the six finite readback rows:*

1. $\mathsf{RatHistoryClassifier}(s(n), t(n))$.
2. *positive unary denominator rows for $s(n)$ and $t(n)$.*
3. *unary endpoint-shape rows for $s(n)$ and $t(n)$.*
4. *empty-endpoint exclusions for $s(n)$ and $t(n)$.*
5. *zero-headed endpoint exclusions for $s(n)$ and $t(n)$.*
6. *one-tail agreement for the displayed tails a and b.*

No RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *seal, metric row, quotient representative, or standard bridge is used.*

Proof. First restrict the common classifier over B to the relevant component window. Apply Definition 126.308. If the selected observation is carried by B_L, take the left component classifier; if it is carried by B_R, take the right component classifier.

Now apply Definition 126.27 to that component classifier, the displayed component membership of n, the unary witness for n, and the two one-extension endpoint displays. The theorem returns

the selected RatHistoryClassifier row, positive unary denominators, unary endpoint shape, empty exclusion, zero-headed exclusion, and one-tail agreement for a and b.

The construction has only restricted a finite ProbeBundle classifier and then read the selected $\mathsf{Rat}^{\uparrow}$ endpoint package. It therefore never invokes RegSeqRat regularity, a RealUp seal, metric data, quotient representatives, or standard-bridge structure. □

Theorem 126.310 (StreamNameUp empty finite-window vacuity)**.** *For certified observation maps* $s, t : \mathsf{Hist} \to \mathsf{Hist}$*,* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{Bnil})$ *holds. Equivalently, the public finite-window interface has a neutral empty observation boundary: it contributes no RatUp endpoint classifier rows and no finite-observation ledger token.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier empty vacuity`

Proof. Unfold Definition 126.21. It remains to show that every certified unary observation bundled in Bnil receives a RatUp point classifier.

Fix $n : \mathsf{Hist}$ together with $\mathsf{InBundle}(n, \mathsf{Bnil})$ and $\mathsf{UnaryHistory}(n)$. By Definition 6.1, Bnil has no membership constructors, and the Lean bundle inversion theorem BEDC.FKernel.Bundle.inBundle_nil_elim eliminates the displayed membership witness.

The desired point classifier follows from this contradiction. Hence the empty finite window is neutral: it imposes no endpoint RatUp classifier row and records no finite observation in the ledger. □

The empty-window certificate fit has ten fields: traditional target empty finite observation window; BEDC source $\mathsf{StreamName}^{\uparrow}$ plus ProbeBundle; carrier certified observation maps; classifier finite-window pointwise RatUp classification; stability vacuous; ledger empty; core theorem Definition 126.310; exactness no bundled observations; standard bridge empty finite prefix; status ProofTarget.

The certificate template has ten fields: traditional target certified countable rational-observation names; BEDC source $\mathsf{Rat}^{\uparrow}$ over BHist; carrier RatStreamNameCarrier; classifier RatStreamNameClassifier; stability obligations as the fields of Definition 126.13, the reindexing and mapped stream stability clauses from Definition 126.19, the composed reindexing stability law from Definition 126.20, the constant stream witness from Definition 126.48, constant reindexing classification from Definition 126.50, and constant-point exactness from Definition 126.55 and Definition 126.52; ledger finite observation index plus pointwise rational witnesses, and for a constant stream the hidden constant seed together with the observation index; core theorems Definition 126.13 and Definition 126.19 and Definition 126.20 and Definition 126.48 and Definition 126.50 and Definition 126.55 and Definition 126.52; exactness pointwise over the RatUp classifier; standard bridge ordinary rational streams; status ProofTarget.

Theorem 126.311 (StreamNameUp public interface export package)**.** *The public* $\mathsf{StreamName}^{\uparrow}$ *export over* BHist *is exactly the union of Definition 126.300 and Definition 126.301. Its exported countable-name rows are the carrier* RatStreamNameCarrier*, the classifier* RatStreamNameClassifier*, the pointwise RatUp carrier/classifier fields, the constant stream rows, reindexing and RatUp-preserving map stability, and unary reindexing composition. Its exported finite-window rows are* RatStreamNameFiniteWindowClassifier*, finite-window coverage/exhaustion, certified reindexing and point-map coverage, finite-window structural laws, the selected endpoint package, and finite-window stability fields, together with empty-window vacuity.*

No further rows are part of this public $\mathsf{StreamName}^{\uparrow}$ *package: it excludes RegSeqRat regularity, RealUp completion and completeness, metric completeness, arithmetic and order closure, and standard-bridge data.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNamePublicInterfaceExportPackage`

Proof. Apply Definition 126.300. It fixes the carrier and classifier as RatStreamNameCarrier and RatStreamNameClassifier and lists the pointwise RatUp carrier/classifier rows, constant stream rows, reindexing and RatUp-preserving map stability, and reindexing composition. These are precisely the countable-name rows of the public export.

Apply Definition 126.301. It adds RatStreamNameFiniteWindowClassifier, window restriction, coverage/exhaustion, certified reindexing and point-map coverage, the finite-window structural laws, selected endpoint package, stability rows, and the empty finite-window boundary. These are precisely the finite-window rows of the public export.

The two cited public theorems list all exported rows and both leave completion, regularity, metric, arithmetic/order, and bridge structure outside their claims. Repacking their rows therefore gives a public $\mathsf{StreamName}^{\uparrow}$ interface package, not a $\mathsf{Real}^{\uparrow}$ completion theorem or a RegSeqRat regularity theorem. □

Theorem 126.312 (StreamNameUp public L10 exit handoff)**.** *The public* $\mathsf{StreamName}^{\uparrow}$ *finite-window interface supplies exactly the countable-name observation row required by the L10 Real-and-Completion exit bundle. A* $\mathsf{Real}^{\uparrow}$ *consumer may read that row only as the StreamName face of the four-object route: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger and the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular readback must still be displayed before any terminal* $\mathsf{Real}^{\uparrow}$ *seal is consumed.*

Proof. Apply Definition 126.301 and Definition 126.311. They identify the public finite-window and countable-name rows exported by $\mathsf{StreamName}^{\uparrow}$ and leave dyadic tolerance, regularity, and Real completion outside the StreamName package.

Therefore the L10 exit bundle may use $\mathsf{StreamName}^{\uparrow}$ as its observation row, but the downstream Real read still factors through the separate $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ faces before the $\mathsf{Real}^{\uparrow}$ seal is visible. □

Theorem 126.313 (StreamNameUp public scoped dependency package)**.** *The public* $\mathsf{StreamName}^{\uparrow}$ *export has the following exact scoped dependency surface for downstream* RegSeqRat *and* $\mathsf{Real}^{\uparrow}$ *boundary theorems. It is scoped over precisely* BHist*,* UnaryHistory*,* hsame*,* RatHistoryCarrier*,* RatHistoryClassifier*,* RatStreamNameCarrier*,* RatStreamNameClassifier*,* ProbeBundle*,* InBundle*, and* RatStreamNameFiniteWindowClassifier*.*

Within that scope its exported rows are exactly the countable-name package, finite-window package, empty-window vacuity, constant-stream rows, reindexing and RatUp-preserving map stability, finite-window coverage/exhaustion, selected endpoint package, and finite-window stability fields. No RegSeqRat *regularity,* $\mathsf{Real}^{\uparrow}$ *seal,* $\mathsf{Real}^{\uparrow}$ *completeness, metric data, quotient representative, or standard bridge is part of this scoped export.*

Proof. Apply Definition 126.300. It fixes the history scope through BHist, UnaryHistory, and hsame, and it exports the pointwise $\mathsf{Rat}^{\uparrow}$ rows through RatHistoryCarrier and RatHistoryClassifier together with RatStreamNameCarrier and RatStreamNameClassifier.

The same countable-name interface supplies the constant stream rows, reindexing rows, RatUp-preserving map stability, and unary reindexing composition. These are the countable-name rows consumed downstream, and they do not introduce quotient representatives, metric data, or completion objects.

Apply Definition 126.301. It restricts the finite side to ProbeBundle, InBundle, and RatStreamNameFiniteWindow then supplies finite-window coverage/exhaustion, certified reindexing and point-map coverage, structural laws, the selected endpoint package, and finite-window stability fields.

Apply Definition 126.310 for the empty bundle boundary. Repacking the three cited sites gives exactly the dependency surface available to RegSeqRat and Real$^{\uparrow}$ boundary theorems: a public stream-name and finite-window package, with no regularity, seal, completeness, metric, quotient, or standard-bridge row added. □

Theorem 126.314 (StreamNameUp ordinary rational sequence bridge)**.** *The public* StreamName$^{\uparrow}$ *rows over* BHist *admit a conservative ordinary-sequence interpretation indexed by certified unary observations. In that interpretation, a stream is in* RatStreamNameCarrier *exactly when every indexed history lies in the pointwise* Rat$^{\uparrow}$ *carrier row, and two streams are related by* RatStreamNameClassifier *exactly when every indexed pair is related by the pointwise* Rat$^{\uparrow}$ *classifier row. The finite-window classifier* RatStreamNameFiniteWindowClassifier *is interpreted by the bundled finite prefix with the same pointwise classifier rows, with the empty prefix covered by the public vacuity law. Constant streams and certified unary reindexing commute with this interpretation, and finite-window restriction is the ordinary prefix restriction of the same indexed rational-history sequence.*

The interpretation is conservative: it adds no quotient, completion, metric, or Real$^{\uparrow}$ *completeness claim beyond the public* StreamName$^{\uparrow}$ *package.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameUp StdBridge`

Proof. Unpack Definition 126.1 and Definition 126.2. Their rows already describe an indexed family of rational histories together with the pointwise Rat$^{\uparrow}$ carrier and classifier obligations, so the ordinary-sequence carrier and classifier are obtained by reading those fields componentwise.

Apply Definition 126.300. It supplies the public carrier/classifier rows, constant streams, unary reindexing, RatUp preserving maps, and reindexing composition. These clauses give exactly the commutation laws for constants and certified unary reindexing under the ordinary-sequence reading.

Apply Definition 126.301. It supplies RatStreamNameFiniteWindowClassifier together with finite-window restriction, coverage/exhaustion, certified reindexing and point-map coverage, selected endpoints, and finite-window stability. The bundled finite prefix is therefore the ordinary prefix of the same indexed rational-history sequence, with the same pointwise classifier rows.

Apply Definition 126.310 for the empty prefix case. Finally apply Definition 126.311 to identify these countable-name and finite-window rows as the full public StreamName$^{\uparrow}$ package. Since that package explicitly excludes RegSeqRat regularity, Real$^{\uparrow}$ completion and completeness, metric completeness, arithmetic/order closure, and extra bridge structure, the interpretation is conservative. □

Theorem 126.315 (StreamNameUp scoped interface package)**.** *The scoped public package for* StreamName$^{\uparrow}$ *consumed by* RegSeqRat *and* Real$^{\uparrow}$ *is the union of Definition 126.300, Definition 126.301, Definition 126.311, and Definition 126.314. It presents the public carrier* RatStreamNameCarrier*, classifier* RatStreamNameClassifier*, finite-window classifier, constant stream rows, reindexing and RatUp-preserving map stability, finite-window stability, empty-window vacuity, and the conservative ordinary rational-sequence reading indexed by certified unary observations.*

This package does not include RegSeqRat regularity, Real$^{\uparrow}$ *completion or completeness, metric completeness, arithmetic or order closure, or machine-checked bridge data.*

Proof. Apply Definition 126.300. It fixes RatStreamNameCarrier and RatStreamNameClassifier and supplies the pointwise RatUp carrier/classifier fields, constant stream rows, reindexing and RatUp-preserving map stability, and unary reindexing composition.

Apply Definition 126.301. It adds RatStreamNameFiniteWindowClassifier, finite-window coverage/exhaustion, certified reindexing and point-map coverage, finite-window structural laws, the

selected endpoint package, finite-window stability fields, and the empty-window boundary. The empty case is the vacuity theorem Definition 126.310.

Apply Definition 126.311 to repack the countable-name and finite-window rows as the public export. Apply Definition 126.314 to read that export conservatively as ordinary rational-history sequences indexed by certified unary observations.

The same four sites state the negative boundary: no RegSeqRat regularity, no $\mathsf{Real}^{\uparrow}$ completion or completeness, no metric completeness, no arithmetic or order closure, and no machine-checked bridge data. Repacking exactly those rows establishes the scoped $\mathsf{StreamName}^{\uparrow}$ interface and no stronger bridge or completion claim. □

Theorem 126.316 (StreamNameUp RealUp finite-window seal boundary)**.** *A public* $\mathsf{StreamName}^{\uparrow}$ *package, together with finite-window classifier rows, constant and reindexing laws, and RatUp endpoint observations, supplies exactly the finite observation interface consumed by later* $\mathsf{Real}^{\uparrow}$ *and* RegSeqRat *seal rows. The interface consists of the* RatStreamNameCarrier *and* RatStreamNameClassifier *rows over* BHist*, the* RatStreamNameFiniteWindowClassifier *rows over certified finite bundles, the empty-window boundary, endpoint readbacks in* $\mathsf{Rat}^{\uparrow}$*, and the constant/reindexing stability rows.*

This boundary supplies no RegSeqRat regularity, RealUp completion, metric completeness, quotient carrier, arithmetic or order closure, or trichotomy.

Proof. Apply Definition 126.301. It provides the finite-window classifier rows, endpoint package, coverage/exhaustion, reindexing stability, and finite-window structural laws.

Apply Definition 126.303 for certified transport of those windows, and apply Definition 126.311 to repack the countable-name and finite-window rows as the public export.

Finally apply Definition 126.315. Its negative boundary is inherited unchanged, so the exported rows can be read by $\mathsf{Real}^{\uparrow}$ and RegSeqRat seal sites only as finite observations, not as regularity, completion, metric, quotient, or trichotomy data. □

Closure status for $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$**.**

Constructive story: A stream name is generated by a certified observation map from unary BHist indices to rational histories, so every accepted stream exposes, at each unary observation, a $\mathsf{Rat}^{\uparrow}$ carrier row for the selected endpoint. The carrier accepts exactly those observation maps with pointwise rational-history witnesses, and the finite-window surface accepts exactly bundled unary observations whose selected endpoints carry the corresponding pointwise $\mathsf{Rat}^{\uparrow}$ classifier; maps with no unary schedule, no rational endpoint witness, or no bundle membership row are excluded. Two stream names are classified when both endpoint streams are carried and every certified unary observation is related by the pointwise rational classifier, while finite windows restrict that same classifier to a displayed ProbeBundle rather than creating a second equality. The source specification is UnaryHistory plus $\mathsf{Rat}^{\uparrow}$ over BHist, the pattern specification records constant streams, empty-window vacuity, endpoint shape exclusions, one-tail readback, finite-window coverage and exhaustion, reindexing, RatUp-preserving point maps, and reindexing composition, and the ledger keeps the observation index, bundle membership, endpoint carrier, point classifier, and transport witness visible. The five name-certificate obligations come from the pointwise RatUp certificate: constant rational streams inhabit the carrier, reflexivity, symmetry, and transitivity are proved at each unary observation, and pointwise hsame transport repacks classified streams and windows as accepted rows. A stream packet h lies in the signature gap of a $\mathsf{StreamName}^{\uparrow}$ token p when the source-domain accepts its unary observation map, the signature relation pairs it with an answer stream and evidence ledger, and the token-introduction relation names that answer as p; unfolded, every finite observation selected by p reads the same rational endpoint and classifier ledger. The checked ordinary-sequence bridge reads the public countable name and finite windows as the corresponding rational sequence and finite prefix, but the chapter registers $\mathsf{StreamName}^{\uparrow}$ without adding regularity, real completion, metric completeness, arithmetic/order closure, quotient representatives, or any independent sequence carrier.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 126.311, Definition 126.314, and Definition 126.315 bind the mature paper scope: the public countable-name rows, finite-window rows, constant and reindexing laws, empty-window boundary, ordinary rational-sequence bridge, and the RegSeqRat/RealUp consumer interface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$, bridgeChecked)

126.19 Public obligation surface

Definition 126.317 (StreamNameUp public reindexing obligation)**.** *The public reindexing obligation for* $\mathsf{StreamName}^{\uparrow}$ *is the finite BEDC row package that, for every certified unary observation reindexer and every* ProbeBundle *window, transports the pointwise* $\mathsf{Rat}^{\uparrow}$ *rows of the public countable-name interface through the finite-window interface and records the resulting observation rows in the same* BHist *ledger. The obligation cites Definition 126.300, Definition 126.301, Definition 126.303, and Definition 126.304; it introduces no completion, metric, or quotient row.*

Theorem 126.318 (StreamNameUp public constant obligation)**.** *Every public constant* $\mathsf{StreamName}^{\uparrow}$ *packet is accepted by the countable-name interface and by every finite-window interface obtained from certified unary observations. Its visible rows are exactly the constant* $\mathsf{Rat}^{\uparrow}$ *seed row, the pointwise carrier/classifier rows, the empty-window boundary, and the finite ledger entries selected by the observation bundle.*

Proof. Apply Definition 126.300. It exports the constant stream witness together with the pointwise $\mathsf{Rat}^{\uparrow}$ carrier and classifier rows over certified unary observations.

Next apply Definition 126.301. A finite window only restricts those pointwise rows to the observations named by the bundle, while the empty-window boundary contributes the vacuous case.

Thus the public constant obligation is the same constant seed read through each selected observation row. No regularity witness, metric datum, completion endpoint, or quotient representative is present in the public packet. □

Theorem 126.319 (StreamNameUp public transport obligation)**.** *Let two certified* $\mathsf{StreamName}^{\uparrow}$ *observation maps be related by displayed* hsame *rows, and let the finite-window* Cont *routes and* Pkg *provenance rows be transported componentwise. Then every public finite-window classifier row for the first map transports to a public finite-window classifier row for the second map over the same certified unary observations.*

Proof. Use Definition 126.300 to read the public carrier and classifier rows as pointwise $\mathsf{Rat}^{\uparrow}$ rows over certified unary observations. The supplied hsame rows transport those pointwise rows.

Then use Definition 126.301 to restrict the transported pointwise rows to the selected ProbeBundle window. The transported Cont and Pkg rows preserve the same finite provenance route through the public interface.

The resulting packet is therefore a public finite-window classifier row for the second map. The construction does not add a completion or regularity row; it only repacks the transported public rows. □

Theorem 126.320 (StreamNameUp public finite-ledger obligation)**.** *For every public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet, the exported ledger is exactly the finite family of certified unary observation rows selected by its* ProbeBundle *together with the corresponding pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows. Reindexing, restriction, and composition do not expose any row outside that finite ledger.*

Proof. Start with Definition 126.301. It identifies the finite-window surface as the restriction of the public countable-name interface to the observations carried by the bundle.

For reindexing, apply Definition 126.303. The reindexed window reads pointwise rows only at observations whose images are members of the original bundle.

For composition, apply Definition 126.304. The two-step and one-step reindexing routes repack the same endpoint, classifier, hsame, and finite ledger rows over the target bundle. Hence no hidden observation source is exported. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier public ledger obligation`

Theorem 126.321 (StreamNameUp public RealUp handoff obligation)**.** *The public* $\mathsf{StreamName}^{\uparrow}$ *handoff to downstream* RegSeqRat *and* $\mathsf{Real}^{\uparrow}$ *consumers is the package consisting of the countable-name interface, the finite-window interface, the public reindexing obligation of Definition 126.317, the constant-stream obligation of Definition 126.318, the transport obligation of Definition 126.319, and the finite-ledger obligation of Definition 126.320. The handoff supplies certified unary observation rows and pointwise rational classifier rows only; it does not supply* RegSeqRat *regularity,* $\mathsf{Real}^{\uparrow}$ *completeness, or a standard bridge.*

Proof. The countable-name and finite-window interfaces provide the public carrier, classifier, pointwise rational rows, and bundle restriction rows. The reindexing obligation records how these rows move through certified unary observation maps.

The constant, transport, and finite-ledger obligations give the three public consumer cases: constant names, hsame/Cont transport, and finite-window ledger readback. Each case cites only the public StreamNameUp rows already listed above.

Downstream RegSeqRat and $\mathsf{Real}^{\uparrow}$ chapters may therefore consume a stable stream-name observation surface, but any regular Cauchy condition, completion witness, or standard bridge must be supplied in the downstream chapter rather than by this handoff. □

Theorem 126.322 (StreamNameUp finite-window schedule exhaustion)**.** *Any downstream finite-window request whose rows consist of a public* $\mathsf{StreamName}^{\uparrow}$ *observation map, certified* UnaryHistory *indices, a* ProbeBundle *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *endpoint rows, and* RegSeqRat *or* $\mathsf{Real}^{\uparrow}$ *consumer provenance is exhausted by the public finite-window interface of Definition 126.301, the public reindexing obligation of Definition 126.317, the transport obligation of Definition 126.319, the finite ledger of Definition 126.320, and the handoff boundary of Definition 126.321. The request introduces no additional* RegSeqRat *regularity row,* $\mathsf{Real}^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or observation source beyond that union.*

Proof. Read the carrier and classifier through Definition 126.301. The public observation map and certified UnaryHistory indices determine the displayed pointwise $\mathsf{Rat}^{\uparrow}$ rows, while the ProbeBundle schedule restricts those rows to the requested finite window.

Next apply Definition 126.317. It repacks the same scheduled rows after any certified unary reindexing, so the displayed bundle is a restriction and reindexing of the public countable-name surface rather than a separate request for stream data.

Use Definition 126.319 for the pointwise rational endpoint rows. The supplied hsame, Cont, and Pkg rows transport the endpoint classifiers componentwise and preserve the same finite-window provenance.

Finally combine Definition 126.320 with Definition 126.321. The ledger identifies all exposed rows as scheduled public observation rows and pointwise rational classifiers, and the handoff theorem states that downstream RegSeqRat and $\mathsf{Real}^{\uparrow}$ consumers must supply their own regularity,

completion, quotient, and limit-selection data. Hence the finite-window request is exhausted by the listed public StreamNameUp obligations. □

Theorem 126.323 (StreamNameUp RegSeqRat denominator-source exhaustion)**.** *Let a downstream* RegSeqRat *finite-window consumer receive as input a public* StreamName$^{\uparrow}$ *finite-window request together with dyadic denominator rows. Then the consumer reads exactly the selected* RatHistoryClassifier *rows, certified* UnaryHistory *observation rows, finite* ProbeBundle *ledger,* InBundle *membership rows, displayed* hsame *comparisons,* Cont *routes,* Pkg *provenance, and the* DyadicRatCore$^{\uparrow}$ *denominator-ledger rows already exported by the dyadic real-phase source boundary. It reads no* RegSeqRat *regularity witness, seal classifier, completion datum, quotient representative, hidden limit selector, or host index equality.*

Proof. Start with the public real handoff of Definition 126.321. It exposes the countable-name and finite-window StreamNameUp rows, the certified unary observation surface, and the public pointwise rational classifier rows.

Next use Definition 126.322. The finite request is therefore exhausted by the displayed observation indices, probe bundle, bundle-membership rows, rational endpoint rows, hsame comparisons, continuation routes, and package provenance.

The RegSeqRat-facing handoff of Definition 126.79 identifies the same finite rows as the rows consumed by the downstream regular-sequence interface. The denominator side is supplied separately by Definition 291.18, which contributes only the dyadic denominator ledger exported by the real-phase source boundary.

Combining these two source boundaries gives the displayed row inventory. None of the cited boundaries exports a regularity witness, seal classifier, completion datum, quotient representative, hidden limit selector, or host index equality, so no such datum can be read by the finite-window consumer. □

Theorem 126.324 (StreamNameUp RegSeqRat window union exhaustion)**.** *Let two downstream finite-window requests over a common public* StreamName$^{\uparrow}$ *observation map be displayed by probe bundles B_1 and B_2. Suppose each request is exhausted by Definition 126.323. Then the combined request over the displayed bundle union is exhausted by the public StreamName finite-window interface, the two displayed* InBundle *membership families for B_1 and B_2, the pointwise* Rat$^{\uparrow}$ *classifier rows, the dyadic denominator ledger rows,* hsame*,* Cont*, and* Pkg *provenance. The union request exports no* RegSeqRat *regularity witness,* Real$^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. Start from the common public classifier supplied by Definition 126.301. It fixes the observation map, the certified UnaryHistory observation rows, and the pointwise Rat$^{\uparrow}$ classifier rows before either downstream finite request is chosen.

Apply Definition 126.322 separately to B_1 and to B_2. This gives two finite schedules with their displayed InBundle membership families, hsame comparisons, Cont routes, and Pkg provenance, all over the same public StreamName observation surface.

Next use Definition 126.323 for each scheduled request. The first request contributes only its displayed observation rows and dyadic denominator ledger rows, and the second request contributes the same kind of displayed rows over its own membership family.

It remains to repack the two finite ledgers. For an observation in the displayed bundle union, case on whether the membership row comes from B_1 or from B_2. In the first case read the row from the first exhausted request; in the second case read it from the second exhausted request. If

a row is displayed by both bundles, the common public classifier and the displayed hsame rows identify the two readbacks as the same public StreamName observation row.

Thus every row in the combined finite request is one of the displayed public observation, membership, rational-classifier, denominator-ledger, continuation, or provenance rows already listed. Since neither component exhaustion theorem exports regularity, completion, quotient, limit-selection, or host index equality data, the bundle-union request exports none of those rows. □

Theorem 126.325 (StreamName finite-window terminal schedule idempotence)**.** *Let a public* StreamName$^{\uparrow}$ *observation map be read over certified* UnaryHistory *indices, and let a finite* ProbeBundle *schedule B display the downstream source request. Suppose a terminal downstream* RegSeqRat *or* Real$^{\uparrow}$ *consumer has source rows exactly the scheduled* RatStreamNameFiniteWindowClassifier *rows, the displayed* InBundle *membership rows for B, the pointwise* RatHistoryClassifier *rows, the dyadic denominator rows,* hsame*,* Cont*, and* Pkg *provenance. Then applying the same schedule boundary a second time exposes the same finite source projection.*

The second pass supplies no additional regularity witness, completion datum, quotient representative, hidden limit selector, or host index row.

Proof. Apply Definition 126.322 to the first pass through B. This identifies the public observation packet as the displayed finite schedule: certified UnaryHistory indices, the RatStreamNameFiniteWindowClassifier rows, membership in B, pointwise rational classifier rows, hsame, Cont, and Pkg provenance.

Attach the denominator side by Definition 126.323. The terminal consumer may therefore read the dyadic denominator boundary only as part of the displayed finite source ledger, not as an independent RegSeqRat regularity or Real$^{\uparrow}$ completion row.

Now use Definition 126.324 with $B_1 = B_2 = B$. The displayed bundle union is again B, so the second boundary request reads the same membership family, the same rational classifier rows, the same denominator rows, and the same continuation and provenance rows as the first request.

Finally apply Definition 126.320 and Definition 126.321. These obligations exclude non-displayed rows from the public StreamName handoff, so a repeated boundary cannot create a fresh regularity witness, completion datum, quotient representative, hidden limit selector, or host index row. The terminal source projection is therefore idempotent under the repeated finite schedule. □

Theorem 126.326 (StreamNameUp pointwise hsame reindexing stability)**.** *Let a public* StreamName$^{\uparrow}$ *observation map be read through certified* UnaryHistory *reindexers, and let a finite* ProbeBundle *window B display the source request. Suppose the source and target observation rows are related pointwise by the displayed* hsame *relation, and suppose the reindexing routes are carried by the same* Cont *and* Pkg *provenance rows. Then the public finite-window classifier packet transports to the reindexed window.*

The transported packet exposes only certified unary observation rows, pointwise Rat$^{\uparrow}$ *classifier rows,* InBundle *membership,* hsame*,* Cont*, and* Pkg *provenance. It supplies no* RegSeqRat *regularity,* Real$^{\uparrow}$ *completion, quotient representative, hidden limit selector, or host index equality.*

Proof. Start from the public reindexing obligation of Definition 126.317. It identifies the source and target observation rows through certified UnaryHistory reindexers and keeps the route inside the displayed Cont and Pkg provenance.

Apply Definition 126.319 to the pointwise hsame comparisons. The rational classifier row attached to each source observation is carried to the corresponding target observation without creating a host index equality or a quotient representative.

Project the finite rows by Definition 126.322. The reindexed window therefore has exactly the certified observation rows, InBundle membership rows, pointwise rational rows, continuation routes, and package provenance listed by the public window schedule.

Finally use Definition 126.320 and the union exhaustion of Definition 126.324 to rule out extra consumer rows. Since those ledgers contain no regularity, completion, quotient, limit-selection, or host-equality coordinate, the transported finite-window packet exposes none of that data. □

Theorem 126.327 (StreamNameUp public reindexing composition)**.** *Let r and s be certified* UnaryHistory *reindexers displayed over finite* ProbeBundle *windows for a public* StreamName$^{\uparrow}$ *observation map. Suppose the r leg transports every displayed public observation row by pointwise* hsame *through its recorded* Cont *route and* Pkg *provenance, and suppose the s leg does the same for the reindexed window. Then the composite reindexer transports the same finite-window classifier packet.*

The composite packet consists only of UnaryHistory *observation rows,* InBundle *membership, pointwise* Rat$^{\uparrow}$ *classifier rows,* hsame *comparisons, composed* Cont *provenance, and the displayed* Pkg *rows. It does not export* RegSeqRat *regularity,* Real$^{\uparrow}$ *completion, quotient representatives, selected limits, or host index equality.*

Proof. Apply the public reindexing obligation of Definition 126.317 to the r leg and then to the s leg. Each application reads only certified UnaryHistory observation rows, displayed membership, pointwise rational classifier rows, and the recorded Cont and Pkg provenance for that leg.

Use Definition 126.319 on the pointwise hsame rows supplied by both legs. The first application transports the source classifier row to the intermediate window, and the second transports the intermediate row to the target window. Composing the two displayed Cont routes gives the route used by the composite packet, while the Pkg rows remain exactly the provenance rows displayed by the two legs.

Project the finite target window by Definition 126.322. The projection lists precisely the UnaryHistory observation rows, InBundle membership, pointwise Rat$^{\uparrow}$ classifier rows, hsame comparisons, continuation routes, and package provenance exposed by the composite finite-window schedule.

Finally combine Definition 126.320 with the window-union exhaustion of Definition 126.324. Any row seen by a consumer of the composite window must already appear in one of the two displayed leg ledgers or in their finite union. Since those ledgers carry no regularity, completion, quotient, selected-limit, or host-index coordinate, the composite public packet exports none of those objects. □

Theorem 126.328 (StreamNameUp public RegSeqRat reindexing cover lock)**.** *Let a finite cover of public* StreamName$^{\uparrow}$ *windows feed downstream* RegSeqRat$^{\uparrow}$ *or finite* Real$^{\uparrow}$ *consumers. Suppose each cover member is carried by certified unary reindexing and by displayed* hsame*,* Cont*, and* Pkg *transport. Then the reindexed cover preserves the same union and overlap inventories: unary observation rows,* InBundle *membership, pointwise* Rat$^{\uparrow}$ *classifier rows,* DyadicRatCore$^{\uparrow}$ *denominator rows, and provenance.*

The cover lock exports no RegSeqRat$^{\uparrow}$ *regularity witness,* Real$^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. Begin with the reindexing composition theorem Definition 126.327. It shows that certified unary reindexing carries exactly the displayed public observation rows, membership rows, pointwise rational classifier rows, hsame comparisons, continuation routes, and package provenance.

Use Definition 126.324 to read the finite cover as one public union inventory. On intersections of cover members, apply Definition 126.329; the overlap rows are the common displayed StreamName observations, membership rows, pointwise rational rows, denominator rows, and provenance.

Finally apply Definition 126.323 to each downstream read. It accounts for the dyadic denominator rows consumed by regular-rational and finite real-facing windows, while the preceding union and intersection steps show that reindexing has added no regularity, completion, quotient, hidden selector, or host-equality coordinate. □

Theorem 126.329 (StreamNameUp RegSeqRat window intersection exhaustion)**.** *Let two downstream finite-window requests over a common public* $\mathsf{StreamName}^{\uparrow}$ *observation map be exhausted by Definition 126.323. Suppose the two requests both restrict to a certified common sub-bundle* K*. Then the common restricted request over* K *is exhausted by the public StreamName finite-window interface, the displayed* $\mathsf{InBundle}(-, K)$ *membership rows, the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, the dyadic denominator ledger rows,* hsame*,* Cont*, and* Pkg *provenance. The common restricted request exports no* RegSeqRat *regularity witness,* $\mathsf{Real}^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. Start with the two displayed downstream finite-window requests and restrict each one to the certified common sub-bundle K. By Definition 126.322, each restriction has only the public observation rows, $\mathsf{InBundle}(-, K)$ membership rows, pointwise rational classifier rows, hsame comparisons, Cont routes, and Pkg provenance inherited from the common $\mathsf{StreamName}^{\uparrow}$ observation surface.

Apply Definition 126.323 to each restricted side. The two reads may add the displayed dyadic denominator ledger rows, but they add no regularity witness, completion row, quotient representative, hidden limit selector, or host index equality.

It remains to identify the common row inventory. For an observation in K, membership is witnessed on both restricted requests by the displayed $\mathsf{InBundle}(-, K)$ row. Reading the row from either side gives the same public StreamName observation, because the observation map is common and the displayed hsame rows compare the same pointwise $\mathsf{Rat}^{\uparrow}$ classifier data.

Thus the common restricted request contains only the public finite-window rows, common membership rows, pointwise rational rows, denominator-ledger rows, continuation rows, and provenance rows listed in the statement. Since the cited component exhaustions export none of the excluded downstream data, the common subwindow exports none of it. □

Theorem 126.330 (StreamName pointwise classifier finite-window separation)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be certified rational StreamName observation maps, and let their public* NameCert *rows display the* BHist *carrier,* hsame *transport,* Cont *routes, and* Pkg *provenance required by the finite-window interface. If the pointwise StreamName classifier for* s *and* t *does not hold, then there is a certified unary index* n*, a finite* ProbeBundle *window* K *carrying* n*, and a finite-window* Pkg *row over* K *such that the selected endpoint packages* $s(n)$ *and* $t(n)$ *are not identified by the downstream* $\mathsf{RegSeqRat}/\mathsf{Real}^{\uparrow}$ *seal classifier read from that row.*

Conversely, if a certified finite-window package over some K *carries a certified unary index* n *and displays endpoint packages* $s(n)$ *and* $t(n)$ *which the* $\mathsf{RegSeqRat}/\mathsf{Real}^{\uparrow}$ *seal classifier does not identify, then the pointwise StreamName classifier for* s *and* t *fails. The separating package uses only the displayed* BHist *observations,* hsame*,* Cont*,* Pkg*,* InBundle*, pointwise* $\mathsf{Rat}^{\uparrow}$ *rows, and* NameCert *provenance.*

Proof. For the forward direction, restrict the failed pointwise classifier to a certified unary observation at which its displayed endpoint row is not identified. The finite-window interface supplies

a singleton ProbeBundle carrying that observation, and Definition 126.322 identifies the resulting packet as a public BHist window with the corresponding hsame, Cont, and Pkg rows.

Next pass the singleton packet through the common-window machinery. Apply Definition 126.308 to regard the singleton as a certified subwindow of any displayed comparison window, and use Definition 126.309 to read back the selected endpoint packages $s(n)$ and $t(n)$ from the same finite NameCert provenance row.

Finally use Definition 126.329 together with Definition 126.79. The handoff theorem says the downstream RegSeqRat/Real$^{\uparrow}$ read sees exactly the selected StreamName endpoint packages and the displayed denominator ledger; the intersection exhaustion prevents any hidden regularity, completion, quotient, or host-index row from identifying endpoints that the selected package separates.

For the reverse direction, start with the separating certified package over K. The selected InBundle(n, K) row and the UnaryHistory certificate restrict the public StreamName classifier to the endpoint comparison at n.

If the pointwise classifier for s and t held, the finite-window restriction theorem would transport that pointwise row into the same Pkg packet, and the RegSeqRat/RealUp handoff would read an identified seal endpoint there. This contradicts the displayed separating seal row, so the pointwise classifier fails. □

Theorem 126.331 (StreamName RegSeqRat RealUp observation coverage)**.** *Every finite-window handoff from public* StreamName$^{\uparrow}$ *to a downstream* RegSeqRat *consumer or finite-window* Real$^{\uparrow}$ *consumer is covered exactly by certified* UnaryHistory *observation rows,* ProbeBundle *scheduling rows,* InBundle *membership rows, pointwise* Rat$^{\uparrow}$ *classifier rows, displayed* hsame *comparisons,* Cont *routes,* Pkg *provenance, and the* DyadicRatCore$^{\uparrow}$ *denominator ledger exposed at the real-phase source boundary. The handoff exports no* RegSeqRat *regularity witness,* Real$^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. Apply Definition 126.321. It fixes the public observation surface for downstream RegSeqRat and finite-window Real$^{\uparrow}$ consumers, and it restricts the handoff to displayed StreamNameUp rows rather than to host streams.

Apply Definition 126.322. The finite request is then exhausted by the certified UnaryHistory observation rows, the ProbeBundle schedule, InBundle membership, pointwise Rat$^{\uparrow}$ classifier rows, displayed hsame comparisons, continuation routes, and package provenance.

For a RegSeqRat consumer, use Definition 126.323. It identifies the same public observation rows and adds only the dyadic denominator ledger needed by the regular-sequence interface.

Finally, Definition 291.18 supplies the source boundary for that denominator ledger. Thus the public observation rows, the dyadic denominator rows, and the downstream seal boundary form one finite BEDC source inventory. The exclusion clauses follow because none of the four cited boundaries exports regularity witnesses, completion rows, quotient representatives, hidden limit selectors, or host index equality. □

Theorem 126.332 (StreamName public denominator positive source fit)**.** *Every finite-window public* StreamName$^{\uparrow}$ *handoff accepted by Definition 126.331 has its selected denominator source read from the displayed* DyadicRatCore$^{\uparrow}$ *denominator ledger. The selected denominator rows are positive unary denominator rows in the* Rat$^{\uparrow}$ *classifier sense, are stable under the displayed* hsame*,* Cont*, and* Pkg *transport, and are exactly the source consumed by the downstream* RegSeqRat *or finite-window* Real$^{\uparrow}$ *read. The handoff introduces no regularity witness, completion datum, quotient representative, hidden limit selector, or host index equality.*

Proof. Begin with Definition 126.331. It confines the finite-window handoff to certified UnaryHistory observation rows, the finite ProbeBundle and InBundle rows, pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, displayed transport rows, provenance rows, and the $\mathsf{DyadicRatCore}^{\uparrow}$ denominator ledger.

Next apply Definition 126.323. The downstream regular-sequence read can therefore choose its denominator source only from the same displayed denominator ledger named by the public handoff.

Use Definition 291.18 for the dyadic source row. Its denominator boundary supplies positive unary denominator rows in the $\mathsf{Rat}^{\uparrow}$ classifier sense, and the displayed hsame, Cont, and Pkg rows transport those rows without changing the finite source inventory.

Repack the handoff with that denominator row as the consumed source. Since all cited boundaries are finite ledger statements and none exports regularity, completion, quotient, limit-selection, or host equality data, the selected positive denominator source is exactly the visible source available downstream. □

Theorem 126.333 (StreamName RegSeqRat public overlap lock)**.** *Let two public* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoffs feed downstream* RegSeqRat *consumers or finite-window* $\mathsf{Real}^{\uparrow}$ *consumers over the same observation map. If an observation row lies in the certified overlap of the two displayed* ProbeBundle *windows, then both consumers read the same public* $\mathsf{StreamName}^{\uparrow}$ *observation row, the same pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier row, the same dyadic denominator ledger row, and the same displayed* hsame*,* Cont*, and* Pkg *provenance.*

The overlap lock exposes no RegSeqRat *regularity witness, completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. First restrict both handoff requests to the certified common window. Apply Definition 126.329; each consumer read over the overlap is exhausted by the same public StreamName observation row, the same InBundle membership row, and the same pointwise classifier surface.

Next compare the two finite-window ledgers inside the combined display. Apply Definition 126.324. The union ledger has no extra consumer coordinate beyond the rows already exposed by the two windows, so an overlap row is read through one shared public bundle inventory.

Now identify the denominator source. Use Definition 126.323 together with Definition 126.332. The downstream denominator row is the displayed positive $\mathsf{DyadicRatCore}^{\uparrow}$ source row, and the same hsame, Cont, and Pkg rows carry it through both handoffs.

Finally apply Definition 126.331. Its exclusion clauses rule out regularity witnesses, completion rows, quotient representatives, hidden limit selectors, and host index equality. Hence the overlap determines only the visible public rows listed above. □

Theorem 126.334 (StreamNameUp RegSeqRat cover-refinement exhaustion)**.** *Let* $\mathcal{U} = \{B_i\}_{i \in I}$ *be a finite cover family of public* $\mathsf{StreamName}^{\uparrow}$ *windows over a common observation map. Suppose every* B_i *is exhausted by Definition 126.323, and let* $\mathcal{R}$ *be a certified common refinement cover read by a downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer. Then the refinement read is exhausted by the public StreamName finite-window interface, the displayed* InBundle *membership rows for the cover members and for* $\mathcal{R}$*, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *denominator ledger,* hsame*,* Cont*, and* Pkg *provenance. The refinement read exports no* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity witness,* $\mathsf{Real}^{\uparrow}$ *completion row, quotient representative, hidden limit selector, or host index equality.*

Proof. Begin with the public finite-window interface. It fixes the common $\mathsf{StreamName}^{\uparrow}$ observation map, the visible observation histories, the pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, and the public transport and provenance rows before the downstream cover refinement is read.

For each cover member B_i, apply Definition 126.323. The member read contributes only its displayed $\mathsf{InBundle}(-, B_i)$ rows, public observation rows, pointwise rational classifier rows, dyadic denominator ledger rows, hsame comparisons, Cont routes, and Pkg provenance.

Next pass through the finite cover by the union and intersection exhaustion theorems. Use Definition 126.324 to combine the member inventories, and use Definition 126.329 on overlap rows so that a refinement point covered by more than one B_i has one common public row inventory.

It remains to repack the certified common refinement. Case on the displayed $\mathsf{InBundle}$ membership row for a refinement element of $\mathcal{R}$. The certification names a cover member B_i containing that element, so the row is read from the exhausted inventory of B_i; on overlaps, the intersection exhaustion identifies the alternative reads by the common public classifier and the displayed hsame rows.

Thus every row consumed by the downstream $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ refinement read is one of the displayed public StreamName window rows, refinement-membership rows, pointwise rational rows, denominator-ledger rows, continuation rows, or provenance rows. Since the member, union, and intersection exhaustions export none of the excluded regularity, completion, quotient, limit-selection, or host-equality data, the common refinement cover exports none of those rows. □

Theorem 126.335 (StreamNameUp RegSeqRat cover-refinement transitivity)**.** *Let $\mathcal{U} = \{B_i\}_{i \in I}$ be a finite cover family of public $\mathsf{StreamName}^{\uparrow}$ windows over a common observation map, and suppose the cover is exhausted by Definition 126.334. Let $\mathcal{R}$ be a certified refinement cover whose downstream $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ read is exhausted by the same public rows, and let $\mathcal{S}$ be a second certified refinement cover refining $\mathcal{R}$. Then every downstream $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ read over $\mathcal{S}$ is exhausted by the original public StreamName finite-window interface, the displayed memberships*

$$\mathsf{InBundle}(-, B_i),$$
$$\mathsf{InBundle}(-, \mathcal{R}),$$
$$\mathsf{InBundle}(-, \mathcal{S}),$$

the pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ denominator ledger, hsame, Cont, and Pkg provenance.

This transitive refinement read exports no $\mathsf{RegSeqRat}^{\uparrow}$ regularity witness, no $\mathsf{Real}^{\uparrow}$ completion row, no quotient representative, no hidden limit selector, and no host index equality.

Proof. First apply Definition 126.334 to the $\mathcal{R}$ cover. The result identifies every read over $\mathcal{R}$ with the public $\mathsf{StreamName}^{\uparrow}$ finite-window interface, the member $\mathsf{InBundle}(-, B_i)$ rows, the refinement-membership rows for $\mathcal{R}$, the pointwise classifier rows, and the displayed denominator, transport, continuation, and provenance ledger.

Next compose the membership route for the second refinement. Use Definition 126.307 to send each $\mathcal{S}$ row through its certified $\mathcal{R}$ row and then through the containing public window B_i. This gives a single public route

$$\mathcal{S} \to \mathcal{R} \to \mathcal{U}$$

for the displayed $\mathsf{InBundle}$ evidence at all three cover levels.

Now transport the endpoint rows along that route. Apply Definition 126.266. The transported endpoint rows remain the same public observation rows, pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, $\mathsf{DyadicRatCore}^{\uparrow}$ denominator rows, hsame comparisons, Cont continuations, and Pkg provenance rows already named by the first refinement read.

Finally compare overlapping reads in the composed cover. Use Definition 126.324 to combine the visible inventories and Definition 126.329 to identify rows that enter through two cover members. These exhaustion results preserve the same exclusion clauses as the first refinement, so the downstream $\mathcal{S}$ read contains no regularity witness, completion row, quotient representative, hidden limit selector, or host index equality. □

Theorem 126.336 (StreamNameUp L10 architectural gate stability surface)**.** *The L10 countable-name gateway of* $\mathsf{StreamName}^{\uparrow}$ *is exactly the union of the public countable-name interface of Definition 126.300, the public finite-window interface of Definition 126.301, the public reindexing obligation of Definition 126.317, the public constant obligation of Definition 126.318, the public transport obligation of Definition 126.319, the public finite-ledger obligation of Definition 126.320, and the downstream* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *handoff boundary of Definition 126.321.*

Consequently every L10 consumer receives only the displayed $\mathsf{StreamName}^{\uparrow}$ *carrier rows, certified unary observation rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, finite* ProbeBundle *windows,* InBundle *membership, componentwise* hsame *comparisons, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The gateway supplies no* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity witness,* $\mathsf{Real}^{\uparrow}$ *completion row, quotient representative, host* Nat *stream, hidden limit selector, or standard bridge.*

Proof. Unpack the countable-name interface through Definition 126.300. Its carrier and classifier are the displayed RatStreamNameCarrier and RatStreamNameClassifier rows, read pointwise as $\mathsf{Rat}^{\uparrow}$ data over certified unary observations in BHist.

Restrict those rows through the public finite-window interface of Definition 126.301. A ProbeBundle selects only finitely many certified observations, and the finite-window classifier adds only bundle membership, endpoint, stability, and empty-window boundary rows already listed by that interface.

Next apply the reindexing, constant, transport, and finite-ledger obligations: Definition 126.317, Definition 126.318, Definition 126.319, and Definition 126.320. These clauses respectively repack certified unary reindexing, constant point rows, displayed hsame/Cont/Pkg transport, and the finite observation ledger without adding any off-ledger source.

Finally use the downstream handoff boundary Definition 126.321. It is precisely the interface consumed by later $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ chapters, and it states that regularity, completion, quotient, limit-selection, host-stream, and standard-bridge data must be supplied downstream rather than by $\mathsf{StreamName}^{\uparrow}$. Thus the L10 gateway is exactly the listed union and has the stated non-escape boundary. □

126.20 StreamName Finite-Window Regular Seal Non-Escape

Theorem 126.337 (StreamName finite-window regularity Real seal non-escape)**.** *Let W be a finite public* $\mathsf{StreamName}^{\uparrow}$ *window consumed by a* RegSeqRat *regularity row and then by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal read. If the handoff uses the displayed* ProbeBundle *membership rows, certified unary observations, pointwise rational classifier rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows, then the exported seal ledger consists only of the following finite data:*

1. *the displayed StreamName window W and its* InBundle *membership rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows used by the rational endpoint reads;*
3. *the* RegSeqRat *pointwise classifier row accepted over the same certified observations;*
4. *the componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows naming the packet.*

The exported ledger does not contain quotient stream equality, host sequence equality, a selected limit, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First project the public finite-window interface of Definition 126.301. It supplies exactly the displayed StreamName window, bundle membership, certified unary observations, pointwise rational classifier rows, transport rows, continuation routes, package provenance, and local certificate data.

Next apply the pointwise handoff of Definition 126.170. The RegSeqRat consumer receives only the pointwise StreamName rows over the finite bundle, so the regularity row is read as downstream classifier data rather than as a quotient or host sequence equality.

Finally use the seal boundary of Definition 126.142. It factors the finite-window $\mathsf{Real}^{\uparrow}$ read through the same StreamName, RegSeqRat, hsame, Cont, Pkg, and certificate rows.

Repacking these three routes gives one finite ledger. Since none of the cited public routes has a coordinate for selected limits, metric completeness, quotient stream equality, host sequence equality, or ambient $\mathsf{Real}^{\uparrow}$ completeness, none of that data is exported by the seal. □

Theorem 126.338 (StreamName finite-window Real seal route exhaustion)**.** *Let W be an accepted finite public* $\mathsf{StreamName}^{\uparrow}$ *window whose observations are consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *pointwise row and then by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal read. Then every public row visible to the Real seal consumer is exhausted by the StreamName window row,* ProbeBundle *and* InBundle *membership rows, certified* UnaryHistory *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The route has no coordinate for quotient stream equality, host sequence equality, a selected limit, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or an off-ledger seal source.*

Proof. Begin with Definition 126.132. It confines the accepted handoff to the displayed finite StreamName window, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ rows, Real seal boundary, transports, continuations, provenance, and local names.

Next apply Definition 126.356. The RegSeqRat readback and $\mathsf{DyadicRatCore}^{\uparrow}$ ledger are read on the same finite pullback surface as the StreamName window and Real seal row.

Use Definition 126.358 to pin the seal-facing consumer to that four-row surface. Then apply Definition 126.359 to project only the listed BHist, hsame, Cont, Pkg, and NameCert coordinates.

Finally combine this exhaustion with Definition 126.337. The non-escape theorem already rules out quotient stream equality, host sequence equality, selected limits, metric completeness, and ambient $\mathsf{Real}^{\uparrow}$ completeness, so the composed route exports no additional seal source. □

Theorem 126.339 (StreamName RegSeqRat Real budgeted common pullback)**.** *Let P and Q be finite observation budgets for two accepted* $\mathsf{StreamName}^{\uparrow}$ *windows consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and then by finite-window* $\mathsf{Real}^{\uparrow}$ *seal reads. Suppose their certified common budget displays the same StreamName window row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the same* $\mathsf{Real}^{\uparrow}$ *seal boundary on the overlap. Then both budgeted reads factor through one common finite pullback packet with only the displayed* BHist *observations,* ProbeBundle *and* InBundle *rows, certified unary observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Consequently changing from P to Q on an accepted common window cannot expose quotient streams, host equality, selected limits, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or a second Real seal source.*

Proof. First read each budgeted handoff through Definition 126.132. Both sides are already finite StreamName-to-RegSeqRat-to-Real packets with the same kinds of transport, continuation, provenance, and naming rows.

Apply Definition 126.356 on the certified overlap. The hypotheses identify the four visible sibling rows on the overlap: StreamName window, RegSeqRat readback, DyadicRatCore ledger, and Real seal boundary.

Next use Definition 126.358. The two budgeted seal reads therefore reach the same finite seal-facing surface once the four rows agree.

Finally apply Definition 126.359 and Definition 126.338. The common packet contains only the displayed finite BEDC rows, so neither budget can contribute quotient streams, host equality, selected limits, metric completeness, ambient completeness, or an alternate seal source. □

Theorem 126.340 (StreamName Real handoff completion non-escape)**.** *Every accepted finite-window* $\mathsf{Real}^{\uparrow}$ *seal read obtained from a* $\mathsf{StreamName}^{\uparrow}$ *handoff through* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *completes at the level of the displayed pullback packet. Its public completion-facing data are exactly the accepted StreamName window, RegSeqRat readback, DyadicRatCore observation ledger, Real seal boundary, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

No completion consumer can read a quotient stream, host sequence equality, selected limit, metric completeness proof, ambient $\mathsf{Real}^{\uparrow}$ *completeness principle, or independent completed-real carrier from that handoff.*

Proof. Start from the accepted finite-window Real seal read and apply Definition 126.338. This gives the complete list of visible rows available to the seal consumer before any completion-facing interpretation is made.

Now apply Definition 126.339 to any two finite budgets presenting the same accepted common window. The common pullback packet is unchanged by the budget presentation, so a completion consumer has a single finite StreamName-RegSeqRat-DyadicRatCore-Real route to inspect.

Use the seal boundary from Definition 126.142. The Real read repacks exactly the displayed StreamName point rows, accepted RegSeqRat rows, bundle rows, unary observations, continuations, transports, and provenance; the reverse packing does not introduce completion data.

The non-escape conclusion follows from Definition 126.337 and Definition 126.359. Their coordinate lists omit quotient streams, host sequence equality, selected limits, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ completeness, and independent completed-real carriers, so those objects cannot be read through the handoff. □

Theorem 126.341 (StreamName RegSeqRat Real tail-window exactness)**.** *Let W be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *tail window consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation readback, and a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then the seal-facing packet has exactly the displayed rows: the StreamName window W,* ProbeBundle *and* InBundle *membership, certified* UnaryHistory *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

There is no extra coordinate for quotient streams, host sequence equality, selected limits, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or an independent completed-real carrier.*

Proof. First apply Definition 126.338. It gives the complete list of public rows visible to a Real seal consumer from an accepted finite StreamName window.

Next use Definition 126.339. The tail-window presentation and any budgeted readback presentation factor through the same finite pullback packet when the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and Real seal boundary agree.

Finally apply Definition 126.340. Completion-facing use remains at the displayed pullback packet, so the exact packet is the finite row list already named above.

The exclusions follow because each cited route omits quotient streams, host sequence equality, selected limits, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ completeness, and independent completed-real carriers. Since the composition only repacks the same finite rows, it cannot create any of those objects. □

Theorem 126.342 (StreamName finite-window regular seal budget functoriality)**.** *Let $P \leq Q \leq R$ be accepted finite observation budgets presenting the same finite* $\mathsf{StreamName}^{\uparrow}$ *window W, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same displayed support rows:* ProbeBundle *and* InBundle *membership, certified* UnaryHistory *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. Then the seal-facing packet obtained by refining from P to Q and then from Q to R is the same finite public packet as the direct refinement from P to R.*

The common packet exports no quotient stream, selected limit, host sequence equality, ambient completeness, metric-completeness datum, countable-choice row, standard bridge row, or off-ledger $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First apply Definition 126.339 to the accepted overlaps $P \leq Q$ and $Q \leq R$. The hypotheses identify the four visible sibling rows on each overlap: the StreamName window, the RegSeqRat readback row, the DyadicRatCore ledger, and the Real seal boundary.

Next apply Definition 126.341. Once the four sibling rows and their displayed support rows agree, the seal-facing packet is exactly the finite row list named in the statement, so the two-step refinement has no separate coordinate left to remember the intermediate budget Q.

Finally use Definition 126.338. The direct refinement from P to R exhausts the same public rows and has no slot for quotient streams, selected limits, host sequence equality, ambient completeness, metric-completeness data, countable-choice rows, standard bridge rows, or off-ledger Real seal sources. Repacking the two certified overlaps therefore gives the same finite public packet as the direct refinement. □

Theorem 126.343 (StreamName finite-window regularity selector nonchoice)**.** *Let W be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window consumed through* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation readback, and a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity row visible at the seal is only a displayed downstream budget row in the finite packet. It cannot be re-entered as a hidden selector, host function, countable-choice witness, quotient stream representative, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate, or independent completed-real carrier.*

Equivalently, every seal-facing use of that regularity row factors through the public StreamName window, bundle and membership rows, certified unary observations, pointwise hsame *comparisons,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal boundary, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Proof. Start with the public finite-window interface of Definition 126.301. It exposes the accepted StreamName window as finite BEDC data: the displayed carrier row, bundle membership, certified unary observations, transport rows, continuation routes, package provenance, and local certificate names.

Next use Definition 126.170. The $\mathsf{RegSeqRat}^{\uparrow}$ consumer receives the same finite pointwise rows, so regularity is read downstream as classifier evidence over the displayed observations rather than as a host stream, selector function, or representative of a quotient stream.

Now apply Definition 126.338. The finite-window $\mathsf{Real}^{\uparrow}$ seal has no public coordinate beyond the listed StreamName, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, seal-boundary, transport, continuation, provenance, and certificate rows.

Finally compose this exhaustion with Definition 126.341. Tail-window exactness says the seal-facing packet is exactly that finite row list. Since the composed packet contains no slot for a selector, host function, countable-choice witness, quotient representative, selected limit, ambient completeness coordinate, or independent completed-real carrier, the regularity row cannot re-enter as any of those data. □

Theorem 126.344 (StreamName Real terminal support minimality)**.** *Let W be an accepted finite terminal* $\mathsf{StreamName}^{\uparrow}$ *window consumed through a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity row, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then every support row required to present the same seal-visible source is one of the displayed* BHist *observations,* ProbeBundle *rows,* InBundle *membership rows, certified* UnaryHistory *observations, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows.*

Deleting any one row from this displayed support prevents the same $\mathsf{Real}^{\uparrow}$ *seal-visible source from being presented by the finite StreamName-to-RegSeqRat-to-DyadicRatCore-to-Real route. No quotient stream equality, host sequence equality, selected limit, countable-choice row, metric completeness proof, ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate, standard bridge row, or replacement regularity selector can serve as a substitute support coordinate.*

Proof. First apply Definition 126.338. The seal consumer sees only the StreamName window row, the bundle and membership rows, the certified unary observations, the RegSeqRat readback row, the DyadicRatCore ledger, the Real seal boundary, componentwise transports, continuations, provenance, and local certificate rows.

Next apply Definition 126.341. It identifies the seal-facing packet with exactly that finite row list. Thus presenting the same seal-visible source requires each displayed support row that the packet consumes; removing one row breaks the finite packet rather than moving the obligation to an unlisted coordinate.

Finally use Definition 126.343. The regularity row cannot be re-entered as a hidden selector, host function, countable-choice witness, quotient representative, selected limit, ambient completeness coordinate, or independent completed-real carrier. Combining this with the exhaustion clauses also excludes metric completeness, standard bridge rows, host sequence equality, quotient stream equality, and off-ledger seal sources as substitutes.

The remaining presentation is therefore support-row exact: the same $\mathsf{Real}^{\uparrow}$ seal-visible source is available precisely through the displayed finite BEDC support rows, and deletion of any required displayed row leaves no admissible replacement coordinate inside the StreamName-to-RegSeqRat-to-DyadicRatCore-to-Real route. □

Theorem 126.345 (StreamName finite-window regular seal terminal route)**.** *Let W be an accepted finite terminal* $\mathsf{StreamName}^{\uparrow}$ *window consumed through* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation readback, and a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then the terminal public route consumed by the* $\mathsf{Real}^{\uparrow}$ *seal is the four-face packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist *observations,* ProbeBundle *rows,* InBundle *membership rows, certified* UnaryHistory *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance rows, and local* NameCert *support rows.*

This route is invariant under accepted budget refinement. It has no coordinate for quotient stream equality, host sequence equality, a selected limit, countable-choice row, metric-completeness datum, standard bridge row, ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate, hidden regularity selector, off-ledger seal source, or independent completed-real carrier.*

Proof. First apply Definition 126.338. It supplies the full row inventory available to the finite-window $\mathsf{Real}^{\uparrow}$ seal consumer: the StreamName window row, bundle and membership rows, unary observations, RegSeqRat readback, DyadicRatCore ledger, Real seal boundary, transports, continuations, provenance, and local certificates.

Next apply Definition 126.341. This identifies the seal-facing inventory with the four visible faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ plus exactly the displayed support rows, so the terminal route is a positive packet rather than only an exclusion list.

The refinement clause follows from Definition 126.342. Accepted refinements compose through the same finite public packet, and the direct refinement sees no additional coordinate.

Finally use Definition 126.343 and Definition 126.344. The selector theorem rules out re-entry through hidden choice, quotient, host, limit, completion, bridge, or off-ledger seal data, while support minimality says the displayed local support rows are the rows actually consumed by the terminal packet. Combining these clauses gives the stated terminal route and its exclusions. □

126.21 StreamName Lattice Dependency

The finite-window $\mathsf{StreamName}^{\uparrow}$ package is consumed by the $\mathsf{RegularCauchyName}^{\uparrow}$ certificate of chapter 371. Its public rows supply the scheduled window, bundle membership, certified unary observations, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ classifier data, transport routes, package provenance, and local NameCert rows that the regular Cauchy name packet reads before exposing a real-name seal.

This edge is the L10 scheduled finite-window handoff from $\mathsf{StreamName}^{\uparrow}$ into the $\mathsf{RegularCauchyName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ chain. The handoff is recorded before the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ seal rows, so the later consumer can cite the StreamName window surface without importing quotient stream equality, host sequence equality, selected limits, or ambient completeness.

Theorem 126.346 (StreamName RatUp to RegSeqRat lattice source)**.** *Let W be an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *row and then by an accepted* $\mathsf{Real}^{\uparrow}$ *seal row. Then every gateway read of W first exposes its point observations as* $\mathsf{Rat}^{\uparrow}$ *carrier and classifier rows: the carrier rows are the pointwise* RatHistoryCarrier *witnesses of Definition 126.1, and the classifier rows are the pointwise* RatHistoryClassifier *witnesses of Definition 126.2. The* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer may read those same point rows only through the* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *certificate surfaces of chapter 37, chapter 301, and chapter 38.*

Consequently the downstream lattice edge is sourced by RatUp point rows before any regular-sequence or real-seal row is exposed. The edge exports no quotient stream equality, host sequence equality, selected limit, host real equality, or ambient completeness datum.

Proof. Project the accepted StreamName carrier first. Definitions Definition 126.1 and Definition 126.2 say exactly that a StreamName window reads certified unary observations pointwise as RatHistoryCarrier and RatHistoryClassifier rows. Those are the RatUp carrier and classifier rows named by chapter 37.

Next apply the pointwise handoff theorems in this StreamName chapter. The package theorem Definition 126.170 sends the finite window to $\mathsf{RegSeqRat}^{\uparrow}$ only through the StreamName carrier rows, the finite-window classifier row, certified unary observations, membership rows, and pointwise hsame comparisons. The exhaustion theorem Definition 126.100 identifies those rows with the same pointwise RatUp observations before any regularity or seal-facing datum is read.

Now pass through the displayed downstream certificates. The $\mathsf{RegSeqRat}^{\uparrow}$ row is therefore a consumer of the same point rows through chapter 301, and the $\mathsf{Real}^{\uparrow}$ seal row reads the resulting handoff through chapter 38. The carrier source remains the RatUp point surface; neither consumer introduces a second source for the finite window.

Finally apply the L10 gateway factorization of Definition 126.347. Its route sends the already exposed StreamName point rows through the $\mathsf{RegSeqRat}^{\uparrow}$ regular source row, dyadic ledger, finite tail witness, finite approximation row, and $\mathsf{Real}^{\uparrow}$ seal row. Its boundary clause excludes quotient stream equality, host sequence equality, selected limits, host real equality, and ambient completeness from the gateway source. □

Theorem 126.347 (StreamName L10 gateway factorization)**.** *Let W be an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by accepted* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchyName}^{\uparrow}$, $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$, $\mathsf{FiniteCauchyApproximation}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. Then every accepted L10 read of W factors through one finite displayed route:*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window rows} \longrightarrow \textit{unary observations} \longrightarrow \mathsf{ProbeBundle/InBundle}\ \textit{ledger} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{regular sour}$$
$$\longrightarrow \textit{dyadic observation ledger} \longrightarrow \textit{finite tail witness} \longrightarrow \textit{finite approximation error row} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal row.}$$

The route is mediated only by the displayed hsame *transports,* Cont *continuations,* Pkg *provenance, and local* NameCert *rows of the consumed packets. It exports no quotient stream equality, selected limit, host real equality, or ambient completeness principle.*

Proof. First build the shared finite-window spine. The StreamName window rows, unary observations, and ProbeBundle/InBundle ledger are the public surface of the accepted $\mathsf{StreamName}^{\uparrow}$ packet, and the $\mathsf{RegSeqRat}^{\uparrow}$ row reads that same surface through the regular source coordinate.

Next compose the sibling handoffs. The finite-window diagonal fusion of Definition 126.348 identifies the common route through the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$, $\mathsf{FiniteCauchyApproximation}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows. The real regular-sequence handoff of Definition 126.79 fixes the same window before the real-name seal is exposed.

The remaining coordinates are supplied by the cited consumer chapters. The $\mathsf{RegularCauchyName}^{\uparrow}$ chapter reads the regular source row, the $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ chapter supplies the finite tail witness, and the $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ chapter supplies the dyadic observation ledger and finite approximation error row. The $\mathsf{Real}^{\uparrow}$ chapter receives only the resulting seal-facing finite route.

Coordinate exhaustion gives the boundary clause. None of the displayed rows is a quotient stream, a limit selector, a host real equality witness, or an ambient completeness object, and the transport and continuation rows only replay the listed finite coordinates. □

Theorem 126.348 (StreamName finite-window diagonal fusion)**.** *Let W be an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed simultaneously by an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *row, an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *packet, and an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Then the three consumers determine one shared finite observation route into the* $\mathsf{Real}^{\uparrow}$ *seal: the window rows of W, the regular source row, the dyadic ledger, the selected tail witness, and the finite approximation error row agree through the displayed* hsame *transports and the displayed* Cont *routes.*

Equivalently, every $\mathsf{Real}^{\uparrow}$ *seal-facing read factors through the common route*

$$\mathsf{StreamName}^{\uparrow} \xrightarrow{\mathsf{hsame},\mathsf{Cont}} \mathsf{RegSeqRat}^{\uparrow} \xrightarrow{\mathsf{hsame},\mathsf{Cont}} \mathsf{FiniteTailDiagonalSeal}^{\uparrow} \xrightarrow{\mathsf{hsame},\mathsf{Cont}} \mathsf{FiniteCauchyApproximation}^{\uparrow} \xrightarrow{\mathsf{hsam}}$$

The route exports only finite window rows, the accepted regular source row, dyadic observation ledgers, the selected tail witness, finite approximation error data, componentwise transport, continuation replay, package provenance, and local naming. It does not assert quotient stream equality, selected limits, host real equality, or ambient completeness.

Proof. Start from the accepted $\mathsf{StreamName}^{\uparrow}$ finite-window packet. Its public rows supply the scheduled finite window, bundle membership, unary observations, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ classifier data, componentwise hsame transports, and displayed Cont routes.

The $\mathsf{RegSeqRat}^{\uparrow}$ consumer reads those rows through chapter 371. This fixes the regular source row on the same finite window before any real-seal row is exposed.

Next use chapter 559. The accepted $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ packet reads the same finite window, the same regular source row, and the selected tail witness before its $\mathsf{Real}^{\uparrow}$ seal handoff.

Finally use chapter 601. The accepted $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ packet reads the same source and window together with the dyadic observation ledger and finite error row. Its handoff therefore meets the finite-tail route on the displayed hsame and Cont rows.

Coordinate exhaustion gives the exclusion clause. None of the three accepted consumers contains a coordinate for quotient stream equality, a selected limit, host real equality, or ambient completeness, so the fused route cannot export any of those endpoints. □

Theorem 126.349 (StreamName dyadic RegSeqRat Real pullback exactness)**.** *Let W be an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by accepted* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. Then the pullback source of the accepted read is the same whether the consumer reads through the StreamName point rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular source row, or the* $\mathsf{Real}^{\uparrow}$ *seal row.*

Equivalently, the four visible routes agree through the displayed BHist *observations,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows of chapter 291, chapter 301, and chapter 38. The common pullback exports no quotient stream equality, selected limit, host real equality, or ambient completeness principle.*

Proof. First identify the source rows. Apply Definition 126.346 to read the accepted StreamName finite window as pointwise carrier and classifier rows before the regular-sequence or real-seal consumer is exposed.

Next factor the L10 route. By Definition 126.347, every accepted L10 read passes through the StreamName window rows, unary observations, bundle ledger, $\mathsf{RegSeqRat}^{\uparrow}$ regular source row, dyadic observation ledger, finite tail witness, finite approximation row, and $\mathsf{Real}^{\uparrow}$ seal row.

Now fuse the finite windows. Apply Definition 126.348 to identify the shared route into the $\mathsf{Real}^{\uparrow}$ seal through the displayed hsame transports and Cont routes.

Project the four sibling rows. The StreamName point rows, dyadic observation ledger, RegSeqRat regular source row, and RealUp seal row all read the same displayed window, transport, route, provenance, and local naming coordinates. Coordinate exhaustion then gives the pullback exactness claim and excludes quotient stream equality, selected limits, host real equality, and ambient completeness from the common source. □

Theorem 126.350 (StreamName budgeted L10 pullback exactness)**.** *Let W be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *packet consumed through accepted* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$,

and $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *rows. Then every consumer-visible route out of* W *factors through one displayed finite packet consisting only of* BHist *observations,* $\mathsf{ProbeBundle}$ *rows,* $\mathsf{InBundle}$ *rows, certified unary observations, dyadic ledger rows, regular-source rows, real-seal rows, budget-limiter request, cap, and window rows, tail-budget service rows, displayed* hsame *transports, displayed* Cont *continuations,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows.*

The common packet is the pullback source for the StreamName point route, the $\mathsf{DyadicRatCore}^{\uparrow}$ *observation route, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular route, the* $\mathsf{Real}^{\uparrow}$ *seal route, the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *service route, and the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *tail-service route. It exports no quotient stream equality, host sequence equality, selected limit, countable-choice selector, host real equality, ambient completeness principle, or alternate seal source.*

Proof. Start with the unbudgeted L10 pullback. Theorem 126.349 identifies one common source for the StreamName point rows, the dyadic ledger, the regular source row, and the real-seal row through the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ coordinates.

Next attach the finite budget route. Theorem 126.391 sends every accepted StreamName budget handoff through the sibling $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ and $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ chapter surfaces before the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal rows are consumed.

Now use the budget chapters to fix the visible service rows. Theorem 903.23 contributes the request, cap, and window service triad, and Theorem 906.3 orders the regular source, tail threshold, observation limiter, finite StreamName window, dyadic ledger, readback, and seal as one finite service route.

The displayed rows therefore form a single pullback packet for all six routes named in the statement. Coordinate exhaustion gives the boundary clause: none of the participating packets has a coordinate for quotient stream equality, host sequence equality, selected limits, countable-choice selection, host real equality, ambient completeness, or a second seal source, so none can be exported by the composed route. □

Theorem 126.351 (StreamName L10 four-step source lattice)**.** *Every accepted Phase Real and Completion consumer of a finite* $\mathsf{StreamName}^{\uparrow}$ *packet factors through exactly the ordered source faces*

$$\mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{StreamName}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{Real}^{\uparrow}.$$

The factorization uses only the displayed BHist *observations,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows supplied by the four packet surfaces of chapter 291, this* $\mathsf{StreamName}^{\uparrow}$ *chapter, chapter 301, and chapter 38. It exports no quotient stream equality, host sequence equality, selected limit, countable-choice selector, host real equality, ambient completeness, arithmetic package, order package, or metric-completeness row.*

Proof. First read the unbudgeted four-face pullback. Theorem 126.349 identifies the common source of the StreamName point route, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ regular source row, and the $\mathsf{Real}^{\uparrow}$ seal row through the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ coordinates.

Next impose the accepted L10 consumer boundary. Theorem 126.350 says that the budgeted Phase Real route and the Completion-facing tail route still read the same finite packet before any seal-facing row is consumed. These added service rows do not introduce a second source for the StreamName packet.

The named source faces are then fixed by the local certificates. The $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ NameCert chapters provide the only displayed rows available at the dyadic ledger, regular-source, and real-seal faces, and the current $\mathsf{StreamName}^{\uparrow}$ chapter provides the finite-window face between them.

Coordinate exhaustion gives both exact ordering and the exclusion clause. The participating packets contain no coordinate for quotient stream equality, host sequence equality, selected limits, countable-choice selection, host real equality, ambient completeness, arithmetic packages, order packages, or metric-completeness rows; hence every accepted Phase Real and Completion consumer factors through exactly the four listed faces and exports none of those objects. □

126.22 StreamName RegularCauchyName Lattice Link

Theorem 126.352 (StreamName scheduled-window RegularCauchyName link)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule consumed by* $\mathsf{RegularCauchyName}^{\uparrow}$ *is read as the scheduled-window sibling route of chapter 371. The route carries the displayed window rows, certified unary observations, pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, transport data, continuation data, package provenance, and local naming rows into the regular Cauchy name packet. It exports no host sequence, quotient-stream equality, selected limit, independent real carrier, or ambient completeness coordinate.*

Proof. Start with the finite-window rows already displayed in the $\mathsf{StreamName}^{\uparrow}$ packet. The public interface and lattice dependency rows expose scheduled windows, bundle membership, certified unary observations, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ classifier data, componentwise hsame transport, displayed Cont routes, package provenance, and local naming.

The $\mathsf{RegularCauchyName}^{\uparrow}$ handoff of chapter 371 consumes exactly that scheduled-window surface before exposing its dyadic-radius row, regularity ledger, and $\mathsf{Real}^{\uparrow}$ seal. Hence the StreamName schedule is not a free-floating kernel row; it is the window sibling route through which the regular Cauchy name reads its source observations.

The non-escape clause is coordinate exhaustion. Neither the StreamName finite-window package nor the RegularCauchyName handoff contains a host sequence, quotient-stream equality, selected limit, independent real carrier, or ambient completeness coordinate, so the routed lattice link cannot export one. □

Theorem 126.353 (StreamName real-seal lattice route)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule consumed by* $\mathsf{RegularCauchyName}^{\uparrow}$ *reaches the* $\mathsf{Real}^{\uparrow}$ *seal only through the displayed route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window rows} \longrightarrow \mathsf{RegularCauchyName}^{\uparrow}\ \textit{schedule, radius, ledger, and seal rows} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{regul}$$

The $\mathsf{RegularCauchyName}^{\uparrow}$ *segment is the schedule-and-radius packet of chapter 371, the* $\mathsf{RegSeqRat}^{\uparrow}$ *segment is the regular source handoff of chapter 301, and the terminal seal is the real-facing packet of chapter 38. The route exports no quotient stream equality, selected limit, host sequence equality, host real equality, or ambient completeness coordinate.*

Proof. Project the StreamName-to-RegularCauchyName lattice edge of Definition 126.352. It identifies the accepted finite-window schedule as the only surface through which $\mathsf{RegularCauchyName}^{\uparrow}$ reads the source observations, together with the displayed certified unary observations, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ classifier rows, transport rows, continuation rows, package provenance, and local naming data.

The $\mathsf{RegularCauchyName}^{\uparrow}$ packet then exposes the dyadic-radius row, regularity ledger, and real-seal-facing row named in chapter 371. The regular source information is the same finite-window $\mathsf{RegSeqRat}^{\uparrow}$ handoff recorded in chapter 301, so the route cannot bypass the regular rational source rows before reaching the real-facing seal.

Finally, the terminal consumer is the $\mathsf{Real}^{\uparrow}$ seal row of chapter 38. Coordinate exhaustion now gives the non-escape clause: none of the displayed packets contains a quotient stream equality, selected limit, host sequence equality, host real equality, or ambient completeness coordinate, and therefore no such coordinate is exported by their composite route. □

Theorem 126.354 (StreamName pointwise reindexing RegularCauchyName route)**.** *Let a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule be reindexed pointwise by unary observation rows and transported componentwise by displayed* hsame *rows, as in Definition 126.3 and Definition 126.8. Then every accepted* $\mathsf{RegularCauchyName}^{\uparrow}$ *consumer reads the reindexed schedule only through the scheduled-window route of Definition 126.352, and the route to the* $\mathsf{Real}^{\uparrow}$ *seal is exactly the route of Definition 126.353. The displayed rows are precisely the* BHist *observation rows,* UnaryHistory *certificates, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, local* NameCert *rows, pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. The consumer exports no quotient stream equality, host sequence equality, selected limit, host real equality, or ambient completeness coordinate.*

Proof. Start with the public finite-window $\mathsf{StreamName}^{\uparrow}$ schedule and its unary reindexing row. The pointwise carrier transport theorem Definition 126.3 carries each certified unary observation along its displayed hsame row, while Definition 126.8 repacks the transported observations as the finite-window classifier surface read by the reindexed schedule.

Now apply Definition 126.352. It forces every accepted $\mathsf{RegularCauchyName}^{\uparrow}$ consumer to read the transported schedule through the same scheduled-window sibling route, so the only available data are the BHist rows, UnaryHistory certificates, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ classifier rows, displayed hsame transports, Cont routes, Pkg provenance, and local NameCert rows.

Finally compose with Definition 126.353. The seal read reaches $\mathsf{Real}^{\uparrow}$ only after the transported StreamName window has passed through the RegularCauchyName schedule, radius, ledger, and seal rows. Coordinate exhaustion gives the non-escape clause: none of these displayed rows contains quotient stream equality, host sequence equality, a selected limit, host real equality, or ambient completeness data, so the reindexing route cannot export any such coordinate. □

126.23 StreamName RegSeqRat Real Lattice Dependency

The $\mathsf{StreamName}^{\uparrow}$ finite-window packet is not an isolated kernel float. Its consumer route is the $\mathsf{RegSeqRat}^{\uparrow}$ readback surface of chapter 301, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger of chapter 291, and the $\mathsf{Real}^{\uparrow}$ seal surface of chapter 38; the lattice edge is carried through the child route below rather than by the hub file.

Theorem 126.355 (StreamName RegSeqRat Real lattice dependency)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and then by* $\mathsf{Real}^{\uparrow}$ *factors through the same visible sibling route. The route begins with the StreamName finite-window rows, passes through the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows of chapter 301, and ends at the* $\mathsf{Real}^{\uparrow}$ *seal rows of chapter 38. Along the entire route the only shared carrier coordinates are the displayed* BHist *observations, the componentwise* hsame *transports, the finite* Cont *continuation rows, the* Pkg *provenance rows, and the local* NameCert *rows naming the consumed packets.*

The dependency exports no quotient stream, no host real equality, no selected limit, and no ambient completeness principle. In particular, the $\mathsf{Real}^{\uparrow}$ *seal is read only as the downstream seal surface reached through the accepted finite StreamName and RegSeqRat packets.*

Proof. Start with the StreamName finite-window surface. By Definition 126.132, the handoff exposes the finite observation window, the pointwise $\mathsf{RegSeqRat}^{\uparrow}$ rows, the $\mathsf{Real}^{\uparrow}$ seal boundary, componentwise hsame transport, displayed Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows.

Next read the RegSeqRat sibling dependency. The pointwise handoff of Definition 126.170 identifies the rows sent to $\mathsf{RegSeqRat}^{\uparrow}$ with the same StreamName carrier rows, finite-window classifier rows, certified unary observations, membership rows, and pointwise hsame comparisons. Thus the RegSeqRat readback surface of chapter 301 is not a second carrier; it is the finite StreamName window read through the accepted pointwise packet.

Finally pass to the Real seal boundary. The factorization theorem Definition 126.142 says that a finite-window $\mathsf{Real}^{\uparrow}$ seal read arising from the StreamName-to-RegSeqRat handoff factors through the StreamName point rows, accepted $\mathsf{RegSeqRat}^{\uparrow}$ seal rows, bundle and membership rows, unary observations, finite Cont ledger, displayed hsame transports, and Pkg provenance. This is exactly the seal-facing surface cited in chapter 38.

Coordinate exhaustion gives the exclusion clause. None of the cited finite-window, pointwise, or seal-factorization rows contains a quotient stream, host real equality witness, selected limit, or ambient completeness coordinate, so composing them cannot export one. □

Theorem 126.356 (StreamName RegSeqRat Real dyadic-window pullback)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *factors through the same finite pullback surface with four visible sibling rows: the StreamName finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row of chapter 301, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger of chapter 291, and the* $\mathsf{Real}^{\uparrow}$ *seal row of chapter 38. The pullback coordinates are only the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* $\mathsf{NameCert}$ *rows already visible on those four sibling surfaces.*

Consequently a downstream consumer of the packet may read the dyadic-window ledger as a common finite route from StreamName windows through RegSeqRat readback into the Real seal, but it obtains no quotient stream, no host real equality, no selected limit, and no ambient completeness principle.

Proof. First build the window surface. By Definition 126.132, the accepted finite-window handoff exposes the StreamName observation window together with the pointwise $\mathsf{RegSeqRat}^{\uparrow}$ rows, the $\mathsf{Real}^{\uparrow}$ seal boundary, componentwise hsame transport, finite Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows.

Next read the regular-rational side. The pointwise handoff theorem Definition 126.170 identifies the $\mathsf{RegSeqRat}^{\uparrow}$ readback rows with the same StreamName carrier rows, finite-window classifier rows, certified unary observations, membership rows, and pointwise hsame comparisons. These are precisely the RegSeqRat rows named by chapter 301.

Now attach the dyadic ledger. The finite-window packet already exposes only visible observation rows before the RegSeqRat readback is consumed, and the dyadic observation surface of chapter 291 supplies the endpoint and radius ledger through the same displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ coordinates. Thus the StreamName window, RegSeqRat readback, and dyadic ledger occupy one finite pullback surface rather than three independent carriers.

Finally pass to the Real seal. The boundary factorization of Definition 126.142 says that the $\mathsf{Real}^{\uparrow}$ seal read arising from the StreamName-to-RegSeqRat handoff factors through the StreamName point rows, accepted $\mathsf{RegSeqRat}^{\uparrow}$ seal rows, bundle and membership rows, unary observations, finite Cont ledger, displayed hsame transports, and Pkg provenance. This is the Real-facing row cited in chapter 38.

Coordinate exhaustion proves the non-escape clause. The four sibling rows just composed contain no coordinate for a quotient stream, host real equality witness, selected limit, or ambient completeness operation, so the pullback route cannot export any of those objects to its downstream consumer. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRegseqratRealDyadicWindowPullback`

Theorem 126.357 (StreamName RegSeqRat Real window source triangle)**.** *For every accepted finite* StreamName$^{\uparrow}$ *window consumed by a* RegSeqRat$^{\uparrow}$ *row and then by a* Real$^{\uparrow}$ *seal row, the StreamName window row, the* RegSeqRat$^{\uparrow}$ *readback row, the* DyadicRatCore$^{\uparrow}$ *endpoint ledger, and the* Real$^{\uparrow}$ *seal boundary form one finite pullback triangle of sources. Every route among the StreamName, RegSeqRat, and Real-facing surfaces factors through the same* BHist *packet,* ProbeBundle *and* InBundle *membership rows,* UnaryHistory *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The triangle exports no quotient stream equality, no host sequence equality, no selected limit, no metric-completeness witness, and no ambient Real$^{\uparrow}$ *completeness principle.*

Proof. First expose the point source. By Definition 126.346, the accepted window is read through the StreamName row together with the rational and RegSeqRat point rows, bundle membership, unary observations, transport, continuation, provenance, and local naming coordinates.

Next use Definition 126.356. It identifies the shared finite dyadic window on which the StreamName window row, RegSeqRat readback row, DyadicRatCore endpoint ledger, and Real seal boundary are all projected. Thus a route from any one of the three surfaces to another must pass through that same finite packet.

Finally apply the local non-escape clauses in this StreamName lattice section. The cited pullback and consumer-exhaustion rows list all available coordinates, and none is a quotient stream equality, host sequence equality, selected limit, metric-completeness witness, or ambient RealUp completeness principle. Hence the source triangle closes only the finite BEDC rows named in the statement. □

Theorem 126.358 (StreamName RegSeqRat Real dyadic-pullback seal determinacy)**.** *Let two accepted* StreamName$^{\uparrow}$ *finite-window packets be consumed through the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* NameCert *rows. If the two packets induce the same visible StreamName finite-window row, the same* RegSeqRat$^{\uparrow}$ *readback row, the same* DyadicRatCore$^{\uparrow}$ *observation ledger, and the same* Real$^{\uparrow}$ *seal row, then every* Real$^{\uparrow}$ *seal consumer reads the same finite pullback surface.*

In particular, the seal-facing read is determined by those four visible rows. No quotient stream, host real equality, selected limit, or ambient completeness datum can supply an alternate Real$^{\uparrow}$ *seal source for either packet.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRegseqratRealDyadicPullbackSealDeterminacy`

Proof. First use Definition 126.355. It identifies the visible sibling route from the accepted StreamName finite-window rows through the RegSeqRat$^{\uparrow}$ readback rows and into the Real$^{\uparrow}$ seal rows using only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates.

Next apply Definition 126.356. Since the two packets have the same StreamName window row, RegSeqRat readback row, DyadicRatCore ledger, and Real seal row, the four-row finite pullback surface available to a downstream seal consumer is the same on both sides.

The Real seal route is pinned by Definition 126.142: any Real$^{\uparrow}$ seal read arising from the StreamName-to-RegSeqRat handoff factors through the displayed finite-window rows, accepted

RegSeqRat seal rows, bundle and membership rows, unary observations, finite Cont ledger, displayed hsame transports, and Pkg provenance. The RegSeqRat readback coordinate is the same coordinate described by Definition 126.170.

Thus every seal-facing consumer reaches one finite pullback surface. The cited rows contain no coordinate for quotient streams, host real equality witnesses, selected limits, or ambient completeness data, so none of those objects can act as a second source for the $\mathsf{Real}^{\uparrow}$ seal. □

Theorem 126.359 (StreamName RegSeqRat Real dyadic-pullback consumer exhaustion)**.** *Any downstream consumer citing the dyadic pullback route can project only the StreamName finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates on those rows. It cannot extract a quotient stream, host real equality, selected limit, or ambient completeness datum from the pullback.*

Proof. Apply Definition 126.356. The pullback route is exactly the four-row finite surface consisting of the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and Real seal, with only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates attached.

Use Definition 126.358. The Real seal consumer is determined by those four rows, so any cited pullback route must read the same finite surface rather than an external seal source.

Exhaust the listed coordinates. None of the four sibling rows or boundary coordinates contains a quotient stream, host real equality witness, selected limit, or ambient completeness datum, and a downstream consumer cannot recover data absent from the displayed pullback packet. □

Theorem 126.360 (StreamName RegSeqRat Real terminal pullback exactness)**.** *Every terminal* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet factors through exactly the shared finite-window surface with four visible sibling rows: the StreamName finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal row. The only shared coordinates available on that surface are the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* NameCert *rows already attached to those four rows.*

Consequently the terminal consumer has no alternate source through quotient streams, host real equality, selected limits, metric completeness, or ambient completeness. Its exact source is the displayed finite pullback packet.

Proof. First isolate the common surface. By Definition 126.356, the accepted finite-window packet is projected simultaneously to the StreamName finite-window row, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ seal row, with only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates.

Next pin the terminal seal read. Apply Definition 126.358. Once those four visible rows agree, every $\mathsf{Real}^{\uparrow}$ seal consumer reads the same finite pullback surface rather than a second seal-facing source.

Finally exhaust the consumer interface by Definition 126.359. A terminal consumer can project only the four rows and their displayed coordinates, so quotient streams, host real equality, selected limits, metric completeness, and ambient completeness have no coordinate from which an alternate source could be recovered. □

Theorem 126.361 (StreamName RegSeqRat Real uniform pullback non-escape)**.** *Let an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet be read through the uniform finite-window seal and then consumed by a downstream* $\mathsf{Real}^{\uparrow}$ *seal consumer. The consumer factors through the same four visible*

rows isolated in Definition 126.356: the StreamName finite-window row, the $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal row. Its only shared coordinates are the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* NameCert *rows attached to those four rows.*

Consequently the uniform finite-window seal and the dyadic pullback present a single finite BEDC carrier route to every such $\mathsf{Real}^{\uparrow}$ *seal consumer. No quotient stream, host real equality, selected limit, trichotomy row, or ambient completeness datum is exported by that route.*

Proof. First apply Definition 126.111. It places the accepted StreamName packet behind the uniform finite-window seal using the visible finite window, the displayed BHist observations, componentwise hsame transport, finite Cont rows, Pkg provenance, and local NameCert coordinates.

Next use Definition 126.356. The same sealed packet is read as the four-row pullback surface consisting of the StreamName finite-window row, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ seal row. Thus the uniform seal does not create a route parallel to the dyadic pullback; it feeds the same finite carrier surface.

Apply Definition 126.358 to pin the downstream $\mathsf{Real}^{\uparrow}$ seal consumer to those four visible rows. Since the seal-facing read is determined by the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and Real seal row, no second seal source can enter through an external equality, limit, or completeness coordinate.

Finally apply Definition 126.359. The consumer can project only the four rows and their displayed BHist, hsame, Cont, Pkg, and NameCert coordinates. The listed surface has no quotient stream, host real equality, selected limit, trichotomy row, or ambient completeness datum, so none of those objects escapes through the uniform pullback route. □

Theorem 126.362 (StreamName RegSeqRat Real route transitivity)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet whose visible StreamName row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and* $\mathsf{Real}^{\uparrow}$ *seal row agree with the dyadic pullback route and with the uniform finite-window seal route has a single composite* $\mathsf{Real}^{\uparrow}$ *seal consumer route. That route has only the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* NameCert *rows attached to those four sibling surfaces.*

The composite route exports no quotient stream, no host real equality, no selected limit, no trichotomy row, and no ambient completeness datum. Thus a downstream $\mathsf{Real}^{\uparrow}$ *seal consumer may cite one finite route from StreamName windows through* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *rows into the* $\mathsf{Real}^{\uparrow}$ *seal, rather than separately choosing among the local handoff surfaces.*

Proof. First identify the finite four-row surface. Apply Definition 126.356. It places the accepted StreamName packet, the dyadic observation ledger, the RegSeqRat readback row, and the Real seal row on one pullback surface whose coordinates are exactly the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next compare the uniform seal with that surface. By Definition 126.361, the uniform finite-window seal feeds the same StreamName, DyadicRatCore, RegSeqRat, and Real rows instead of producing a parallel consumer route. Hence the dyadic pullback and the uniform seal name the same finite carrier path for the downstream $\mathsf{Real}^{\uparrow}$ seal read.

Finally exhaust the consumer coordinates. Apply Definition 126.359. A downstream consumer can project only the four displayed sibling rows and their BHist, hsame, Cont, Pkg, and NameCert coordinates. Since those rows contain no quotient stream, host real equality, selected limit, trichotomy row, or ambient completeness datum, no external coordinate can escape through the composite seal route. □

Theorem 126.363 (StreamName Real observation-budget factorization)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by a* $\mathsf{RealObservationBudget}^{\uparrow}$ *precision request factors through the same visible route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

The consumer may use only the displayed BHist *observations, componentwise* hsame *transports, finite* Cont *routes,* Pkg *provenance, and local* NameCert *rows available on that route. The request supplies no quotient stream, no host equality, no hidden limit selection, and no ambient completeness coordinate.*

Proof. Start with the finite StreamName packet. By Definition 126.356, the packet is already read through the four visible sibling rows: StreamName finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal boundary.

Next attach the observation-budget consumer. The finite-route coverage theorem Definition 611.20 routes every accepted $\mathsf{RealObservationBudget}^{\uparrow}$ seal read through its precision request, finite window family, dyadic readback rows, regular-sequence handoff rows, and real seal rows. The consumer factorization theorem Definition 611.31 confines the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads to the same displayed hsame, Cont, Pkg, and local NameCert data.

Finally use Definition 126.359. The StreamName handoff exposes only the four finite rows and their listed BEDC coordinates, while the observation-budget theorems consume exactly those rows. No cited surface carries a quotient stream, host equality, hidden limit selection, or ambient completeness datum, so the precision request cannot introduce one. □

Theorem 126.364 (StreamName Real budget route determinacy)**.** *Let two accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets induce the same visible StreamName window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal row, and the same accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *precision-request route. Then every budget consumer reads the same finite BEDC route through the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance, and local* NameCert *coordinates.*

No quotient stream, host equality, selected limit, trichotomy row, or ambient completeness datum can provide an alternate budget source for either packet.

Proof. First use Definition 126.356. The shared visible StreamName window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal row place both accepted packets on the same four-row pullback surface.

Next attach the budget route. By Definition 126.363, any $\mathsf{RealObservationBudget}^{\uparrow}$ precision request consuming either packet factors through that StreamName-to-dyadic-to-regular-sequence-to-real route. The consumer route theorem Definition 611.31 confines the budget-facing $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads to the displayed hsame, Cont, Pkg, and local NameCert coordinates.

Apply Definition 126.358. Since the two packets agree on the four visible rows and on the accepted precision request route, the downstream seal-facing consumer has no second row from which to choose a different finite budget source.

Finally use consumer exhaustion for the pullback surface. The available consumer projections are exactly the listed BHist, hsame, Cont, Pkg, and NameCert coordinates, so quotient streams, host equalities, selected limits, trichotomy rows, and ambient completeness data cannot enter as alternate budget inputs. □

Theorem 126.365 (StreamName observation-budget CauchyLimitSeal compatibility)**.** *Let an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet be read both by a* $\mathsf{RealObservationBudget}^{\uparrow}$ *precision*

request and by a CauchyLimitSeal$^{\uparrow}$ *consumer. The two reads factor through the same visible four-row surface: the StreamName finite window, the* DyadicRatCore$^{\uparrow}$ *observation ledger, the* RegSeqRat$^{\uparrow}$ *readback, and the* Real$^{\uparrow}$ *seal row.*

The common route may project only the displayed BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance, and local* NameCert *coordinates on that finite pullback. It exports no quotient stream, host equality, selected limit, ambient completeness, metric-completion row, or standard bridge row.*

Proof. First read the precision-budget route. By Definition 126.363, every RealObservationBudget$^{\uparrow}$ request consumes the accepted StreamName packet through the displayed StreamName window, DyadicRatCore$^{\uparrow}$ ledger, RegSeqRat$^{\uparrow}$ readback, Real$^{\uparrow}$ seal, and the visible BHist, hsame, Cont, Pkg, and NameCert coordinates.

Next read the CauchyLimitSeal route. The forward lattice theorem Definition 126.411 places the seal consumer on the StreamName window, RegSeqRat readback, dyadic ledger, Real seal row, and displayed finite-window seal surface. The reverse source exhaustion theorem Definition 126.412 says that no other public source row is available to that consumer.

Finally identify the two routes. Apply Definition 126.356 to read the StreamName finite window, DyadicRatCore$^{\uparrow}$ ledger, RegSeqRat$^{\uparrow}$ readback, and Real$^{\uparrow}$ seal as one finite pullback surface. Then use Definition 126.359: both consumers can project only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates of that pullback. Since neither cited route contains a quotient stream, host equality, selected limit, ambient completeness, metric-completion row, or standard bridge row, the two consumers cannot diverge into hidden completion routes. □

Theorem 126.366 (StreamName Real RegSeqRat seal pullback exhaustion)**.** *Every accepted* Real$^{\uparrow}$ *seal pullback read routed through an accepted* StreamName$^{\uparrow}$ *finite-window packet, the* RegSeqRat$^{\uparrow}$ *classifier row, and the* Real$^{\uparrow}$ *seal factors through exactly the displayed rows of this route: the StreamName finite-window row, the* DyadicRatCore$^{\uparrow}$ *observation ledger, the* RegSeqRat$^{\uparrow}$ *readback and classifier surface, the* Real$^{\uparrow}$ *seal row, and the attached* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates.*

Thus the Real seal pullback route exports no quotient stream, no selected limit, no host real equality, and no ambient completeness witness. A downstream seal consumer receives only the same finite packet presented by the StreamName finite window, the RegSeqRat row, and the Real seal boundary.

Proof. Start with the source lattice. By Definition 126.355, the accepted StreamName-to-RegSeqRat-to-Real route is already confined to the visible finite-window rows and the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates. The theorem also records that the route has no quotient stream, host real equality, selected limit, or ambient completeness coordinate.

Next force the finite pullback route. Apply Definition 126.356 to read the StreamName finite-window row, the DyadicRatCore$^{\uparrow}$ ledger, the RegSeqRat$^{\uparrow}$ readback row, and the Real$^{\uparrow}$ seal row as one finite surface. Then use Definition 126.359 to restrict every downstream consumer of that surface to the four displayed rows and their listed BEDC coordinates.

Finally compare the seal consumer. The compatibility theorem Definition 126.365 identifies the observation-budget read and the CauchyLimitSeal$^{\uparrow}$ read on the same finite pullback packet. Hence a Real seal pullback read routed through StreamName, RegSeqRat, and Real cannot select another source: it delivers precisely that finite packet to downstream seal consumers and no hidden completion witness beyond it. □

Theorem 126.367 (StreamName RealCompletionExactBoundary terminal pullback lock)**.** *Every accepted four-face* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *finite pullback consumed by a* $\mathsf{RealCompletionExactBoundaryUp}$ *packet factors through the exact terminal route*

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

The StreamName window is read as W, the RegSeqRat readback as R, the DyadicRatCore ledger as D, and the Real seal as E after the governing seal, classifier, witness-ledger, and budget rows L, K, J, S.

Conversely, the exact-boundary packet reads the same StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal as the four faces of the StreamName pullback. The lock exports no quotient stream, host sequence equality, selected limit, countable choice, ambient completeness, metric completeness, or bridge row.

Proof. First isolate the StreamName-side surface. By Definition 126.356, the accepted finite-window packet exposes exactly the StreamName finite-window row, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, the $\mathsf{Real}^{\uparrow}$ seal row, and their displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ coordinates.

Next exhaust the seal read. Apply Definition 126.366: a Real seal pullback routed through StreamName, RegSeqRat, and Real delivers precisely that finite packet to downstream seal consumers and supplies no quotient stream, selected limit, host real equality, or ambient completeness witness.

Now read the completion boundary. The four-face exactness theorem Definition 1120.6 says that an accepted $\mathsf{RealCompletionExactBoundaryUp}$ packet exposes the four Phase Real and Completion faces W, R, D, E after the rows L, K, J, S and before the structural rows H, C, P, N. The terminal-route theorem Definition 1120.9 then pins the terminal $\mathsf{Real}^{\uparrow}(E)$ read to the same route $L, K, J, S, W, R, D, E, H, C, P, N$.

It remains to identify the two reads. The StreamName pullback names its four faces as the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal; the exact-boundary packet names the same four faces as W, R, D, E. Since both cited routes expose only their displayed finite BEDC coordinates, there is no additional row on which the two reads could diverge.

The exclusion clause follows from the same inventories. Neither the StreamName pullback exhaustion nor the exact-boundary terminal route contains a quotient stream, host sequence equality, selected limit, countable-choice row, ambient-completeness row, metric-completeness row, or bridge row, so an accepted consumer of one surface cannot import any of those objects into the other. □

Theorem 126.368 (StreamName RegSeqRat RealUp lattice budget cover)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet used as a Phase Real and Completion budget cover factors through exactly four sibling rows: the StreamName finite-window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and classifier surface, and the* $\mathsf{Real}^{\uparrow}$ *seal row. The cover exposes only the displayed* BHist *observations, componentwise* hsame *transports, finite* Cont *continuations,* Pkg *provenance rows, and local* $\mathsf{NameCert}$ *coordinates attached to those four rows.*

Consequently the budget cover supplies a finite route from StreamName windows through dyadic observation and regular-rational readback into the Real seal. It exports no quotient stream, no host real equality, no selected limit, no ambient completeness coordinate, no metric-completion row, and no standard bridge row.

Proof. First isolate the four-row pullback. By Definition 126.356, every accepted finite-window packet consumed by $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ is read through the StreamName finite-window row,

the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the $\mathsf{Real}^{\uparrow}$ seal row, with only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates.

Next exhaust the consumer projections. The theorem Definition 126.359 says that any downstream consumer citing that dyadic pullback can project only those four rows and their listed coordinates. Thus a budget cover cannot add a second carrier surface while remaining a consumer of the accepted finite-window packet.

Now attach the Phase Real budget route. By Definition 126.363, every $\mathsf{RealObservationBudget}^{\uparrow}$ precision request using the accepted packet factors through the same route from $\mathsf{StreamName}^{\uparrow}$ to $\mathsf{DyadicRatCore}^{\uparrow}$ to $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$. The request supplies no quotient stream, host equality, hidden limit selection, or ambient completeness coordinate.

Finally pass to the Completion exit boundary. Apply Definition 126.366: the Real seal pullback read routed through StreamName, RegSeqRat, and Real delivers exactly the same finite packet to downstream seal consumers. Since the preceding factorization already lists all available BHist, hsame, Cont, Pkg, and NameCert coordinates, there is no remaining coordinate from which a metric-completion row or standard bridge row could be recovered. □

Theorem 126.369 (StreamName hub real-completion lattice pointer)**.** *Every public* $\mathsf{StreamName}^{\uparrow}$ *hub read used by the Phase Real and Completion route is routed through the sibling chain*

$$\textit{chapter } 37 \longrightarrow \textit{chapter } 301 \longrightarrow \textit{chapter } 38$$

and through the local finite-window child theorems of this hub. The route exports only displayed BHist *observations, componentwise* hsame *transports, finite* Cont *windows,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream equality, host sequence equality, selected limit, or ambient completeness row.*

Proof. Read the hub as its ordered child surfaces. The carrier definition, certificate fields, finite-window endpoint package, and public interface expose only finite StreamName windows and their local naming rows.

Pass next through the Real and Completion sibling chain. The Rat surface of chapter 37, the RegSeqRat surface of chapter 301, and the Real surface of chapter 38 are reached through the local handoff and lattice-dependency children already included by the hub.

Use the local finite-window theorems to exhaust the route. The finite-window lattice meet, regular seal non-escape, real seal factorization boundary, and RegSeqRat real lattice dependency rows account for every public read used by the completion-facing consumer.

Since the hub contributes only child rows and no theorem body of its own, no quotient stream equality, host sequence equality, selected limit, or ambient completeness coordinate is exported from the hub read. □

Theorem 126.370 (Top-level StreamName Real-completion dependency)**.** *Every top-level* $\mathsf{StreamName}^{\uparrow}$ *certificate read used by the Real-and-completion route factors through the finite-window* $\mathsf{StreamName}^{\uparrow}$ *rows, the regular-source rows consumed by chapter 301, the dyadic observation ledger read by chapter 291, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary of chapter 38. The route exports no quotient stream equality, selected host limit, countable-choice selector, or ambient completeness principle.*

Proof. Project the top-level $\mathsf{StreamName}^{\uparrow}$ certificate to its finite-window rows. These are the only rows available before the Real-and-completion route reads any regular-source or dyadic observation data.

Send the finite-window rows first through the RegSeqRat dependency in chapter 301. The regular-source read is therefore a finite certificate handoff, not a selected limiting operation or a countable-choice selector.

Next route the same source surface through the DyadicRatCore observation ledger of chapter 291. Dyadic observations are read as displayed ledger rows, so they do not identify streams by quotient equality or by a host-level representative.

Finally close the route at the $\mathsf{Real}^{\uparrow}$ seal boundary of chapter 38. The seal receives only the finite-window, regular-source, and dyadic ledger rows already displayed, and it imports no ambient completeness principle or selected host limit. □

Theorem 126.371 (StreamName RegSeqRat DyadicRatCore RealUp endpoint correspondence)**.** *A top-level Real-completion* $\mathsf{StreamName}^{\uparrow}$ *certificate read reaches a* $\mathsf{Real}^{\uparrow}$ *endpoint exactly when the same finite-window surface factors through the regular-source row of chapter 301, the observation ledger of chapter 291, and the seal boundary of chapter 38. The correspondence is a four-object handoff among* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*; it is not quotient stream equality, a selected host limit, a countable-choice selector, or an ambient completeness principle.*

Proof. Start with Definition 126.370. It identifies the only top-level Real-completion route available from $\mathsf{StreamName}^{\uparrow}$: finite-window rows followed by regular-source, dyadic observation, and Real seal reads.

For the forward direction, a $\mathsf{Real}^{\uparrow}$ endpoint read must already have passed through the finite-window StreamName surface. The dependency theorem then forces the same displayed surface through the $\mathsf{RegSeqRat}^{\uparrow}$ regular-source row and the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger before the $\mathsf{Real}^{\uparrow}$ seal can be read.

For the reverse direction, assume the finite-window surface has these three sibling readings. The regular-source row supplies the source discipline, the dyadic ledger supplies the observation boundary, and the $\mathsf{Real}^{\uparrow}$ seal supplies the endpoint boundary, so the composed certificate read is exactly the licensed Real-completion endpoint route.

The excluded objects are absent at every stage of the composition. None of the cited routes adds quotient stream equality, selected host limits, countable-choice selectors, or ambient completeness; hence the endpoint correspondence remains a finite certificate handoff. □

Theorem 126.372 (StreamName four-object Real-completion exit exactness)**.** *A top-level Real-and-completion consumer reaches a public* $\mathsf{Real}^{\uparrow}$ *exit if and only if its read factors through exactly the finite* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-source row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary named by Definition 126.370 and Definition 126.371. This exact exit route is the handoff surface shared with chapter 301, chapter 291, and chapter 38. No quotient stream equality, selected host limit, countable-choice selector, ambient completeness principle, or bridge row is part of the public exit.*

Proof. First apply Definition 126.370. It restricts every top-level Real-and-completion read to the finite $\mathsf{StreamName}^{\uparrow}$ window, the regular-source row, the dyadic observation ledger, and the $\mathsf{Real}^{\uparrow}$ seal boundary, and it excludes quotient stream equality, selected limits, choice selectors, and ambient completeness from the route.

For the forward direction, suppose a consumer reaches a public $\mathsf{Real}^{\uparrow}$ exit. By the endpoint correspondence of Definition 126.371, the same finite window must pass through the $\mathsf{RegSeqRat}^{\uparrow}$ row of chapter 301, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger of chapter 291, and the $\mathsf{Real}^{\uparrow}$ seal boundary of chapter 38. Thus the public exit read has exactly the four displayed objects as its route.

For the reverse direction, assume a read factors through those four displayed objects and no additional exit coordinate. The dependency theorem supplies the top-level StreamName route, while the endpoint correspondence repacks the regular-source, dyadic-ledger, and seal-boundary readings as the public $\mathsf{Real}^{\uparrow}$ endpoint. Therefore the consumer reaches the public Real-and-completion exit.

The exactness claim is negative as well as positive. The preceding two theorems give no coordinate for quotient stream equality, selected host limits, countable-choice selectors, ambient completeness, or bridge rows; the three cited sibling chapters provide only their named finite certificate surfaces. Hence no extra public RealUp exit route remains beyond the four-object handoff. □

Theorem 126.373 (StreamName four-object exit status product)**.** *A public Real-and-completion exit from the top-level* $\mathsf{StreamName}^{\uparrow}$ *route is licensed exactly by the product of two independent records: the paper-side four-object route of Definition 126.372, and the verification-axis evidence separately attached to the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *targets. The route component supplies the finite-window StreamName read, the regular-source row of chapter 301, the dyadic observation ledger of chapter 291, and the Real seal boundary of chapter 38; the verification component supplies only the objectwise formal-status records governed by section 9467.2. Neither component determines the other, and the product contains no quotient stream equality, selected host limit, countable-choice selector, ambient completeness principle, or inference from closure grade to formal status or conversely.*

Proof. First read the paper-side route through Definition 126.370, Definition 126.371, and Definition 126.372. These results identify the only route to a public $\mathsf{Real}^{\uparrow}$ exit as the four displayed objects: the finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ regular-source row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ seal boundary.

Next read the status side through section 9467.2. That discipline treats paper closure, formal verification, and bridge status as distinct coordinates, so the four-object route cannot manufacture a formal-status row, and a formal-status row cannot manufacture the paper-side exit route.

Combining the two reads gives the stated product. The sibling chapters named above provide the four object surfaces, while the roadmap axis discipline supplies only the rule that their closure and verification records are reported independently.

The exclusions are inherited coordinatewise. The route theorems contain no quotient stream equality, selected host limit, countable-choice selector, or ambient completeness principle, and the verification-axis record contributes no additional mathematical exit route. Therefore neither direction of the product permits an inference from closure grade to formal status, from formal status to closure grade, or from either axis to any of the excluded completion principles. □

Theorem 126.374 (StreamName four-object exit support minimality)**.** *A public Phase Real and Completion exit from the top-level* $\mathsf{StreamName}^{\uparrow}$ *route is available exactly when one finite support displays all four object faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *together with the shared certificate faces* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Dropping any one of these displayed faces leaves only a partial interface: without* $\mathsf{StreamName}^{\uparrow}$ *there is no finite source window, without* $\mathsf{DyadicRatCore}^{\uparrow}$ *there is no observation ledger, without* $\mathsf{RegSeqRat}^{\uparrow}$ *there is no regularity row, without* $\mathsf{Real}^{\uparrow}$ *there is no seal boundary, and without one of* BHist*,* hsame*,* Cont*,* Pkg*, or* NameCert *there is no common certificate surface on which the four object faces can be read as one public exit.*

Proof. The four object faces are forced by Definition 126.372. That theorem identifies the public Real-and-completion exit precisely with the route through the finite $\mathsf{StreamName}^{\uparrow}$ window, the

$\mathsf{RegSeqRat}^{\uparrow}$ regular-source row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ seal boundary.

The status-product theorem Definition 126.373 keeps this route separate from verification-axis bookkeeping. Hence the support-minimality statement is a paper-side route claim about the finite support itself, not an inference from a closure grade, formal status, or bridge coordinate.

It remains to justify the common certificate faces. Apply Definition 126.651: any reindexed support row that can be read by the exit route must carry the displayed BHist, hsame, Cont, Pkg, and NameCert surface. Removing one of those faces leaves at most a source row, observation row, regularity row, or seal row in isolation.

Combining these two requirements gives minimality. The four object faces provide exactly the source, observation, regularity, and seal components of the public exit, while the five certificate faces provide the common finite support on which those components are read together. If any displayed face is absent, one component of the public exit or its shared support is absent, so the remaining data describes only the corresponding partial interface. □

126.24 StreamName finite-window transport obligations

Theorem 126.375 (StreamName finite-window pointwise transport)**.** *Let* $s, t, s', t' : \mathsf{BHist} \to \mathsf{BHist}$ *be certified* $\mathsf{StreamName}^{\uparrow}$ *rows, let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite observation bundle, and suppose*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathcal{P})$$

is displayed together with the finite ledger rows $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$ *for every selected observation. Suppose also that every selected* n *carries the pointwise transport rows*

$$\mathsf{hsame}(s(n), s'(n)) \qquad \textit{and} \qquad \mathsf{hsame}(t(n), t'(n)),$$

and that the consumer route reads the source window only through displayed Cont *rows. Then the transported window exported to any* RegSeqRat *or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer is exactly*

$$\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{P})$$

with the same ProbeBundle*,* InBundle*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

No infinite stream object, quotient stream equality, selected real value, host Nat stream, or $\mathsf{Real}^{\uparrow}$ *completeness principle is exported by this transport.*

Proof. First read the source finite window through the public handoff surface of Definition 126.79. The available rows are the selected rational-history classifier rows, the finite ProbeBundle ledger, membership rows, unary observation rows, and their local naming data.

Next apply the pointwise handoff and transport rows of Definition 126.170 and Definition 126.171. These identify the transported classifier by using only the displayed pointwise hsame rows at the certified observations of $\mathcal{P}$.

Finally replay the result through the finite pullback criterion of Definition 126.152. The criterion records the same Cont, Pkg, and local certificate rows as consumer-visible coordinates, so the transported packet remains the finite window over $\mathcal{P}$ and exports none of the excluded stream, quotient, real-value, host-index, or completeness data. □

Theorem 126.376 (StreamName constant-window classifier stability)**.** *Let* $d, e : \mathsf{BHist}$ *be rational-history endpoints and let* $r, q : \mathsf{BHist} \to \mathsf{BHist}$ *be certified observation schedules over a finite bundle*

$\mathcal{P}$: ProbeBundle. *Suppose the constant window displays the rational point classifier for d and e, the selected bundle rows* InBundle$(n, \mathcal{P})$*, the unary ledger rows* UnaryHistory(n)*, pointwise* hsame *transport for the scheduled constant observations, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row. Then every transported constant certified window preserves the same point classifier and ledger rows for the* RegSeqRat *and finite-window* $\mathsf{Real}^{\uparrow}$ *handoff.*

The stable constant-window packet contains no infinite stream object, quotient stream equality, selected real value, host Nat stream, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Begin with the constant boundary of Definition 126.81. It says that the constant window contributes only the rational point classifier, finite bundle ledger, membership rows, unary observation rows, and local naming data.

Transport the scheduled constant observations by Definition 126.172. The handoff reads the same endpoint classifier pointwise and leaves regularity, dyadic seal data, and the $\mathsf{Real}^{\uparrow}$ seal classifier on the consumer side.

Now use Definition 126.170 to identify the consumer-facing packet. The pointwise rows, bundle membership, unary ledger, displayed hsame transport, Cont route, Pkg provenance, and local certificate row are precisely the rows named by the theorem statement, so the constant classifier and ledger are stable under the certified transport. □

Theorem 126.377 (StreamName RegSeqRat window handoff exactness)**.** *Let $\mathcal{W}$ be a finite* $\mathsf{StreamName}^{\uparrow}$ *window over s, t :* BHist $\to$ BHist *with selected bundle $\mathcal{P}$:* ProbeBundle*. The exact* RegSeqRat *handoff surface read from $\mathcal{W}$ consists only of the finite window classifier* RatStreamNameFiniteWindowCla *the selected point certificates* RatHistoryClassifier$(s(n), t(n))$*, the pointwise* UnaryHistory *and* InBundle *ledger rows, the displayed* hsame *transports, the* Cont *route rows, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row.*

Conversely, those finite rows determine the whole source packet handed to RegSeqRat*; no other StreamName coordinate is read. In particular, the handoff exports no infinite stream object, quotient stream equality, selected real value, host Nat stream,* RegSeqRat *regularity witness supplied by StreamName, or* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. For the forward direction, project $\mathcal{W}$ through Definition 126.79. It exposes the finite StreamName window rows, selected rational-history classifier rows, probe-bundle ledger, bundle membership, and unary-history observations.

Apply the pointwise handoff theorem Definition 126.170. It refines the same source packet to point certificates RatHistoryClassifier$(s(n), t(n))$ at exactly the selected certified observations of $\mathcal{P}$.

For the reverse direction, repack the displayed classifier, point certificates, ledger rows, hsame transports, route rows, package provenance, and local certificate row through Definition 126.152. The criterion says that these are precisely the finite pullback coordinates seen by the downstream consumers, so the source handoff is fully determined.

Finally use Definition 126.82. It keeps RegSeqRat regularity and $\mathsf{Real}^{\uparrow}$ seal or completeness obligations outside the StreamName source packet, and it rules out the infinite-stream, quotient, selected-real, and host-index data excluded above. □

Theorem 126.378 (StreamName finite-window transport RegSeqRat Real readiness)**.** *A transported finite* $\mathsf{StreamName}^{\uparrow}$ *window is ready for* RegSeqRat *and finite-window* $\mathsf{Real}^{\uparrow}$ *consumers exactly when the finite-window classifier, selected point certificates,* UnaryHistory *rows,* InBundle *rows, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row are all present in the source packet. This readiness surface exports no quotient stream equality, host Nat stream, selected real value,* RegSeqRat *regularity row, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply pointwise transport, Definition 126.375. It moves the finite classifier to the transported window while preserving the same bundle, membership, unary-history, pointwise hsame, route, provenance, and local naming rows.

Use constant-window classifier stability when the selected observations are constant endpoints. Theorem 126.376 shows that the same finite classifier and ledger rows remain the consumer-facing surface for RegSeqRat and finite-window $\mathsf{Real}^{\uparrow}$ handoff.

Next apply RegSeqRat window handoff exactness, Definition 126.377. It identifies the complete source packet as the finite-window classifier, selected point certificates, UnaryHistory and InBundle rows, hsame, Cont, Pkg, and local NameCert data.

Finally cite the pointwise handoff theorem Definition 126.170. It keeps RegSeqRat regularity and $\mathsf{Real}^{\uparrow}$ completion obligations on the downstream side, so the transported StreamName source packet is ready for those consumers without exporting quotient stream equality, a host Nat stream, a selected real value, regularity, or completeness. □

Theorem 126.379 (StreamName finite-window section transport closure)**.** *Let $\mathcal{S}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window section whose displayed rows contain the finite classifier, selected point certificates,* UnaryHistory *observations,* InBundle *ledger, componentwise* BHist *rows,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *registration. If $\mathcal{S}$ is transported through those displayed* hsame *and* Cont *rows, then the downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal remain on that same transported section route.*

Conversely, any current Phase Real and Completion read that exposes the same finite $\mathsf{StreamName}^{\uparrow}$ *window, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, and displayed* BHist, hsame, Cont, Pkg, NameCert *rows is read as the transported section $\mathcal{S}$. This section closure exports no quotient stream, selected limit, host sequence equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, or standard bridge row.*

Proof. For the forward direction, apply the pointwise transport theorem Definition 126.375. It moves the accepted finite window through the displayed hsame rows while preserving the same bundle, membership, unary-history, continuation, provenance, and local naming surface.

Next apply RegSeqRat window handoff exactness, Definition 126.377. The handoff identifies the downstream readback with exactly the transported finite-window classifier and selected point certificates, so the $\mathsf{RegSeqRat}^{\uparrow}$ read remains on the same section route.

Finally use the readiness theorem Definition 126.378. It states that the finite classifier, point certificates, dyadic tolerance ledger, transports, routes, provenance, and local naming are sufficient for the finite-window $\mathsf{Real}^{\uparrow}$ consumer, while regularity and completion obligations stay downstream.

For the converse direction, inspect the exposed Phase Real and Completion read. If it shows the same finite StreamName window, dyadic ledger, RegSeqRat readback, Real seal, and displayed BHist, hsame, Cont, Pkg, NameCert rows, then the preceding exactness and readiness results reconstruct the unique transported section route read by those consumers. The exclusions follow because none of the cited rows contains quotient streams, selected limits, host sequence equality, ambient Real completeness, metric completeness, or standard bridge data. □

Theorem 126.380 (StreamName finite-window section pullback stability)**.** *Let $\mathcal{S}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window section whose source rows display the finite classifier, selected point certificates,* UnaryHistory *observations,* InBundle *ledger, componentwise* BHist *entries,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *registration. If $\mathcal{S}$ is transported through those displayed* BHist, hsame, Cont, Pkg, *and local* NameCert *rows, then every downstream finite* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumer reading that section pulls back to the same*

transported four-face route: the transported finite $\mathsf{StreamName}^{\uparrow}$ *classifier, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal.*

This pullback stability exports no quotient stream equality, host sequence equality, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ *completeness principle, metric-completeness datum, or standard bridge row.*

Proof. First use the pointwise transport theorem Definition 126.375. It transports the finite classifier and selected point certificates through the displayed BHist and hsame rows while preserving the same bundle membership, unary-history, continuation, provenance, and local naming surface.

Next apply RegSeqRat window handoff exactness, Definition 126.377. The handoff says that the $\mathsf{RegSeqRat}^{\uparrow}$ consumer reads exactly the transported finite-window classifier, selected point certificates, support rows, transports, routes, provenance, and local certificate rows; no second StreamName coordinate is available for the readback.

Now use downstream readiness, Definition 126.378. Readiness carries the same transported source packet to the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger and the finite-window $\mathsf{Real}^{\uparrow}$ seal without importing regularity, limit-selection, choice, or completeness rows from StreamName.

Finally compose with the existing section route, Definition 126.379. That closure result identifies the exposed Phase Real and Completion read with the transported section $\mathcal{S}$. Therefore each downstream consumer pulls back to the same four-face route, and the exclusion list follows from the fact that none of the cited handoff, readiness, or section rows contains quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric completeness, or standard bridge data. □

Theorem 126.381 (StreamName pointwise transport scope)**.** *Let* $\mathcal{S}$ *be an accepted transported finite* $\mathsf{StreamName}^{\uparrow}$ *packet over a finite bundle* $\mathcal{P} : \mathsf{ProbeBundle}$*, with source and target schedules* $s, t, s', t' : \mathsf{BHist} \to \mathsf{BHist}$*. Before any* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer reads* $\mathcal{S}$*, the packet exposes exactly the following StreamName-side rows: the finite classifier* $\mathsf{RatStreamNameFiniteWindowClassifier}(s', t', \mathcal{P})$*, the selected point-certificate rows* $\mathsf{RatHistoryClassifier}(s'(n), t'(n))$ *at the displayed observations, the support rows* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$*, the componentwise* hsame *transports from* $s(n), t(n)$ *to* $s'(n), t'(n)$*, the replayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row.*

The same scope exports no quotient stream equality, host sequence equality, selected limit, $\mathsf{Real}^{\uparrow}$ *completeness principle, metric-completeness datum, countable-choice row, or standard bridge row. Thus the finite-window packet seen by* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumers is a finite transported row packet, not a hidden stream quotient or completion claim.*

Proof. Start with pointwise transport, Definition 126.375. It transports the finite classifier across the displayed hsame rows and preserves the same bundle, support, continuation, provenance, and local naming surface.

Next use the handoff exactness theorem Definition 126.377. This identifies the rows read by $\mathsf{RegSeqRat}^{\uparrow}$ as the finite classifier, selected point certificates, support rows, transports, routes, provenance, and local certificate, and it rules out any additional StreamName coordinate.

Then apply readiness, Definition 126.378. Readiness says that the same rows are sufficient for the finite-window $\mathsf{Real}^{\uparrow}$ route while quotient equality, host sequence data, selected real values, regularity, and completeness obligations remain outside the source packet.

Finally compose with section transport closure, Definition 126.379. The closure theorem keeps the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, and the finite-window $\mathsf{Real}^{\uparrow}$ seal on the same transported section route. Its exclusion list supplies the stated absence of selected

limits, metric completeness, and standard bridge rows, so the displayed row list is exactly the scope available before the downstream consumers read the packet. □

Theorem 126.382 (StreamName finite-window global classifier exhaustion)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be certified StreamName schedules. Assume that for every certified unary history* $n : \mathsf{BHist}$ *the singleton window* $\mathsf{Bcons}(n, \mathsf{Bnil})$ *is supplied with a finite row* $\mathsf{RatStreamNameFiniteWindowClassifier}(s, t, \mathsf{Bcons}(n, \mathsf{Bni}$ *its* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathsf{Bcons}(n, \mathsf{Bnil}))$ *support rows, the pointwise classifier* $\mathsf{RatHistoryClassifier}(s(n), t($ *displayed* hsame *transport,* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^\uparrow}$ *support. Then the public StreamName source available to any* $\mathsf{RegSeqRat}^\uparrow$*,* $\mathsf{DyadicRatCore}^\uparrow$*, or finite-window* $\mathsf{Real}^\uparrow$ *consumer is exactly the reconstructed global classifier* $\mathsf{RatStreamNameClassifier}(s, t)$*.*

After this reconstruction, the downstream read is only through the existing handoff rows Definition 126.170, Definition 126.377, and Definition 126.152. It exports no quotient stream equality, host sequence equality, selected limit, regularity row, completeness datum, metric-completion row, or standard bridge row from the StreamName source packet.

Proof. First rebuild the source classifier. Apply Definition 126.23 to the family of singleton-window classifiers. Since every certified unary history is supplied with its singleton finite row, support rows, and pointwise RatHistoryClassifier witness, singleton exhaustion repacks those rows as the global $\mathsf{RatStreamNameClassifier}(s, t)$.

Next identify what the regular-rational consumer can read. Apply Definition 126.170 to the reconstructed classifier and to the displayed singleton rows. The $\mathsf{RegSeqRat}^\uparrow$ interface receives the selected rational rows as StreamName pointwise data, together with the same unary-history, bundle-membership, hsame, Cont, Pkg, and local naming rows.

Now apply the finite-window handoff exactness theorem, Definition 126.377. It says that the complete finite handoff packet is precisely the finite classifier and selected point certificates already used to reconstruct the global StreamName classifier, so the downstream read has no second source coordinate.

Finally apply the finite-window pullback criterion, Definition 126.152. The $\mathsf{Real}^\uparrow$ and $\mathsf{DyadicRatCore}^\uparrow$ consumers therefore pull back only along the same finite StreamName rows. Quotient stream equality, host sequence equality, selected limits, regularity, completeness, metric completion, and standard bridge data remain downstream obligations rather than StreamName source rows. □

Theorem 126.383 (StreamName pointwise finite-window transport)**.** *Let* $s, t, s', t' : \mathsf{BHist} \to \mathsf{BHist}$ *be displayed* $\mathsf{StreamName}^\uparrow$ *rows and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite certified observation window. Suppose the source window exposes*

$$\mathsf{RatStreamNameCarrier}(s), \quad \mathsf{RatStreamNameCarrier}(t), \quad \mathsf{RatStreamNameClassifier}(s, t), \quad \mathsf{RatStreamNameFiniteWi}$$

together with the finite request ledger rows $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$ *for every selected observation. If each selected observation carries pointwise transports* $\mathsf{hsame}(s(n), s'(n))$ *and* $\mathsf{hsame}(t(n), t'(n))$*, and the same* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^\uparrow}$ *rows replay the transported window, then the transported packet preserves StreamCarrier membership, StreamSame classification, and the finite request ledger:*

$$\mathsf{RatStreamNameCarrier}(s'), \quad \mathsf{RatStreamNameCarrier}(t'), \quad \mathsf{RatStreamNameClassifier}(s', t'), \quad \mathsf{RatStreamNameFiniteW}$$

The handoff exports exactly the same finite bundle, unary-history ledger, membership rows, pointwise hsame *transports, replay, provenance, and local naming rows to downstream* $\mathsf{RegSeqRat}^\uparrow$ *and* $\mathsf{Real}^\uparrow$ *consumers. It exports no quotient stream equality, host sequence equality, selected real value, countable-choice schedule, or ambient* $\mathsf{Real}^\uparrow$ *completeness principle.*

Proof. Project the source finite window. Carrier membership for s and t, the StreamSame classifier, the finite-window classifier, and the ledger rows are all displayed before any downstream consumer reads the packet.

Apply the pointwise transport rows at each certified observation of $\mathcal{P}$. The rows $\mathsf{hsame}(s(n), s'(n))$ and $\mathsf{hsame}(t(n), t'(n))$ transport the opened BHist observations without changing the bundle membership or unary-history ledger.

Use the finite-window transport obligations of Definition 126.375 together with the RegSeqRat pointwise handoff of Definition 126.170. They identify the transported carrier and classifier rows over the same finite bundle and keep regular readback and Real sealing on the consumer side.

Finally replay the transported packet through the displayed Cont row and record its Pkg provenance and local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ row. Since every exported coordinate is one of the displayed finite rows, no quotient stream equality, host sequence equality, selected real value, countable-choice schedule, or ambient completeness datum can enter the handoff. □

126.25 StreamName finite-window nonempty-index handoff

Theorem 126.384 (StreamName finite-window nonempty-index handoff)**.** *Let $\mathcal{W}$ be a finite* $\mathsf{StreamName}^{\uparrow}$ *package consumed by a* $\mathsf{RegSeqRat}$ *certificate or by a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer. Before any regularity row, dyadic ledger row, or* $\mathsf{Real}^{\uparrow}$ *seal row is readable, the handoff from $\mathcal{W}$ must expose at least one displayed observation row through a finite* $\mathsf{ProbeBundle}$*, an* $\mathsf{InBundle}(n, \mathcal{P})$ *membership row, and a certified* $\mathsf{UnaryHistory}(n)$ *index. This exported index is only a finite observation witness for the displayed window.*

The handoff exports no host index equality, quotient stream equality, selected limit, or ambient completeness principle.

Proof. First read the public finite-window handoff. By Definition 126.79, a downstream $\mathsf{RegSeqRat}$ or finite-window $\mathsf{Real}^{\uparrow}$ consumer can receive only the selected rational-history classifier rows, the finite $\mathsf{ProbeBundle}$ ledger, the $\mathsf{InBundle}$ membership rows, and the certified $\mathsf{UnaryHistory}$ observation rows from the StreamName side.

Next place that source row inside the finite meet packet of Definition 126.256. The meet packet lists the common classifier row, probe bundle, membership family, unary observation family, dyadic ledger surface, componentwise transports, continuation routes, package provenance, and local names. Hence any downstream dyadic or seal read already has a visible finite observation coordinate before it can be consumed.

Now apply the exhaustion theorem Definition 126.257. It says that every $\mathsf{RegSeqRat}$ or finite-window $\mathsf{Real}^{\uparrow}$ consumer of the meet reads only the displayed finite observation surface and its ledger rows. Therefore the first consumer-visible index is a certified member of the probe bundle, not a host index equality or a quotient-stream coordinate.

Finally use the sibling dependency theorem Definition 126.355. The route from StreamName through $\mathsf{RegSeqRat}^{\uparrow}$ into $\mathsf{Real}^{\uparrow}$ is the same visible finite-window route, so regularity, dyadic ledger, and Real seal rows are downstream consumers of the already displayed observation witness. The exclusion clauses in the cited handoff, meet, exhaustion, and dependency results rule out quotient stream equality, selected limits, and ambient completeness as exported StreamName data. □

Theorem 126.385 (StreamName finite-window support minimality)**.** *Any downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *finite-window consumer that reads a* $\mathsf{StreamName}^{\uparrow}$ *package must preserve at least one displayed* $\mathsf{ProbeBundle}$ *membership row together with its* $\mathsf{UnaryHistory}$ *index through the same* hsame*,*

Cont, Pkg, *and* NameCert *support. Deleting that row destroys the consumer route rather than moving it to quotient stream equality, selected limits, or ambient completeness.*

Proof. Start with Definition 126.384. It forces any RegSeqRat or Real finite-window consumer to expose a displayed observation through a finite ProbeBundle, its membership row, and the certified UnaryHistory index before regularity or seal data are readable.

Place the same row in the finite-window meet of Definition 126.257. The exhaustion result says that the consumer can only read the displayed classifier, membership, unary-history, dyadic ledger, transport, replay, provenance, and local-name rows carried by that finite surface.

Now apply Definition 126.355. The RegSeqRat readback and Real seal are downstream of the same StreamName finite-window surface, so their hsame, Cont, Pkg, and NameCert support still contains the nonempty observation row.

If that row is deleted, the displayed membership and unary-history coordinates needed by the handoff are absent. The exclusion clauses in the handoff, exhaustion, and dependency results leave no coordinate for quotient stream equality, selected limits, or ambient completeness to supply a replacement route. □

Theorem 126.386 (StreamName window-index route determinacy)**.** *Let $\mathcal{W}$ and $\mathcal{W}'$ be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *packets consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *rows. If both packets expose the same finite* ProbeBundle *member n, the same certified* $\mathsf{UnaryHistory}(n)$ *row, and the same finite-window meet coordinates, then every downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *seal consumer reads the same finite route through the StreamName window, the RegSeqRat readback, the dyadic ledger, and the Real seal.*

No quotient stream equality, host index equality, selected limit, or ambient completeness theorem can provide an alternate route for either packet.

Proof. Apply Definition 126.384 to both packets. The common visible index is a certified member of the finite ProbeBundle and is already paired with the displayed $\mathsf{UnaryHistory}(n)$ row before any RegSeqRat or Real consumer reads the packet.

Place both packets in the finite meet packet of Definition 126.256. The hypothesis that the meet coordinates agree identifies the common classifier row, probe-bundle membership row, unary observation row, dyadic ledger surface, componentwise transport, continuation, provenance, and local name.

Use Definition 126.257 together with Definition 126.355. These results force the RegSeqRat readback and Real seal to be downstream reads of the same finite meet surface, so the consumer route is determined by the displayed coordinates.

Coordinate exhaustion closes the claim. The agreed meet surface has no coordinate for quotient stream equality, host index equality, selected limits, or ambient completeness, so none of those objects can act as a second route to the downstream seal. □

Theorem 126.387 (StreamName window-index sibling route certificate)**.** *Let $\mathcal{W}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *packet whose nonempty index handoff is consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal. Then the consumer route factors through the same finite sibling route: the* ProbeBundle *row, the* $\mathsf{InBundle}(n, \mathcal{P})$ *membership row, and the* $\mathsf{UnaryHistory}(n)$ *index row first exposed by the StreamName window; the RegSeqRat readback surface of chapter 301; the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger of chapter 291; and the* $\mathsf{Real}^{\uparrow}$ *seal of chapter 38.*

This certificate exports no host index equality, quotient stream equality, selected limit, trichotomy, or ambient completeness theorem.

Proof. Start with Definition 126.384. The accepted finite packet must expose a displayed observation row through the finite ProbeBundle, its InBundle membership witness, and the certified UnaryHistory index before any RegSeqRat or Real consumer can read it.

Use Definition 126.386 to make that row the unique finite route for the downstream read. Once the displayed index, unary history, and meet coordinates are fixed, the readback and seal consumers cannot select a second path through host index equality or quotient stream equality.

Now apply Definition 126.355. The RegSeqRat surface named by chapter 301 is a downstream consumer of the StreamName finite-window row, and the Real seal named by chapter 38 is reached only through that displayed readback route.

Finally use Definition 126.356. The pullback inserts the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger of chapter 291 between the RegSeqRat readback and the Real seal without adding any coordinate for a selected limit, trichotomy, or ambient completeness. Hence every accepted consumer route factors through the same four sibling surfaces and through the same nonempty window-index row. □

Theorem 126.388 (StreamName Real RegSeq observation pullback lock)**.** *Let $\mathcal{W}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window consumed first by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and then by a* $\mathsf{Real}^{\uparrow}$ *seal. The first observation exposed to that route is only the certified* ProbeBundle *member together with its* UnaryHistory *row, and every downstream seal read factors through the same four-row pullback: the StreamName finite-window row, the RegSeqRat readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, and the* $\mathsf{Real}^{\uparrow}$ *seal row.*

The lock exports no host index equality, quotient stream equality, selected limit, trichotomy, or ambient completeness theorem.

Proof. Start with Definition 126.384. It forces the first visible observation to be a finite ProbeBundle member paired with its certified UnaryHistory row before a RegSeqRat or Real consumer can read the packet.

Use Definition 126.386 to keep that observation on one finite route. Once the displayed window coordinate, membership row, unary history row, and meet coordinates are fixed, no host index equality or quotient stream equality can supply a second downstream path.

Now apply Definition 126.356 and Definition 126.359. These results identify the downstream surface as the four displayed rows: StreamName finite window, RegSeqRat readback, DyadicRatCore ledger, and Real seal.

Coordinate exhaustion gives the lock. The four-row pullback has no coordinate for a selected limit, trichotomy, or ambient completeness, and the initial observation coordinate remains the certified bundle member plus unary history row throughout the downstream seal read. □

Theorem 126.389 (StreamName window-refinement first-observation stability)**.** *Let $\mathcal{W}$ and $\mathcal{W}'$ be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *windows. Suppose that $\mathcal{W}'$ refines $\mathcal{W}$ by a displayed* ProbeBundle *inclusion, preserves the same* $\mathsf{InBundle}(n, \mathcal{P})$ *membership row, preserves the certified* $\mathsf{UnaryHistory}(n)$ *observation index, and feeds the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{Real}^{\uparrow}$ *seal route as $\mathcal{W}$. Then the first observation exposed to the downstream consumer is the same displayed bundle member n with the same unary-history row in both windows.*

The stable first observation is carried only by the displayed finite-window route. Neither window admits an alternate route through host index equality, quotient stream equality, selected limits, trichotomy, or ambient completeness.

Proof. First apply Definition 126.384 to both accepted windows. Each downstream RegSeqRat or Real consumer must receive a first visible observation through a finite ProbeBundle member, its $\mathsf{InBundle}(n, \mathcal{P})$ row, and the certified $\mathsf{UnaryHistory}(n)$ index.

The refinement hypotheses identify those visible rows. The displayed ProbeBundle inclusion carries the same member n, and the preserved membership and unary-history rows keep the first observation at the same finite coordinate before any readback or seal row is consumed.

Now use Definition 126.386. Once the index, membership row, unary-history row, and finite meet coordinates agree, the downstream route is forced to be the same StreamName window route for the RegSeqRat readback and the Real seal.

Next apply Definition 126.387. The common route factors through the displayed StreamName row, the RegSeqRat readback surface, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and the $\mathsf{Real}^{\uparrow}$ seal, so the refined window cannot expose a different first observation to the same consumer.

Finally apply Definition 126.388. The Real seal pulls back along the same four displayed rows and keeps the initial bundle member plus unary-history row fixed. The exclusion clauses in the determinacy, sibling-route, and pullback-lock results leave no coordinate for host index equality, quotient stream equality, selected limits, trichotomy, or ambient completeness to serve as a second route. □

126.26 StreamName finite-window budget handoff

Theorem 126.390 (StreamName Real RegSeq finite-window budget handoff)**.** *Let $\mathcal{W}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *package consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *certificate, by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal route, or by a route that passes through a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *or* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Then any consumer-visible regularity row, dyadic tolerance row, or* $\mathsf{Real}^{\uparrow}$ *seal row must be downstream of the same finite observation-budget surface:*

$$\mathsf{ProbeBundle},\quad \mathsf{InBundle},\quad \mathsf{UnaryHistory},\quad \mathsf{ObservationBudgetLimiter}^{\uparrow},\quad \mathsf{RegularCauchyTailBudget}^{\uparrow}.$$

Thus the StreamName handoff first exposes the finite window, membership, unary-history, budget-limiter, and tail-budget rows before any RegSeqRat regularity, dyadic tolerance, or Real seal row is consumed.

The handoff exports no quotient stream, selected host limit, countable-choice selector, or host real equality.

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealRegseqFiniteWindowBudgetHandoff`

Proof. Start with Definition 126.79. The public StreamName package exports only selected rational-history classifier rows, the finite ProbeBundle ledger, InBundle membership rows, and UnaryHistory observation rows to a $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ consumer.

Next apply Definition 126.82. It places regularity and dyadic-tolerance rows on the $\mathsf{RegSeqRat}^{\uparrow}$ side and the seal classifier on the $\mathsf{Real}^{\uparrow}$ side, so none of those rows can be consumed as StreamName source data.

Now route the same finite observation surface through the sibling budget chapters. The limiter factorization Definition 903.23 forces any $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ use of the limiter row through the request-budget-cap service triad before tail windows, dyadic observations, readback, and seal rows are served.

Finally use Definition 906.3. It orders the regular source, tail threshold, observation limiter, finite StreamName window, dyadic ledger, RegSeqRat readback, and Real seal as one finite route. Since the cited StreamName, limiter, and tail-budget surfaces contain no coordinates for quotient streams, selected host limits, countable choice, or host real equality, those objects cannot be alternate sources for the handoff. □

Theorem 126.391 (StreamName budget handoff sibling chapter route)**.** *Every accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window consumed through the finite observation-budget surface factors through the sibling chapter surface of chapter 903 before the tail-budget service of chapter 906. Its consumer-visible route then passes through the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{Real}^{\uparrow}$ *seal rows already named in Definition 126.390. No accepted finite StreamName handoff obtains an alternate source for quotient streams, selected host limits, countable choice, or host real equality.*

Proof. Apply Definition 126.390 to the accepted finite StreamName window. It already identifies the finite observation surface that must be exposed before any $\mathsf{RegSeqRat}^{\uparrow}$ regularity, dyadic-tolerance, or $\mathsf{Real}^{\uparrow}$ seal row is consumed.

Next read the limiter leg through Definition 903.23. The factorization places the handoff on the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ request-budget-cap service triad before any $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ tail window, dyadic observation, readback, or seal row can be served.

Finally use Definition 906.3. It orders the tail-budget route through the regular source, tail threshold, observation limiter, finite StreamName window, dyadic ledger, RegSeqRat readback, and Real seal. The non-escape sentence in Definition 126.390 therefore applies to the whole sibling chapter route. □

Theorem 126.392 (StreamName budget RegSeq Real route coherence)**.** *Any accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window consumed through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *and* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{Real}^{\uparrow}$ *seal through the same ordered finite route. The route cannot fork into quotient streams, selected host limits, countable-choice schedules, or host real equality.*

Proof. Start with Definition 126.390. It places the accepted finite StreamName window behind the finite observation-budget surface before any $\mathsf{RegSeqRat}^{\uparrow}$ regularity, dyadic tolerance, or $\mathsf{Real}^{\uparrow}$ seal row can be consumed.

Next apply Definition 126.391. The sibling route first reads the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ surface and then the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ service surface before the regular readback and seal rows are available.

Use Definition 903.23 for the limiter leg and Definition 906.3 for the tail-budget leg. Together they identify one ordered finite route through the limiter request-budget-cap service, the tail threshold, the finite StreamName window, the dyadic ledger, the RegSeqRat readback, and the Real seal.

Since each cited route uses the same displayed finite rows and none carries a quotient stream, selected host limit, countable-choice schedule, or host real equality coordinate, no consumer can fork the budget handoff into an alternate readback or seal route. □

Theorem 126.393 (StreamName regular seal sibling route)**.** *Any finite* $\mathsf{StreamName}^{\uparrow}$ *window routed through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *and* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *reaches a* $\mathsf{Real}^{\uparrow}$ *finite-window seal only through the same rows used by Definition 126.337:*

$$\mathsf{ProbeBundle},\quad \mathsf{InBundle},\quad \mathsf{UnaryHistory},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The sibling route exports no quotient stream, selected host limit, countable-choice selector, host real equality, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 126.390. It places every finite-window regularity, dyadic tolerance, and Real seal read behind the finite observation-budget surface.

Use Definition 126.391 to pass that surface through the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ and $\mathsf{RegularCauchyTailBudget}$ sibling chapters. The route still exposes only the finite window, membership, unary-history, budget, tail-budget, readback, and seal rows.

Finally apply Definition 126.337. Its finite-window Real seal boundary is exactly the row list displayed above, so the sibling handoff cannot export quotient stream equality, selected limits, countable-choice selectors, host real equality, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.394 (StreamName finite-window prefix induction)**.** *Any accepted finite* $\mathsf{StreamName}^{\uparrow}$ *handoff consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or by a* $\mathsf{Real}^{\uparrow}$ *finite-window seal admits induction on the displayed finite prefix rows*

$\mathsf{ProbeBundle}$, $\mathsf{InBundle}$, $\mathsf{UnaryHistory}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$.

At each induction step the same $\mathsf{RegSeqRat}^{\uparrow}$ *readback row and the same* $\mathsf{Real}^{\uparrow}$ *seal boundary are preserved by componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row. No later tail, quotient stream, selected host limit, countable-choice schedule, or host real equality can enter the induction.*

Proof. Project the finite handoff theorem Definition 126.390. It places every regularity read, dyadic tolerance read, and finite-window Real seal behind the displayed finite observation rows.

Use the sibling route of Definition 126.393. It identifies the handoff consumed by $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ with the same finite prefix surface routed through $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ and $\mathsf{RegularCauchyTailBudget}^{\uparrow}$.

Induct over the displayed prefix rows in the listed order. The base case is the empty displayed prefix, where the readback and seal boundary are only the structural hsame, Cont, Pkg, and $\mathsf{NameCert}$ support. The step case appends one visible prefix row and replays the same transport and continuation rows, so the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal boundary remain the inherited ones.

Since the induction variable is the displayed finite prefix, no later tail coordinate, quotient stream, selected host limit, countable-choice schedule, or host real equality coordinate is available to the step. □

Theorem 126.395 (StreamName budget tail regular seal lock)**.** *Any finite* $\mathsf{StreamName}^{\uparrow}$ *window routed through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *and* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *reaches* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and* $\mathsf{Real}^{\uparrow}$ *finite-seal data only through the shared budget cap, tail threshold, finite window, dyadic ledger, readback, and seal rows. The locked route exports no quotient streams, selected limits, countable-choice selectors, host real equality, metric completeness, or ambient completeness row.*

Proof. Start with Definition 126.390. It places every regularity row, dyadic tolerance row, and finite Real seal read behind the shared observation-budget surface.

Next apply Definition 126.391 and Definition 126.393. These force the limiter cap, tail threshold, finite StreamName window, dyadic ledger, RegSeqRat readback, and Real seal rows to remain a single sibling route.

Finally use Definition 903.23, Definition 906.3, and Definition 126.337. Their combined non-escape clauses exclude quotient streams, selected limits, countable-choice selectors, host real equality, metric completeness, and ambient completeness from the locked tail-budget seal read. □

Theorem 126.396 (StreamName budget CauchyLimitSeal pullback)**.** *Let an accepted finite* StreamName$^{\uparrow}$ *window be routed through* ObservationBudgetLimiter$^{\uparrow}$ *and* RegularCauchyTailBudget$^{\uparrow}$*, and let a public* Real$^{\uparrow}$ *or completion-facing* CauchyLimitSeal$^{\uparrow}$ *consumer read that route. Then the consumed route factors through the same finite rows:*

ProbeBundle, InBundle, UnaryHistory, ObservationBudgetLimiter$^{\uparrow}$, RegularCauchyTailBudget$^{\uparrow}$, DyadicRatC

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The pullback exposes exactly the budget cap, tail threshold, finite StreamName window, dyadic ledger, RegSeqRat readback, and Real seal already locked by the StreamName budget route. It exports no quotient streams, selected host limits, countable-choice selectors, host real equality, metric completeness, or ambient* Real$^{\uparrow}$ *completeness.*

Proof. Start with the finite-window budget handoff of Definition 126.390. It places the accepted StreamName window, ProbeBundle ledger, InBundle membership rows, and UnaryHistory observations before any regularity row, dyadic tolerance row, or Real$^{\uparrow}$ seal row is consumed.

Next attach the sibling route of Definition 126.391. The route passes through the ObservationBudgetLimiter$^{\uparrow}$ budget cap and then through the RegularCauchyTailBudget$^{\uparrow}$ tail service before the dyadic ledger, RegSeqRat$^{\uparrow}$ readback, and Real$^{\uparrow}$ seal are exposed.

Now use the tail regular seal lock of Definition 126.395. It identifies the budget cap, tail threshold, finite window, dyadic ledger, readback, seal rows, and visible BHist, hsame, Cont, Pkg, and NameCert provenance as one locked finite route.

Finally pass the locked route through the CauchyLimitSeal$^{\uparrow}$ consumer boundary. The public route boundary of Definition 386.8 confines every public Real$^{\uparrow}$ or completion-facing read to the displayed route packet, and the downstream completion handoff of Definition 386.15 lets a completion consumer pull back only along that same scheduled window, dyadic observation ledger, regular source row, completion row, and seal row. The non-escape clauses from the cited StreamName and CauchyLimitSeal boundaries rule out quotient streams, selected host limits, countable-choice selectors, host real equality, metric completeness, and ambient Real$^{\uparrow}$ completeness. □

Theorem 126.397 (StreamName budget regular readback exhaustion)**.** *Every accepted finite* StreamName$^{\uparrow}$ *window routed through* ObservationBudgetLimiter$^{\uparrow}$ *and* RegularCauchyTailBudget$^{\uparrow}$ *to a public* Real$^{\uparrow}$ *consumer or a completion-facing* CauchyLimitSeal$^{\uparrow}$ *consumer is exhausted by the same finite readback route:*

ProbeBundle, InBundle, UnaryHistory, ObservationBudgetLimiter$^{\uparrow}$, RegularCauchyTailBudget$^{\uparrow}$, DyadicRatC

The exhausted packet carries exactly the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance of the StreamName budget handoff. It exports no quotient stream, selected host limit, countable-choice selector, host real equality, metric completeness, or ambient completeness.*

Proof. Apply Definition 126.396. It already pulls every public Real$^{\uparrow}$ read and every completion-facing CauchyLimitSeal$^{\uparrow}$ read back to the finite StreamName budget route through ProbeBundle, InBundle, UnaryHistory, the budget limiter, the regular tail budget, the dyadic core, the regular sequence row, and the Real seal.

Next use Definition 126.395. The lock identifies the shared budget cap, tail threshold, finite window, dyadic ledger, readback, and seal rows as a single route with its visible BHist, hsame, Cont, Pkg, and NameCert coordinates.

Finally apply Definition 126.337. Its non-escape clause excludes quotient streams, selected host limits, countable-choice selectors, host real equality, metric completeness, and ambient completeness from any such consumer read. Since the pullback and the lock name the same carrier coordinates, the consumer has no remaining route outside the displayed finite packet. □

Theorem 126.398 (StreamName RegSeqRat RealUp dyadic budget correspondence)**.** *Let $\mathcal{W}$ be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and sealed as a finite-window* $\mathsf{Real}^{\uparrow}$ *route. Then the public route determined by $\mathcal{W}$ is exactly the visible dyadic-budget route carried by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger: finite StreamName window rows,* ProbeBundle*,* InBundle*, certified unary observations, DyadicRatCore ledger and radius rows, RegSeqRat readback rows, RealUp finite seal rows, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Conversely, any public route displaying those same rows factors back through the StreamName finite-window budget handoff before a RegSeqRat readback or RealUp finite seal can be consumed. The correspondence exports no quotient stream, selected host limit, countable-choice selector, host real equality, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, start with Definition 126.390. It places the accepted StreamName window, ProbeBundle ledger, InBundle membership rows, and certified unary observations before any regularity, dyadic tolerance, or Real seal row is read.

Next apply Definition 126.395 and Definition 126.397. These identify the budget cap, tail threshold, finite window, dyadic ledger, RegSeqRat readback, Real seal, and visible BHist, hsame, Cont, Pkg, and NameCert provenance as one exhausted finite packet.

Now read that packet through the sibling ledger and endpoint gates. Use Definition 126.105, Definition 757.3, Definition 906.3, and Definition 38.314. Together they force the StreamName finite window, tail-budget service, DyadicRatCore radius ledger, RegSeqRat readback, and RealUp finite seal to expose the same visible dyadic-budget route.

For the reverse direction, suppose a public route already displays exactly those rows. Tail-budget coverage places its radius read inside the finite precision, tail-window, StreamName-window, and dyadic readback segment, while the regular Cauchy observation gate orders that segment before the RegSeqRat and Real seal reads.

The RealUp finite-window exhaustion obligation then leaves no endpoint row outside the displayed finite seal. Repacking the same rows gives the StreamName finite-window budget handoff of Definition 126.390, and the non-escape clauses in the cited results exclude quotient streams, selected host limits, countable-choice selectors, host real equality, metric completeness, and ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.399 (StreamName ObserverFilter finite-window handoff)**.** *Every accepted finite* $\mathsf{ObserverFilter}^{\uparrow}$ *selected-subhistory handoff to* $\mathsf{StreamName}^{\uparrow}$ *enters the finite-window budget surface only through the selected row S, observer ledger L, componentwise transports R, continuation routes C, provenance P, and local name N. The omitted rows O remain boundary witnesses in the observer-filter ledger. They do not supply RegSeqRat regularity, Real seal data, quotient stream equality, selected host limits, countable-choice selectors, or host real equality to the StreamName consumer.*

Proof. Start with the ObserverFilter handoff theorem Definition 514.4. It identifies the stream-facing route of an accepted filter packet as the selected subhistory through S, L, R, C, P, N.

Apply Definition 514.6. The finite source ledger is exhausted by the selected side and the omitted side, and the omitted side is kept as O rather than exported as StreamName data.

Now use Definition 126.390. Once the selected subhistory is read as a finite $\mathsf{StreamName}^{\uparrow}$ window, every regularity, dyadic tolerance, and $\mathsf{Real}^{\uparrow}$ seal row must pass through the finite observation-budget surface.

Finally apply Definition 126.393. The sibling route carries no coordinates for quotient stream equality, selected host limits, countable-choice selectors, host real equality, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Since O is not part of the selected StreamName source, omitted rows remain boundary ledger witnesses and cannot serve any of those downstream roles. □

126.27 StreamName Real-RegSeq shared-tail budget route

Theorem 126.400 (StreamName Real-RegSeq shared-tail budget route)**.** *Let W_0 and W_1 be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *windows consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback route, by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal route, or by a shared-tail route that serves both consumers. Suppose the two reads pass through the same* $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$ *coverage row of Definition 757.3 and the same* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row of Definition 560.11. Then every public seal or readback consumer of the two windows factors through exactly the finite StreamName window rows,* ProbeBundle, InBundle, UnaryHistory*, the dyadic tail-radius ledger, the shared threshold, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{Real}^{\uparrow}$ *finite-window ledger boundary.*

The route exports no quotient stream, host real equality, selected limit, independent tail oracle, countable-choice selector, or completeness principle.

Proof. Start with the local finite-window budget handoff. By Definition 126.390, every regularity row, dyadic tolerance row, and $\mathsf{Real}^{\uparrow}$ seal row consumed from a finite $\mathsf{StreamName}^{\uparrow}$ window is downstream of ProbeBundle, InBundle, UnaryHistory, the observation-budget surface, and the tail-budget rows.

Use the sibling StreamName route Definition 126.391 to keep this handoff inside the same finite observation-budget and tail-budget chain. The accepted windows W_0 and W_1 therefore present public data only through their displayed finite window rows and their attached transport, continuation, package, and naming rows.

Now read the common dyadic ledger. Apply Definition 757.3 to place each admitted tail-radius read inside the finite precision, tail-window, StreamName-window, and dyadic readback rows. Then apply Definition 757.6 to route the $\mathsf{RegSeqRat}^{\uparrow}$ readback and the $\mathsf{Real}^{\uparrow}$ seal boundary after that same ledger row.

Finally attach the shared threshold. The public shared-threshold certificate Definition 560.11 exposes the paired source, window, modulus, dyadic threshold, comparison, transport, continuation, provenance, and local naming rows, while Definition 560.56 fixes the displayed threshold ledger for duplicate transported reads of the same source-window-modulus route.

The carrier inventory is now exhausted. A consumer can project only the finite StreamName windows, ProbeBundle, InBundle, UnaryHistory, the dyadic tail-radius ledger, the shared threshold, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, and the $\mathsf{Real}^{\uparrow}$ finite-window ledger boundary, together with the displayed BHist, hsame, Cont, Pkg, and NameCert rows. None of the cited carriers contains a quotient stream, host real equality witness, selected limit, independent tail oracle, countable-choice selector, or completeness principle, so none can escape through the public route. □

Theorem 126.401 (StreamName shared-tail window pullback exactness)**.** *Let W_0 and W_1 be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *windows, and let*

$$S = (M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N)$$

be an accepted CauchySharedTailModulus$^{\uparrow}$ *packet whose displayed windows are the same* W_0 *and* W_1*. Every* Real$^{\uparrow}$ *seal read or* RegSeqRat$^{\uparrow}$ *readback pullback from these windows factors through the shared threshold* τ*, the dyadic ledger* D*, the paired windows* W_0, W_1*, the paired readbacks* Q_0, Q_1*, and the seal route* E, H, C, P, N *displayed by* S*.*

Replacing one side by a private threshold, quotient stream, selected limit, host real equality, or independent inverse-budget route is not a read of the packet S*.*

Proof. Apply Definition 126.400. It places the two finite windows on the common StreamName budget path through the dyadic tail-radius ledger, the shared threshold, the RegSeqRat$^{\uparrow}$ readback boundary, and the Real$^{\uparrow}$ finite-window seal boundary.

Now read the CauchySharedTailModulus$^{\uparrow}$ packet through Definition 983.4. It identifies any seal-facing consumer with the rows $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$. The paired-window service of Definition 983.6 keeps the two windows attached to the same threshold and dyadic ledger.

Finally compare reciprocal-window consumers only through the Definition 703.6. That comparison supplies no private threshold, quotient stream, selected limit, host real equality, or independent inverse-budget route, so every displayed pullback remains the read of the single packet S. □

Theorem 126.402 (StreamName shared-tail terminal face noncollapse)**.** *Every shared-tail packet accepted by the* StreamName$^{\uparrow}$ *route reports its terminal L10 read as four separate local faces: the* DyadicRatCore$^{\uparrow}$ *tolerance ledger, the* StreamName$^{\uparrow}$ *finite window, the* RegSeqRat$^{\uparrow}$ *readback and classifier row, and the* Real$^{\uparrow}$ *finite-window seal. The packet transports those faces only by the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The terminal read cannot be collapsed into quotient stream equality, host real equality, a selected limit, countable choice, ambient completeness, route-level formalstatus*, or an aggregate bridge row. None of these substitutes is a local face of the accepted shared-tail packet.*

Proof. Start with Definition 126.400. It places the accepted windows on the common StreamName route through the dyadic tail-radius ledger, the shared threshold, the RegSeqRat$^{\uparrow}$ readback boundary, and the Real$^{\uparrow}$ finite-window seal boundary.

Next apply Definition 126.401. Any seal read or readback pulled from the shared windows must read the single displayed packet through its threshold, dyadic ledger, paired windows, paired readbacks, and seal rows. Hence the terminal read is already local to the displayed packet.

Use Definition 301.173 to identify the same endpoint as the product of the four local status faces: DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$. The only shared transport permitted in that product is the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Finally apply Definition 38.536 together with the two-axis discipline of chapter 9203. Closure rows, verification rows, and bridge rows are read objectwise on the corresponding face; they do not combine into a route-level witness and cannot replace a missing terminal face. The excluded quotient, host-equality, selected-limit, choice, and completeness data are therefore outside the accepted shared-tail terminal read. □

126.28 StreamName Common-Refinement Terminal Real Seal

Theorem 126.403 (StreamName common-refinement terminal Real seal)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be finite-window* StreamName$^{\uparrow}$ *packages over the same certified endpoint maps, and let* $\mathcal{R}$ *be a certified common-refinement package restricting to both selected windows. Then every downstream*

$\mathsf{RegSeqRat}^{\uparrow}$ *handoff followed by a finite-window* $\mathsf{Real}^{\uparrow}$ *seal read factors through the single terminal finite tuple displayed by* $\mathcal{R}$*:*

$(\mathsf{RatStreamNameFiniteWindowClassifier}_{\mathcal{R}}, \mathsf{ProbeBundle}_{\mathcal{R}}, \mathsf{InBundle}_{\mathcal{R}}, \mathsf{UnaryHistory}_{\mathcal{R}}, \mathsf{RatHistoryClassifier}_{\mathcal{R}}, \mathsf{DyadicLed}$

The factorization reads the finite-window classifier, the ProbeBundle *row,* InBundle *membership rows,* UnaryHistory *observations, pointwise* RatHistoryClassifier *rows, dyadic ledger rows, displayed* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *rows. It does not identify quotient streams, assert host sequence equality, select limits, use ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or import metric-completeness data.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameCommonRefinementTerminalRealSeal`
↪ variant `BEDC.Derived.StreamNameUp.StreamName common refinement terminal real seal`

Proof. Begin with Definition 126.240. It pins the two selected windows to the common-refinement source tuple of $\mathcal{R}$ and keeps the downstream $\mathsf{RegSeqRat}^{\uparrow}$ and finite $\mathsf{Real}^{\uparrow}$ handoff reads on that public packet.

Next apply Definition 126.132. The finite seal read exposes only the StreamName window, pointwise rational rows, the finite Real seal boundary, componentwise transport, continuation routes, provenance, and local names.

Use Definition 126.137 to place the two selected windows in one common finite-window lattice. The classifier observations, bundle rows, membership rows, unary-history observations, dyadic ledger, transports, routes, provenance, and names are therefore read from the same finite packet.

Finally apply Definition 126.261. The meet packet is terminal for the RegSeqRat readback and finite Real seal handoff, so there is no carrier coordinate left for quotient equality, host sequence equality, selected limits, ambient Real completeness, or metric-completeness rows. □

Theorem 126.404 (StreamName Real-RegSeq terminal common-window lock)**.** *Let* $\mathcal{R}$ *be a common-refinement* $\mathsf{StreamName}^{\uparrow}$ *package whose selected finite window is consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and sealed as a finite-window* $\mathsf{Real}^{\uparrow}$ *row. Then the public consumer surface is the single terminal packet consisting of the finite* BHist *window,* RatHistoryClassifier *observations,* ProbeBundle *rows,* InBundle *rows,* UnaryHistory *observations, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the induced* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The packet exports no quotient stream, host sequence equality, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, independent* $\mathsf{Real}^{\uparrow}$ *carrier, or metric-completeness row.*

Proof. First apply Definition 126.403. It reduces every selected-window RegSeqRat handoff followed by a finite Real seal read to the finite tuple carried by the common-refinement package $\mathcal{R}$.

Next use Definition 126.257. The selected finite window is the meet-facing packet seen by both the StreamName observations and the downstream RegSeqRat consumer, so the classifier, bundle, membership, unary-history, dyadic, transport, continuation, provenance, and naming rows all come from one finite surface.

Apply Definition 126.356 to identify the StreamName window, RegSeqRat readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and Real seal boundary as a common finite pullback. Then use Definition 126.358 to make the Real-facing seal read deterministic on that pullback.

Finally apply Definition 126.140. The downstream consumer therefore factors through the listed terminal packet and has no exported coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, independent Real carriers, or metric-completeness data. □

Theorem 126.405 (StreamName-RegSeqRat-Real common-refinement seal pullback)**.** *Any common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window package consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and sealed as a* $\mathsf{Real}^{\uparrow}$ *finite-window row factors through exactly one finite pullback. The pullback consists of the StreamName window, the RegSeqRat readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. It exports no quotient stream, host sequence equality, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, or metric-completeness row.*

Proof. First apply Definition 126.403. The common-refinement package supplies the finite StreamName observations, bundle membership, unary history, dyadic ledger, transports, routes, provenance, and local names used by the downstream seal read.

Next apply Definition 126.404. The consumer surface is locked to the same selected finite window, RegSeqRat readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and induced $\mathsf{Real}^{\uparrow}$ seal row.

Use Definition 126.356 to read these four sibling rows as one finite pullback. Then apply Definition 126.358 to make the seal-facing route unique on that pullback.

The remaining displayed rows are exactly the BHist observations, hsame transports, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows already retained by the common-refinement packet. Since the packet contains no quotient-stream coordinate, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ completeness, or metric-completeness row, none of those claims is exported by the pullback. □

Theorem 126.406 (StreamName common-refinement Real seal uniqueness)**.** *Let* $\mathcal{R}_0$ *and* $\mathcal{R}_1$ *be common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packages over the same certified endpoint maps. Suppose that both packages expose the same terminal coordinates listed in Definition 126.403: the finite-window classifier,* $\mathsf{ProbeBundle}$ *row,* $\mathsf{InBundle}$ *membership rows,* $\mathsf{UnaryHistory}$ *observations,* $\mathsf{RatHistoryClassifier}$ *rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. If both packages feed the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, then every finite-window* $\mathsf{Real}^{\uparrow}$ *seal read produced from* $\mathcal{R}_0$ *and every finite-window* $\mathsf{Real}^{\uparrow}$ *seal read produced from* $\mathcal{R}_1$ *are the same public seal row under those displayed* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *coordinates. This equality is only the finite public seal row exposed by the common-refinement packet: it does not assert quotient-stream equality, host sequence equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, selected limits, or metric-completeness rows.*

Proof. Apply Definition 126.403 to both $\mathcal{R}_0$ and $\mathcal{R}_1$. Since the exposed terminal coordinates are assumed identical, both downstream reads factor through the same finite-window classifier, bundle rows, membership rows, unary-history observations, rational-history rows, dyadic ledger, transports, routes, provenance, and local names.

Next use Definition 126.404. The accepted $\mathsf{RegSeqRat}^{\uparrow}$ readback and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger are therefore locked to the same terminal common window for both packages, so neither package contributes an independent Real-facing carrier coordinate.

Now apply Definition 126.405. The shared terminal window, shared readback, and shared dyadic ledger place both finite-window $\mathsf{Real}^{\uparrow}$ seal reads on the same finite pullback with the displayed hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Finally use Definition 126.358. Determinacy on that pullback identifies the two seal reads as the same public seal row. The preceding factorization lists all exported coordinates, so the conclusion leaves no coordinate for quotient-stream equality, host sequence equality, ambient $\mathsf{Real}^{\uparrow}$ completeness, selected limits, or metric-completeness rows. □

Theorem 126.407 (StreamName common-refinement terminal subcover exactness)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets over certified endpoint maps. Suppose that each retained packet is consumed by the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and a finite-window* $\mathsf{Real}^{\uparrow}$ *seal read through the terminal surface of Definition 126.403. For every finite subfamily $J \subseteq I$, restrict the visible windows, classifier rows,* ProbeBundle *rows,* InBundle *membership rows,* UnaryHistory *observations,* RatHistoryClassifier *rows, dyadic ledger rows, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows to the indices in J.*

Then the restriction of the terminal Real-seal packet on I to J is exactly the terminal packet obtained by assembling the common-refinement windows indexed by J alone. The restricted packet has precisely the inherited $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows, and it introduces no quotient streams, host sequence equality, selected limits, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or independent seal coordinates.*

Proof. Restrict the finite family along $J \subseteq I$. The projection keeps exactly the selected StreamName windows, classifier rows, bundle rows, membership rows, unary-history observations, rational-history rows, dyadic ledger rows, transports, routes, provenance, and local names indexed by J.

Apply Definition 126.403 to the restricted family. Each retained consumer still reaches the same kind of terminal common-refinement packet before its $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and finite $\mathsf{Real}^{\uparrow}$ seal row are inspected.

Next use Definition 126.404. The restricted readback and seal rows are locked to the retained StreamName windows, so the subfamily cannot acquire a separate Real-facing carrier or seal coordinate.

Apply Definition 126.405. The retained StreamName window, accepted RegSeqRat readback, dyadic ledger, and Real seal row form the same finite pullback whether they are read as a restriction of the original family or assembled from the subfamily alone.

Finally use Definition 126.406. The restricted packet and the packet assembled from J have identical displayed terminal coordinates, hence they are the same public finite-window seal packet. The row inventory leaves no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, or independent seal coordinates. □

Theorem 126.408 (StreamName common-refinement terminal subcover associativity)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets whose retained consumers pass through the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal row of Definition 126.403. For nested finite subfamilies $K \subseteq J \subseteq I$, restrict the terminal packet on I first to J and then to K, retaining only the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *finite* BHist *observation,* hsame, Cont, Pkg, *and local* NameCert *rows. Then this two-step restriction is the same public finite-window packet as the direct restriction of the terminal packet on I to K.*

The associativity claim is only about those displayed public rows. It does not identify quotient streams, assert host sequence equality, select limits, use ambient $\mathsf{Real}^{\uparrow}$ *completeness, import metric-completeness data, or introduce independent seal coordinates.*

Proof. Apply Definition 126.407 to the inclusion $J \subseteq I$. The first restriction is exactly the terminal packet assembled from the common-refinement windows indexed by J, with only the displayed StreamName, RegSeqRat, dyadic, Real, history, transport, route, provenance, and naming rows.

Apply the same theorem to the inclusion $K \subseteq J$. The second restriction therefore has precisely the terminal coordinates obtained by assembling the windows indexed by K inside the already restricted J-packet.

Apply Definition 126.407 once more to the direct inclusion $K \subseteq I$. The direct packet and the two-step packet expose identical terminal coordinate lists, so Definition 126.406 identifies them as the same public finite-window seal packet. The coordinate inventory contains no slot for quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, or independent seal coordinates. □

Theorem 126.409 (StreamName common-refinement objectwise status stability)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets whose terminal packets feed the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal row. For nested finite subfamilies $K \subseteq J \subseteq I$, restrict the terminal packet on I first to J and then to K, retaining the displayed finite* BHist *observations,* hsame *transports,* Cont *routes,* Pkg *provenance, local* NameCert *rows, and the four local objectwise status records for* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$.

Then the restricted terminal packet preserves exactly those four local objectwise closurestatus, formalstatus, leantarget, and bridgestatus records. Equivalently, the terminal packet restricted to K satisfies the Phase $\mathsf{Real}^{\uparrow}$ *and Completion objectwise exit read exactly when the unrestricted terminal packet satisfies that read after projection to K. The claim excludes quotient stream equality, host sequence equality, selected limits, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, and standard bridge rows.*

Proof. First apply Definition 126.407. Restriction along a finite subfamily keeps precisely the displayed StreamName window, RegSeqRat readback, dyadic ledger, Real seal row, finite BHist observation, hsame, Cont, Pkg, and local NameCert rows.

Next apply Definition 126.408. The two-step restriction through J and then K has the same public terminal packet as the direct restriction from I to K, so the status read is independent of the route used to reach the retained finite subfamily.

Use Definition 126.405 and Definition 126.404. These two results keep the $\mathsf{StreamName}^{\uparrow}$ window, accepted $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and finite $\mathsf{Real}^{\uparrow}$ seal row on the same finite pullback after restriction.

Finally invoke Definition 38.792. The Phase Real and Completion exit criterion reads exactly the four local face records together with the displayed finite support rows. Since the preceding restrictions preserve those rows objectwise, the projected packet and the unrestricted packet projected to K satisfy the exit read together, and no aggregate formalstatus row, aggregate bridge row, standard bridge row, quotient stream equality, host sequence equality, selected limit, ambient Real completeness, or metric-completeness datum is introduced. □

Theorem 126.410 (StreamName common-refinement objectwise status sharpness)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets whose terminal packets feed the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the finite-window* $\mathsf{Real}^{\uparrow}$ *seal row. For every finite subfamily $K \subseteq I$, the restriction of the common-refinement terminal packet to K is accepted by the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion objectwise exit read if and only if the restricted packet preserves exactly the four local face records for* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *together with the displayed finite* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *support rows.*

The equivalence is sharp at that objectwise surface. It does not use or export an aggregate formalstatus row, an aggregate bridge row, a standard bridge substitute, quotient stream equality, host sequence equality, selected limits, countable choice, metric-completeness data, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For preservation, apply Definition 126.409. It already shows that finite-subfamily restriction keeps the four local objectwise closurestatus, formalstatus, leantarget, and bridgestatus records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, along with the displayed finite support rows.

The route used to reach the retained subfamily contributes no extra status datum. Use Definition 126.407 to identify the restriction of the ambient terminal packet with the packet assembled from the subfamily alone, and then use Definition 126.408 to remove dependence on any intermediate finite subfamily.

For the converse readback, start with the four preserved local face records and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows. Apply Definition 126.510 to read these rows as exactly the current Phase Real and Completion objectwise threshold. Then apply Definition 301.66 to place the RegSeqRat terminal read on the same four-face support surface.

Combining the two directions gives the stated equivalence for the restricted common-refinement terminal packet. Since every step reads only the four local face records and the listed finite support rows, the certificate has no coordinate for aggregate formalstatus data, aggregate bridge data, standard bridge substitutes, quotient stream equality, host sequence equality, selected limits, countable choice, metric-completeness data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.411 (StreamName CauchyLimitSeal forward lattice)**.** *Any common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and then by* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *factors through the StreamName window, the RegSeqRat readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the finite-window seal surface of chapter 386. The forward route carries only displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no quotient streams, host sequence equality, selected limits, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or metric-completeness data.*

Proof. First apply Definition 126.403. It places the common-refinement consumer read on the finite StreamName packet before any RegSeqRat or Real-facing row is inspected.

Next apply Definition 126.404 and Definition 126.405. These two results identify the same selected finite window with the RegSeqRat readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and the $\mathsf{Real}^{\uparrow}$ seal row, and they make that pullback terminal for the common-refinement packet.

Finally route the seal-facing consumer through the CauchyLimitSeal sibling chapter chapter 386. Its finite-window seal surface consumes the displayed StreamName schedule, RegSeqRat source, dyadic ledger, Real seal, transport, route, provenance, and naming rows; it does not add quotient streams, host sequence equality, selected limits, ambient Real completeness, or metric-completeness data. □

Theorem 126.412 (StreamName CauchyLimitSeal reverse source exhaustion)**.** *Whenever a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer route enters the* $\mathsf{StreamName}^{\uparrow}$ *common-refinement terminal packet through the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *finite-window seal surface, every public row contributed by that route is already one of the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The route exports no additional hidden tail witness, quotient stream, host sequence equality, selected external limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completion row, or standard bridge row.*

Proof. Start with the forward factorization in Definition 126.411. It places the StreamName-to-CauchyLimitSeal route on the selected finite window, the RegSeqRat readback, the dyadic ledger, the Real seal row, and the displayed transport, route, provenance, and naming rows.

On the CauchyLimitSeal side, apply Definition 386.116. Every sealed-limit read must pass through the scheduled $\mathsf{StreamName}^{\uparrow}$ window before the seal row is consumed. Then use Definition 386.121; its sibling-lattice statement keeps the route on the displayed finite seal surface and rules out a host-level substitute.

It remains to exhaust the coordinates of the two public packets. The StreamName terminal packet lists only the selected window, RegSeqRat readback, dyadic ledger, Real seal, BHist observations, hsame transports, Cont routes, Pkg provenance, and local NameCert rows, while the CauchyLimitSeal surface contributes only its displayed finite-window seal coordinates. Their common coordinates are exactly the rows named in the statement, so there is no remaining slot for a hidden tail witness, quotient stream, host sequence equality, selected external limit, ambient Real completeness row, metric-completion row, or standard bridge row. □

Theorem 126.413 (StreamName common-refinement terminal status pullback)**.** *Let $\mathcal{R}$ be a certified common-refinement* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet whose terminal read is consumed by the Phase* $\mathsf{Real}^{\uparrow}$ *and Completion route. Then the terminal read satisfies the face-local status readback exactly when the four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

retain their own local `closurestatus`*,* `formalstatus`*,* `leantarget`*, and* `bridgestatus` *rows over the same displayed support*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The pullback is only the four-face common-refinement route. It excludes aggregate status rows, quotient streams, selected limits, countable choice, metric-completeness data, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 126.403. The certified common-refinement packet places every terminal Real-facing read on the single finite surface carrying the StreamName window, RegSeqRat readback, dyadic ledger, Real seal row, displayed BHist, componentwise hsame, displayed Cont, Pkg, and local NameCert rows.

Next apply Definition 126.409. Restricting the common-refinement route preserves exactly the four local objectwise status records for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ over that same support, without creating an aggregate status coordinate.

For the forward direction, use Definition 126.425. A Phase Real and Completion terminal read obtains its status rows from the concrete sibling faces themselves, so any accepted read through $\mathcal{R}$ must read the four local `closurestatus`, `formalstatus`, `leantarget`, and `bridgestatus` rows on the displayed support.

For the reverse direction, assume those four face-local rows are retained over the displayed BHist, hsame, Cont, Pkg, and NameCert support. Apply Definition 126.427 to repack precisely those rows as the terminal Phase Real and Completion status read. The preceding terminal seal and objectwise-stability results keep the read on the common-refinement packet, so there is no coordinate from which to form aggregate status rows, quotient streams, selected limits, countable choice, metric-completeness data, standard bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.414 (StreamName CauchyLimitSeal downstream orphan route)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet used by a completion-facing seal consumer is consumed through the sibling* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route of chapter 386 after the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and*

$\mathsf{Real}^{\uparrow}$ *seal rows are displayed. The route carries only the selected StreamName window, regular-rational readback, dyadic ledger, Real seal, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

It exports no quotient streams, selected host limits, host real equality, hidden tail witnesses, ambient completeness, or metric-completion rows.

Proof. Start with Definition 126.411. It places every StreamName-to-CauchyLimitSeal consumer read on the selected finite window, the RegSeqRat readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{Real}^{\uparrow}$ seal row, and the displayed transport, route, provenance, and naming rows.

Use reverse source exhaustion, Definition 126.412. A route entering the StreamName common-refinement packet from the CauchyLimitSeal finite-window seal surface contributes no additional row beyond the selected window, readback, dyadic ledger, Real seal, and local BEDC routing coordinates.

Finally apply the sibling CauchyLimitSeal route, Definition 386.118 and Definition 386.49. These rows force the completion-facing consumer through the displayed StreamName schedule before the seal is consumed, and they leave no carrier coordinate for quotient streams, selected host limits, host real equality, hidden tail witnesses, ambient completeness, or metric-completion data. □

126.29 StreamName Open-Phase Terminal Route

Theorem 126.415 (StreamName open-phase terminal route)**.** *Every Phase Real and Completion finite-window* $\mathsf{StreamName}^{\uparrow}$ *consumer whose route reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface of chapter 301 and then the* $\mathsf{Real}^{\uparrow}$ *seal surface of chapter 38 factors through one terminal finite packet. The packet consists of the StreamName window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger of chapter 291, the* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The boundary is a finite BEDC handoff route. It exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. First apply Definition 126.403. It places the StreamName finite-window consumer on the common-refinement packet carrying the visible window, observation rows, transports, routes, provenance, and local names.

Next apply Definition 126.404. The route from the StreamName window into the $\mathsf{RegSeqRat}^{\uparrow}$ readback and the finite $\mathsf{Real}^{\uparrow}$ seal is locked to a single terminal consumer surface.

Now use Definition 126.356. The StreamName window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback of chapter 301, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger of chapter 291, and the $\mathsf{Real}^{\uparrow}$ seal row of chapter 38 occupy one finite pullback rather than independent carrier routes.

Finally apply Definition 126.358. The seal-facing consumer is determined by that pullback, so the Phase Real and Completion boundary reads only the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates already present in the terminal packet. □

Theorem 126.416 (StreamName open-phase terminal non-escape)**.** *Every Phase Real and Completion consumer satisfying the terminal finite packet route of Definition 126.415 receives only the StreamName window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It receives no quotient stream, no host sequence equality, no selected limit, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Proof. First invoke Definition 126.415. It identifies the consumer route with the terminal finite packet and names the StreamName window, readback, ledger, seal row, observations, transports, displayed routes, provenance, and local naming rows that the packet exposes.

Next apply Definition 126.403 and Definition 126.404. These results place the Phase Real and Completion read on the common-refinement terminal surface and lock the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal access to the same finite window.

Use Definition 126.356. The StreamName window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row form one finite pullback, so a consumer read has no independent carrier route outside that packet.

Finally apply Definition 126.358. Pullback seal determinacy exhausts the seal-facing read by the displayed packet coordinates, excluding quotient streams, host sequence equality, selected limits, ambient completeness rows, metric-completeness data, and standard bridge rows. □

Theorem 126.417 (StreamName open-phase four-face lock)**.** *Every open-phase terminal consumer for the Phase Real and Completion boundary factors through exactly the ordered four-face route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}.$$

The only transport available along this route is the displayed BHist *observation data, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *naming. The route exports no quotient stream, no host sequence equality, no selected limit, no ambient completeness row, no metric-completeness datum, and no standard bridge row.*

Proof. First invoke Definition 126.415. It places every Phase Real and Completion consumer on the terminal finite packet and names the StreamName window, readback, ledger, seal row, observations, transports, routes, provenance, and local naming rows.

Next apply Definition 126.416. This excludes any consumer coordinate outside the terminal packet, including quotient streams, host sequence equality, selected limits, ambient completeness rows, metric-completeness data, and bridge rows.

Use Definition 126.356. The StreamName window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal occupy one finite pullback, so they are consumed as one ordered route rather than four independent faces.

Finally apply Definition 126.358. The seal-facing read is determined by that pullback, and the only remaining support rows are the displayed BHist, hsame, Cont, Pkg, and NameCert coordinates. □

Theorem 126.418 (StreamName terminal four-face exit completeness)**.** *An accepted Phase Real and Completion terminal read through* $\mathsf{StreamName}^{\uparrow}$ *is exit-complete exactly when it exposes the four local faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *together with the displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *support rows of the terminal packet. Conversely, those four faces and support rows determine the terminal exit packet for the Phase Real and Completion boundary.*

The exit packet exports no quotient stream, no host sequence equality, no selected limit, no countable-choice coordinate, no metric-completeness datum, no aggregate formalstatus row, no aggregate bridge row, no standard bridge row, and no ambient $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply Definition 126.415. It places the accepted Phase Real and Completion read on the terminal finite packet and lists the StreamName window, the readback surface, the dyadic ledger, the Real seal row, observations, transports, routes, provenance, and local names.

Next use Definition 126.416. This removes every coordinate outside the terminal packet, including quotient streams, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, and bridge rows. The same displayed route leaves no countable-choice or aggregate status coordinate because the packet records only local BEDC support rows.

Now apply Definition 126.417. The terminal packet is therefore read in the ordered four-face route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, rather than as a claim about independent carrier surfaces.

Finally invoke Definition 126.358. Once the four local faces and displayed BHist, hsame, Cont, Pkg, and NameCert rows are fixed, seal determinacy leaves one terminal exit packet. The roadmap two-axis discipline keeps these local face status records separate from the construction route, so the theorem records the exit surface without asserting ambient $\mathsf{Real}^{\uparrow}$ completeness or an aggregate verification or bridge row. □

126.30 StreamName Open-Phase Terminal Exactness

Theorem 126.419 (StreamName open-phase terminal seal exactness)**.** *Every Phase Real and Completion seal read available from an open-phase terminal* $\mathsf{StreamName}^{\uparrow}$ *consumer is available exactly through the four-face route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}.$$

The supporting rows are the displayed BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, local* NameCert *rows, the StreamName finite-window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. The seal read exports no quotient stream, no host sequence equality, no selected limit, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Proof. Apply Definition 126.415. It places the Phase Real and Completion seal read on the terminal finite packet carrying the StreamName window, the DyadicRatCore ledger, the RegSeqRat readback, the RealUp seal row, observations, transports, routes, provenance, and local names.

Next use Definition 126.615 and Definition 126.488. The open-phase consumer can reach the seal only through the ordered four-face route displayed in the statement.

Finally apply Definition 126.358. The seal-facing read is determined by those four faces and their displayed support rows, so there is no second route through quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, or standard bridge rows. □

Theorem 126.420 (StreamName open-phase terminal ledger coverage)**.** *Every public coordinate of the open-phase terminal route for a Phase Real and Completion consumer is one of the displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, local* NameCert *rows, the StreamName window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, or the* $\mathsf{Real}^{\uparrow}$ *seal. In particular, the terminal ledger contains no quotient stream coordinate, no host sequence equality coordinate, no selected-limit coordinate, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate, no metric-completeness coordinate, and no standard bridge coordinate.*

Proof. First apply Definition 126.416. It exhausts the consumer surface by the terminal packet rows and excludes quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, and standard bridge rows.

Now use Definition 126.403. The common-refinement terminal seal theorem supplies the finite public inventory: the displayed window observations, classifier rows, bundle rows, dyadic ledger rows, transports, routes, provenance, and local names that feed the RegSeqRat readback and RealUp seal.

Combining the two inventories leaves exactly the rows named in the statement. Since every public coordinate is already accounted for in the terminal packet and the common-refinement seal surface, no hidden quotient, host sequence, selected-limit, completeness, metric-completeness, or standard bridge coordinate remains. □

Theorem 126.421 (StreamName open-phase terminal readback determinacy)**.** *Let two Phase Real and Completion consumers read the same open-phase terminal route. If they have the same StreamName window face, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the same* $\mathsf{Real}^{\uparrow}$ *seal face, and the same displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *transport and provenance rows, then they determine the same terminal packet. The determined packet is only the finite BEDC packet of the four displayed faces and their support rows; it is not a quotient stream, host sequence equality, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness object, metric-completeness datum, or standard bridge row.*

Proof. Apply Definition 126.358 to the two consumer reads. Equality of the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and displayed support rows gives the same seal-facing finite pullback surface.

Next apply Definition 126.420. Every public coordinate of either terminal packet is one of the four displayed faces or one of the listed transport, route, provenance, observation, and naming rows.

The two packets therefore have the same complete public inventory. Since the coverage theorem leaves no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, or standard bridge rows, there is no remaining source from which two distinct terminal packets could be read. □

Theorem 126.422 (StreamName Real-RegSeqRat terminal factorization)**.** *Any Phase Real and Completion consumer that reaches a* $\mathsf{Real}^{\uparrow}$ *seal through* $\mathsf{StreamName}^{\uparrow}$ *factors uniquely through the ordered four-face route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}$$

with displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The factorization is the consumer contract for the terminal seal read: no quotient stream, host sequence equality, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness row, or bridge row can serve as an alternate factor.*

Proof. Apply Definition 126.419. It supplies existence of the ordered route from the StreamName window through the DyadicRatCore ledger and RegSeqRat readback to the RealUp seal.

Use Definition 126.615 and Definition 126.488 to identify that route as the L10 source order.

Next apply Definition 126.420. The coverage theorem exhausts the terminal ledger by the four faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Use Definition 126.421 for uniqueness. Once the four faces and support rows agree, two consumer reads determine the same finite terminal packet.

Finally use Definition 126.423. The boundary theorem rules out quotient stream, host sequence equality, selected limit, ambient Real completeness, metric-completeness, and bridge rows as alternate routes, so the factorization is the unique consumer contract. □

Theorem 126.423 (StreamName-RegSeqRat-RealUp terminal seal boundary)**.** *Any Phase Real and Completion consumer that reaches a quotient-refusal or seal-facing boundary through* $\mathsf{StreamName}^{\uparrow}$ *must expose exactly the terminal four-face route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}$$

together with the displayed BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows before any refusal ledger is read. Consequently the refusal ledger cannot supply quotient streams, host sequence equality, selected limits, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or standard bridge rows.*

Proof. Apply Definition 126.419. It fixes every seal-facing read available through the open-phase terminal $\mathsf{StreamName}^{\uparrow}$ consumer on the four displayed faces and their support rows.

Next use Definition 126.420. The terminal packet has no public coordinate outside the StreamName finite window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{Real}^{\uparrow}$ seal, and the displayed observation, transport, route, provenance, and local naming rows.

Apply Definition 126.421. Once those rows agree, the terminal packet is determined as the finite BEDC packet and not as a quotient stream, host sequence equality, selected limit, ambient completeness object, metric-completeness datum, or standard bridge row.

Finally use the QuotientStreamRefusal route-ordering surface of Definition 998.8 together with Definition 126.615. A quotient-refusal consumer may read its refusal ledger only after the ordered StreamName, DyadicRatCore, RegSeqRat, and RealUp route has been exposed. At the StreamName terminal seal boundary, the dyadic ledger supplies the finite tolerance face consumed before the RegSeqRat readback, so the refusal row records non-export rather than adding quotient, equality, limit, completeness, metric, or bridge data. □

Theorem 126.424 (StreamName terminal face status readback)**.** *Any Phase Real and Completion terminal read through* $\mathsf{StreamName}^{\uparrow}$ *reports the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces by reading each face's own local* `closurestatus`*,* `formalstatus`*,* `leantarget`*, and* `bridgestatus` *rows. The readback is facewise: no aggregate route-level status, bridge token, quotient stream, selected limit, ambient completeness, metric-completeness datum, countable-choice row, or host equality can replace one face's local status record.*

Proof. Apply Definition 126.419. It fixes the terminal read on the four-face route from the StreamName window through the DyadicRatCore ledger and RegSeqRat readback to the RealUp seal.

Next apply Definition 126.420. The terminal ledger exposes only the four named faces and their displayed observation, transport, route, provenance, and local naming rows, so the status rows available at the terminal boundary are the local rows attached to those faces.

Use Definition 126.421. Once the four faces and their support rows agree, a consumer read determines the same finite terminal packet; there is no second packet whose aggregate status, bridge token, quotient stream, selected limit, ambient completeness, metric-completeness datum, countable-choice row, or host equality could stand in for a local face record.

Finally apply Definition 126.423. The boundary theorem keeps every seal-facing read inside the displayed terminal route before any refusal ledger is read. The two-axis discipline of section 9203.6 then reads paper closure and Lean verification independently at each local face, so the `closurestatus`, `formalstatus`, `leantarget`, and `bridgestatus` rows remain face-local rather than route-level summaries. □

Theorem 126.425 (StreamName terminal sibling status readback)**.** *Any Phase Real and Completion terminal read through* $\mathsf{StreamName}^{\uparrow}$ *reads its terminal face-status records from the concrete*

sibling chapters chapter 291, chapter 301, and chapter 38, together with the local $\mathsf{StreamName}^{\uparrow}$ *face itself. The read is chapter-local at each face:* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *each contribute their own* `closurestatus`, `formalstatus`, `leantarget`, *and* `bridgestatus` *rows. No aggregate formalstatus row, aggregate bridge token, quotient stream, selected limit, ambient completeness row, metric-completeness datum, countable-choice row, or host equality row can replace those concrete sibling records.*

Proof. Apply Definition 126.424. It already forces the terminal read to inspect closure, formal status, Lean target, and bridge status face by face rather than through a route-level summary.

Next apply Definition 126.420. The finite terminal inventory contains only the StreamName window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{Real}^{\uparrow}$ seal, and their displayed observation, transport, route, provenance, and local naming rows.

Use Definition 126.423 to place that inventory on the terminal route before any refusal ledger is read. The concrete sibling chapters chapter 291, chapter 301, and chapter 38 identify the dyadic ledger, regular readback, and real-seal faces, while the present $\mathsf{StreamName}^{\uparrow}$ chapter supplies the finite-window face.

Therefore the terminal status read has exactly four local chapter sources. Since every excluded coordinate lies outside the finite ledger and outside the terminal boundary, none of those coordinates can serve as a substitute status record for any face. □

Theorem 126.426 (StreamName terminal face-local status strengthening)**.** *Let* $\mathcal{T}$ *be a Phase Real and Completion terminal packet read through* $\mathsf{StreamName}^{\uparrow}$ *along the four displayed faces* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Let* F *be one of these four faces. Form* $\mathcal{T}_F^{+}$ *by replacing only the local* `formalstatus`, `leantarget`, *or* `bridgestatus` *row attached to* F *by a stronger local row attached to the same face.*

Assume that the other three face records are unchanged and that the displayed BHist, hsame, Cont, Pkg, *and* NameCert *support rows are unchanged. Then* $\mathcal{T}_F^{+}$ *presents the same four-face terminal packet as* $\mathcal{T}$. *Conversely, any Phase Real and Completion terminal packet with the same face-status readback and with the same displayed support rows can differ from* $\mathcal{T}$ *only by such a face-local strengthening on one of the four status, Lean-target, or bridge-status rows.*

This invariance is confined to local face records. It does not introduce an aggregate formalstatus row, aggregate leantarget row, aggregate bridge row, quotient stream, selected limit, countable-choice row, metric-completeness datum, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, or any replacement for the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Proof. For the forward direction, apply Definition 126.424. The terminal read inspects status, Lean-target, and bridge-status data face by face, so replacing a row attached to F by a stronger row attached to the same face keeps the read on the same local source.

Next apply Definition 126.425. The concrete sibling sources for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the local $\mathsf{StreamName}^{\uparrow}$ source, are unchanged except for the stronger row on F. The terminal packet therefore still has the same four chapter-local face sources.

Now use Definition 126.420. Since the other three face records and all displayed BHist, hsame, Cont, Pkg, and NameCert support rows are fixed, the public inventory of the terminal ledger is the same finite four-face inventory before and after the local strengthening.

For the converse direction, suppose another terminal packet has the same face-status readback and the same displayed support rows. The face-status readback theorem fixes all status-bearing rows to local faces, while the sibling readback theorem fixes the concrete chapter source of each face. Ledger coverage leaves no public coordinate outside those four face records and their displayed support rows.

Finally apply Definition 126.423. The terminal boundary rules out alternate reads through quotient streams, selected limits, countable-choice rows, metric-completeness data, aggregate status rows, aggregate Lean-target rows, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness. Hence any remaining difference between the packets is exactly a stronger local `formalstatus`, `leantarget`, or `bridgestatus` row attached to one of the four faces. □

Theorem 126.427 (StreamName open-phase terminal local threshold equivalence)**.** *Let $\mathcal{T}$ be a Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal packet read through* $\mathsf{StreamName}^{\uparrow}$ *along the four displayed faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Then $\mathcal{T}$ satisfies the current Phase Real and Completion roadmap exit read if and only if each of the four faces exposes its own local scoped-closure and audit-clean threshold rows, and $\mathcal{T}$ carries only the displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The equivalence is terminal and face-local. It does not introduce or consume aggregate `formalstatus`*, aggregate* `leantarget`*, or aggregate* `bridgestatus` *rows, quotient streams, selected limits, countable-choice rows, metric-completeness data, standard bridge rows, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, read the terminal packet by Definition 126.424. The Phase Real and Completion terminal read reaches the four displayed faces by their own local status records, not by an aggregate route credential.

Next apply Definition 126.425. The dyadic, finite-window, regular-readback, and real-seal status records are localized at the concrete $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ sources. The current exit read can therefore be handed to the Real-side threshold criterion as a four-face objectwise packet.

Use Definition 38.796. It identifies the current Phase Real and Completion exit criterion with exactly the product of the four scoped-closure and audit-clean local threshold rows, supported only by BHist, hsame, Cont, Pkg, and NameCert.

For the reverse direction, assume the four local threshold records and the displayed support rows are present. The Real-side threshold theorem repacks those rows as the current roadmap exit read. Apply Definition 126.426 to transport any same-face status refinement without changing the terminal packet or adding a route-level status row.

Finally apply Definition 126.423. The terminal boundary keeps the packet on the displayed four-face route before any refusal ledger is read, so there is no coordinate from which to form aggregate formalstatus, leantarget, or bridgestatus rows, quotient streams, selected limits, countable-choice rows, metric-completeness data, standard bridge rows, or $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.428 (StreamName terminal local threshold pullback)**.** *Let $\mathcal{T}$ and $\mathcal{T}'$ be Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal packets read through* $\mathsf{StreamName}^{\uparrow}$ *along the four displayed faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Assume that a certified pullback or support-preserving refinement from $\mathcal{T}$ to $\mathcal{T}'$ preserves the $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *face rows and preserves the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then $\mathcal{T}$ satisfies the current Phase Real and Completion local-threshold exit read if and only if $\mathcal{T}'$ satisfies the same exit read.*

This pullback invariance is confined to the four L10 faces and their displayed support. It does not introduce or consume quotient streams, selected limits, countable-choice rows, metric-completeness data, aggregate `formalstatus` *rows, aggregate* `leantarget` *rows, aggregate bridge rows, standard bridge rows, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, apply Definition 126.427 to $\mathcal{T}$. The exit read is exactly the four local scoped-closure and audit-clean threshold rows over the displayed BHist, hsame, Cont, Pkg, and NameCert support.

The certified pullback or refinement preserves each of those four face rows and preserves the displayed support rows. Apply Definition 126.426 face by face to transport any same-face status strengthening without changing the terminal packet or creating a route-level status coordinate. Applying Definition 126.427 to $\mathcal{T}'$ then yields the same current exit read.

For the reverse direction, use the same argument with $\mathcal{T}'$ as the packet satisfying the exit read and $\mathcal{T}$ as the packet obtained by reading the preserved four-face support back along the certified pullback. The equivalence theorem again reduces the exit read to the four local threshold rows, and facewise preservation carries those rows back to the original packet.

It remains to exclude non-face support. Apply Definition 126.420 to both packets: every public coordinate is one of the four displayed faces or one of the displayed BHist, hsame, Cont, Pkg, and NameCert support rows. Finally apply Definition 126.423. The terminal boundary rules out quotient streams, selected limits, countable-choice rows, metric-completeness data, aggregate formalstatus rows, aggregate leantarget rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness, so no outside coordinate can affect the threshold read. □

126.31 StreamName Open-Phase Window Budget Routes

Theorem 126.429 (StreamName open-phase window index nonempty)**.** *Every Phase Real and Completion consumer satisfying the open-phase terminal route of Definition 126.415 reads a nonempty finite window-index surface before it reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback of chapter 301, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger of chapter 291, and the finite* $\mathsf{Real}^{\uparrow}$ *handoff rows of chapter 38. The window-index surface is the one carried by the common-refinement terminal Real seal of Definition 126.403; it consists only of displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The route exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. Start with Definition 126.415. It places the Phase Real and Completion consumer on the terminal finite packet whose visible entries include the StreamName window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and the finite $\mathsf{Real}^{\uparrow}$ seal row.

Apply Definition 126.403. The common-refinement packet displays the finite-window classifier, probe rows, membership rows, unary-history observations, rational-history rows, dyadic ledger rows, transports, routes, provenance, and local names before the downstream handoff is read.

Now use Definition 126.384. The accepted finite-window handoff must expose a nonempty index row on that displayed packet, so the Phase Real and Completion route has a finite window-index surface before it can reach the RegSeqRat, DyadicRatCore, or Real-facing rows.

Finally apply Definition 126.416. Since the terminal packet contains no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, or metric-completeness data, none of those objects is exported by the nonempty index route. □

Theorem 126.430 (StreamName open-phase finite-window budget)**.** *Every Phase Real and Completion consumer routed through the terminal StreamName packet has a finite-window budget route whose source is the nonempty StreamName window index, whose middle rows are the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and whose target is the finite* $\mathsf{Real}^{\uparrow}$ *seal handoff. The budget is consumed on the common-refinement terminal surface of Definition 126.403 and the open-phase terminal route of Definition 126.415.*

The budget route carries only displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. It exports no quotient stream, no host sequence equality, no selected limit, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. First apply Definition 126.429. The consumer has a finite nonempty StreamName window-index surface before any downstream Real-facing read occurs.

Next use Definition 126.136. Enlarging or transporting the selected finite window changes only the displayed budget rows and keeps the consumer inside the finite StreamName packet.

Apply Definition 126.356. The StreamName window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and finite $\mathsf{Real}^{\uparrow}$ seal row form one finite pullback, so the same window budget supports all three downstream faces.

Finally invoke Definition 126.358 and Definition 126.416. Seal determinacy pins the Real-facing read to that finite pullback, and non-escape removes quotient streams, host sequence equality, selected limits, ambient Real completeness, and metric-completeness data from the exported surface. □

Theorem 126.431 (StreamName open-phase budget source determinacy)**.** *Every Phase Real and Completion consumer that reaches a finite* $\mathsf{Real}^{\uparrow}$ *seal through the StreamName finite-window budget has a unique displayed source route. The route is the ordered four-face handoff*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window budget} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{finite seal.}$$

If a second displayed route has the same BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows, then that route factors through the same finite-window budget packet. Thus the source of the finite* $\mathsf{Real}^{\uparrow}$ *seal is determined by the StreamName budget packet together with its RegSeqRat readback and DyadicRatCore ledger.*

The determinacy statement exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. Begin with Definition 126.430. It places the Phase Real and Completion consumer on a displayed finite packet whose source is the nonempty StreamName window budget and whose downstream faces are the RegSeqRat readback, the DyadicRatCore ledger, and the finite Real seal row.

Apply Definition 126.356. The four displayed faces are not independent rows: they form one finite pullback over the same StreamName window budget packet, with the same BHist observations, hsame transports, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows.

Now use Definition 126.358. Any second displayed route with the same observations, transports, routes, provenance, and name rows reaches the same finite Real seal only by factoring through that pullback. Hence it factors through the original finite-window budget packet and cannot supply a distinct source for the seal.

Finally invoke Definition 126.416. The terminal packet has no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, or metric-completeness data, so the determinacy claim is entirely a finite displayed-route statement. □

Theorem 126.432 (StreamName open-phase tail-budget stability)**.** *Every Phase Real and Completion consumer routed through the finite-window budget of Definition 126.430 keeps the same nonempty StreamName window-budget source after certified successor and tail reindexing. The transported read still factors through the ordered public route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window budget} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{finite seal.}$$

In particular, every $\mathsf{RegSeqRat}^{\uparrow}$ *tail read obtained from that reindexing remains a read of the original finite budget packet, with transported* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream, no host sequence equality, no selected limit, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. Start with Definition 126.430. It supplies the nonempty StreamName window-budget source and places the $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and finite $\mathsf{Real}^{\uparrow}$ seal row on the same common-refinement terminal packet.

Apply Definition 126.7 to the certified successor read. Then use Definition 126.221 and Definition 126.202 to transport the visible tail window back through the common StreamName refinement. These steps change only the selected finite window indices and their displayed transport rows; they do not introduce a new source for the budget.

Now invoke Definition 126.356. The transported StreamName window, the RegSeqRat tail readback, the DyadicRatCore ledger, and the finite Real seal row are still one finite pullback, so the successor-tail read factors through the same four-face route as the original budget.

Finally apply Definition 126.416. Since the terminal packet has no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, or metric-completeness data, the transported tail-budget route cannot export any of those objects. □

Theorem 126.433 (StreamName open-phase tail-budget normal form)**.** *Every Phase Real and Completion consumer obtained from a certified successor or tail reindexing of the StreamName finite-window budget returns to the same ordered normal form*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window budget} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{finite seal.}$$

The reindexed read has no additional source surface: it is supported only by displayed BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows on the finite budget packet.*

Consequently every such successor or tail read factors through the same four-face route as the original open-phase budget. It exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no bridge row.*

Proof. First use Definition 126.430. It supplies the finite budget packet whose visible source is the StreamName window and whose downstream faces are the RegSeqRat readback, the DyadicRatCore ledger, and the finite Real seal.

Next apply Definition 126.432. Certified successor and tail reindexing preserve that packet as the source of the transported read, so the consumer cannot leave the finite-window budget while passing to the reindexed RegSeqRat face.

Now invoke Definition 126.434 and Definition 126.435. The first result orders the public route through the four displayed faces, and the second locks the RegSeqRat readback to the same nonempty StreamName budget source.

Finally use terminal non-escape for the open-phase packet. Since the terminal surface contains only displayed BHist, hsame, Cont, Pkg, and NameCert support rows, there is no coordinate from which a quotient stream, host equality, selected limit, ambient completeness row, metric-completeness datum, or bridge row could be exported. □

Theorem 126.434 (StreamName open-phase Real seal route)**.** *Every Phase Real and Completion handoff that begins at a* $\mathsf{StreamName}^{\uparrow}$ *finite window and ends at a finite* $\mathsf{Real}^{\uparrow}$ *seal row factors through the finite-window budget route of Definition 126.430. The handoff therefore has the ordered public route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window budget} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{finite seal.}$$

The route is the terminal BEDC surface already exposed by Definition 126.415 and Definition 126.403.

It exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. Begin with the finite-window budget route of Definition 126.430. It supplies the nonempty window-index source, the RegSeqRat readback, the DyadicRatCore ledger, and the finite Real seal row on one displayed packet.

Next apply Definition 126.404. The RegSeqRat readback and Real seal access are locked to the same common finite window, with the dyadic ledger read from that packet rather than from an independent carrier.

Use Definition 126.405. The common-refinement seal pullback is unique for the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and Real seal row.

Finally apply Definition 126.417. The Phase Real and Completion handoff is exactly the displayed four-face route, and the non-escape clauses already attached to that route exclude quotient streams, host sequence equality, selected limits, ambient Real completeness, and metric-completeness data. □

Theorem 126.435 (StreamName open-phase RegSeqRat budget source lock)**.** *Every Phase Real and Completion consumer whose* $\mathsf{RegSeqRat}^{\uparrow}$ *readback is obtained through the StreamName finite-window budget must consume the same nonempty StreamName window-index source before it reads any downstream row. Its ordered public route is*

$$\mathsf{StreamName}^{\uparrow}\ \textit{nonempty window index} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{finite seal.}$$

The $\mathsf{RegSeqRat}^{\uparrow}$ *readback is therefore locked as a consumer of the same nonempty source that supports the finite-window budget, and the Real-facing seal row is reached only after the DyadicRatCore ledger has been read from that packet.*

The route exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness datum.*

Proof. Begin with Definition 126.429. It supplies the nonempty StreamName window-index source that every Phase Real and Completion consumer must meet before any $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ row is read.

Apply Definition 126.430. The budget route places the $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and finite $\mathsf{Real}^{\uparrow}$ seal on the same common-refinement packet whose source is that nonempty window index.

Use Definition 126.432. Certified successor and tail reindexing keep the RegSeqRat readback on the original finite budget packet, so the readback cannot acquire a separate source.

Finally invoke Definition 126.434. The Real handoff is the displayed four-face route through StreamName, RegSeqRat, DyadicRatCore, and the finite Real seal, and its non-escape clauses exclude quotient streams, host sequence equality, selected limits, ambient Real completeness, and metric-completeness data. □

Theorem 126.436 (StreamName open-phase finite-window support row minimality)**.** *Every accepted four-face Phase Real and Completion read through the open StreamName route exposes exactly the StreamName finite-window budget, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the finite* $\mathsf{Real}^{\uparrow}$ *seal, supported by the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Dropping any one of those support rows leaves the accepted finite packet without the row needed to read the next face of the route.*

Conversely, adding quotient stream equality, selected limit data, ambient completeness, countable choice, metric-completeness, arithmetic or order package data, or a bridge row leaves the current open-phase route. Such data are not coordinates of the terminal finite packet and cannot be read as part of the accepted Phase Real and Completion surface.

Proof. Start from the finite-window budget theorem, Definition 126.430. It identifies the accepted budget as a finite StreamName packet whose downstream faces are exactly the RegSeqRat readback, the DyadicRatCore ledger, and the finite Real seal.

Use the RegSeqRat budget source lock, Definition 126.435. The readback cannot acquire an independent source, so removing the StreamName budget or any displayed support row needed by that budget breaks the route rather than producing another accepted four-face read.

Now apply the Real seal route theorem, Definition 126.434. The Real-facing handoff is reached only through the ordered StreamName, RegSeqRat, DyadicRatCore, and Real faces, so the ledger and seal rows are necessary parts of the same finite packet.

Finally invoke terminal non-escape. Since the terminal packet has no coordinate for quotient stream equality, selected limits, ambient completeness, countable choice, metric-completeness, arithmetic or order packages, or bridge rows, adding any such row moves the consumer outside the open-phase route instead of extending it. □

126.32 StreamName Open-Phase Dependency Lattice

Theorem 126.437 (StreamName RegSeqRat Real open-phase dependency lattice)**.** *Every Phase Real and Completion consumer of an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *window whose route reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface of chapter 301 and the* $\mathsf{Real}^{\uparrow}$ *seal surface of chapter 38 factors through the ordered finite route*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}.$$

The $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger is the observation ledger of chapter 291. Along the route the only public coordinates available to the consumer are displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows attached to the four finite surfaces.*

Thus the open-phase lattice exposes a finite BEDC route from StreamName windows into RegSeqRat readback, DyadicRatCore ledger data, and the Real seal. It exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Proof. First apply Definition 126.415. It places the Phase Real and Completion consumer on the accepted terminal finite packet and names the StreamName window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{Real}^{\uparrow}$ seal row, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ coordinates.

Next use Definition 126.417. The terminal packet is read as the ordered four-face route from the StreamName window through RegSeqRat readback and the DyadicRatCore ledger into the Real seal. This removes any interpretation in which those faces are independent carrier routes.

Now invoke Definition 126.356. The four faces occupy one finite pullback surface, so a consumer reaching the RegSeqRat and Real surfaces must pass through the same finite StreamName-to-RegSeqRat-to-DyadicRatCore-to-Real packet.

Finally apply Definition 126.359. The consumer can project only the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows on that pullback. Since those rows contain no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, or standard bridge rows, none of those objects is exported by the open-phase lattice. □

Theorem 126.438 (StreamName open-phase face-order no shortcut)**.** *An accepted Phase Real and Completion consumer starting from a finite* $\mathsf{StreamName}^{\uparrow}$ *window reaches the public* $\mathsf{Real}^{\uparrow}$ *seal if and only if its displayed support factors through the ordered four faces*

$$\mathsf{StreamName}^{\uparrow}\ \textit{window} \longrightarrow \mathsf{RegSeqRat}^{\uparrow}\ \textit{readback} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}\ \textit{ledger} \longrightarrow \mathsf{Real}^{\uparrow}\ \textit{seal}$$

with the shared BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows on that finite route. Any route omitting* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{DyadicRatCore}^{\uparrow}$*, swapping their public read order, or replacing a face by quotient stream equality, host sequence equality, a selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, or a standard bridge row lies outside the accepted open-phase lattice.*

Proof. For the forward direction, begin with Definition 126.437. It identifies every accepted consumer that reaches the public $\mathsf{Real}^{\uparrow}$ seal through the open phase with the displayed StreamName, RegSeqRat, DyadicRatCore, and Real faces, and it restricts the visible coordinates to the listed finite BEDC rows.

Next apply Definition 126.415 and Definition 126.417. The terminal route names the finite packet, while the lock reads that packet in the public order $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, then $\mathsf{Real}^{\uparrow}$. Thus the consumer support factors through the ordered four-face route and not through independent carrier faces.

For the reverse direction, use Definition 126.356. A displayed support with those four faces and the shared BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows is one finite pullback packet, so its target row is precisely the public $\mathsf{Real}^{\uparrow}$ seal exposed by the open-phase route.

It remains to exclude shortcuts. Apply Definition 126.359. The consumer projections of the pullback packet are exhausted by the four displayed faces and their shared BEDC coordinates. Omitting either middle face, permuting the RegSeqRat and DyadicRatCore public reads, or substituting quotient equality, host equality, selected limits, completeness data, or a standard bridge row would require a coordinate absent from that exhaustion list. Hence such a route is not an accepted open-phase lattice route. □

Theorem 126.439 (StreamName L10 sibling route)**.** *The* $\mathsf{StreamName}^{\uparrow}$ *public finite-window route is the sibling source consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Every such sibling read passes through finite* BHist *observations, componentwise* hsame *transport, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows before a regularity, dyadic observation, or terminal Real seal surface is available.*

Proof. Project the public finite-window route from chapter 126. The route exposes the finite StreamName window and its unary history observations as the common source row.

The three sibling chapters consume that source in distinct ways. The $\mathsf{RegSeqRat}^{\uparrow}$ chapter reads it as the regular-rational source schedule, chapter 291 reads it as the window support for dyadic observations, and chapter 38 reads it as the terminal Real seal source.

Because each sibling read is routed through the displayed BHist, hsame, Cont, Pkg, and NameCert rows, the StreamName route is a citeable L10 sibling dependency rather than a hidden host sequence or completed stream. □

Theorem 126.440 (StreamName Cauchy window transducer source route)**.** *The finite-window row exported by* $\mathsf{StreamName}^{\uparrow}$ *is the source row* S *consumed by every accepted* $\mathsf{CauchyWindowTransducer}^{\uparrow}$ *packet. The route passes through chapter 1020 only as displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *data.*

Proof. Apply Definition 126.439. It identifies the StreamName public finite-window route as the sibling source consumed by RegSeqRat, DyadicRatCore, and Real-facing rows before any terminal seal can be read.

Now inspect Definition 1020.1. The first analytic coordinate of a transducer packet is exactly the StreamName source row S, and every later row is routed through $D, W, R, E, L, H, C, P, N$.

Coordinate exhaustion gives the exclusion. Since the transducer carrier has no host sequence coordinate and no completed stream coordinate, the StreamName contribution to the packet is precisely the displayed finite-window row transported through BHist, hsame, Cont, Pkg, and NameCert data. □

Theorem 126.441 (StreamName Real-completion sibling route)**.** *Every finite-window* $\mathsf{StreamName}^{\uparrow}$ *read consumed by the Real and Completion route factors through the sibling surfaces chapter 301, chapter 291, and chapter 38 before it can become* $\mathsf{Real}^{\uparrow}$ *seal data. The route exposes finite-window transport and Real handoff rows only; it does not turn a stream window into quotient stream equality or host real equality.*

Proof. Start with the existing Real handoff rows for $\mathsf{StreamName}^{\uparrow}$. They expose a finite-window read before any Real-facing consumer can inspect the stream data.

Apply the finite-window transport rows already carried by the StreamName child files. These rows keep the window index, transport budget, and common refinement data inside the displayed $\mathsf{StreamName}^{\uparrow}$ packet.

The sibling route then passes through chapter 301, chapter 291, and chapter 38. The regular-rational row supplies the finite sequence handoff, the dyadic row supplies the tolerance ledger, and the Real row supplies only the terminal seal data. □

Theorem 126.442 (StreamName DyadicRatCore window anchor)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *finite-window read consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or by a* $\mathsf{Real}^{\uparrow}$ *seal route factors through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation and tolerance rows before it becomes a regular-rational handoff. The concrete route is the StreamName finite-window surface, the DyadicRatCore observation ledger of chapter 291, the RegSeqRat handoff surface of chapter 301, and the Real seal boundary of chapter 38; it exports no quotient stream equality, selected host limit, countable-choice selector, or ambient completeness row.*

Proof. Project the accepted StreamName read to its finite-window carrier rows. Those rows are the only visible source available to a downstream regular-rational or Real seal consumer.

Route the window through the DyadicRatCore sibling first. The observation and tolerance ledger of chapter 291 reads the same finite window as displayed BHist, componentwise hsame, finite Cont, Pkg, and local NameCert data, so the dyadic anchor is still a finite certificate row rather than a quotient-stream comparison.

Pass the anchored window to RegSeqRat and then to Real. The handoff surface of chapter 301 consumes the dyadic-window rows as regular rational data, and the seal boundary of chapter 38 receives only that displayed handoff. Hence every such StreamName read factors through DyadicRatCore observation and tolerance before becoming the regular-rational input seen by the Real route. □

The StreamName$^{\uparrow}$ finite-window ledger consumes DyadicRatCore$^{\uparrow}$ point certificates through chapter 291 and RegSeqRat$^{\uparrow}$ regular sequence windows through chapter 301, so its Real-facing route records the open L10 dependency lattice without introducing a second point carrier or quotient stream equality.

Definition 126.443 (StreamName Dyadic-RegSeq route packet)**.** *The* StreamName$^{\uparrow}$ *Dyadic-RegSeq route packet is the finite certificate packet read by a* StreamName$^{\uparrow}$ *finite-window consumer before it reaches a* RegSeqRat$^{\uparrow}$ *readback or a* Real$^{\uparrow}$ *seal boundary. Its coordinates are:*

1. *the StreamName finite-window rows;*
2. *the* DyadicRatCore$^{\uparrow}$ *observation and tolerance ledger of chapter 291;*
3. *the* RegSeqRat$^{\uparrow}$ *regular-source readback rows of chapter 301;*
4. *the* Real$^{\uparrow}$ *seal-boundary rows of chapter 38;*
5. *the displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows that name the packet.*

No other coordinate belongs to the packet.

Theorem 126.444 (StreamName Dyadic-RegSeq route factorization)**.** *Every accepted* StreamName$^{\uparrow}$ *finite-window consumer whose route reaches the* RegSeqRat$^{\uparrow}$ *readback surface or the* Real$^{\uparrow}$ *seal boundary factors through the finite packet of Definition 126.443. The factorization reads the StreamName window first, anchors it in the* DyadicRatCore$^{\uparrow}$ *observation and tolerance ledger, transports the anchored rows to the* RegSeqRat$^{\uparrow}$ *regular-source readback, and only then presents the* Real$^{\uparrow}$ *seal-boundary rows. The only structural data exposed along the route are the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *coordinates of the packet.*

Proof. Start with Definition 126.442. It places every StreamName finite-window read consumed by RegSeqRat$^{\uparrow}$ or by a Real$^{\uparrow}$ seal route on the DyadicRatCore$^{\uparrow}$ observation and tolerance ledger before any regular-rational handoff is read.

The three sibling chapters provide the packet faces. The dyadic ledger comes from chapter 291, the regular-source readback comes from chapter 301, and the terminal seal boundary comes from chapter 38.

Finally, repack the accepted consumer by the finite coordinates listed in Definition 126.443. The packet contains the StreamName rows, the dyadic ledger, the RegSeqRat readback, the Real seal boundary, and the displayed BHist, hsame, Cont, Pkg, and local NameCert data, so the consumer factors through exactly that route. □

Theorem 126.445 (StreamName Dyadic-RegSeq route no-completion leak)**.** *The packet of Definition 126.443 exports no quotient stream equality, host sequence equality, selected limit, countable-choice selector,* $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, or standard bridge row. Therefore an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window consumer that factors through the packet has no coordinate from which to read completion structure beyond the displayed* $\mathsf{Real}^{\uparrow}$ *seal boundary.*

Proof. Inspect the coordinates of Definition 126.443. They are exactly the StreamName finite-window rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation and tolerance ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ regular-source readback, the $\mathsf{Real}^{\uparrow}$ seal boundary, and the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Apply the factorization theorem, Definition 126.444. Any accepted consumer reaching $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ is read through those coordinates and through no independent route outside the packet.

The coordinate list contains no quotient stream equality, host sequence equality, selected limit, countable-choice selector, $\mathsf{Real}^{\uparrow}$ completeness row, metric-completeness datum, or standard bridge row. Exhaustion of the defined packet therefore excludes each of those reads from the accepted consumer surface. □

126.33 StreamName Open-Phase Exit Boundary

Theorem 126.446 (StreamName open-phase exit boundary)**.** *Every current Phase Real and Completion consumer whose* $\mathsf{StreamName}^{\uparrow}$ *finite-window route reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal factors through exactly one finite BEDC exit boundary. The boundary is the StreamName window, the RegSeqRat readback, the DyadicRatCore ledger, the RealUp seal, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows on those finite surfaces.*

The boundary exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameOpenPhaseExitBoundary`

Proof. First apply Definition 126.415. It places every such Phase Real and Completion consumer on the terminal finite packet and identifies the StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, displayed observations, transports, routes, provenance, and local naming rows.

Next use Definition 126.419 and Definition 126.421. Terminal seal exactness fixes the four-face route, and readback determinacy says that two consumers with the same four faces and displayed support rows determine the same terminal packet.

Now invoke Definition 126.442. It anchors every StreamName finite-window read consumed by RegSeqRat or by the Real seal through the DyadicRatCore observation and tolerance rows before the regular-rational handoff.

Finally apply Definition 126.437. The open-phase lattice exhausts the public consumer coordinates by the finite route and its displayed BHist, hsame, Cont, Pkg, and NameCert support. Therefore the exit boundary is exactly that finite BEDC packet, and no quotient stream, host sequence equality, selected limit, ambient completeness, metric-completeness datum, or standard bridge row is exported. □

Theorem 126.447 (StreamName finite-window exit determinacy)**.** *Let two Phase Real and Completion consumers read accepted* $\mathsf{StreamName}^{\uparrow}$ *exit packets. If they expose the same StreamName*

finite window, RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* Real$^{\uparrow}$ *seal, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows, then they determine the same finite BEDC exit boundary. Conversely, every accepted exit boundary in this open phase is read through exactly those four faces and their displayed support rows.*

The determined boundary carries no quotient stream, host sequence equality, selected limit, ambient Real$^{\uparrow}$ *completeness row, metric-completeness datum, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameOpenPhaseFiniteWindowExitDeterminacy`

Proof. Start with Definition 126.446. It identifies the boundary of every Phase Real and Completion consumer as the finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

For determinacy, use Definition 126.419 and Definition 126.421. The seal exactness pins the Real-facing coordinate to the same four-face packet, and readback determinacy says that equality of those displayed rows forces equality of the terminal finite packet.

Now apply Definition 126.442. The StreamName window read is anchored through the DyadicRatCore observation and tolerance ledger before RegSeqRat or Real consumers can inspect it.

Finally use Definition 126.437. The lattice gives the converse direction: any accepted open-phase exit boundary is read through the StreamName, RegSeqRat, DyadicRatCore, and Real faces with the displayed support rows only. Since the cited boundaries expose no quotient stream, host sequence equality, selected limit, ambient completeness, metric-completeness datum, or standard bridge row, the finite BEDC packet is the whole exit boundary. □

Theorem 126.448 (StreamName Real-completion exit certificate)**.** *Every Phase Real and Completion exit read from the current* StreamName$^{\uparrow}$ *open phase factors through the four finite sibling faces: the StreamName finite window, the* DyadicRatCore$^{\uparrow}$ *tolerance ledger, the* RegSeqRat$^{\uparrow}$ *readback, and the* Real$^{\uparrow}$ *seal. The certificate exposes only the displayed rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

on those four faces, together with the finite window, tolerance, readback, and seal coordinates already named by the open-phase boundary.

The certificate exports no quotient stream, no selected limit, no host sequence equality, no Real$^{\uparrow}$ *completeness theorem, and no standard bridge row.*

Proof. First use Definition 126.446. It identifies the exit boundary for Phase Real and Completion consumers as the finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, and the displayed support rows.

Next apply Definition 126.419. The terminal seal makes the Real-facing coordinate exact inside the same finite packet rather than by a selected limit or ambient completeness assertion.

Then use Definition 126.442. The tolerance ledger is pinned to the StreamName finite window before the RegSeqRat and Real consumers can read it.

Finally apply Definition 126.437. The dependency lattice puts the RegSeqRat readback and RealUp seal on the same finite route, so the certificate is exactly the displayed BHist, hsame, Cont, Pkg, and NameCert packet. Since the component theorems expose no quotient stream, host sequence equality, selected limit, RealUp completeness row, or standard bridge, the packaged exit certificate exports none. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionExitCertificate`

Theorem 126.449 (StreamName open-phase four-face terminality)**.** *Let two Phase Real and Completion exit reads expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the same* $\mathsf{Real}^{\uparrow}$ *seal, and the same displayed rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the two reads determine the same terminal finite BEDC route through those four faces. Conversely, any terminal route available to the current open phase is read through exactly the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the displayed support rows named above.

The terminal route contains no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Proof. Begin with Definition 126.446. It identifies every Phase Real and Completion exit boundary with the finite StreamName, RegSeqRat, DyadicRatCore, and Real faces together with their displayed BHist, hsame, Cont, Pkg, and NameCert support.

Next use Definition 126.448. The certificate repacks the same four faces as the public exit read, so two reads with matching windows, ledgers, readbacks, seals, and displayed support rows have no remaining coordinate on which their terminal finite routes can differ.

Now apply Definition 126.442. The DyadicRatCore tolerance ledger is anchored to the StreamName finite window before either RegSeqRat readback or RealUp seal can be consumed, which prevents a second tolerance route from entering the terminal packet.

Finally invoke Definition 126.437. The lattice supplies the converse direction by exhausting the open-phase route through the four required faces. Since the cited routes export no quotient stream, host sequence equality, selected limit, ambient completeness, metric-completeness datum, or standard bridge row, terminality belongs to that finite BEDC route alone. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier open phase four face terminality`

Theorem 126.450 (StreamName four-face exit readback)**.** *Every Phase Real and Completion exit read that exposes the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

has exactly the finite readback surface named by the open-phase exit boundary. Conversely, every current Phase Real and Completion exit read factors through those four faces and those displayed support rows.

The readback exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier open phase four face exit readback`

Proof. Begin with Definition 126.446. It identifies the public exit surface as the StreamName finite window, the RegSeqRat readback, the DyadicRatCore ledger, the RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 126.448. The certificate places the four faces in one finite packet, so the tolerance ledger, regular-rational readback, and Real-facing seal are read together rather than through an ambient completion object.

Use Definition 126.449 for the reverse direction. Any terminal route available to the current open phase is already exhausted by the same four faces and displayed support rows.

Finally combine terminal seal exactness with terminal readback determinacy. These references identify matching four-face packets with the same finite readback surface and leave no coordinate for quotient streams, host sequence equality, selected limits, Real completeness, metric completeness, or bridge rows. □

Theorem 126.451 (StreamName open-phase four-object sufficiency)**.** *The four finite faces*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows, are sufficient for the paper-side boundary required by Phase Real and Completion. Any remaining failure belongs to the per-object closurestatus entries or to Lean verification for those four faces, not to a hidden fifth mathematical object.*

The sufficient packet contains no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameOpenPhaseFourObjectSufficiency`

Proof. First apply Definition 126.446 and Definition 126.448. The boundary theorem names the current Phase Real and Completion consumer surface, and the certificate repacks that surface as the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and displayed support rows.

Next use Definition 126.449 and Definition 126.450. Terminality says that matching four faces and support rows determine the terminal finite route, while readback says that every current exit read is read through exactly those rows.

Finally invoke Definition 126.500. It aligns the same four faces with the roadmap objects DyadicRatCore, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Therefore the paper-side exit package is already sufficient for Phase Real and Completion, and any later failure must be read from the individual closurestatus or verification axes rather than from an undisplayed fifth object. □

Theorem 126.452 (StreamName open-phase Lean touchpoint triad)**.** *Every current Phase Real and Completion exit read through the four faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *is paper-audit-ready exactly along the three existing Lean touchpoints named by the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. This triad exports only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows already present on those four faces.*

The triad adds no Lean marker at this paper site, no quotient stream equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness row, and no standard bridge row.*

Proof. First apply Definition 126.451. It says that the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the displayed BHist, hsame, Cont, Pkg, and NameCert rows, already suffice for the current Phase Real and Completion boundary.

Next use Definition 126.450. The readback theorem fixes every current exit read on exactly those four faces and displayed support rows, so the paper audit has no hidden fifth object to inspect.

Finally invoke Definition 126.500. It aligns the same boundary with the roadmap route. The existing machine-side route is then the three-touchpoint path named in Lean as `BEDC.Derived.StreamNameUp.RatStr`

`BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness`, and `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_real_seal_handoff`. These names identify the future formalization route only; they do not create a current paper marker or export quotient equality, selected limits, ambient completeness, metric completeness, or a standard bridge row. □

Theorem 126.453 (StreamName Real-completion exit Lean route boundary)**.** *Every current Phase Real and Completion four-face exit read consumes machine support only through the three primary paper sites already carrying the route markers: the StreamName singleton finite-window handoff of Definition 126.173, the DyadicRatCore RegSeqRat bridge handoff exactness of Definition 291.28, and the RegSeqRat Real seal handoff of Definition 301.22. Equivalently, the route uses*

`BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff`,
`BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness`,
`BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_real_seal_handoff`

only at those primary sites.

This paper site records the route boundary but adds no additional Lean marker. It exports no quotient stream equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, countable choice, or bridge row.*

Proof. First apply Definition 126.451. It fixes the current exit packet as the four displayed faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the visible BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 126.452. The triad says that the machine-facing support of that packet is exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.

Finally invoke Definition 126.500. It identifies the same four-face packet as the Phase Real and Completion route, while the primary markers are already attached at Definition 126.173, Definition 291.28, and Definition 301.22. Therefore this boundary site can only point to those primary sites and cannot create a second marker or an extra coordinate for quotient streams, selected limits, ambient completeness, metric completeness, countable choice, or bridge data. □

Theorem 126.454 (StreamName Real-completion exit obligation ledger)**.** *The current Phase Real and Completion exit obligation ledger is exactly the four faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *together with displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. The ledger has no separate aggregate object beyond those four faces and their support rows.*

Proof. First apply Definition 126.446 and Definition 126.448. These theorems name the exit packet as the finite StreamName window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and the displayed support rows.

Next use Definition 126.449 and Definition 126.450. Terminality fixes the route once the four faces and support rows agree, while readback says that every current exit read is consumed through those rows.

Finally apply Definition 126.453. The Lean-facing route is confined to the existing primary touchpoints for the StreamName finite window, DyadicRatCore RegSeqRat handoff, and RegSeqRat Real seal. Hence the paper obligation ledger is exactly the four displayed faces with BHist, hsame, Cont, Pkg, and NameCert support. □

Theorem 126.455 (StreamName open-phase Lean route totality)**.** *Every current Phase Real and Completion exit read through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *is machine-facing exactly through the three primary Lean touchpoints named in Definition 126.453. Thus the current route is exhausted by the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Any consumer that needs further machine support has left the current open-phase exit ledger.*

Proof. First apply Definition 126.454. It fixes the current ledger as the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows.

Next use Definition 126.453 and Definition 126.452. These identify the machine-facing route of that ledger with exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.

Finally invoke Definition 126.451. Since the four listed faces already suffice for the current Phase Real and Completion boundary, a consumer asking for another machine support row is no longer reading the displayed open-phase exit ledger. The theorem adds no marker and asserts no quotient stream, selected limit, completeness row, countable-choice row, or bridge row. □

Theorem 126.456 (StreamName L10 gateway scope)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *gateway read for the current L10 phase is scoped by the finite window row together with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Conversely, those four faces and support rows are sufficient for the public gateway packet. The gateway exports no quotient stream equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, countable-choice row, aggregate formalstatus row, aggregate bridge row, or standard bridge row.*

Proof. For necessity, start with Definition 126.446. It identifies the accepted gateway read with the finite StreamName window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Next apply Definition 126.447. The finite window row determines the same exit packet whenever the dyadic, regular-sequence, Real seal, and support rows agree, so a gateway read cannot be scoped by a separate quotient or limiting coordinate.

For sufficiency, use Definition 126.448 and Definition 126.437. The certificate packages the four faces as the L10 exit surface, and the dependency lattice supplies the converse route through exactly those rows.

Finally apply Definition 126.455. The Lean-facing side of the current gateway is exhausted by the displayed touchpoints of the same finite route. Thus the public gateway packet is exactly the scoped four-face packet, with no quotient stream equality, selected limit, ambient completeness, metric-completeness datum, countable-choice row, aggregate status, aggregate bridge, or standard bridge row. □

Theorem 126.457 (StreamName Real-completion touchpoint minimality)**.** *A current Phase Real and Completion exit read is paper-audit-complete if and only if it exposes exactly the four paper faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and its machine-facing support is confined to the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.*

Equivalently, the paper audit surface is precisely the four-face ledger named by Definition 126.451, while the machine route is precisely the three-touchpoint route named by Definition 126.453 and exhausted by Definition 126.455. The complete read contains no quotient stream equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, countable-choice row, or standard bridge row.*

Proof. For the forward direction, start from a paper-audit-complete current exit read. Apply Definition 126.451 to identify the paper surface with exactly the four displayed faces and their visible BHist, hsame, Cont, Pkg, and NameCert rows.

Then use Definition 126.453. It confines the machine-facing support to the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Finally apply Definition 126.455; any requested machine coordinate outside those three sites leaves the current open-phase exit ledger.

For the reverse direction, assume the read exposes the four faces and only the three named machine touchpoints. The four-face sufficiency theorem supplies the paper audit packet, while the Lean-route boundary supplies the complete machine-facing route for that packet.

The route-totality theorem rules out missing support inside the current exit read. Since neither the four-face packet nor the three-touchpoint route has a coordinate for quotient stream equality, selected limits, ambient completeness, metric-completeness data, countable choice, or standard bridge rows, the read is paper-audit-complete exactly at the displayed boundary. □

Theorem 126.458 (StreamName Real-completion objectwise status completeness)**.** *A current Phase Real and Completion exit read through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *is status-complete exactly when it exposes those four faces, confines machine support to the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff, and also reads the four local face closurestatus, formalstatus, leantarget, and bridgestatus rows objectwise.*

Equivalently, the three-touchpoint route is necessary for the machine-facing side of the current roadmap exit certificate, but it is not by itself sufficient for the roadmap exit certificate. The certificate is complete only when the four local face-status records are present alongside the displayed finite support rows BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

The status-complete read contains no quotient stream equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, countable-choice row, aggregate formalstatus row, aggregate bridge row, or standard bridge row.*

Proof. First identify the underlying exit surface. By Definition 126.457, the current paper audit surface exposes exactly the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while the machine-facing support is confined to the three named touchpoints.

Next exhaust the route. Apply Definition 126.454 to keep the obligation ledger on the four faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows. Apply Definition 126.455 to rule out any further machine coordinate inside the current open-phase ledger.

It remains to read the roadmap exit certificate on its own axes. The roadmap discipline of section 9467.2 and the Phase Real and Completion exit criterion of section 9467.19 require the four objects to be read locally on independent closure and verification axes. By Definition 38.792, that read is the objectwise product of the four local closurestatus, formalstatus, leantarget, and bridgestatus records, together with the displayed finite support rows.

Therefore the three-touchpoint route is necessary for the machine-facing support, but it cannot replace the four local status rows. Conversely, when the four faces, the three touchpoints, and the

four objectwise status records are all present, the same cited results supply exactly the current Phase Real and Completion exit certificate.

Finally exclude substitute coordinates. The touchpoint-minimality theorem and the Real-side objectwise face-status theorem jointly leave no coordinate for quotient stream equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, countable choice, aggregate formal-status rows, aggregate bridge rows, or standard bridge rows. □

Theorem 126.459 (StreamName open-phase four-face scope exactness)**.** *Any current Phase Real and Completion route that exposes the four faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *has no fifth object. In particular it does not contain a quotient stream, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness object, metric-completeness datum, countable-choice row, or standard bridge row.*

Proof. Begin with Definition 126.449. Once the four faces and their displayed support rows are fixed, the terminal finite route is determined.

Use Definition 126.450. It reads every current exit through the same four local faces, so any proposed fifth object would have to appear in that readback surface.

Now apply Definition 126.448 and Definition 126.453. The certificate and machine-route boundary list only the finite window, dyadic ledger, RegSeqRat readback, Real seal, and the three existing primary machine touchpoints. None of those rows is a quotient stream, selected limit, ambient completeness object, metric-completeness datum, countable-choice row, or standard bridge. □

Theorem 126.460 (StreamName Real-RegSeqRat dyadic window pullback)**.** *The* $\mathsf{Real}^{\uparrow}$ *seal and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback in the current Phase Real and Completion exit share the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger through the finite* $\mathsf{StreamName}^{\uparrow}$ *window. Thus any exit read that preserves the Real seal and the RegSeqRat readback pulls back to the same dyadic tolerance window, rather than to a selected limit, quotient stream, host equality, ambient completeness theorem, or bridge coordinate.*

Proof. First use Definition 126.448. It displays the Real seal and RegSeqRat readback in the same certificate as the finite StreamName window and DyadicRatCore tolerance ledger.

Next apply Definition 126.449 and Definition 126.450. These results force both reads through the same four-face terminal packet, so the $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ faces cannot select different dyadic ledgers once the StreamName finite window is fixed.

Finally invoke Definition 126.453. The machine-facing support is exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Those touchpoints align the dyadic tolerance ledger with the finite window and provide no coordinate for selected limits, quotient streams, host equality, ambient completeness, or bridge data. □

Theorem 126.461 (StreamName Real-completion four-face terminal pullback)**.** *Let X and Y be current Phase Real and Completion exit reads. Suppose both reads expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the same* $\mathsf{Real}^{\uparrow}$ *seal, and the same displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then X and Y pull back to the same terminal finite BEDC route.*

No quotient stream, selected limit, host equality, ambient completeness theorem, metric-completeness datum, choice row, or bridge row can distinguish the two reads once those four faces and displayed support rows agree.

Proof. First apply Definition 126.451. It identifies the current Phase Real and Completion boundary with exactly the four objects $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the visible BHist, hsame, Cont, Pkg, and NameCert rows.

Next use Definition 126.450. Every current exit read is read through precisely those four faces and support rows, so the hypotheses on X and Y place them on the same finite readback surface.

Finally apply Definition 126.453. The machine-facing route is confined to the three primary touchpoints already attached to the StreamName finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Since those touchpoints carry no quotient, limit-selection, host-equality, completeness, choice, or bridge coordinate, the two reads determine the same terminal finite BEDC route. □

Theorem 126.462 (StreamName four-face Lean route consistency)**.** *Every current four-face exit read through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumes machine support only through the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Conversely, those three touchpoints cover exactly the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of the paper route through the four faces.*

This consistency statement adds no Lean marker at this paper site. It does not claim quotient streams, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, countable choice, or standard bridge status.*

Proof. First apply Definition 126.446. It identifies the current open-phase exit boundary with the finite StreamName window, DyadicRatCore ledger, RegSeqRat readback, Real seal, and displayed support rows.

Next use Definition 126.451 and Definition 126.449. These theorems say that the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ suffice for the current exit packet and that matching those faces with their support rows determines the terminal route.

Now apply Definition 126.453. The machine-facing support route is confined to the three named touchpoints: the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.

For the converse direction, read those same touchpoints back along the four-face terminal packet. The StreamName handoff covers the finite-window face, the DyadicRatCore handoff covers the dyadic ledger and bridge face, and the RegSeqRat handoff covers the Real seal face; together with the terminality and sufficiency results, these are exactly the displayed BHist, hsame, Cont, Pkg, and NameCert rows of the paper route. No additional machine support coordinate remains in the open-phase boundary. □

Theorem 126.463 (StreamName open-phase facewise record completeness)**.** *A Phase Real and Completion exit read through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *is complete as a* $\mathsf{StreamName}^{\uparrow}$*-side boundary exactly when the four canonical local face records are displayed separately: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger status, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window status, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and seal status, and the* $\mathsf{Real}^{\uparrow}$ *seal status. These are the local records attached to the four displayed faces, not a composite route token.*

For the reverse direction, the only machine-route sites used are the three primary sites already named by Definition 126.453. No aggregate formalstatus token, aggregate bridge, selected limit, quotient stream, ambient completeness theorem, countable-choice row, or metric-completeness datum can replace a missing face record.

Proof. For the forward direction, apply Definition 126.451. It says that the current Phase Real and Completion boundary is exhausted by the four displayed faces together with the visible BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 126.450. The readback theorem identifies every current exit read with exactly those four faces and their displayed support rows. Thus audit completeness can only be checked componentwise, by reading the StreamName, DyadicRatCore, RegSeqRat, and Real records that already belong to the packet.

For the reverse direction, assume that the four canonical local face records are displayed separately. Apply Definition 126.451 to identify the packet with exactly the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and their visible support rows.

Next apply Definition 126.450. It reads every current exit through those same four face records, so the displayed local rows cover the StreamName-side boundary rather than merely a downstream summary of it.

Finally apply Definition 126.453. That theorem restricts the reverse route to the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff; those are precisely the primary machine-route sites already attached to the four local records. The roadmap two-axis discipline is used only to keep the four local theory and verification reports from collapsing into one token. Hence no aggregate formalstatus token, aggregate bridge, selected limit, quotient stream, ambient completeness theorem, countable-choice row, or metric-completeness datum can repair an absent face record. □

Theorem 126.464 (StreamName–Real open-phase facewise audit correspondence)**.** *A current Phase Real and Completion exit read is complete as a* $\mathsf{StreamName}^{\uparrow}$*-side facewise record exactly when it satisfies the* $\mathsf{Real}^{\uparrow}$*-side facewise audit obstruction. Both conditions require the same four local records for* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Thus the StreamName-side open-phase completeness criterion and the Real-side L10 audit obstruction name the same componentwise four-face boundary. No aggregate formalstatus token, bridge row, completeness row, quotient stream, selected limit, or host equality row is part of this correspondence.

Proof. For the StreamName-to-Real direction, apply Definition 126.463. A complete StreamName-side read already displays the DyadicRatCore tolerance-ledger record, the StreamName finite-window record, the RegSeqRat readback and seal record, and the Real seal record as separate local rows.

Next use Definition 38.729 and Definition 38.728. The Real-side obstruction asks for exactly those four local records and refuses any aggregate audit substitute. Since the visible support rows are the same BHist, hsame, Cont, Pkg, and NameCert rows, the StreamName-side complete read satisfies the Real-side audit condition.

For the Real-to-StreamName direction, start from the Real-side facewise audit condition. It supplies the four local audit records separately, so Definition 126.451 identifies the current open-phase packet with the same $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and their displayed support rows.

Finally apply Definition 126.453. The only machine-facing route available to this packet is the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. These are the route sites already attached to the same four local records, so the Real-side audit condition gives the StreamName-side facewise record completeness.

The last sentence of the theorem is the common boundary condition, not an extra certificate. The cited results leave no coordinate for an aggregate formalstatus token, bridge row, completeness row, quotient stream, selected limit, or host equality row. □

Theorem 126.465 (StreamName budgeted real window handoff totality)**.** *Every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *consumer of a* $\mathsf{StreamName}^{\uparrow}$ *finite-window exit read factors through the displayed handoff rows*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},\quad \mathsf{RealWindowBudget}^{\uparrow},\quad \mathsf{BudgetedRealSealRoute}^{\uparrow}$$

together with only the support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The factorization is total for such consumers: the $\mathsf{StreamName}^{\uparrow}$ *finite window is first read through the four local face records, then through the* $\mathsf{RealWindowBudget}^{\uparrow}$ *packet, and finally through the* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *carrier and local* $\mathsf{NameCert}$ *surface.*

No selected limit, quotient stream, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, countable-choice row, metric-completeness datum, host equality row, or standard bridge row is part of this consumer handoff.*

Proof. Start with Definition 126.463. It gives the $\mathsf{StreamName}^{\uparrow}$-side exit read as four separately displayed local records: the StreamName finite window, the DyadicRatCore tolerance ledger, the RegSeqRat readback and seal status, and the RealUp seal status.

Next apply Definition 126.473 and Definition 126.474. The pullback places every accepted $\mathsf{RealWindowBudget}^{\uparrow}$ consumer over the same finite request, window, dyadic, regularity, and Real seal rows, while terminality prevents any further discriminator once those rows and the displayed support rows agree.

Now use Definition 1164.4. The $\mathsf{RealWindowBudget}^{\uparrow}$ packet therefore hands the finite StreamName window, dyadic readbacks, RegSeqRat handoff, and Real seal to the Real-facing completion route without adding a selected limit, quotient stream, or ambient completeness coordinate.

Finally read the $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ carrier and NameCert obligations of Definition 913.1 and Definition 913.2. Its accepted packet consumes the displayed selector, threshold, observation-budget, limit-seal, Real readback, transport, continuation, provenance, and local naming rows; along the StreamName exit boundary these are reached only through the already displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{RealWindowBudget}^{\uparrow}$ rows. The non-escape theorem Definition 913.6 then excludes host equality, selected limits, quotient streams, ambient completeness, countable choice, metric-completeness data, and standard bridge rows from the handoff. □

Theorem 126.466 (StreamName open-phase budget route lock)**.** *Any accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *consumer whose finite window is read through* $\mathsf{StreamName}^{\uparrow}$ *factors through the same four-face open-phase exit boundary*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

with only BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support rows. The budgeted route is therefore a consumer of the boundary, not a fifth Real-completion object, and it cannot smuggle quotient streams, selected limits, host real equality, ambient completeness, countable choice, or metric-completeness data into the exit packet.*

Proof. Start with the open-phase exit boundary, Definition 126.446. It identifies the current Real-completion exit with the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat regularity readback, RealUp seal, and the visible support rows.

Next use budgeted real window handoff totality, Definition 126.465. It already routes an accepted $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ consumer through the four local faces, the $\mathsf{RealWindowBudget}^{\uparrow}$ packet, and only BHist, hsame, Cont, Pkg, and NameCert support.

Finally read the budgeted route selector, TailMeet threshold, Real-seal readback, and non-escape theorems from chapter 913. The selector and threshold rows feed the route into the RealObservationBudget and CauchyLimitSeal handoff, while the Real readback and non-escape rows prevent a separate completion object or hidden stream source from appearing. □

Theorem 126.467 (StreamName open-phase local status nonescape)**.** *For any current Phase Real and Completion exit read through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, suppose one of the four local face status records is absent: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger status, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window status, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and seal status, or the* $\mathsf{Real}^{\uparrow}$ *seal status. Then the absent local record is not supplied by any aggregate formalstatus token, aggregate bridge row, selected limit, quotient stream, ambient completeness theorem, countable-choice row, metric-completeness datum, or standard bridge row.*

Equivalently, the current open-phase exit boundary has no escape route from a missing local face record to a route-level verification or bridge coordinate. Each of the four objects must display its own local status row before the $\mathsf{StreamName}^{\uparrow}$*-side boundary is complete.*

Proof. Start with Definition 126.463. It identifies boundary completeness with the four canonical local records displayed separately, so an absent DyadicRatCore, StreamName, RegSeqRat, or Real record is already a failure at the objectwise status surface.

Next apply Definition 126.451 and Definition 126.450. Sufficiency says that the current exit packet has only the four displayed objects and their visible BHist, hsame, Cont, Pkg, and NameCert rows. Readback says that every current exit read is read through exactly those four local faces.

Now use Definition 126.453. The only machine-facing route available to the current read is the three primary touchpoints already attached to the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Those touchpoints can report the route they occupy, but they do not manufacture a missing local status row for any face.

Finally exhaust the possible substitutes. The four-face route has no quotient stream, selected limit, ambient completeness theorem, countable-choice row, metric-completeness datum, or standard bridge row by the cited boundary results. Aggregate formalstatus and bridge prose therefore remain summaries of displayed local records, not replacements for one of them. □

Theorem 126.468 (StreamName open-phase local-status exit lock)**.** *A current Phase Real and Completion exit read is accepted at the* $\mathsf{StreamName}^{\uparrow}$ *side exactly when the four local status records are present together: the* $\mathsf{StreamName}^{\uparrow}$ *finite-window status, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger status, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and seal status, and the* $\mathsf{Real}^{\uparrow}$ *seal status. The four records must be matched to the same displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

When those four records and those support rows agree, they jointly determine the current exit route through the terminal four-face packet. When one record is absent or mismatched, the route is not accepted as the current $\mathsf{StreamName}^{\uparrow}$*-side exit read.*

This lock is local to the open-phase boundary. It does not introduce quotient streams, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, aggregate formal-status rows, or aggregate bridge rows.*

Proof. For necessity, apply Definition 126.463. It says that boundary completeness is exactly the separate display of the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ local status records over the visible BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next use Definition 126.467. If any one of the four local records is absent, no route-level status token, bridge row, selected limit, quotient stream, completeness datum, or countable-choice row can replace it. Thus every accepted current exit read must carry all four local records.

For sufficiency, apply Definition 126.470. Once the four face records and the displayed support rows match, public acceptance factors through the terminal four-face classifier surface and has no further coordinate.

Finally apply Definition 126.472. It identifies the accepted route with the unique normal-form packet consisting of the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and the same support rows. Hence the four local records jointly determine the current exit route, while the excluded quotient, limit, completeness, choice, aggregate status, and bridge rows remain outside the packet. □

Theorem 126.469 (StreamName open-phase handoff terminal cover)**.** *Every current Phase Real and Completion handoff that reaches the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{Real}^{\uparrow}$ *seal is covered by the terminal finite BEDC packet displayed in this section. The cover is exactly the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows.*

The cover exports no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. Begin with Definition 126.446. It identifies the public handoff boundary with the finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, and the displayed support rows.

Next apply Definition 126.448. The certificate repacks the same boundary as the four-face packet, so the StreamName window, tolerance ledger, readback, and seal are read as one finite BEDC surface.

Use Definition 126.449 and Definition 126.450. Terminality says that matching four faces and support rows determine the terminal finite route, while readback says that every current exit read is already read through exactly those rows.

Finally combine Definition 126.451 with Definition 126.453. The sufficiency theorem aligns the packet with the open construction order, and the machine-touchpoint boundary restricts the route to the named primary sites. Therefore every current handoff reaching those four faces is covered by the displayed terminal packet, with no additional quotient, host equality, selected limit, completeness, choice, or bridge coordinate. □

Theorem 126.470 (StreamName open-phase terminal classifier exactness)**.** *A current Phase Real and Completion read is publicly accepted exactly when its* $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, and displayed rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

factor through the terminal four-face classifier surface for the open phase.

Equivalently, public acceptance has no further coordinate beyond that terminal classifier packet: no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. For necessity, start with Definition 126.449 and Definition 126.450. Terminality identifies the finite route determined by the four faces and displayed support rows, while readback says every current Phase Real and Completion exit read is read through exactly those faces and rows.

Next apply Definition 126.500. It aligns the same StreamName window, DyadicRatCore ledger, RegSeqRat readback, and RealUp seal with the current Real-completion exit route, so the open-phase terminal route is the four-object route already used by Phase Real and Completion.

For sufficiency, use Definition 126.514. Once the four faces and displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows factor through that classifier surface, the public read is determined componentwise by the same finite packet.

Finally invoke Definition 126.518. Dependency exactness says that the four dependency faces with the displayed support rows are precisely the public acceptance boundary, and it excludes quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, countable choice, and standard bridge rows. Hence public acceptance is exact for the terminal four-face classifier surface and for no larger object. □

Theorem 126.471 (StreamName open-phase four-face ledger exactness)**.** *For every current Phase Real and Completion read accepted through the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert},$$

the ledger coordinate is exactly the finite four-face ledger already exposed by those rows. Equivalently, any $\mathsf{RealWindowBudget}^{\uparrow}$ *consumer can project the ledger from the four faces themselves, and any hidden compression, selected limit, quotient stream, host sequence equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness row, countable-choice row, or standard bridge row lies outside the accepted packet.*

Proof. First apply Definition 126.470. It identifies public acceptance with the terminal four-face classifier surface over the StreamName window, DyadicRatCore ledger, RegSeqRat readback, Real seal, and displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next apply Definition 126.451. The current boundary has only the four objects $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ as its exposed mathematical faces, so the ledger coordinate cannot be supplied by a fifth object or an undisplayed completion row.

Now use Definition 126.453. The machine-facing support route is confined to the three primary sites already attached to the StreamName finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff, and the RegSeqRat Real seal handoff; this theorem adds no marker here and contributes no extra ledger coordinate.

Finally read the downstream budget surface. By Definition 1164.1 and Definition 1164.4, a $\mathsf{RealWindowBudget}^{\uparrow}$ packet projects its finite StreamName window, dyadic readbacks, RegSeqRat handoff, and Real seal from the same displayed route. Thus the accepted packet exposes exactly the four-face ledger consumed downstream, and hidden compression, selected limits, quotient streams, host equality, ambient completeness, metric completeness, countable choice, and standard bridge data remain outside the packet. □

Theorem 126.472 (StreamName open-phase four-face normal form)**.** *Every accepted Phase Real and Completion exit read has a unique normal form at the terminal finite BEDC route. The normal form consists exactly of the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Conversely, any packet whose exposed coordinates are exactly those four faces and those support rows is accepted by the terminal classifier surface for the open phase.

The normal form has no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. For existence, apply Definition 126.451. It identifies the current Phase Real and Completion boundary with the four displayed faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the visible BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 126.450. Every accepted exit read is read through those same faces and rows, so the displayed packet is a normal-form representative of the current open-phase exit read rather than a downstream summary.

For uniqueness, use Definition 126.470. Public acceptance is exact for the terminal four-face classifier surface, so two accepted packets with the same four faces and support rows determine the same terminal finite BEDC route.

For the converse direction, apply Definition 126.471. A packet exposing exactly the StreamName window, DyadicRatCore ledger, RegSeqRat readback, Real seal, and displayed support rows already supplies the ledger coordinate consumed by the terminal classifier surface.

Finally exhaust the excluded coordinates. The same cited theorems leave no place for quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, countable choice, or standard bridge data. Therefore the four-face packet is the canonical Phase Real and Completion exit object, and any packet with precisely those coordinates is accepted by the terminal classifier surface. □

Theorem 126.473 (StreamName Real-window budget pullback)**.** *Any accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window exit read consumed by a* $\mathsf{RealWindowBudget}^{\uparrow}$ *packet factors through the same finite request,* $\mathsf{StreamName}^{\uparrow}$ *window rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *route,* Pkg *provenance, and local* NameCert *row. Conversely, every accepted* $\mathsf{RealWindowBudget}^{\uparrow}$ *packet exposes a* $\mathsf{StreamName}^{\uparrow}$ *finite-window face through its displayed window rows.*

The pullback adds no quotient stream, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, metric-completeness datum, countable-choice row, or standard bridge row.*

Proof. For the forward direction, apply Definition 126.470. It identifies accepted open-phase reads with the terminal four-face classifier surface over the StreamName window, DyadicRatCore ledger, RegSeqRat readback, Real seal, and displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next read the $\mathsf{RealWindowBudget}^{\uparrow}$ carrier of Definition 1164.1. Its request, window, dyadic, handoff, seal, selector, disclosure, transport, continuation, provenance, and local naming rows are precisely the finite route available to a Real-window budget consumer.

For the reverse direction, project an accepted $\mathsf{RealWindowBudget}^{\uparrow}$ packet onto its V coordinate. By the carrier definition and the Real-completion handoff of Definition 1164.4, V is the StreamName finite-window face of the same packet.

Finally compose with the sibling budget surfaces. The selector stability of Definition 1164.3, the CauchyDiagonalBudget surface of chapter 853, and the RealObservationBudget disclosure route of chapter 611 keep the pullback on the same finite request and support rows. Since none of these surfaces carries quotient streams, host equality, selected limits, ambient completeness, metric completeness, countable choice, or a standard bridge, the pullback exports none. □

Lean4 ✓ `BEDC.Derived.RealWindowBudgetUp.RealWindowBudgetCarrier streamname pullback route`

Theorem 126.474 (StreamName open-phase budget-consumer terminality)**.** *Every accepted* RealWindowBudget$^{\uparrow}$ *consumer of a* StreamName$^{\uparrow}$ *finite-window exit read determines the same terminal four-face route through* StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$. *The route is read only through the displayed rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Once two such consumers agree on their budget rows, no quotient stream, selected limit, host equality, ambient completeness theorem, countable-choice row, metric-completeness datum, or standard bridge row can distinguish them.

Proof. Begin with the pullback of Definition 126.473. It says that every accepted budget consumer of the StreamName finite-window exit read factors through the finite request, StreamName window rows, DyadicRatCore readbacks, RegSeqRat handoff, Real seal, componentwise hsame transports, displayed Cont route, Pkg provenance, and local NameCert row.

Next apply Definition 126.470 and Definition 126.500. The classifier exactness theorem makes the accepted open-phase read terminal over the displayed four faces, and the four-object exit route identifies those faces as the StreamName, DyadicRatCore, RegSeqRat, and RealUp route already used by Phase Real and Completion.

Finally read the budget carrier. By Definition 1164.1 and Definition 1164.4, a RealWindowBudget$^{\uparrow}$ consumer exposes its Real-facing route as the same finite chain from the StreamName window through dyadic readback and regular handoff to the Real seal. Thus agreement on the displayed budget rows leaves only that terminal four-face route, while quotient streams, selected limits, host equality, ambient completeness, choice, metric completeness, and standard bridge data remain outside the accepted packet. □

Theorem 126.475 (StreamName open-phase exit route completeness)**.** *A current Phase Real and Completion exit packet is accepted exactly when it is a terminal finite route through the* StreamName$^{\uparrow}$ *finite window, the* DyadicRatCore$^{\uparrow}$ *tolerance ledger, the* RegSeqRat$^{\uparrow}$ *readback, the* Real$^{\uparrow}$ *seal, and the displayed support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Equivalently, every accepted packet exposes precisely those four L10 faces and those rows, and conversely any packet exposing exactly those coordinates is accepted by the terminal open-phase classifier surface.

The route has no quotient stream equality, no host sequence equality, no selected limit, no ambient Real$^{\uparrow}$ *completeness row, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. For necessity, apply Definition 126.472. It identifies every accepted Phase Real and Completion exit read with the normal-form packet consisting of the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next use Definition 126.471. The tolerance-ledger coordinate is not an external budget summary; it is the finite ledger already exposed by the four faces and their support rows.

Then pull the downstream consumer back by Definition 126.473. Any $\mathsf{RealWindowBudget}^{\uparrow}$ consumer of the StreamName finite-window exit read factors through the same finite request, window rows, dyadic readbacks, RegSeqRat handoff, Real seal, componentwise transports, continuation route, provenance, and local naming row.

Finally apply Definition 126.474. Once the four faces and displayed budget rows agree, every accepted budget consumer determines the same terminal four-face route. The converse clause of the normal form and ledger exactness therefore accepts any packet exposing exactly those rows at the terminal classifier surface, and the cited exclusions leave no coordinate for quotient stream equality, host sequence equality, selected limits, ambient RealUp completeness, metric-completeness data, countable choice, or standard bridge rows. □

Theorem 126.476 (StreamName open-phase no-fifth-object exhaustion)**.** *Every accepted Phase Real and Completion exit route in the current open phase is exhausted by the four L10 faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. There is no fifth object, aggregate verification token, quotient stream, selected limit, ambient completeness row, metric-completeness datum, countable-choice row, or standard bridge row hidden behind the terminal exit route.*

Proof. First apply the four-face normal form of Definition 126.472. It identifies accepted exit reads with the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and the displayed support rows.

Next use budget-consumer terminality from Definition 126.474. Any accepted budget consumer determines the same terminal route once the four faces and budget rows agree, so a separate consumer token cannot add an object beyond the listed faces.

Apply Definition 126.475. It supplies the converse direction: a packet exposing exactly the four faces and support rows is accepted by the terminal open-phase classifier surface.

Finally use the four-face ledger exactness of Definition 126.471 and the four-face exit readback of Definition 126.450. They keep the tolerance ledger and readback rows inside the same displayed packet, leaving no route for a quotient stream, selected limit, ambient completeness theorem, metric-completeness datum, countable-choice row, standard bridge row, or hidden fifth object. □

Theorem 126.477 (StreamName open-phase roadmap exit conjunction)**.** *The current Phase Real and Completion paper-side boundary condition is the conjunction of the four local faces*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

read componentwise through their own local closurestatus and formalstatus records and through the shared support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

This conjunction is sufficient only for the current paper-side boundary and audit-readiness route. Full phase exit is read objectwise from each face's own closurestatus and formalstatus records; no aggregate bridge or formalstatus token is created. It does not assert selected limits, quotient stream equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, countable choice, or standard bridge completion.*

Proof. Start with Definition 126.475. It states that an accepted Phase Real and Completion exit packet is exactly the terminal finite route through the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and the displayed support rows.

Next apply Definition 126.476. This removes any hidden fifth object or aggregate token from the boundary, so the route can only be read as the four displayed faces with their BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Align this route with the roadmap by Definition 126.500. The four objects named there are the same DyadicRatCore, StreamName, RegSeqRat, and Real faces, so the open-phase boundary and the Real-completion roadmap boundary have the same visible coordinates.

Finally use Definition 38.728 and Definition 38.729. They require each face to contribute its own closurestatus and formalstatus record and prevent any support row or aggregate audit token from replacing a missing local face record. Therefore the componentwise four-face conjunction is sufficient only for the paper-side boundary and audit-readiness route. Full phase exit remains an objectwise read from the four local records, and the excluded selected-limit, quotient-equality, completeness, choice, metric, aggregate bridge, and aggregate formalstatus claims remain outside the theorem. □

Theorem 126.478 (StreamName open-phase exit audit consolidation)**.** *An accepted Phase Real and Completion audit packet for the current* $\mathsf{StreamName}^{\uparrow}$ *open-phase exit is valid exactly when it exposes exactly the four local faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with each of $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *exposing its own current-roadmap local theory-closure record and a verification record at least as strong as the audit-clean threshold, read from that face's own closurestatus block, with* $\mathsf{bridgeChecked}$ *read only as the local face bridge token where that face records it, together with the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Equivalently, validity is the conjunction of those four objectwise threshold records and those finite support rows, and nothing else.

The audit packet excludes quotient stream equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, countable choice, standard bridge completion, and any aggregate formalstatus or bridge token.*

Proof. For sufficiency, apply Definition 126.477. It identifies the paper-side boundary condition as the four local Phase Real and Completion faces read through their own local records, plus the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Then apply Definition 38.494 as a threshold read. The Real-side criterion says those local records must meet the current objectwise threshold: each face supplies the required local theory-closure row and a local formalstatus row meeting or exceeding $\mathsf{auditClean}$, read from its own closurestatus block. If a face records $\mathsf{bridgeChecked}$, that token is read only as that face's local bridge record; it is not converted into an aggregate formalstatus or bridge token.

Use Definition 126.475 to read that thresholded visible packet as an accepted terminal finite route.

For necessity, apply Definition 126.476. It says every accepted open-phase exit route is exhausted by the same four faces and displayed rows. The ledger exactness of Definition 126.471 fixes the tolerance-ledger coordinate inside the finite packet, while the readback theorem Definition 126.450 fixes every current exit read on exactly those rows.

Finally use Definition 38.494 and Definition 38.729. Mere record presence is not enough: the local rows must satisfy the threshold, and no aggregate support row can compensate for a missing or sub-threshold face. Thus the necessary and sufficient audit criterion is exactly the four facewise threshold records with the displayed support rows, with each face keeping its own local formalstatus token and with no aggregate formalstatus, bridge token, quotient equality, selected limits, ambient completeness, metric completeness, countable choice, or standard bridge completion. □

Theorem 126.479 (StreamName RegSeqRat–Real selector-budget normal form)**.** *Every accepted Phase Real and Completion exit read whose visible faces are*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

factors through one selector-budget packet. The packet consists exactly of the finite request row, selected-window row, dyadic tolerance row, regularity handoff row, $\mathsf{Real}^{\uparrow}$ *seal row, support and provenance rows, and local* NameCert *row.*

The factorization is read through the same surfaces used by the sibling $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *chapters, namely chapter 38, chapter 301, chapter 291, and chapter 885. It excludes quotient streams, host equality, selected limits, ambient completeness, and any fifth object.*

Proof. First pull the Real and RegSeqRat faces back to the same dyadic window. By Definition 126.460, the $\mathsf{Real}^{\uparrow}$ seal and $\mathsf{RegSeqRat}^{\uparrow}$ readback share the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger through the finite $\mathsf{StreamName}^{\uparrow}$ window.

Next expose the selector-budget rows. The Real-window budget pullback of Definition 126.473 identifies the finite request, selected window, dyadic readbacks, regular handoff, Real seal, componentwise transport, continuation route, provenance, and local naming rows as one packet rather than as separate completion data.

Now use Definition 126.474. Agreement on the displayed budget rows determines the terminal four-face consumer route, so any Phase Real or Completion exit read with those visible faces factors through the same selector-budget surface.

Finally apply Definition 126.476. Since the terminal exit route is exhausted by the four displayed faces and support rows, no quotient stream, host equality, selected limit, ambient completeness row, or fifth object remains as an additional factor. □

Theorem 126.480 (StreamName selector-budget defect localization)**.** *Let an accepted Phase Real and Completion exit read expose the visible faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

If this read fails to factor through the selector-budget packet of Definition 126.479, then the defect is witnessed by at least one displayed finite request row, selected-window row, dyadic tolerance row, regularity handoff row, $\mathsf{Real}^{\uparrow}$ *seal row,* BHist *row,* hsame *row,* Cont *row,* Pkg *row, or local* NameCert *support row.*

The defect cannot be witnessed by quotient stream equality, host equality, selected limits, ambient completeness, aggregate formalstatus, aggregate bridge rows, countable choice, or any fifth object.

Proof. Apply Definition 126.479. It identifies the only selector-budget packet available to an accepted exit read with the four displayed faces, so a failure of factorization must be a failure of one coordinate in that packet.

The packet coordinates are local. The dyadic-window pullback of Definition 126.460 fixes the shared $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger for the $\mathsf{RegSeqRat}^{\uparrow}$ readback and the $\mathsf{Real}^{\uparrow}$ seal. The Real-window budget pullback of Definition 126.473 identifies the finite request, selected-window, dyadic tolerance, regularity handoff, seal, support, provenance, and local naming rows as the displayed selector budget.

Now use Definition 126.474. Every accepted consumer coordinate is determined by those displayed rows, including the BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows. Hence a defect in the factorization has to appear on at least one of those finite rows.

Finally apply Definition 126.476. Since the terminal route is exhausted by the four visible faces and their support rows, quotient stream equality, host equality, selected limits, ambient completeness, aggregate formalstatus, aggregate bridge rows, countable choice, and any fifth object are not admissible witnesses for the defect. □

Theorem 126.481 (StreamName selector-budget defect face-status obstruction)**.** *Let an accepted Phase Real and Completion exit read expose exactly the visible faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

If the read either fails to factor through the selector-budget packet of Definition 126.479 or fails the audit-packet criterion of Definition 126.478, then the obstruction is witnessed by at least one displayed finite request row, selected-window row, dyadic tolerance row, regularity handoff row, $\mathsf{Real}^{\uparrow}$ *seal row,* BHist *row,* hsame *row,* Cont *row,* Pkg *row, local* $\mathsf{NameCert}$ *support row, or by one of the four objectwise local closurestatus and formalstatus records attached to* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

The obstruction cannot be repaired or witnessed by quotient stream equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, countable choice, aggregate formalstatus, aggregate bridge rows, or standard bridge completion.*

Proof. First consider failure of selector-budget factorization. By Definition 126.480, every such failure is already localized on one of the finite selector rows or support rows displayed by the four-face packet. The excluded quotient, limit, completeness, choice, aggregate, and bridge coordinates do not occur in that packet.

Now consider failure of the audit-packet criterion. Apply Definition 126.478. It reads audit validity as exactly the four objectwise local closurestatus and formalstatus records, together with the displayed support rows. Hence a failed audit packet is witnessed either by one of those local face-status records or by one of the finite support rows already named above.

Finally combine the two cases with Definition 126.477 and Definition 126.476. The roadmap theorem keeps full phase exit objectwise over the four displayed faces, while no-fifth-object exhaustion removes every hidden route behind the terminal classifier surface. Thus aggregate formalstatus, aggregate bridge rows, standard bridge completion, quotient stream equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric completeness, and countable choice cannot substitute for a missing finite row or a missing local face-status record. □

Theorem 126.482 (StreamName open-phase face-status obstruction localization)**.** *Let a current Phase Real and Completion exit read expose exactly the four visible faces*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

If the read fails the roadmap exit audit, then the failure is witnessed by one of those four local closurestatus, formalstatus, leantarget, or bridgestatus records, or by one of the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows.*

No aggregate formalstatus, aggregate bridge row, selected limit, quotient stream equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, countable choice, or standard bridge row can substitute for the missing local witness.*

Proof. First identify the audit surface. By Definition 126.478, the StreamName-side audit criterion is exactly the four local Phase Real and Completion face records together with the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next identify the roadmap boundary. Apply Definition 126.477. It reads the current exit as the same four-face conjunction over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so failure of the roadmap exit audit must occur on a row carried by that conjunction.

Now import the Real-side componentwise obstruction. The objectwise face-status exit of Definition 38.792 fixes the $\mathsf{Real}^{\uparrow}$ L10 boundary as the four named face records plus the same displayed support rows, and Definition 38.729 says an audit failure cannot be absorbed by an aggregate row when one of those local face records is missing or sub-threshold.

Finally apply Definition 126.476. Since the open-phase route has no hidden replacement coordinate beyond the four displayed faces and their support rows, selected limits, quotient stream equality, ambient completeness, metric completeness, countable choice, aggregate formalstatus, aggregate bridge rows, and standard bridge rows are not available substitutes. The failure is therefore localized to one of the four local status records or to one of the displayed support rows. □

126.34 StreamName L10 Real-Completion Sibling Spine

Theorem 126.483 (StreamName L10 Real-completion sibling spine)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *open-phase consumer that reaches the* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *endpoint surfaces factors through the sibling spine chapter 301, chapter 291, chapter 38, and chapter 386 before any endpoint seal is public. The spine exposes finite stream windows, regular-rational readback, dyadic tolerance ledgers, Real seal rows, Cauchy-limit seal rows, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows only.*

Proof. Start with Definition 126.441. It sends every Real and Completion finite-window read through the RegSeqRat, DyadicRatCore, and Real sibling surfaces before the read can become seal data.

Next apply Definition 126.446. The open-phase exit boundary identifies the public StreamName, RegSeqRat, DyadicRatCore, Real, observation, transport, route, provenance, and local naming rows, and excludes quotient streams, host sequence equality, selected limits, ambient completeness, metric-completeness data, and standard bridge rows.

Finally attach the Cauchy-limit seal sibling. The endpoint seal is public only after the displayed finite-window readback and dyadic ledger have reached the Cauchy-limit seal surface, so the route is the listed sibling spine rather than an additional endpoint selector. □

126.35 StreamName Real-Completion Gateway Package

Definition 126.484 (StreamName Real-completion gateway carrier)**.** *A* $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet is a finite* BHist *packet*

$$G = (S, D, R, E, B, H, C, P, N)$$

with the following displayed rows:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row read by the open phase;*
2. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger row anchored to the same finite window;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row produced from that anchored window;*
4. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reachable only after the displayed readback;*
5. *B records the displayed* BHist *observations on S, D, R, E;*
6. *H records componentwise* hsame *transports for the window, ledger, readback, seal, route, provenance, and local naming rows;*
7. *C records displayed* Cont *routes from S to D, from S, D to R, and from R to E;*
8. *P records* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N records the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *rows for the four faces and their displayed support.*

The packet is a gateway for the finite Real-completion route. It contains no coordinate for quotient stream equality, host sequence equality, a selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or a standard bridge row.*

Theorem 126.485 (StreamName Real-completion gateway obligations)**.** *For the carrier of Definition 126.484, the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *obligations are exactly carrier admission for*

$$G = (S, D, R, E, B, H, C, P, N),$$

StreamName finite-window exposure through S, DyadicRatCore tolerance-ledger exposure through D, RegSeqRat readback exposure through R, RealUp seal exposure through E, displayed BHist *observation through B, componentwise* hsame *transport through H, displayed route replay through C, package provenance through P, and local naming through N.*

Proof. Start with Definition 126.446. It identifies every Phase Real and Completion consumer with the finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, and the displayed observation, transport, route, provenance, and local naming rows.

Next apply Definition 126.448. The certificate repacks the same exit boundary as a four-face read and names exactly the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows used by the gateway packet.

Finally use Definition 126.442. The tolerance ledger is pinned to the StreamName finite window before the RegSeqRat readback or the RealUp seal can be consumed. Therefore the listed rows exhaust the local NameCert obligations for the gateway carrier. □

Theorem 126.486 (StreamName Real-completion gateway non-escape)**.** *No accepted* $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet exports quotient stream equality, host sequence equality, a selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable-choice selection, or a standard bridge row. Every accepted gateway read factors through*

$$S, D, R, E, B, H, C, P, N$$

as displayed in Definition 126.484.

Proof. Begin with the gateway obligation theorem. It says that every public read of the packet is one of $S, D, R, E, B, H, C, P, N$ and that the structural rows only transport, replay, package, and name that displayed inventory.

Use Definition 126.446 and Definition 126.448. Both exclude quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, and standard bridge rows from the same four-face boundary.

It remains to exclude a bypass through the dyadic ledger. Apply Definition 126.442: the ledger is anchored to the StreamName finite window before RegSeqRat or Real consumers can inspect it. Thus the gateway has no second route through which any excluded object can enter. □

Theorem 126.487 (StreamName Real-completion gateway terminality)**.** *Let two accepted* $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway reads expose the same StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, displayed* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. Then the two reads determine the same finite BEDC route through the Real-completion gateway. Conversely, every terminal route available to the current Real-completion open phase is read through exactly those four faces and support rows.*

Proof. First apply Definition 126.449. It states that agreement on the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and displayed support rows determines the same terminal finite BEDC route.

Next use Definition 126.437. The lattice gives the converse direction: every terminal open-phase route is exhausted by the same four faces and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Finally compare with Definition 126.484. The carrier lists exactly those rows and no additional coordinate. Therefore two gateway reads with the same four faces and support rows determine the same finite BEDC gateway route, and every terminal route in the current Real-completion open phase is read through that packet. □

Theorem 126.488 (StreamName Real-completion gateway ordered source readback)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway read consumes the source in the strict order*

$$S \longrightarrow D \longrightarrow R \longrightarrow E.$$

The StreamName finite window S is read first, the $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger D is anchored to that window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R is available only from S, D, and the* $\mathsf{Real}^{\uparrow}$ *seal E is available only after R. The gateway exports no permutation of these four faces, no bypass through D, and no direct $S \longrightarrow E$ route.*

Proof. Project the carrier of Definition 126.484. Its displayed route rows name S before D, name R only from the paired S, D read, and name E only after the readback row.

Apply Definition 126.485. The NameCert surface exposes the same ordered rows as the accepted gateway packet, so every consumer reads the four faces through the displayed BHist, hsame, Cont, Pkg, and local naming support.

Use Definition 126.442 to rule out a dyadic bypass. The tolerance ledger is attached to the StreamName window before any RegSeqRat or RealUp consumer can inspect the route.

Finally apply Definition 126.487. Since all terminal Real-completion routes factor through the same four-face packet, a consumer cannot reorder the faces or jump directly from S to E without leaving the exported gateway carrier. □

Theorem 126.489 (StreamName Real-completion gateway touchpoint factorization)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet whose source readback follows*

$$S \longrightarrow D \longrightarrow R \longrightarrow E.$$

Then the machine-facing surface of G is exactly the factorization through the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. Equivalently, the only Lean-route positions consumed by the gateway are

`BEDC.Derived.StreamNameUp.RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff`,
`BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness`,
`BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_real_seal_handoff`.

The factorization exports no quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable-choice row, standard bridge row, or bridge-row substitute.*

Proof. Start with Definition 126.488. It fixes the gateway source order as S before D, R only from the paired S, D route, and E only after R.

Next apply Definition 126.485. The accepted packet exposes exactly the four faces S, D, R, E and the support rows B, H, C, P, N, so the gateway has no machine-facing coordinate outside the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ inventory.

Now use Definition 126.453 together with Definition 126.452. These bind the same four-face exit read to exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. The three touchpoints are route positions for the existing window, ledger, readback, and seal rows, not additional carrier data.

Finally invoke Definition 126.486. Since every accepted gateway read factors through $S, D, R, E, B, H, C, P, N$, the cited Lean-route boundary cannot introduce quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, a standard bridge row, or any bridge-row substitute. Thus the ordered gateway packet and the three touchpoints form one exact factorization surface. □

Theorem 126.490 (StreamName Real-completion gateway status exactness)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet. The packet is status-exact for the current Phase Real and Completion boundary exactly when the four public status faces are read as the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *closurestatus and formalstatus records, respectively, with only B, H, C, P, N as support rows. No aggregate token, fifth completion object, quotient stream, selected limit, countable-choice row, metric-completeness datum, or standard bridge row can replace any one of the four faces or enter as an additional status face.*

Proof. Project the gateway carrier of Definition 126.484. Its accepted packet exposes exactly the four faces S, D, R, E and the support rows B, H, C, P, N, so status information has no carrier coordinate outside that displayed list.

Use Definition 126.488. The gateway reads S before D, reads R only from the paired S, D route, and reads E only after R. Thus the four status faces cannot be permuted, fused into an aggregate token, or bypassed through a direct completion row.

Apply Definition 126.500 and Definition 126.516. These theorems identify the same four Phase Real and Completion faces as the StreamName finite window, DyadicRatCore finite dyadic budget, RegSeqRat regularity handoff, and RealUp seal route.

Finally use the two-axis discipline recorded by the roadmap closurestatus blocks. The closurestatus and formalstatus rows are read per object, while B, H, C, P, N only observe, transport, replay, package, and name the displayed faces. Therefore the gateway is status-exact precisely for those four per-object records, with no extra completion, quotient, choice, metric-completeness, selected-limit, or bridge status row hidden in the route. □

Theorem 126.491 (StreamName Real-completion gateway face-record noncollapse)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet. The four public record faces of* G *are exactly the local* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *closurestatus, formalstatus, leantarget, and bridgestatus rows. The support rows* B, H, C, P, N *observe, transport, replay, package, and name those faces, respectively, but they do not create an aggregate formalstatus, replacement leantarget, route-level bridgestatus, standard bridge row, selected limit, quotient stream equality, countable-choice row, metric-completeness datum, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Project the gateway carrier of Definition 126.484. The accepted packet exposes only the four public faces S, D, R, E and the support rows B, H, C, P, N, so every audit-facing record must be read through that displayed objectwise surface.

Apply Definition 126.490. It identifies the closurestatus and formalstatus records as the four local $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, with B, H, C, P, N remaining support rows rather than status carriers.

Next use Definition 126.489. The Lean-facing route has exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. These are route positions attached to the same four faces, not replacement leantargets or route-level bridgestatus data.

Finally invoke Definition 126.486 and Definition 126.488. The source order $S \longrightarrow D \longrightarrow R \longrightarrow E$ has no bypass through quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, countable choice, a standard bridge row, or any bridge-row substitute. Therefore the four public records remain objectwise face records, while B, H, C, P, N only carry the named support roles. □

Theorem 126.492 (StreamName Real-completion gateway no-choice normal form)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet. Every terminal seal consumer or completion-facing consumer of* G *that is status-exact and machine-facing through the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff has the normal form*

$$S \longrightarrow D \longrightarrow R \longrightarrow E$$

with support rows B, H, C, P, N. Any read mentioning quotient stream equality, host sequence equality, a selected limit, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, a standard bridge row, or a bridge-row substitute lies outside the exported gateway carrier.*

Proof. Use Definition 126.488. It fixes the only consumer order exported by the accepted gateway packet as S before D, R only from the paired S, D read, and E only after R.

Apply Definition 126.490 and Definition 126.491. A status-exact consumer reads the four public status faces as the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ objectwise records, while B, H, C, P, N remain support rows rather than aggregate formalstatus, replacement leantarget, route-level bridgestatus, or additional completion data.

Next use Definition 126.489. The machine-facing route is exactly the three existing touchpoints named in the statement, so no fourth machine coordinate can supply quotient equality, a selected limit, choice, completeness, or bridge data.

Finally invoke Definition 126.486. Since every accepted gateway read factors through $S, D, R, E, B, H, C, P, N$, any consumer that mentions one of the excluded coordinates has left the exported carrier. Thus every terminal seal or completion-facing consumer that remains inside the gateway has precisely the displayed no-choice normal form. □

Theorem 126.493 (StreamName Real-completion gateway support-row minimality)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet for the current Phase Real and Completion boundary. The five support rows B, H, C, P, N are independently necessary for the gateway surface:*

1. *without B, there is no displayed observation surface for the four faces S, D, R, E;*
2. *without H, componentwise transport cannot identify the same finite route through the window, ledger, readback, seal, route, provenance, and local naming rows;*
3. *without C, the ordered route $S \longrightarrow D \longrightarrow R \longrightarrow E$ cannot be replayed inside the packet;*
4. *without P, provenance over the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces is absent;*
5. *without N, the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row for the four faces and their displayed support is absent.*

When the four faces and all five support rows are present, Definition 126.492 gives the unique no-choice normal form. The minimality claim exports no quotient stream equality, host sequence equality, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, standard bridge row, or bridge-row substitute.*

Proof. Project the carrier in Definition 126.484. It displays exactly the four faces S, D, R, E and the five support rows B, H, C, P, N, with no extra coordinate that could replace one of those support rows.

Apply Definition 126.485. The accepted local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ surface assigns B to displayed BHist observation, H to componentwise hsame transport, C to displayed Cont route replay, P to Pkg provenance, and N to local naming. Removing any one row removes exactly the corresponding obligation from the accepted packet surface.

1. The B row is necessary because the carrier and obligation theorem expose the four faces through displayed BHist observations. Without B, the packet may still name S, D, R, E, but it has no displayed observation surface for them.
2. The H row is necessary because the same finite route is compared componentwise through hsame across the window, ledger, readback, seal, route, provenance, and local naming rows. Without H, terminal agreement cannot identify that the read is the same finite route.
3. The C row is necessary by Definition 126.488. The source order $S \longrightarrow D \longrightarrow R \longrightarrow E$ is part of the displayed route replay, so deleting C deletes the internal replay of that order.
4. The P row is necessary by Definition 126.489. The machine-facing factorization is over the four named faces and their existing route positions; without P, the packet has no provenance tying those faces to the gateway package.
5. The N row is necessary by Definition 126.490. Status exactness is read through local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ rows for the four faces and their support, so without N the gateway lacks the local naming row that records the status surface.

With all five support rows present, the same carrier, obligation, ordered-readback, factorization, and status-exactness theorems place the accepted packet back inside the hypotheses of Definition 126.492. That theorem returns the unique no-choice normal form for the current gateway.

The exclusions are preserved because none of the five support rows is a quotient stream equality, host sequence equality, selected limit, countable-choice row, ambient Real completeness datum, metric-completeness datum, standard bridge row, or bridge-row substitute, and the no-choice normal form already rejects every read mentioning those coordinates. □

Theorem 126.494 (StreamName Real-completion gateway face minimality)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet for the current Phase Real and Completion boundary. The packet satisfies the current gateway read only when all four object faces* S, D, R, E *are present:*

1. *deleting the* $\mathsf{StreamName}^{\uparrow}$ *finite-window face* S *leaves no accepted gateway route;*
2. *deleting the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger face* D *leaves no accepted gateway route;*
3. *deleting the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face* R *leaves no accepted gateway route;*
4. *deleting the* $\mathsf{Real}^{\uparrow}$ *seal face* E *leaves no accepted gateway route.*

This face minimality is internal to the displayed gateway carrier and exports no quotient stream, host sequence equality, selected limit, countable-choice row, metric-completeness datum, standard bridge row, bridge-row substitute, or $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. First identify the accepted gateway surface. By Definition 126.485, an accepted packet carries the four faces S, D, R, E together with the displayed support rows B, H, C, P, N as a local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ package; no extra carrier coordinate is available to stand in for a missing face.

Next read the source order. Apply Definition 126.488. The only gateway route has the form

$$S \longrightarrow D \longrightarrow R \longrightarrow E.$$

Thus the window face is the route source, the tolerance-ledger face is the dyadic budget read after that source, the readback face consumes the paired S, D data, and the seal face is available only after the readback.

Now remove one face. If S is absent, the ordered source read has no StreamName window from which to start. If D is absent, the same route has no DyadicRatCore tolerance ledger to pass from the window into the regular sequence read. If R is absent, there is no RegSeqRat readback consuming the S, D pair. If E is absent, there is no RealUp seal endpoint. In each case the ordered readback theorem leaves no accepted gateway route on the remaining three faces.

It remains to rule out replacement data. By Definition 126.490, the status records are exactly the objectwise $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows; by Definition 38.793, the Real-side current Phase Real and Completion exit certificate also needs each of those four faces. These two minimality reads agree with the gateway obligations, so quotient streams, host sequence equality, selected limits, countable choice, metric-completeness data, standard bridge rows, bridge-row substitutes, and $\mathsf{Real}^{\uparrow}$ completeness cannot fill any deleted face. □

Theorem 126.495 (StreamName Real-completion gateway choice-free face determinacy)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

and

$$G' = (S', D', R', E', B', H', C', P', N')$$

be accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packets for the current Phase Real and Completion boundary. Suppose the four object faces agree through the displayed componentwise* hsame *transports*

$$S\mathsf{hsame}S', \qquad D\mathsf{hsame}D', \qquad R\mathsf{hsame}R', \qquad E\mathsf{hsame}E',$$

and suppose the support rows B, H, C, P, N *and* B', H', C', P', N' *agree as local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *rows for those transported faces. Then every terminal Real-completion consumer of* G *and every terminal Real-completion consumer of* G' *determine the same finite public* $\mathsf{Real}^{\uparrow}$ *seal row through the route*

$$S \longrightarrow D \longrightarrow R \longrightarrow E.$$

The determined public seal row is independent of quotient stream equality, host sequence equality, selected limits, countable choice, metric-completeness data, standard bridge rows, bridge-row substitutes, and ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 126.491. For each accepted packet, every public record is read through the four objectwise faces and the support rows B, H, C, P, N or B', H', C', P', N'. The displayed hsame transports identify the two StreamName windows, DyadicRatCore ledgers, RegSeqRat readbacks, and RealUp seal faces as the same public face record.

Next use Definition 126.492 for both terminal consumers. Each consumer has the ordered no-choice route

$$S \longrightarrow D \longrightarrow R \longrightarrow E$$

on G, and the transported route with faces S', D', R', E' on G'. Since the four faces agree componentwise, the two ordered routes have the same public RealUp endpoint.

The support rows cannot introduce a second route. By Definition 126.493, the rows B, H, C, P, N are exactly the observation, transport, replay, provenance, and local naming rows needed for the displayed gateway surface. Their agreement as local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ rows therefore makes the support inventory for G and G' the same finite inventory, not an additional choice parameter.

Finally apply Definition 126.494. No replacement face can stand in for S, D, R, E, and no excluded coordinate can fill the RealUp endpoint. Thus the two terminal consumers determine the same finite public $\mathsf{Real}^{\uparrow}$ seal row, with no quotient stream equality, host sequence equality, selected limit, countable-choice row, metric-completeness datum, standard bridge row, bridge-row substitute, or ambient Real completeness coordinate added to the route. □

Theorem 126.496 (StreamName Real-completion gateway audit-touchpoint separation)**.** *Let*

$$G = (S, D, R, E, B, H, C, P, N)$$

be an accepted $\mathsf{StreamName}^{\uparrow}$ *Real-completion gateway packet for the current Phase Real and Completion boundary. The audit-facing object records of G are exactly the four objectwise closurestatus, formalstatus, leantarget, and bridgestatus faces for* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *The machine-facing touchpoints of G are exactly the three route positions named by Definition 126.489: the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.*

These two readings do not collapse into one another. The audit-facing records do not create a machine route coordinate, and the machine-facing touchpoints do not create an aggregate formalstatus, replacement leantarget, route-level bridgestatus, standard bridge row, selected limit, quotient stream equality, countable-choice row, metric-completeness datum, or $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 126.490. It identifies the audit-facing status surface as the four objectwise records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with closurestatus, formalstatus, leantarget, and bridgestatus read locally on those faces rather than through a single gateway-wide status row.

Next use Definition 126.489. The machine-facing route is exhausted by the three named touchpoints: the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. These are positions in the route, not objectwise closurestatus, formalstatus, leantarget, or bridgestatus records.

The two inventories cannot be identified. By Definition 126.491, the public face records remain objectwise over S, D, R, E and their support rows B, H, C, P, N. Thus a touchpoint cannot replace an audit record, and an audit record cannot supply an additional machine-facing handoff.

Finally invoke Definition 126.492 and Definition 126.486. Every accepted gateway read stays inside the ordered no-choice route and the displayed support rows, so neither reading can introduce aggregate formalstatus data, replacement leantargets, route-level bridgestatus data, standard bridge rows, selected limits, quotient stream equality, countable-choice rows, metric-completeness data, or $\mathsf{Real}^{\uparrow}$ completeness claims. □

Theorem 126.497 (StreamName CauchyWitnessLedger exit route)**.** *Any* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *completion-facing read of the current Phase Real and Completion exit boundary of* $\mathsf{StreamName}^{\uparrow}$ *factors through a finite witness-ledger route. The source is the StreamName finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{Real}^{\uparrow}$ *seal named by the open-phase exit certificate, together with the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Only after those four faces and their displayed support rows are fixed may the ledger expose the ordered route

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with structural rows H, C, P, N in the accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet.*

The route exports no quotient stream, no selected limit, no host sequence equality, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. Begin with Definition 126.446. It identifies every current Phase Real and Completion exit read with the StreamName finite window, the RegSeqRat readback, the DyadicRatCore ledger, the RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply Definition 126.448. The certificate repacks the same four faces as a Real-completion exit packet and keeps the tolerance, readback, and seal coordinates on the finite StreamName surface rather than on a quotient stream or selected limit.

Then use Definition 126.449. Once the finite window, tolerance ledger, readback, seal, and support rows are fixed, there is no second terminal route for a completion-facing consumer to choose.

Finally apply Definition 902.5. The accepted ledger consumes that finite source through Q, then B, then S, and only then exposes K, with H, C, P, N preserving transport, replay, provenance, and local naming. Since both the StreamName exit boundary and the ledger factorization have no coordinate for quotient streams, selected limits, host sequence equality, ambient Real completeness, metric completeness, countable choice, or standard bridges, the displayed finite witness-ledger route is the whole export. □

Theorem 126.498 (StreamName CauchyWitnessLedger exit saturation)**.** *Every* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *read of a current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *exit packet is saturated by exactly the four finite faces named by Definition 126.448 and Definition 126.449: the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{Real}^{\uparrow}$ *seal, with only the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

After those four faces are fixed, the witness ledger has only the ordered route

$$Q \longmapsto B \longmapsto S \longmapsto K$$

from Definition 902.5, with structural rows H, C, P, N preserving transport, replay, provenance, and local naming.

The saturated packet exports no quotient stream, no selected limit, no host sequence equality, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. First apply Definition 126.497. It places every completion-facing ledger read on the finite StreamName, DyadicRatCore, RegSeqRat, and Real route, and it already excludes quotient streams, selected limits, host sequence equality, ambient completeness, metric-completeness data, countable-choice rows, and standard bridge rows from the route.

Next use Definition 126.448 and Definition 126.449. The certificate names exactly the four finite faces of the Real-completion exit packet, while terminality says that once those faces and the displayed BHist, hsame, Cont, Pkg, and NameCert rows are fixed, no alternate finite exit boundary remains.

Finally apply Definition 902.5. The witness ledger consumes the fixed packet through Q, then B, then S, and then K, with H, C, P, N carrying only the structural support for that route. Since neither the four-face boundary nor the factorization supplies any further public coordinate, the ledger saturates the current StreamName exit boundary rather than enlarging it. □

Theorem 126.499 (StreamName CauchyWitnessLedger terminal determinacy)**.** *Let two completion-facing* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *reads of the current* $\mathsf{StreamName}^{\uparrow}$ *Real-completion exit packet agree on the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the two reads expose the same terminal $\mathsf{Real}^{\uparrow}$ *seal row. The ledger may order the shared route through*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with structural rows H, C, P, N*, but it cannot introduce quotient streams, selected limits, host sequence equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, or a standard bridge.*

Proof. First apply Definition 126.497. Each read factors through the same finite StreamName, DyadicRatCore, RegSeqRat, and Real faces, with only the displayed BHist, hsame, Cont, Pkg, and NameCert support rows available to the ledger.

Next use Definition 126.498. Since both reads agree on those four faces and support rows, the witness ledger has no additional public coordinate from which a distinct terminal seal row could be read.

Now invoke Definition 126.449. The open Phase Real and Completion boundary is terminal once the finite window, tolerance ledger, readback, seal, and support rows are fixed, so both reads must consume the same terminal $\mathsf{Real}^{\uparrow}$ seal row.

Finally apply Definition 902.5. The fixed order $Q \longmapsto B \longmapsto S \longmapsto K$, with H, C, P, N preserving transport, replay, provenance, and local naming, makes the ledger a consumer of the four finite faces rather than a second source of seal data. The exclusions in the route and saturation statements therefore remain absent from the terminal read. □

126.36 StreamName Real-completion four-object exit route

Theorem 126.500 (StreamName Real-completion four-object exit route)**.** *Every current Phase Real and Completion exit read named by the roadmap for* DyadicRatCore*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *factors through exactly the four finite sibling faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The public rows of the exit boundary are only the finite StreamName window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the RealUp seal, and the displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

No quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row belongs to this exit boundary.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectExitRoute`

Proof. Begin with Definition 126.446. It identifies every current Phase Real and Completion consumer with a finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply Definition 126.448 and Definition 126.449. The certificate names the four finite faces of the exit packet, while terminality says that once those faces and support rows are fixed, the consumer has no second terminal route through which to read the boundary.

Now use Definition 126.483. The L10 spine places the StreamName route against the sibling surfaces consumed by the Real and Completion phase, so the roadmap's four objects are read as sibling faces rather than as a later completion theorem.

Finally apply Definition 126.497. The witness-ledger route consumes the same finite packet without adding quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, or standard bridge rows. Therefore the partial exit boundary, certificate, four-face terminality, sibling spine, and witness-ledger route exhaust the roadmap boundary for $\mathsf{DyadicRatCore}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. □

Theorem 126.501 (StreamName open-phase four-face minimality)**.** *For the current Phase Real and Completion exit boundary, the four displayed faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *are minimal. Deleting any one of the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, or RealUp seal prevents the exit read from satisfying the roadmap boundary named by Definition 126.500. No additional fifth face may replace a deleted one.*

The minimal packet still carries only the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

It does not admit quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, countable choice, metric-completeness data, or bridge substitutes as replacement faces.*

Proof. Start from Definition 126.500. It states the exit read through exactly the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the displayed support rows.

Use Definition 126.446 and Definition 126.449. The boundary theorem fixes the current roadmap surface, while terminality says that the four displayed faces are the terminal route through which that surface is read.

Now separate the four roles. The StreamName window supplies the finite observation window, the DyadicRatCore ledger supplies the tolerance account, the RegSeqRat readback supplies the regular sequence reading, and the RealUp seal supplies the terminal Real-facing boundary.

Finally apply Definition 126.483. The sibling spine keeps those roles distinct and blocks replacement by quotient streams, host equality, selected limits, ambient completeness, choice, metric-completeness rows, or bridges. Therefore deleting any one face removes a required row, and a fifth face cannot restore the current four-face exit boundary. □

Theorem 126.502 (StreamName Real-completion exit consumer exhaustion)**.** *Every downstream consumer of the current Phase Real and Completion exit packet, including completion-facing witness-ledger reads and terminal Real-facing seal reads, factors through the same four finite faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with only the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The consumer boundary exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectExitConsumerExhaustion`

Proof. Start with Definition 126.500. It names the current Phase Real and Completion exit packet as exactly the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next compose Definition 126.446 with Definition 126.448. The open-phase boundary identifies the finite consumer coordinates, and the certificate repacks those coordinates as the public Real-completion exit packet.

Apply Definition 126.449. Once the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and displayed support rows are fixed, a terminal Real-facing seal read has no second coordinate through which to leave the packet.

Finally use Definition 126.497. Completion-facing witness-ledger reads consume the same finite packet, so the witness-ledger route and the terminal Real-facing seal route are exhausted by the four faces and the displayed support rows. The exclusions in the cited routes remove quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable-choice rows, and standard bridge rows from every downstream consumer. □

Theorem 126.503 (StreamName Real-completion four-object exit minimality)**.** *Every current Phase Real and Completion exit read loses its certified boundary if any one of the four displayed sibling faces is omitted. Without the* $\mathsf{StreamName}^{\uparrow}$ *finite window there is no scheduled observation source; without the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger there is no tolerance or observation row; without the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback there is no regular-rational spine; without the local* $\mathsf{Real}^{\uparrow}$ *seal there is no public real-name row.*

Thus the four faces

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

are the minimal visible BEDC support for the current Phase Real and Completion boundary.

Proof. Apply Definition 126.500. It identifies the boundary packet with exactly the four displayed faces and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Next use Definition 126.502. Every downstream completion-facing or Real-seal-facing consumer reads only that packet, so deleting one face deletes the corresponding public coordinate rather than revealing a hidden replacement route.

The necessity of the individual faces is read from Definition 126.446. The $\mathsf{StreamName}^{\uparrow}$ finite window supplies the scheduled observation source, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger supplies tolerance and observation rows, the $\mathsf{RegSeqRat}^{\uparrow}$ readback supplies the regular-rational spine, and the local $\mathsf{Real}^{\uparrow}$ seal supplies the public real-name row.

Finally apply Definition 126.449. Terminality says the accepted read is fixed by those four faces and the displayed support rows, so no quotient stream, host sequence equality, selected limit, ambient completeness, metric-completeness datum, countable-choice row, or standard bridge row can replace a missing face. □

Theorem 126.504 (StreamName Real-completion four-object terminal pullback)**.** *Let two current Phase Real and Completion consumer reads expose the same four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the same displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the two reads determine the same terminal finite BEDC pullback through those four faces. Conversely, every completion-facing consumer and every Real-seal-facing consumer of the current exit packet factors uniquely through that pullback.

The pullback exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectTerminalPullback`

Proof. First apply Definition 126.500. It identifies the current exit packet with exactly the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For uniqueness of the terminal pullback, use Definition 126.502 together with Definition 126.449. Consumer exhaustion removes every downstream coordinate outside the four faces, and four-face terminality identifies two accepted reads once those faces and support rows agree.

For the converse direction, invoke Definition 126.497. Completion-facing witness-ledger reads consume the same finite packet, while the Real-seal-facing reads are already terminal by the open-phase four-face statement.

Combining the route theorem, consumer exhaustion, four-face terminality, and witness-ledger route gives a single terminal finite BEDC pullback for all accepted completion-facing and Real-seal-facing reads. The same cited exclusions leave no place for quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable-choice rows, or standard bridge rows. □

Theorem 126.505 (StreamName Real-completion terminal exactness)**.** *A current Phase Real and Completion read is publicly accepted exactly when it factors through the terminal finite pullback whose four faces are*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and whose support rows are only

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Equivalently, componentwise agreement on the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and displayed support rows is necessary and sufficient for the public classifier surface of the read.

The exact terminal boundary exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. For necessity, begin with Definition 126.500. It identifies every accepted current Phase Real and Completion read with exactly the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, supported only by BHist, hsame, Cont, Pkg, and NameCert.

Apply Definition 126.504. The accepted read must factor through the terminal finite pullback determined by those four faces and rows, so any public acceptance witness has the displayed terminal boundary.

For sufficiency, use Definition 126.518. It states that exposing precisely the four dependency faces with the displayed support rows is enough for the current paper-side Real-completion boundary.

Finally apply Definition 126.514. Componentwise agreement on the four faces and support rows determines the public classifier surface, and the axis separation theorem Definition 126.506 removes quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, choice, and bridge rows from the boundary. Thus terminal factorization through the four L10 faces is necessary and sufficient for public acceptance. □

Theorem 126.506 (StreamName Real-completion exit axis separation)**.** *The current Phase Real and Completion exit packet supplies only the paper-side finite four-face boundary through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

and the support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

It does not raise the verification-axis token of any of those four chapters, does not assert ambient $\mathsf{Real}^{\uparrow}$ *completeness, does not supply metric-completeness data, does not add a countable-choice row, and does not create a standard bridge row.*

Consequently, every downstream consumer may use this exit packet only as a paper-side finite boundary. Claims about verification status, bridge status, or completeness for any of the four faces must still be read from that face's own closurestatus block, Lean target, and stated bridge boundary.

Proof. Apply Definition 126.500. It fixes the exported Phase Real and Completion packet as exactly the four displayed faces and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Next use Definition 126.502 and Definition 126.504. Consumer exhaustion and terminal pullback say that every accepted downstream read factors through that same finite packet, with no additional coordinate for quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, or a standard bridge.

Finally read the packet through the two-axis discipline of section 9467.2 and section 9203.3. The four-face boundary is a manuscript-side route, while the verification status of each face is reported only by its own Lean target and closurestatus entry. Therefore the exit packet can be consumed as a finite paper-side boundary, but it cannot by itself change verification-axis tokens, supply completeness data, or create bridge claims for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionExitAxisSeparation`

Theorem 126.507 (StreamName Real-completion face status pullback)**.** *For any accepted current Phase Real and Completion exit read through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},$$

the paper-side boundary pulls back the four face status records only as references. The closure axis grade, formalstatus token, Lean target, and bridge status of each face remain exactly the entries declared in that face's own closurestatus block.

The exit packet promotes no face status. It introduces no fifth status coordinate, no aggregate verification token, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, and no bridge row beyond the face records already declared by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

Proof. Start with the four-object route of Definition 126.500. It identifies the accepted exit read with the four finite faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply the terminal pullback of Definition 126.504. Every downstream completion-facing or Real-seal-facing read factors through the same finite pullback, so status information can enter the packet only by reference to the already named faces.

Now use the axis separation theorem, Definition 126.506. It blocks the exit packet from changing verification-axis tokens, supplying completeness data, or creating bridge claims for any of the four faces.

Finally read the result through the roadmap two-axis discipline of section 9467.2. Closure axis, formalstatus token, Lean target, and bridge status are reported by each face's own closurestatus block; the exit packet merely gathers those references and adds no promotion or fifth status coordinate. □

Theorem 126.508 (StreamName four-face local record exit boundary)**.** *Assume the four face records for* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *are read objectwise from their own local closurestatus blocks. The* $\mathsf{DyadicRatCore}^{\uparrow}$ *face contributes its* bridgeChecked *bridgeChecked finite-route record, the* $\mathsf{StreamName}^{\uparrow}$ *face contributes its* bridgeChecked *finite-window record, the* $\mathsf{RegSeqRat}^{\uparrow}$ *face contributes its* axiomClean *paperBridge regularity-handoff record, and the* $\mathsf{Real}^{\uparrow}$ *face contributes its* bridgeChecked *seal record. Assume also that the finite handoff rows read by the current Phase Real and Completion roadmap are exactly the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the displayed support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then the current Phase Real and Completion exit boundary is exactly the pullback of those four local records: four independent status faces, with the three machine-route positions naming the finite-window, dyadic-ledger, and regular-to-real seal handoffs, and with no additional completion coordinate.

This boundary is not an aggregate audit-clean token and not an aggregate bridge token. It refuses quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, and bridge rows.*

Proof. First apply Definition 126.500. It identifies the current exit read with the four displayed faces and the finite support rows BHist, hsame, Cont, Pkg, and NameCert.

Read the local closurestatus records objectwise. The $\mathsf{DyadicRatCore}^{\uparrow}$ record supplies the dyadic finite-route face at bridgeChecked with bridgeChecked status, and the $\mathsf{RegSeqRat}^{\uparrow}$ record supplies the regularity-handoff face at axiomClean with paperBridge status. The $\mathsf{StreamName}^{\uparrow}$ record supplies the finite-window face at bridgeChecked, and the $\mathsf{Real}^{\uparrow}$ record supplies the seal face at bridgeChecked.

Next use Definition 126.506. Because these grades are read from four separate local closurestatus blocks, the packet cannot turn paper closure into verification status or verification status into paper closure.

Now apply Definition 126.507. The four local records pull back as four independent face references. The exit read therefore has no aggregate status coordinate and no fifth record that could hide a completion theorem.

It remains to bind the finite handoff rows. Use Definition 126.519: the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff are route positions for the existing window, ledger, readback, and seal rows. Together with the four-object route, axis separation, and face-status pullback, these positions make the four local records exactly the current roadmap exit boundary.

The exclusions are the same exclusions carried by the cited route and separation theorems. Quotient stream equality, selected limits, ambient completeness, metric-completeness data, countable choice, host sequence equality, and bridge rows are absent from the four-face packet. □

Theorem 126.509 (StreamName four-face audit-clean threshold readback)**.** *Assume the local face records for* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *are read from their own closurestatus blocks, and assume each face reports formal verification at least* auditClean*. Then the StreamName-side Phase Real and Completion exit boundary satisfies the roadmap verification threshold objectwise: the accepted boundary is exactly the four local audit-clean face records together with the finite StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

This threshold readback contributes no aggregate formalstatus*, no aggregate bridge token, no completeness row, no quotient stream, no selected limit, and no metric-completeness datum.*

Proof. Start with the four-face local record boundary of Definition 126.508. It identifies the StreamName-side exit boundary with the four local records and the displayed finite handoff rows, rather than with a route-level status token.

Apply the face-status pullback, Definition 126.507. Each closure grade, formalstatus token, Lean target, and bridge row is read only from the corresponding local face closurestatus block. The audit-clean threshold therefore enters only through the explicit hypothesis that every face is at least auditClean, checked object by object.

Next use the exit-axis separation theorem, Definition 126.506. It prevents the paper-side boundary from manufacturing an aggregate verification coordinate, bridge token, completeness row, quotient stream, selected limit, or metric-completeness datum.

Finally compare with the Real-side exit witness, Definition 38.492. That witness states the current Phase Real and Completion exit criterion in exactly the same four local faces, with each verification record read at least auditClean from its own closurestatus block. Therefore the StreamName-side boundary satisfies the roadmap threshold precisely as an objectwise four-face readback and not as any additional completion or bridge datum. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFourFaceAuditCleanThresholdReadback`

Theorem 126.510 (StreamName Real-completion objectwise threshold equivalence)**.** *A StreamName-side Phase Real and Completion exit read satisfies the current objectwise exit threshold if and only if the four local face records for* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *each supply the required local theory-closure row and an audit-clean verification row, read from that face's own closurestatus block.*

This equivalence is only the local four-face threshold. It supplies no aggregate formalstatus*, no aggregate bridge row, no quotient stream equality, no selected limit, no countable-choice row, no metric-completeness datum, and no* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. For the forward direction, apply Definition 126.509. It reads any accepted StreamName-side threshold witness objectwise through the four local faces $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with each verification row checked in that face's own closurestatus block.

Use the same read through Definition 38.494. The Real-side formulation identifies the current Phase Real and Completion threshold with exactly those local theory-closure rows and audit-clean verification rows, so the StreamName-side witness has the same objectwise coordinates.

For the reverse direction, suppose the four local face records each supply the required local theory-closure row and an audit-clean verification row. Apply Definition 126.505 to bind these records to the terminal four-object Real-completion boundary.

Next apply Definition 126.518. The dependency boundary is precisely the four faces together with the displayed BHist, hsame, Cont, Pkg, and NameCert support rows, so those local records are sufficient for the StreamName-side current exit read.

Finally compare again with Definition 38.494. The two formulations have the same four local faces and the same local closure and audit-clean threshold, while the cited StreamName terminal and dependency exactness theorems keep the packet from acquiring any aggregate formalstatus, aggregate bridge row, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, or $\mathsf{Real}^{\uparrow}$ completeness claim. □

Theorem 126.511 (StreamName Real-completion exit status coherence)**.** *A current Phase Real and Completion exit read satisfies the roadmap objectwise exit threshold exactly when the same read is the StreamName four-object route readback of the four local closurestatus records for* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Equivalently, the threshold reading and the local-status reading are the same objectwise four-face status packet: the $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic budget face, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity-handoff face, and the* $\mathsf{Real}^{\uparrow}$ *seal face.*

This coherence theorem adds no aggregate formalstatus*, no aggregate bridge row, no quotient stream equality, no selected limit, no countable-choice row, no metric-completeness datum, and no* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. For the threshold-to-status direction, apply Definition 126.510. It rewrites a current exit-threshold witness as the four local theory-closure and audit-clean verification rows read from the closurestatus blocks for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 126.512. The same four local records are exactly the StreamName-side local face-status readback. Use Definition 126.516 to identify those faces with the dyadic budget, finite window, regularity handoff, and seal route, and to retain only the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For the status-to-threshold direction, start from the four local closurestatus records read through the StreamName four-object route. The local face-status readback gives precisely the same four records, and status-ledger exactness says that no additional status coordinate is present in the accepted exit packet.

Apply Definition 126.510 in the reverse direction. Since the four local records supply exactly the required local theory-closure rows and audit-clean verification rows, the read satisfies the roadmap objectwise exit threshold.

Finally use Definition 126.506. Axis separation prevents the coherence statement from turning the four-face packet into an aggregate formalstatus, an aggregate bridge row, quotient stream equality, a selected limit, countable choice, metric completeness, or a $\mathsf{Real}^{\uparrow}$ completeness theorem. □

Theorem 126.512 (StreamName Real-completion local face status readback)**.** *The current StreamName-side Phase Real and Completion exit packet reads back the four existing local closurestatus records:*

1. $\mathsf{DyadicRatCore}^{\uparrow}$ *supplies its* bridgeChecked *bridgeChecked dyadic finite-route record,*
2. $\mathsf{StreamName}^{\uparrow}$ *supplies its* bridgeChecked *finite-window record,*

3. $\mathsf{RegSeqRat}^{\uparrow}$ *supplies its* axiomClean *paperBridge regularity-handoff record,*

4. $\mathsf{Real}^{\uparrow}$ *supplies its* bridgeChecked *local seal record.*

These four records are only objectwise local face data. They add no aggregate formalstatus*, no aggregate bridge row, no quotient stream equality, no selected limit, no countable-choice row, no metric-completeness datum, and no* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First apply Definition 126.507. It reads closure grade, formalstatus token, Lean target, and bridge status from each face's own closurestatus block, so the four displayed entries remain local records for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. For the dyadic face, the local readback is the same $\mathsf{DyadicRatCore}^{\uparrow}$ bridge anchor recorded by *BEDC.Derived.DyadicRatCoreUp.DyadicRatCo*

Next use Definition 126.508. The exit boundary is exactly the same four-face read: local theory-closure rows together with their actual local verification rows, with no fifth status coordinate. Apply Definition 126.519 to bind the finite window, dyadic route, regularity handoff, and real seal to the existing BHist, hsame, Cont, Pkg, and NameCert support rows.

Finally apply Definition 126.506. Because the four closurestatus records are cited only as local face records, the exit packet cannot promote them into an aggregate verification status, an aggregate bridge, quotient stream equality, a selected limit, countable choice, metric completeness, or a $\mathsf{Real}^{\uparrow}$ completeness theorem. This is precisely the claimed local face status readback. □

Theorem 126.513 (StreamName Real-completion objectwise exit certificate)**.** *A current Phase Real and Completion exit certificate for the StreamName-side route consists exactly of the four objectwise local records for*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

This certificate is necessary and sufficient for the paper-side roadmap exit boundary: the four local records supply the face statuses, the support rows supply the finite route data, and terminal acceptance is read through the four-object Real-completion pullback.

The certificate exports no quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus*, aggregate bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First apply Definition 126.512. It identifies the four local records as the objectwise closurestatus reads for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and it keeps those records from becoming an aggregate status coordinate.

Next use Definition 126.510. The current Phase Real and Completion threshold is satisfied exactly by those four local records together with their local theory-closure and verification rows, read object by object.

For sufficiency, apply Definition 126.505. Terminal exactness says that the four records, carried by BHist, hsame, Cont, Pkg, and NameCert, are enough for public acceptance of the four-object Real-completion boundary. The same theorem gives necessity, since every accepted current read must factor through that terminal four-face packet.

Finally apply Definition 126.506 and Definition 126.517. Axis separation removes quotient stream equality, selected limits, choice, metric-completeness data, and $\mathsf{Real}^{\uparrow}$ completeness from the certificate, while bridge nonaggregation prevents the four local records from forming an aggregate bridge row. Hence the displayed four records and five support rows are exactly the roadmap exit certificate and nothing more. □

Theorem 126.514 (StreamName Real-completion classifier pullback)**.** *Let two current Phase Real and Completion exit reads be accepted by the four-object route through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

They have the same public classifier surface exactly when their finite StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *tolerance ledger,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal, and displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows agree componentwise.*

No quotient stream, host sequence equality, selected limit, ambient Real$^{\uparrow}$ *completeness theorem, countable-choice row, metric-completeness datum, or standard bridge row can distinguish the two reads at the public classifier surface.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameRealCompletionClassifierPullback`

Proof. For the forward direction, apply the four-object route of Definition 126.500. The route exposes only the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the displayed support rows.

Use the terminal pullback, Definition 126.504. Once those rows agree, the two accepted reads factor through the same finite pullback, so there is no second public coordinate on which the classifier can separate them.

For the reverse direction, start from componentwise agreement of the displayed rows. The face-status pullback of Definition 126.507 keeps the four face records as references to the same face surfaces, rather than adding a status coordinate or a completion principle.

The Lean-facing handoff anchors for the finite window, dyadic ledger, and regular-to-real seal certify the same BEDC route positions used by the paper packet. Together with the route and terminality theorems, these handoffs repack the agreed rows as one public classifier surface.

The exclusions follow from Definition 126.506. Since quotient stream equality, host sequence equality, selected limits, ambient completeness, choice, metric-completeness data, and standard bridges are absent from the packet, none can distinguish the accepted reads. □

Theorem 126.515 (StreamName Real-completion terminal semantic readback)**.** *Any current Phase Real and Completion terminal read through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

carries the terminal SemanticNameCert *surface whose carrier is the readback row, whose pattern is exactly the four faces together with the terminal and readback rows, and whose ledger is the readback* Pkg *row.*

This terminal semantic readback exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate status, aggregate bridge row, or Real$^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameOpenPhaseFourFaceExitReadback`

Proof. First apply Definition 126.500. It fixes the terminal read as the four-face route through StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$, carried by the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 126.504. Terminal pullback identifies every accepted current read with the same finite four-object boundary, so the terminal row and the readback row are not additional objects outside the route.

Now apply Definition 126.514. The classifier surface is determined componentwise by the four faces and the support rows, hence the public readback carrier is exactly the readback row and its ledger is exactly the readback Pkg row.

The Lean readback target packages the same BHist, hsame, Cont, Pkg, and SemanticNameCert rows. Because it uses the four faces together with the terminal and readback rows as the whole pattern, it adds no fifth object and cannot export quotient streams, selected limits, choice, metric completeness, aggregate status, aggregate bridges, or $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 126.516 (StreamName Real-completion status ledger exactness)**.** *Every current Phase Real and Completion exit read through the StreamName four-object route has exactly the four displayed status faces:*

1. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite dyadic budget,*
2. *the* $\mathsf{StreamName}^{\uparrow}$ *pointwise certified window,*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity handoff,*
4. *the* $\mathsf{Real}^{\uparrow}$ *seal route.*

This status ledger is exact as a four-object paper-side boundary: it exports no ambient completeness theorem, no quotient stream equality, no host real equality, and no verification-axis upgrade for any of the four faces.

Proof. Start with Definition 126.500. It fixes the accepted exit read as the four sibling faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Apply Definition 126.501. The minimality statement prevents any one of the four faces from being deleted or replaced by a fifth face, so the status ledger has exactly the four named entries: finite dyadic budget, pointwise certified window, regularity handoff, and seal route.

Next use Definition 126.504. Terminal pullback identifies all accepted downstream reads through the same finite boundary once the four faces and support rows agree.

Now apply Definition 126.506 and Definition 126.507. Axis separation blocks verification promotion, completeness claims, quotient stream equality, and host real equality from entering the packet, while face status pullback says that closure and verification records are imported only as references to the four faces.

Finally use Definition 126.514. The public classifier surface is determined componentwise by the same four faces and displayed support rows, so the ledger is exact and axis-separated for every current Phase Real and Completion exit read. □

Theorem 126.517 (StreamName Real-completion bridge nonaggregation)**.** *For the current Phase Real and Completion exit packet, bridge status or audit-clean status on any subset of the four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

does not supply a standard bridge row for the aggregate packet. Even if one or more face records expose paperBridge, bridgeChecked, auditClean, or stronger local status in their own closurestatus blocks, the four-face packet remains a paper-side exit boundary unless an explicit aggregate bridge theorem names a standard bridge for the whole Phase Real and Completion route.

Thus the packet cannot infer a bridge row from the $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic budget, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular handoff, the* $\mathsf{Real}^{\uparrow}$ *seal, or any proper subfamily of these faces.*

Proof. Start with face-status pullback, Definition 126.507. It says that the closure grade, formal-status token, Lean target, and bridge status of each face are imported only as references to that face's own closurestatus block.

Next apply exit-axis separation, Definition 126.506. The current exit packet has no coordinate for turning a local bridge or audit-clean entry into a packet-level standard bridge row.

Use the three-touchpoint handoff route of Definition 126.519. The StreamName finite-window handoff, DyadicRatCore ledger handoff, and RegSeqRat-to-Real seal handoff are route positions for displayed BHist, hsame, Cont, Pkg, and NameCert rows; they are not an aggregate bridge constructor.

Finally read the four local closurestatus blocks for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Those blocks control their own bridge axes only. Therefore no subset of the face records aggregates into a standard bridge for the current Phase Real and Completion packet, and only an explicit aggregate bridge theorem may change the bridge axis of that packet. □

Theorem 126.518 (StreamName Real-completion dependency exactness)**.** *A current Phase Real and Completion exit read is accepted exactly when it exposes the four finite dependency faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and supports them only by the displayed rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The four faces are necessary and sufficient for the paper-side Real-completion boundary: the $\mathsf{StreamName}^{\uparrow}$ *face supplies the pointwise certified finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *face supplies the finite dyadic budget, the* $\mathsf{RegSeqRat}^{\uparrow}$ *face supplies the regularity handoff, and the* $\mathsf{Real}^{\uparrow}$ *face supplies the seal route.*

No quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, metric-completeness datum, countable-choice row, or bridge row is part of this exact dependency boundary.*

Proof. For necessity, begin with Definition 126.500. It identifies any accepted current exit read with the four displayed dependency faces and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Apply Definition 126.501 and Definition 126.516. Minimality prevents deleting or replacing any one face, while status-ledger exactness names the same four dependencies as the finite dyadic budget, pointwise certified window, regularity handoff, and seal route.

For sufficiency, use Definition 126.504. Once the four faces and displayed support rows are exposed, the accepted read factors through the terminal finite pullback of the Real-completion boundary.

Finally apply Definition 126.514. The classifier pullback says the public surface is determined by exactly those component rows, so no additional equality, limit, completeness, choice, metric, or bridge coordinate is needed or available. This gives the exact necessary-and-sufficient dependency boundary for the current paper-side Real-completion exit read. □

Theorem 126.519 (StreamName Real-completion three-touchpoint handoff route)**.** *Every current Phase Real and Completion exit read whose finite-window row is witnessed by the StreamName singleton finite-window handoff, whose tolerance ledger is witnessed by the DyadicRatCore RegSeqRat bridge handoff exactness, and whose real-seal row is witnessed by the RegSeqRat Real seal*

handoff factors through the existing four faces

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

The resulting paper obligation carries only the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The three machine-side route names identify the handoff path for the later formal target. They do not add a Lean marker at this paper site and do not export quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, or a standard bridge row.*

Proof. Begin with Definition 126.516. It says that every accepted current exit read has exactly the four status faces: the $\mathsf{DyadicRatCore}^{\uparrow}$ finite dyadic budget, the $\mathsf{StreamName}^{\uparrow}$ pointwise certified window, the $\mathsf{RegSeqRat}^{\uparrow}$ regularity handoff, and the $\mathsf{Real}^{\uparrow}$ seal route.

Next apply Definition 126.500. The four status faces are the same four finite sibling faces of the Real-completion exit boundary, and the support surface is only BHist, hsame, Cont, Pkg, and NameCert.

It remains to bind the named handoffs to that paper boundary. The prose handoff anchor of Definition 126.452 identifies the three machine-side route names as the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. These are route witnesses for the existing window, ledger, and seal rows, not extra coordinates.

Combining the exact status ledger, the four-object exit route, and the handoff anchor therefore repacks any read witnessed by the three named route positions through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ alone. The same cited exclusions prevent quotient equality, selected limits, completeness data, choice, metric-completeness rows, or bridge rows from entering the obligation. □

Theorem 126.520 (StreamName Real-completion four-face Lean witness composition)**.** *Every current Phase Real and Completion exit read whose four faces are accepted by the StreamName four-object route and whose terminal read is accepted by the terminal pullback has machine-facing support exactly through the three primary touchpoints*

$$\textit{Definition}\ 126.173,\quad \textit{Definition}\ 291.28,\quad \textit{Definition}\ 301.22.$$

The composed witness exposes only the support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

It exports no quotient stream equality, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, aggregate formalstatus token, or standard bridge row.*

Proof. Apply Definition 126.500. The accepted four faces are therefore exactly the current $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ exit faces, carried by the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Apply Definition 126.504. Since the terminal read is accepted, every downstream Real-completion read factors through that same finite pullback; no second coordinate can be recovered for quotient stream equality, selected limits, choice, ambient completeness, metric-completeness data, or bridge rows.

Next use Definition 126.519. It identifies the machine-facing support with the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff, which are precisely the three touchpoint route positions named in the statement.

Finally apply Definition 126.506. Closure status and verification status remain objectwise reports attached to the four accepted faces and terminal pullback. Hence the composed witness has no aggregate formalstatus token and exposes only the named BHist, hsame, Cont, Pkg, and NameCert support rows. □

Theorem 126.521 (StreamName Real-completion four-face audit-clean composition)**.** *Assume a current Phase Real and Completion exit read is accepted by the StreamName four-object route and by the terminal pullback, and assume the four local face records for*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

each report formal verification at least auditClean *from that face's own closurestatus block. Then the StreamName-side packet satisfies the same objectwise exit threshold as the Real-side current phase exit witness of Definition 38.492: the accepted packet is exactly the four local audit-clean face records together with the finite StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

This is only an objectwise exit-threshold composition. It adds no aggregate formalstatus*, no aggregate bridge row, no quotient stream equality, no selected limit, no countable-choice row, no metric-completeness datum, and no* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Begin with the four-face Lean witness composition of Definition 126.520. It binds an accepted four-object route and an accepted terminal pullback to the three machine-facing touchpoints for the StreamName finite-window row, the DyadicRatCore-to-RegSeqRat ledger row, and the RegSeqRat-to-Real seal row.

Next apply the audit-clean threshold readback of Definition 126.509. Under the hypothesis that $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ each report at least auditClean locally, the StreamName-side packet reads the roadmap verification threshold object by object through those four local records.

Use Definition 126.510 to compare that readback with the current objectwise exit-threshold formulation. Then apply the Real-side current phase exit witness, Definition 38.492, which states the same threshold in the Phase Real and Completion exit criterion.

Finally close the boundary exclusions with Definition 126.506 and Definition 126.517. Axis separation prevents the objectwise threshold from producing quotient stream equality, a selected limit, countable choice, metric-completeness data, or a $\mathsf{Real}^{\uparrow}$ completeness theorem, while bridge nonaggregation prevents the four local records from forming a packet-level bridge row. The composed packet therefore satisfies exactly the Real-side objectwise exit threshold and nothing beyond that boundary. □

Theorem 126.522 (StreamName Real-completion no-choice route factorization)**.** *Every current Phase Real and Completion exit read through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

factors through the finite four-face packet together with exactly the displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Equivalently, the route factorization has no coordinate for a countable-choice row, selected limit, quotient stream equality, host sequence equality, metric-completeness datum, or standard bridge row.

Any attempted reading of one of those rows lies outside the packet. It is therefore not part of the current paper obligation carried by the StreamName Real-completion exit route.

Proof. Start with the status ledger exactness theorem, Definition 126.516. It identifies every accepted current exit read with exactly the four status faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and states that the ledger exports no ambient completeness theorem, quotient stream equality, host real equality, or verification-axis promotion.

Apply the four-object exit route theorem, Definition 126.500. This fixes the support surface of the route as BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$, with no further packet coordinate.

Next use the terminal pullback, Definition 126.504. Terminality says that any accepted downstream read agreeing on the four faces and support rows factors through the same finite boundary, so a proposed selector, quotient, completeness, or bridge row cannot be recovered as an additional public component of the route.

Finally bind the named handoff positions by Definition 126.519. The StreamName finite-window row, DyadicRatCore tolerance ledger, and RegSeqRat-to-Real seal are witnesses for existing route entries rather than new data rows.

Reading the result through the roadmap two-axis discipline of section 9467.2, the factorization reports only the current closure and verification records already attached to the four faces. Since choice rows, selected limits, quotient stream equality, host sequence equality, metric-completeness data, and standard bridge rows are absent from that boundary, each such attempted row is outside the packet. □

Theorem 126.523 (StreamName Real-completion failure localization)**.** *Let a current Phase Real and Completion exit read be presented through the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Assume the read cannot be accepted as the public four-face boundary. Then the obstruction is localized to failure of at least one displayed face record or at least one displayed support row

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Equivalently, the failed read has no fifth completion object in which the obstruction can be stored.

In particular, the obstruction is not quotient stream equality, selected limit data, an ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, a metric-completeness datum, a countable-choice row, a standard bridge row, or any hidden fifth face.*

Proof. Begin with dependency exactness, Definition 126.518. Acceptance is exactly exposure of the four finite dependency faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with only the support rows BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Now apply terminal pullback, Definition 126.504. When those faces and rows are present, every accepted downstream read factors through the same finite boundary. Therefore a read that cannot be accepted must fail before this terminal pullback is available, at one of the listed face records or support rows.

Next use no-choice route factorization, Definition 126.522. The factorization has no coordinate for countable choice, selected limits, quotient stream equality, host sequence equality, metric-completeness data, or standard bridge rows, so none of those rows can serve as the missing obstruction carrier.

Finally apply exit-axis separation, Definition 126.506. Axis separation blocks an ambient $\mathsf{Real}^{\uparrow}$ completeness theorem or verification upgrade from becoming an extra paper-side face. The only remaining obstruction sites are the four displayed face records and the five displayed support rows, so the failed read has no hidden fifth object. □

Theorem 126.524 (StreamName Real-completion budget-selector lock)**.** *Let a current Phase Real and Completion consumer take only finite observations mediated by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *request. Then the consumer still factors through exactly the four Real-completion boundary faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

The mediated read carries only the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The observation-budget selector therefore locks into the same four-face boundary as the StreamName Real-completion exit route. It does not introduce quotient stream equality, host real equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, or a standard bridge row.*

Proof. Begin with the exact status ledger of Definition 126.516. Any accepted current Phase Real and Completion exit read has exactly the four status faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no additional status coordinate.

Now insert the finite observation-budget mediation. The StreamName Real observation-budget factorization of Definition 126.363 says that every accepted $\mathsf{StreamName}^{\uparrow}$ finite-window packet consumed by a $\mathsf{RealObservationBudget}^{\uparrow}$ precision request follows the visible route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ using only BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Next apply Definition 611.20. The accepted budget request reaches a seal read only through its finite precision, window, dyadic, regular handoff, and seal rows, so the selector supplies a finite access route rather than a new completion object or hidden observation schedule.

Finally use the exit-axis separation theorem, Definition 126.506. Since the four-object boundary has no quotient stream equality, host real equality, selected limit, ambient completeness, metric-completeness datum, countable-choice row, or standard bridge row, the budget-mediated consumer cannot obtain any of those rows by passing through the selector. The same four boundary faces and the same five support rows are therefore locked for every such finite observation-budget read. □

Theorem 126.525 (RegSeqObservationBudget exit pullback)**.** *Let an accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *consumer read its* $\mathsf{Real}^{\uparrow}$ *row as a current Phase Real and Completion exit read. Then the consumer factors through the same L10 four-face boundary*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

as the StreamName Real-completion exit route. Its support surface is only

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Thus the observation-budget consumer is a consumer of the displayed StreamName window, dyadic tolerance ledger, RegSeqRat readback, Real seal, and support rows. It does not receive quotient stream equality, host real equality, hidden diagonal selectors, unbounded schedules, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable choice, or aggregate bridge rows.*

Proof. First order the budget route. Theorem 1053.4 forces the accepted $\mathsf{RegSeqObservationBudget}^{\uparrow}$ consumer to display the StreamName window before the readback, tolerance, selector, or seal rows are used. Theorem 1053.6 then reaches the $\mathsf{Real}^{\uparrow}$ budget row only after the window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, dyadic tolerance, and diagonal selector rows have already been displayed.

Now read that ordered route through the current Real and Completion exit. Apply Definition 126.500. The exit packet is exactly the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next apply Definition 126.504. Since the RegSeqObservationBudget consumer reads its $\mathsf{Real}^{\uparrow}$ row as a current exit read, the ordered budget route factors through the same terminal finite pullback as every accepted downstream Real-completion read.

Finally use Definition 126.506 together with Definition 1053.8. Axis separation removes quotient stream equality, host real equality, ambient completeness, metric-completeness data, countable choice, and bridge rows from the exit boundary, while public consumer export says the accepted budget packet exports only the displayed finite route. The hidden selector and unbounded schedule alternatives therefore have no carrier coordinate, and the four faces with the five support rows exhaust the consumer boundary. □

Theorem 126.526 (StreamName dual observation-budget exit cofinality)**.** *Let a current Phase Real and Completion consumer be mediated both by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *request and by an accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *request over the same displayed StreamName finite window, DyadicRatCore endpoint-radius ledger, RegSeqRat readback and classifier rows, RealUp seal row, and support surface*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then the two mediated consumers determine the same finite four-face exit boundary

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

In particular, the RealObservationBudget-mediated read is cofinal with the RegSeqObservationBudget-mediated read inside the terminal pullback: any accepted finite exit-boundary read reached by either budget route factors through the same four faces and the same displayed support rows.

The common boundary contains no quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate $\mathsf{formalstatus}$ *row, aggregate bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First apply the budget-selector lock, Definition 126.524. It sends every accepted $\mathsf{RealObservationBudget}^{\uparrow}$ mediation for the current Phase Real and Completion consumer through exactly the four displayed faces with only BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Next apply the RegSeqObservationBudget exit pullback, Definition 126.525. Since the second mediation reads its $\mathsf{Real}^{\uparrow}$ row as the same current exit read, it also factors through the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the same five support rows.

Now compare the two factorizations with the terminal pullback of Definition 126.504. The hypotheses identify the displayed window, endpoint-radius ledger, readback and classifier rows,

seal row, and support surface, so terminality identifies the two mediated consumers as reads of one finite pullback rather than two independent selector coordinates.

Finally use exit-axis separation, Definition 126.506. The common pullback is only the paper-side four-face boundary. It therefore exports no quotient stream, selected limit, choice row, metric-completeness datum, aggregate verification row, aggregate bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness theorem. The two observation-budget routes are cofinal precisely because both terminate at that same finite boundary. □

126.37 StreamName finite-observation section packet

Theorem 126.527 (StreamName finite-observation section)**.** *Every certified finite observation section of a* $\mathsf{StreamName}^{\uparrow}$ *window is exhausted by the displayed* ProbeBundle *membership row, the* UnaryHistory *row, the* RatHistoryClassifier *row, the componentwise* hsame *transport, the displayed* Cont *route,* Pkg *provenance, and the local* NameCert *row of the StreamName packet. The section contributes no regularity witness, quotient stream equality, completion row, host-index equality, selected limit, or ambient completeness coordinate.*

Proof. Start from the certified observation section inside the finite StreamName window. Apply Definition 126.251; it projects any selected certified unary observation to the finite ProbeBundle row, InBundle membership row, UnaryHistory row, pointwise RatHistoryClassifier row, hsame comparison, Cont route, Pkg provenance, and NameCert provenance.

The membership and unary-history rows identify the observation as a finite section of the window rather than as a host-indexed stream. The pointwise classifier and hsame rows identify exactly the rational-history data visible at that section, while Cont, Pkg, and NameCert only replay, package, and name the same finite surface.

The exclusions are therefore inherited from the classifier exhaustion theorem. Regularity witnesses, quotient stream equality, completion rows, host-index equality, selected limits, and ambient completeness coordinates are not fields of the section packet, so no certified finite observation section can export them. □

Theorem 126.528 (StreamName finite-observation constant seed)**.** *For a constant rational stream section* $\mathsf{RatConstStream}_d$*, any two certified observations of the same finite* $\mathsf{StreamName}^{\uparrow}$ *window read the same hidden* $\mathsf{Rat}^{\uparrow}$ *seed* d*. The public section row is therefore the common* hsame *class of the two observed histories, together with the same finite membership, unary-history,* Cont*,* Pkg*, and* NameCert *support rows.*

Proof. Apply Definition 126.48 to the first certified observation. The observed history of $\mathsf{RatConstStream}_d$ is identified by hsame with the hidden seed d.

Apply the same witness theorem to the second certified observation. Its observed history is again identified by hsame with d, using only the certified unary observation row and the constant rational stream definition.

Now use Definition 126.49. It composes the two point-sameness witnesses through the seed and gives the same public history row for both certified observations. The finite membership, unary-history, Cont, Pkg, and NameCert rows are the support rows of the section packet, so the constant section reads one RatUp seed across all certified observations of the window. □

Theorem 126.529 (StreamName finite-observation Real exit handoff)**.** *The finite-observation section packet of Definition 126.527 and the constant-seed packet of Definition 126.528 are exactly the* $\mathsf{StreamName}^{\uparrow}$ *contribution to the Phase Real and Completion four-object exit surface. When the*

exit route is read through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, the StreamName side supplies only finite observation rows, constant-seed determinacy where the stream is constant, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

Proof. First use Definition 126.179. It places every finite-window $\mathsf{Real}^{\uparrow}$ seal read on the StreamName side over the carried endpoints, finite bundle membership, unary observation, and pointwise rational-history classifier rows.

Combine that scope theorem with Definition 126.527. The section packet is therefore the whole StreamName finite-observation contribution before the RegSeqRat and Real-facing rows are consumed.

For constant rational stream sections, insert Definition 126.528. The same finite section surface now also records that all certified observations read the same hidden RatUp seed, without adding a quotient stream, selected limit, or ambient completeness coordinate.

Finally apply Definition 126.500. The four-object route reads the Phase Real and Completion boundary through exactly $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with only the displayed BHist, hsame, Cont, Pkg, and NameCert support rows. Thus the section and constant-seed packets are precisely the StreamName-side finite observation handoff into that exit surface. □

Theorem 126.530 (StreamName RegSeqRat tail-budget section lock)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *observation section consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget read and then by a finite* $\mathsf{Real}^{\uparrow}$ *seal factors through the same displayed section packet. The packet consists of the* ProbeBundle *membership row, the* InBundle *membership row, the* UnaryHistory *observation row, the* RatHistoryClassifier *endpoint row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the displayed* hsame *transports, the* Cont *routes,* Pkg *provenance, and the local* NameCert *rows. It exports no quotient stream equality, host sequence equality, selected limit, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, or second dyadic source.*

Proof. The local section inventory is fixed by Definition 126.527. A certified finite observation section exposes exactly the bundle membership, in-bundle membership, unary-history, rational-history classifier, hsame, Cont, Pkg, and local NameCert rows listed there.

The handoff to the Phase Real and Completion exit surface is the one in Definition 126.529. It says that the StreamName contribution to the four-object route is precisely the finite observation packet before the downstream DyadicRatCore, RegSeqRat, and Real rows are read.

Now route the consumer through Definition 301.109. A tail-budget read is ordered through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and then $\mathsf{Real}^{\uparrow}$, so the dyadic tolerance ledger and the RegSeqRat regularity and classifier rows consume the same finite StreamName section rather than a separate source.

Finally use Definition 126.400. The shared-tail consumer keeps the RegSeqRat readback and the finite Real seal on the same public finite-window route. Since the cited packets contain no fields for a quotient stream equality, host sequence equality, selected limit, ambient Real completeness principle, metric-completeness datum, or second dyadic source, none of those objects can be inserted between the section packet and its tail-budget or seal consumers. □

Theorem 126.531 (StreamName finite-observation section reindex coverage)**.** *Every certified reindexing of a finite* $\mathsf{StreamName}^{\uparrow}$ *observation section preserves the same displayed section packet and the same Phase Real and Completion exit route through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. The reindexed consumer receives only the transported finite observation rows, the constant scheduled-subwindow coherence when the source is constant, the downstream tail-budget rows,*

and the finite $\mathsf{Real}^{\uparrow}$ *seal rows; it receives no quotient stream equality, host-index equality, selected limit, second dyadic source, or ambient completeness row.*

Proof. Begin with the local finite observation packet from Definition 126.527. It identifies the displayed section solely by the bundle membership, unary-history, rational-history classifier, hsame, Cont, Pkg, and local NameCert rows, with no quotient, host-index, limit, or completeness field available to transport.

Apply Definition 126.20. Certified window reindexing composes inside the StreamName certificate surface, so the consumer reads the reindexed section through the same public observation packet rather than through a second stream source or a host-index equality.

For constant scheduled subwindows, use Definition 126.288. The scheduled window and the reindexed window expose the same constant observation row, so reindexing does not add a selected limit or a second dyadic source before the downstream consumer sees the packet.

Finally combine Definition 126.529 with Definition 126.530. The first theorem fixes the four-object Phase Real and Completion route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$; the second keeps the RegSeqRat tail-budget read and the finite Real seal on that same finite section. Thus certified reindexing preserves coverage of the section packet without opening any quotient stream, host-index, selected limit, second-source, or ambient-completeness row. □

Theorem 126.532 (StreamName finite-observation selected transport)**.** *If a certified finite* $\mathsf{StreamName}^{\uparrow}$ *observation section is transported componentwise by displayed* hsame *rows and replayed through the same* Cont *route, then every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the transported section through the same four-object Phase Real and Completion route*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The transport exports no quotient stream equality, host-index equality, selected limit, second dyadic source, or ambient completeness row.

Proof. Begin with Definition 126.527. A certified finite observation section is exhausted by the finite bundle, membership, unary-history, rational-history classifier, componentwise hsame, displayed Cont, provenance, and local naming rows.

Apply Definition 126.529. It identifies the StreamName contribution to the Phase Real and Completion exit surface as the same finite section before the DyadicRatCore, RegSeqRat, and Real-facing rows are consumed.

Finally use Definition 126.531. Certified reindexing and componentwise transport preserve the same section packet and the same four-object route, so a transported consumer cannot open quotient stream equality, host-index equality, selected limits, second dyadic sources, or ambient completeness rows. □

Theorem 126.533 (StreamName finite-observation diagonal selector boundary)**.** *Every diagonal-limit or Real-completion consumer that reads a finite* $\mathsf{StreamName}^{\uparrow}$ *observation section through an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet factors through the same finite route: the StreamName finite observation section, the selector rows* B, S, W, D, R, E*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the terminal* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The boundary preserves the four-object Phase Real and Completion exit surface through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*; it exports no quotient stream equality, host real equality, selected limit, countable choice, hidden diagonal selector, ambient completeness, metric-completeness row, bridge row, or second source for the dyadic observations.*

Proof. Start with the StreamName section itself. By Definition 126.527, a certified finite observation section exposes only the finite membership, history, classifier, hsame, Cont, Pkg, and local NameCert rows of the StreamName packet.

The handoff theorem Definition 126.529 places that section on the Phase Real and Completion route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. The reindex coverage theorem Definition 126.531 keeps any certified reindexed consumer on the same finite section surface.

Now read the accepted selector. By Definition 782.10, any diagonal-limit or Real-completion consumer of the selector factors through the displayed finite route $B \to S \to W \to D \to R \to E$ together with its visible support rows. By Definition 782.9, the dyadic observations in D are exhausted by the selected finite $\mathsf{StreamName}^{\uparrow}$ windows in W.

Therefore the selector consumes the existing finite StreamName section as the source for its dyadic ledger rather than creating a second source. Since the cited section, handoff, reindexing, diagonal-boundary, and exhaustion theorems contain no fields for quotient stream equality, host real equality, selected limits, countable choice, hidden diagonal selectors, ambient completeness, metric-completeness rows, or bridge rows, none of those coordinates can be inserted between the finite section and its diagonal or Real-completion consumer. □

Theorem 126.534 (StreamName finite-observation selector coverage exhaustion)**.** *Every accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *consumer of a finite* $\mathsf{StreamName}^{\uparrow}$ *observation section is exhausted by the displayed selector rows* B, S, W, D, R, E*, the selected* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the terminal* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The accepted selector route exports no quotient stream equality, host real equality, selected limit, countable choice, hidden diagonal selector, ambient completeness, metric-completeness row, bridge row, or second dyadic source.*

Proof. Begin with the finite section. By Definition 126.527, the StreamName side of a certified finite observation exposes only the bundle membership, unary-history, rational-history classifier, hsame, Cont, Pkg, and local NameCert rows.

Next pass to the four-object exit surface using Definition 126.529. The finite section is read through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so the DyadicRatCore ledger, RegSeqRat readback, and terminal Real seal are downstream consumers of the same finite StreamName observation.

Now apply Definition 782.9. For an accepted selector packet, the dyadic observations in D are already exhausted by the selected finite StreamName windows in W. Thus the displayed selector rows B, S, W, D, R, E cover the observation route without opening a second dyadic source.

Finally combine Definition 782.10 with Definition 126.533. These boundary theorems place every compatible diagonal-limit or Real-completion consumer on the same four-object route and the same visible support rows. Since none of the cited packets carries quotient stream equality, host real equality, selected limits, countable choice, hidden diagonal selectors, ambient completeness, metric-completeness rows, bridge rows, or a second dyadic source, no such coordinate is exported by the accepted selector coverage surface. □

126.38 StreamName RegSeqRat Real budget factorization

Theorem 126.535 (StreamName RegSeqRat Real budget factorization)**.** *Every current* $\mathsf{Real}^{\uparrow}$*-and-Completion consumer that reads a StreamName window, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and a* $\mathsf{Real}^{\uparrow}$ *seal factors through exactly the four finite faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with only the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Equivalently, the budget boundary for the open L10 route is the finite StreamName window face, the DyadicRatCore tolerance-ledger face, the RegSeqRat readback face, the RealUp seal face, and the BEDC support rows. No fifth consumer face is needed to read the present Real-and-Completion route.

Proof. First apply Definition 126.500. It names the present Real-and-Completion exit read as the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Next use Definition 126.501. The StreamName window, DyadicRatCore ledger, RegSeqRat readback, and RealUp seal are not optional coordinates of a larger object; each is one required face of the same finite route.

Now invoke Definition 126.504. It identifies any two accepted consumer reads that expose the same four faces and support rows with the same terminal finite BEDC pullback.

Finally read the Real seal through Definition 38.314. The Real-side endpoint is still a finite-window obligation, so the budget route has no ambient completion coordinate beyond the four faces and the displayed support rows. □

Theorem 126.536 (StreamName RegSeqRat Real budget non-escape)**.** *The budget factorization of Definition 126.535 exports no quotient stream equality, no host sequence equality, no selected limit, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness datum, no metric-completeness datum, no countable-choice row, no Classical datum, and no standard bridge row. Every downstream consumer receives only the finite StreamName window, DyadicRatCore tolerance ledger, RegSeqRat readback, RealUp seal, and the rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Proof. Start from Definition 126.535. It reduces the consumer route to the four finite faces and the displayed BEDC support rows.

Apply Definition 126.500 and Definition 126.501. These results list the exclusions already present at the exit boundary and prevent a fifth face from replacing any required coordinate.

Use Definition 126.504 for downstream reads. The terminal pullback has no coordinate in which a quotient equality, host sequence equality, selected limit, completeness datum, choice row, Classical datum, or bridge row could be stored.

Finally cite Definition 38.314. The Real-facing read is exhausted by finite windows, so the budget boundary remains a finite BEDC route rather than an ambient completeness assertion. □

Theorem 126.537 (StreamName RegSeqRat Real budget route exactness)**.** *For every current Phase Real and Completion consumer read, acceptance by the open L10 budget route is equivalent to factoring through exactly the four finite faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

with only the support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Under this equivalence, equality of the public classifier surface is exactly componentwise agreement of the finite StreamName window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the RealUp seal, and those five support rows.

No quotient stream, host sequence equality, selected limit, completeness datum, countable-choice row, Classical datum, or standard bridge row participates in the accepted route or in the public classifier equality.

Proof. For the forward direction, apply Definition 126.535. An accepted consumer read is reduced to the four displayed finite faces and to the BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 126.536. The non-escape boundary removes quotient stream equality, host sequence equality, selected limits, ambient or metric completeness data, countable choice, Classical data, and standard bridge rows from the route packet.

For the reverse direction, start with a read that factors through the displayed four faces and support rows. The terminal pullback of Definition 126.504 repacks that data as the unique finite BEDC pullback available to current completion-facing and Real-seal-facing consumers, so the read is accepted by the open L10 budget route.

Finally apply Definition 126.514. It identifies public classifier equality with componentwise agreement on exactly the four faces and the displayed support rows, while the same non-escape exclusions leave no hidden classifier coordinate outside them. □

Theorem 126.538 (StreamName Real-seal observation factorization)**.** *For every current Phase Real and Completion consumer read, a Real-facing observation is accepted exactly when it factors through the finite StreamName window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Under this acceptance test, equality of Real-facing observation classifiers is componentwise agreement on exactly those four faces and five support rows.

The observation packet has no quotient stream coordinate, host limit, ambient completeness datum, choice row, Classical datum, or bridge row. It is therefore a consumer statement over the current four-face Real-and-Completion route, not an appeal to an external completion object.

Proof. First apply Definition 126.535. It gives the forward factorization through the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and the displayed BEDC support rows.

Next use Definition 126.537. The same finite route is also sufficient for acceptance, and its classifier equality is exactly componentwise agreement on the four faces and five support rows.

Now invoke Definition 126.536. This removes quotient streams, host sequence equality, selected limits, ambient or metric completeness data, countable choice, Classical data, and bridge rows from the observation packet.

Finally use Definition 38.314. The Real-facing seal is read through finite windows, so the combined observation remains a finite BEDC route through the current Phase Real and Completion faces. □

Theorem 126.539 (StreamName RegSeqRat Real terminal pullback naturality)**.** *Any two current Phase Real and Completion terminal consumer reads that preserve the finite StreamName window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

induce the same accepted four-face terminal pullback route. Moreover, any transport of terminal consumer reads preserving exactly those four faces and support rows remains on that accepted route, with the same public classifier surface.

The statement does not assert quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, choice data, Classical data, or standard bridge rows. It is only the naturality of the existing finite terminal pullback route under support-row-preserving transport.*

Proof. First apply Definition 126.535. It identifies the terminal consumer read with the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next use Definition 126.537. Since the two reads preserve those faces and rows, both are accepted by the same open L10 route, and classifier equality is exactly componentwise agreement on the displayed data.

Now invoke Definition 126.538. The Real-facing observations of the two reads therefore factor through the same finite seal boundary and add no hidden coordinate beyond the four faces and support rows.

Finally cite Definition 38.715. The Real-side terminal-budget naturality transports the shared finite budget through terminal consumer maps, so any support-row-preserving transport stays on the same accepted four-face pullback route. The non-escape boundary from Definition 126.536 keeps quotient equality, host equality, selected limits, completeness data, choice, Classical data, and bridge rows outside the route. □

Theorem 126.540 (StreamName Real-completion budget synchronization)**.** *Every accepted current Phase Real and Completion read synchronizes the finite StreamName window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

into one shared budget boundary. Equivalently, any transport preserving the StreamName window face, the DyadicRatCore tolerance-ledger face, the RegSeqRat readback face, the RealUp seal face, and those support rows preserves the accepted public classifier surface.

This synchronized boundary carries no quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness datum, metric-completeness datum, countable-choice row, Classical datum, or standard bridge row.*

Proof. First apply Definition 126.535. It places every accepted Real-and-Completion read on the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows.

Next use Definition 126.537. The accepted public classifier surface is exactly componentwise agreement on those faces and rows, so no extra coordinate can distinguish two reads once that displayed data agrees.

Now invoke Definition 126.538. The Real-facing observation is not a separate boundary: it factors through the same finite StreamName window, tolerance ledger, RegSeqRat readback, RealUp seal, and support rows.

Finally apply Definition 126.539. Any transport preserving those four faces and support rows remains on the accepted terminal pullback route and therefore preserves the same public classifier surface. The four cited faces are thus synchronized into one shared budget boundary. □

Theorem 126.541 (StreamName RegSeqRat Real terminal four-face pullback)**.** *Let two current Phase Real and Completion budget reads first pass through a common finite refinement. Suppose that, after this refinement, each read exposes the same finite StreamName window, the same*

$\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback section, the same* $\mathsf{Real}^{\uparrow}$ *seal, and the same transported support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the two reads determine the same terminal four-face pullback route through

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the same public classifier surface.

The common-refinement route carries no quotient stream coordinate, no selected limit, no host equality, no choice datum, no metric-completeness datum, no standard bridge row, and no ambient $\mathsf{Real}^{\uparrow}$ *completeness assertion. It is a terminality statement for the current finite L10 faces and their BEDC support rows.*

Proof. First apply Definition 126.535 to both refined reads. Each read is placed on exactly the StreamName window face, DyadicRatCore tolerance-ledger face, RegSeqRat readback face, RealUp seal face, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next use Definition 126.537. Since the common refinement identifies the four faces and the five support rows for the two reads, acceptance by the open L10 route is the same for both reads, and the public classifier surface is equality on precisely that displayed data.

Now invoke Definition 126.539. Transport along the common finite refinement preserves the support rows, so both refined reads remain on the same accepted terminal pullback route.

Finally cite Definition 126.540. The synchronized boundary identifies the StreamName window, tolerance ledger, RegSeqRat readback, RealUp seal, and BEDC support rows as one shared budget boundary, leaving no coordinate in which quotient streams, selected limits, host equality, choice, metric completeness, bridge rows, or ambient RealUp completeness could distinguish the two routes. □

126.39 StreamName Tail-Compatible Finite-Window Packet

Theorem 126.542 (StreamName tail-compatible window request)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be public* $\mathsf{StreamName}^{\uparrow}$ *rational stream rows, let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite observation window, and let* $n : \mathsf{BHist}$ *be a certified unary observation with* $\mathsf{InBundle}(n, \mathcal{P})$*. A tail-compatible window request from the L10 countable-name gateway to a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or a finite-window* $\mathsf{Real}^{\uparrow}$ *seal is determined by exactly the following finite rows:*

1. *the observation index* n *together with its* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$ *witnesses;*
2. *the tail-selector route carrying the selected StreamName observation window;*
3. *the finite-window budget surface for the same* $\mathcal{P}$*; and*
4. *the pointwise handoff row* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$ *side.*

No other source row is part of the request. In particular, the request has no coordinate for quotient stream equality, selected limits, host real equality, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with the tail selector route of Definition 126.202. It fixes the selected StreamName window and the downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ readback rows through one finite transport packet.

Next read the finite observation row through Definition 126.203. For the certified index n, the transported source row is exactly the bundled $\mathsf{UnaryHistory}(n)$ and $\mathsf{InBundle}(n, \mathcal{P})$ evidence together with $\mathsf{RatHistoryClassifier}(s(n), t(n))$.

Now attach the budget surface by Definition 126.390. It places the same finite ProbeBundle, membership, unary-history, observation-budget, and tail-budget rows before any regularity, dyadic, or Real-seal consumer row.

Finally apply Definition 126.170. The pointwise handoff has only StreamName carrier, finite-window classifier, membership, unary-history, and rational-history classifier slots. The displayed rows therefore determine the request, and the cited non-escape clauses exclude quotient, limit, host-real, metric-completeness, and ambient completeness data. □

Theorem 126.543 (StreamName tail-compatible window coverage)**.** *Every accepted finite-window handoff from* $\mathsf{StreamName}^{\uparrow}$ *to a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or to a finite-window* $\mathsf{Real}^{\uparrow}$ *seal factors through the tail-compatible window request of Definition 126.542, together with the shared support rows*

$$\mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The factorization is finite: it is read from the selected BHist *observation index, the tail selector route, the finite-window budget row, the pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and the displayed support rows. It does not use a quotient stream class, a chosen limit, host real equality, or an ambient completion theorem.*

Proof. Begin with an accepted finite-window StreamName handoff. By Definition 126.204, the handoff decomposes into the public finite-window classifier, bundled UnaryHistory/InBundle rows, pointwise rational-history classifier rows, the accepted $\mathsf{RegSeqRat}^{\uparrow}$ spine, DyadicRatCore endpoint rows, and the finite $\mathsf{Real}^{\uparrow}$ ledger.

The rowwise source is then the request from Definition 126.542. Its determining data are the certified BHist observation index, the selected tail route, the finite-window budget surface, and the pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Next use Definition 126.205. It reads every consumer-facing $\mathsf{Real}^{\uparrow}$ row through the same finite StreamName-to-RegSeqRat packet and the same DyadicRatCore endpoint rows.

Finally apply Definition 126.500. The exit boundary adds only the visible BHist, hsame, Cont, Pkg, and NameCert support needed by the four sibling faces. Combining these route statements gives the displayed finite factorization and leaves quotient classes, selected limits, host real equality, and ambient completion outside the accepted handoff. □

Theorem 126.544 (StreamName tail-compatible window packet)**.** *The tail-compatible finite-window packet is exactly the tuple consisting of the unary index row, the bundle-membership row, the tail-selector route, the finite-window budget surface, the pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and the support rows*

$$\mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Any accepted downstream $\mathsf{RegSeqRat}^{\uparrow}$ *readback or finite-window* $\mathsf{Real}^{\uparrow}$ *seal read is classified by equality of these displayed rows and by no additional stream-level coordinate.*

Proof. Begin with Definition 126.542. It identifies the request by the certified unary observation, membership in the finite bundle, the selected tail route, the finite-window budget surface, and the pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Apply Definition 126.543. Every admitted downstream finite-window consumer route factors through that request together with the displayed hsame, Cont, Pkg, and NameCert support rows.

Finally use the pointwise transport and budget handoff rows, Definition 126.204 and Definition 126.390. These rows leave no second stream source, quotient stream class, selected limit, host real equality, metric-completeness datum, or ambient completion coordinate, so equality of the displayed tuple is exactly packet equality for downstream reads. □

Theorem 126.545 (StreamName tail-compatible window nonescape)**.** *The tail-compatible finite-window packet exported from* $\mathsf{StreamName}^{\uparrow}$ *to* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *carries only the request rows of Definition 126.542 and the support rows of Definition 126.543. It exports no quotient stream equality, no selected limit, no host real equality, no metric-completeness datum, and no ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 126.542. The request is determined by the certified finite observation, tail-selector route, finite-window budget surface, and pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Apply Definition 126.543. Any accepted finite-window consumer route factors through that request and the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows.

Finally use Definition 126.500. The four-object exit boundary consumes the same finite StreamName, DyadicRatCore, RegSeqRat, and RealUp faces without adding quotient stream equality, host sequence equality, selected limits, metric-completeness data, countable choice, standard bridges, or ambient completeness. Hence the tail-compatible packet has no escaping coordinate of the listed kinds. □

Theorem 126.546 (StreamName tail-compatible window terminality)**.** *Every accepted finite-window handoff from* $\mathsf{StreamName}^{\uparrow}$ *to a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or to a finite-window* $\mathsf{Real}^{\uparrow}$ *seal factors terminally through the request rows of Definition 126.542 and the support rows of Definition 126.543.*

If two accepted finite-window consumers expose the same finite observation, tail-selector route, budget surface, pointwise handoff, and support rows, then they classify through the same tail-compatible window route. The terminal packet exports no quotient stream equality, selected limit, host real equality, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Begin with the request theorem. By Definition 126.542, the finite-window request is determined by the certified observation row, the tail-selector route, the finite-window budget surface, and the pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff row.

Next add the shared support. Apply Definition 126.543; every accepted handoff to a $\mathsf{RegSeqRat}^{\uparrow}$ readback or finite-window $\mathsf{Real}^{\uparrow}$ seal factors through the same request together with the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Now compare two consumers with the same visible inventory. The request rows agree by the first step, and the support rows agree by the second step, so the two consumers replay the same finite StreamName window route into the downstream readback or seal.

Finally use Definition 126.545. It excludes quotient stream equality, selected limits, host real equality, metric-completeness data, and ambient $\mathsf{Real}^{\uparrow}$ completeness from the packet. Thus the displayed request and support rows are terminal for finite-window consumers. □

Theorem 126.547 (StreamName tail-compatible cofinal bundle lock)**.** *Let* $s, t : \mathsf{BHist} \to \mathsf{BHist}$ *be public* $\mathsf{StreamName}^{\uparrow}$ *rational stream rows, let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite bundle of certified unary observation requests, and suppose one StreamName tail-selector route serves every bundled request* n *equipped with* $\mathsf{UnaryHistory}(n)$ *and* $\mathsf{InBundle}(n, \mathcal{P})$*. Every finite family of bundled downstream reads into a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or a finite-window* $\mathsf{Real}^{\uparrow}$ *seal factors through one displayed packet consisting of exactly the following rows:*

1. *the bundled unary index rows n, their* $\mathsf{UnaryHistory}(n)$ *certificates, and their* $\mathsf{InBundle}(n, \mathcal{P})$ *witnesses;*
2. *the shared tail-selector route serving the bundle;*
3. *the shared finite-window budget surface for $\mathcal{P}$;*
4. *the pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows* $\mathsf{RatHistoryClassifier}(s(n), t(n))$ *for the bundled indices; and*
5. *the support rows* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$.

The packet is a finite cofinal lock for the bundled reads: any accepted downstream read through the same tail-compatible route is classified by its displayed bundle row and the shared support rows. The lock contains no quotient stream equality, no selected limit, no host real equality, no metric-completeness datum, and no ambient $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 126.542 to each bundled request. For every certified index in $\mathcal{P}$, the request row is the unary observation, its membership witness, the shared tail route, the finite-window budget surface, and the corresponding pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Next apply Definition 126.543 to every accepted downstream handoff in the finite family. The same support rows hsame, Cont, Pkg, and $\mathsf{NameCert}$ route each admitted read through the request rows just displayed.

Use Definition 126.544 to identify the common finite packet. Since the bundle is finite, collecting the unary rows, membership witnesses, pointwise handoffs, the shared route, the shared budget surface, and the shared support rows produces one displayed packet rather than a separate hidden route for each consumer.

Finally combine Definition 126.546 with Definition 126.545. Terminality makes the displayed packet the unique route for consumers with the same visible inventory, and nonescape excludes quotient stream equality, selected limits, host real equality, metric-completeness data, and ambient $\mathsf{Real}^{\uparrow}$ completeness from the bundle lock. □

Theorem 126.548 (StreamName tail-compatible cofinal exhaustion)**.** *Let $s, t : \mathsf{BHist} \to \mathsf{BHist}$ be public* $\mathsf{StreamName}^{\uparrow}$ *rational stream rows, and let $\mathcal{P} : \mathsf{ProbeBundle}$ be the finite packet of certified unary observations served by the shared tail-compatible selector of Definition 126.547. Every finite family of accepted downstream reads from that same bundled packet into a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or a finite-window* $\mathsf{Real}^{\uparrow}$ *seal is terminally exhausted by the bundled unary rows, their* $\mathsf{InBundle}$ *witnesses, the shared tail selector, the shared budget surface, the pointwise* $\mathsf{RatHistoryClassifier}$ *handoff rows, and the support rows* $\mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}$.

Equality of these rows is exactly equality of the consumer route. No quotient stream equality, selected limit, host real equality, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate remains available to distinguish two accepted finite-window consumers over the packet.*

Proof. First use Definition 126.547. It collects the bundled unary rows, their membership witnesses, the shared tail selector, the shared budget surface, pointwise rational-history classifier rows, and the support rows into one finite packet for the family of downstream reads.

Next apply Definition 126.543. Each accepted $\mathsf{RegSeqRat}^{\uparrow}$ readback or finite-window $\mathsf{Real}^{\uparrow}$ seal route factors through that packet, so the consumer has no source coordinate beyond the displayed rows.

Then apply Definition 126.546. If two accepted consumers expose the same bundled rows and support rows, terminality identifies their finite-window route through the same packet.

Finally use Definition 126.545. The excluded quotient, limit, host-real, metric-completeness, and ambient-completion coordinates are not packet rows, so no remaining downstream distinction can be read after the displayed finite inventory agrees. □

Theorem 126.549 (StreamName RegSeqRat triple-overlap source cocycle)**.** *Let $\mathcal{W}_0, \mathcal{W}_1, \mathcal{W}_2$ be certified finite* $\mathsf{StreamName}^{\uparrow}$ *windows. Suppose each pair carries a certified finite overlap, the three pairwise restrictions agree on every certified unary observation, selected* RatHistoryClassifier *row,* ProbeBundle *ledger row,* InBundle *membership row, and displayed* hsame *row, and the three overlaps have a certified common triple overlap K_{012}. Then the three induced* RegSeqRat *handoff packages, and the three induced finite-window* $\mathsf{Real}^{\uparrow}$ *handoff packages, determine one StreamName source surface on K_{012}.*

The triple source surface consists only of the restricted StreamName finite-window rows on K_{012}. It excludes completion data, quotient data, host index equality, every RegSeqRat *regularity row, every* $\mathsf{Real}^{\uparrow}$ *seal classifier row, and every* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First restrict the three windows to the common triple overlap K_{012}. Each restricted pair is a certified finite overlap with the same displayed unary observations, classifier rows, bundle rows, membership rows, and hsame comparisons.

Apply Definition 126.88 to $(\mathcal{W}_0, \mathcal{W}_1)$ on K_{012} and again to $(\mathcal{W}_1, \mathcal{W}_2)$ on K_{012}. The first application identifies the source surface of $\mathcal{W}_0$ with that of $\mathcal{W}_1$; the second identifies the source surface of $\mathcal{W}_1$ with that of $\mathcal{W}_2$.

The displayed hsame rows compose through the common middle restriction, so the two identifications give a single source surface for all three windows on the triple overlap. The optional third pair $(\mathcal{W}_0, \mathcal{W}_2)$ reads the same restricted rows and therefore lands on that same surface.

Finally use the exclusion clause in Definition 126.88. The cocycle is a statement about the public StreamName finite-window source only; no completion, quotient, host-index, RegSeqRat regularity, RealUp seal, or RealUp completeness row is part of the source surface. □

Theorem 126.550 (StreamName RegSeqRat triple-overlap seal cocycle)**.** *Let $\mathcal{W}_0, \mathcal{W}_1, \mathcal{W}_2$ be certified finite* $\mathsf{StreamName}^{\uparrow}$ *windows with pairwise certified overlaps and a certified common triple overlap K_{012}. Suppose the source hypotheses of Definition 126.549 hold, and suppose the three induced* RegSeqRat *handoff packages consume one shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite ledger on every restriction to K_{012}. Then the* $\mathsf{Real}^{\uparrow}$ *seal classifier rows induced from the three handoffs agree on K_{012}.*

This agreement is only the finite-window seal row agreement produced from the shared StreamName source and shared DyadicRatCore ledger. It does not include completion data, quotient data, host index equality, or a $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First fix the source. By Definition 126.549, the three windows expose one StreamName source surface on K_{012} for their induced RegSeqRat and finite-window RealUp handoffs.

Next compare the first two seal rows. Apply Definition 126.89 to $(\mathcal{W}_0, \mathcal{W}_1)$ after restricting to K_{012}. The source rows are the common rows just fixed, and the DyadicRatCore finite ledger is shared by hypothesis, so the induced RealUp seal classifier rows agree pointwise there.

Compare the second and third seal rows in the same way. The pair $(\mathcal{W}_1, \mathcal{W}_2)$ has the same restricted source and the same consumed dyadic ledger, so pointwise seal stability identifies their induced classifier rows on K_{012}.

These two pointwise agreements have the same middle classifier row. Hence the three induced RealUp seal classifier rows form one row on the triple overlap. The construction never asks for

completion, quotient, host-index, or RealUp completeness data, because pointwise seal stability only reads the finite StreamName source and the shared dyadic ledger. □

Theorem 126.551 (StreamName RegSeqRat finite-cover pasted source exhaustion)**.** *Let* $\{\mathcal{W}_i\}_{i\in I}$ *be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows. Suppose every pair has a certified finite overlap, all pairwise restrictions agree on the displayed StreamName source rows, every triple overlap satisfies the source and seal cocycle hypotheses above, and all induced* RegSeqRat *handoff packages consume the same DyadicRatCore finite ledger on their displayed overlaps. Then the family pastes to one* RegSeqRat *and finite-window* $\mathsf{Real}^{\uparrow}$ *source surface over the finite union of the windows.*

The pasted surface is exhausted by the public StreamName finite-window rows, the displayed hsame *comparisons, and the shared DyadicRatCore ledger rows. It has no completion data, quotient data, host index equality, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Proceed by finite ProbeBundle induction over the cover inventory. The empty inventory has no exposed source row, and the singleton inventory is the certified source surface of its one StreamName window.

For the induction step, assume a finite subcover has already pasted to one RegSeqRat and finite-window RealUp source surface. Let $\mathcal{W}_j$ be the next certified window. On each overlap between $\mathcal{W}_j$ and a member of the subcover, apply Definition 126.88 to obtain the same source rows, and apply Definition 126.89 to stabilize the induced RealUp seal classifier rows over the shared dyadic ledger.

Now paste the new window to the existing subcover surface. Use Definition 126.90 on each displayed overlap, and use Definition 126.91 to see that the order of adjoining the finitely many overlap rows does not change the pasted classifier surface.

The triple-overlap source and seal cocycles supply the compatibility needed when two old windows and the new window meet. They identify the common source and seal rows on each triple intersection, so no additional choice of a source or classifier row is introduced by the induction step.

Finally exhaust the pasted finite union. Every row inserted during the induction is either a public StreamName finite-window row, a displayed hsame comparison, or a shared DyadicRatCore ledger row used by the RegSeqRat handoff. Completion data, quotient data, host index equality, and RealUp completeness rows have no carrier coordinate in this finite pasted source. □

Theorem 126.552 (StreamName RegSeqRat finite-cover pasted seal exhaustion)**.** *Let* $\{\mathcal{W}_i\}_{i\in I}$ *be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows satisfying the source hypotheses of Definition 126.551. Assume moreover that every triple overlap satisfies Definition 126.550, and that all displayed overlaps consume one shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger in the induced* RegSeqRat *handoff packages. Then the induced finite-window* $\mathsf{Real}^{\uparrow}$ *seal classifier rows paste to one seal surface over the finite union of the windows.*

The pasted seal surface is exhausted by the finite-window RealUp classifier rows forced by the common StreamName source and the shared DyadicRatCore ledger. It excludes completion data, quotient data, host index equality, selected limits, and $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First fix the source surface. Apply Definition 126.551 to the family of windows. This gives one RegSeqRat and finite-window RealUp source surface over the finite union, with no completion, quotient, host-index, or completeness coordinate.

We now attach seal rows by finite ProbeBundle induction over the cover inventory. The empty inventory has no classifier row to paste, and the singleton inventory carries the seal row induced from its certified StreamName window and shared DyadicRatCore ledger.

For the induction step, assume a finite subcover already carries one pasted seal surface. Let $\mathcal{W}_j$ be the next certified window. On each displayed overlap with the existing subcover, apply Definition 126.89; the source row is the fixed source surface, and the dyadic ledger is the shared ledger from the hypotheses.

Use Definition 126.90 to attach the seal row of $\mathcal{W}_j$ along those overlap rows. When two old windows and $\mathcal{W}_j$ meet, the triple-overlap seal cocycle identifies the three restricted classifier rows, so the attachment does not depend on which overlap is read first.

Finally apply Definition 126.91. The associativity of pasted seal rows, together with the triple-overlap seal cocycle, makes the finite ProbeBundle induction order-independent. Thus all induced finite-window RealUp seal classifier rows determine one seal surface over the finite union.

Every coordinate used in the construction is a finite-window classifier row obtained from the common StreamName source and the shared DyadicRatCore ledger. Completion data, quotient data, host index equality, selected limits, and RealUp completeness are not introduced by pointwise seal stability, pointwise seal pasting, or pasted seal associativity. □

Theorem 126.553 (StreamName RegSeqRat finite-cover pasted seal terminality)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows satisfying the hypotheses of Definition 126.551. Assume every triple overlap satisfies Definition 126.550, and assume all displayed overlaps consume one shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger in the induced* RegSeqRat *handoff packages. If $\mathcal{S}$ and $\mathcal{S}'$ are two induced finite-window* $\mathsf{Real}^{\uparrow}$ *pasted seal surfaces over the finite union with the same displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows,* RegSeqRat *handoff rows, overlap* hsame *data, and displayed* BHist, Cont, Pkg, *and* NameCert *support rows, then $\mathcal{S} = \mathcal{S}'$ as pasted seal surfaces over the finite union.*

This terminality is a finite L10 seal statement. It contains no completion data, quotient data, host index equality, selected limits, countable choice, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First fix the source side. By Definition 126.551, the displayed StreamName rows, overlap hsame data, and shared DyadicRatCore ledger rows determine one RegSeqRat and finite-window RealUp source surface over the finite union. Thus $\mathcal{S}$ and $\mathcal{S}'$ are compared over the same finite source surface.

Next apply Definition 126.552 to both candidate pasted seal surfaces. Each candidate is exhausted by the same finite-window RealUp classifier rows forced by that source surface and the same shared DyadicRatCore ledger. The displayed RegSeqRat handoff rows and BHist, Cont, Pkg, and NameCert support rows therefore leave no separate seal coordinate that could distinguish the two candidates.

It remains to identify the overlap choices used in the finite pasting. On each displayed pairwise overlap, Definition 126.89 gives the same pointwise seal row for both candidates, because the source row and dyadic ledger row are the same. The triple-overlap compatibility is exactly Definition 126.550, so the pointwise overlap rows agree on every common triple restriction.

Finally use Definition 126.90 and Definition 126.91. Pointwise pasting attaches the same local seal rows along the same overlap data, and associativity makes the finite attachment order irrelevant. Hence both $\mathcal{S}$ and $\mathcal{S}'$ are the same pasted finite-window RealUp seal surface over the finite union.

The argument only reads finite StreamName rows, DyadicRatCore ledger rows, RegSeqRat handoff rows, overlap hsame data, and displayed support rows. Completion data, quotient data, host index equality, selected limits, countable choice, and RealUp completeness are not carrier coordinates in this terminal pasted seal surface. □

126.40 StreamName finite-request section packet

Theorem 126.554 (StreamName Real endpoint finite-request section)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *window request that is displayed to a* $\mathsf{Real}^{\uparrow}$ *endpoint row factors through a section packet whose visible rows are exactly the endpoint rows, the certified finite-window observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows attached to those observations, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget rows used by the read, the componentwise* hsame *transport, the* Cont *replay route,* Pkg *provenance, and the local* NameCert *rows. The section has no coordinate for quotient stream equality, host sequence equality, selected limits, host real equality, or ambient completion.*

Proof. Start with the finite observation packet of Definition 126.527. It projects a displayed window section to the membership, unary-history, rational-history classifier, hsame, Cont, Pkg, and local NameCert rows.

Next apply the Real exit handoff of Definition 126.529. The endpoint consumer reads that same section through $\mathsf{StreamName}^{\uparrow}$ before the downstream $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces are consumed.

Finally use Definition 126.535. It adds exactly the RegSeqRat readback face, the DyadicRatCore budget face, and the RealUp seal face to the StreamName section. Since the cited packets contain no quotient stream, host sequence, selected-limit, host-real, or ambient completion coordinate, none can appear in the endpoint request. □

Theorem 126.555 (StreamName RegSeqRat window-budget section)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *window request consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and then by a* $\mathsf{Real}^{\uparrow}$ *endpoint seal is budgeted by one displayed section packet. The packet displays the finite endpoint rows, RegSeqRat readback rows, DyadicRatCore budget rows, StreamName window rows, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows, and every downstream read is classified by those rows. It exports no quotient stream equality, no host sequence equality, no selected limit, no second dyadic source, and no ambient completion datum.*

Proof. First read the request through Definition 126.542. The finite window is determined by its certified unary observation, bundle membership, tail route, window budget, and pointwise RegSeqRat handoff.

Next apply Definition 126.543. It forces every accepted downstream RegSeqRat or RealUp read to factor through that request together with the displayed hsame, Cont, Pkg, and NameCert support rows.

Now use Definition 126.537. The accepted route is exactly the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with the same support rows, so the endpoint, readback, and budget data are one section packet rather than separate routes.

The non-escape clauses in Definition 126.545 and Definition 126.536 remove quotient streams, host sequence equality, selected limits, second dyadic sources, and ambient completion data from the packet. □

Theorem 126.556 (StreamName finite-request section budget exactness)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *request consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and then by a public* $\mathsf{Real}^{\uparrow}$ *seal uses one displayed budget section. Its rows are precisely the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius budget rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise* hsame*, displayed* Cont*,* Pkg*, and the local* NameCert *rows. Hence two Real-facing presentations over the same finite request cannot be distinguished by a second dyadic budget, a second regular-sequence source, quotient stream equality, a selected limit, host real equality, or any ambient completion coordinate.*

Proof. First apply Definition 126.554. This reads the Real-facing endpoint as a finite $\mathsf{StreamName}^{\uparrow}$ section whose visible rows already include the endpoint, readback, budget, support, package, and naming coordinates.

Next apply Definition 126.555 to the same request. The $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{DyadicRatCore}^{\uparrow}$ budget rows are not parallel witnesses; they are the readback and budget faces of the same displayed section packet.

Now compose with Definition 126.537. The composed route identifies the four public faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the same componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ rows. Thus the Real-facing presentation is determined by that single finite budget section.

Finally close the boundary with Definition 126.545 and Definition 126.536. These non-escape clauses remove second budget sources, second regular-sequence sources, quotient stream equality, selected limits, host real equality, and ambient completion coordinates from the observation packet, so none can separate two presentations over the same finite request. □

Theorem 126.557 (StreamName Real seal request section nonescape)**.** *Every finite StreamName request that reaches a* $\mathsf{Real}^{\uparrow}$ *seal through* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *is exhausted by the finite-request section packet of Definition 126.554 and Definition 126.555. Thus the Real seal can replay only endpoint rows, RegSeqRat readback rows, DyadicRatCore budget rows, StreamName window rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. It cannot obtain quotient equality of streams, quotient equality of Cauchy presentations, selected limits, host real equality, metric-completeness data, or ambient completion.*

Proof. Begin with Definition 126.554. It fixes the Real endpoint read as a finite StreamName section together with the RegSeqRat, DyadicRatCore, RealUp, and BEDC support rows.

Then apply Definition 126.555. The RegSeqRat readback and DyadicRatCore budget rows are the same section packet used by the endpoint seal, so the Real seal does not receive an independent readback source or a second budget source.

Finally compose with Definition 126.536. The four-face budget boundary contains no coordinate for quotient stream equality, quotient Cauchy-presentation equality, selected limits, host real equality, metric-completeness data, or ambient completion. The finite-request section therefore reaches the Real seal only through the displayed rows. □

Theorem 126.558 (StreamName finite-request section terminal coherence)**.** *Let Q and Q' be accepted finite request sections for the current* $\mathsf{StreamName}^{\uparrow}$ *Real-and-Completion route. Suppose that Q and Q' expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same displayed* BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. Then Q and Q' determine the same terminal four-face route through*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Conversely, every current terminal four-face route restricts to a finite request section with exactly those StreamName window, DyadicRatCore budget, RegSeqRat readback, RealUp seal, and displayed support rows. The coherence claim includes no quotient stream equality, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Proof. First read each accepted section through Definition 126.556. The budget row and the RegSeqRat readback row are not separate witnesses; they are faces of the same finite request section under the displayed support rows.

Next apply Definition 126.557. The Real seal cannot add quotient stream equality, Cauchy-presentation equality, selected limits, host equality, metric-completeness data, or ambient completion to the section.

Use Definition 126.587 for the two sections. Since their StreamName window, DyadicRatCore budget, RegSeqRat readback, RealUp seal, and support rows agree, the carrier and classifier verdicts at the terminal route agree.

Finally apply Definition 126.592. Its forward direction identifies same-section reads with the terminal four-face route, and its converse restricts every current terminal route back to such a finite request section. The listed exclusions are exactly the coordinates absent from that terminal completeness surface. □

Theorem 126.559 (StreamName finite-request terminal coherence)**.** *Any finite* $\mathsf{StreamName}^{\uparrow}$ *request that is read both as a* $\mathsf{Real}^{\uparrow}$ *endpoint finite-request section and as a* $\mathsf{RegSeqRat}^{\uparrow}$ *window-budget section determines a unique terminal public row. That row is the four-face Real-and-Completion packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with only the displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The same packet is therefore the terminal exit route for the request, and it contains no quotient stream equality, no quotient equality of Cauchy presentations, no host sequence equality, no selected limit, no host real equality, no ambient or metric-completeness datum, no countable-choice row, no Classical row, and no standard bridge row.

Proof. First apply Definition 126.554. The endpoint reading fixes the finite request as a $\mathsf{Real}^{\uparrow}$ section with the StreamName window, RegSeqRat readback, DyadicRatCore budget, RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 126.555. The RegSeqRat window-budget reading uses the same finite section packet, so the readback and budget faces are not second routes parallel to the endpoint section.

Now compose with Definition 126.557. It removes every Real-seal escape coordinate outside the displayed section rows. Invoke Definition 126.500 to identify those rows with the four-object Real-and-Completion exit packet.

Finally use Definition 126.449. Once the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and displayed support rows agree, there is only one terminal finite BEDC route for the request. The exclusions are exactly the non-escape exclusions of Definition 126.536, so no quotient, selected-limit, ambient-completeness, choice, Classical, or bridge coordinate can replace the terminal four-face packet. □

Theorem 126.560 (StreamName finite-request section terminal reflection)**.** *Let Q be an accepted finite* $\mathsf{StreamName}^{\uparrow}$ *request section for the current L10 Phase Real and Completion route. Suppose the visible rows of Q display one* $\mathsf{StreamName}^{\uparrow}$ *finite window, one* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget row, one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, one* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the displayed* BHist, hsame, Cont, Pkg, *and local* NameCert *support rows. Then Q is the public reflection surface for the terminal four-face L10 route*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Every accepted finite request section with the same displayed rows reflects to that same terminal route, and every terminal four-face L10 route pulls back to that finite request section. Thus the

finite section is both the only public exit route available to the current L10 packet and the only pullback surface available to later $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and completion-facing consumers. It exports no quotient stream equality, selected limit, host real equality, ambient completion, metric-completeness datum, countable-choice row, Classical row, or standard bridge row.*

Proof. First apply Definition 126.556. The accepted section has exactly one displayed StreamName window, dyadic budget, regular readback, Real seal, and BEDC support packet, so no later consumer can replace the section by a second dyadic source or a second regular-sequence source.

Next apply Definition 126.557. The Real seal reads only the finite request section just described. Hence quotient stream equality, selected limits, host real equality, ambient completion, and metric-completeness data are not coordinates of the route seen by the seal.

Now compare any other accepted finite request section whose visible rows agree with those of Q. By Definition 126.558, the two sections determine the same terminal four-face packet. By Definition 126.587, the public carrier and classifier verdicts are therefore the same displayed section verdicts, not a quotient or host-equality verdict.

For the reverse direction, take a terminal four-face L10 route. The converse clause of Definition 126.558 restricts it to a finite request section with exactly the StreamName window, DyadicRatCore budget, RegSeqRat readback, RealUp seal, and displayed support rows. Applying classifier determinacy again identifies that pullback with Q whenever those visible rows agree.

Therefore the same finite section is the public exit surface and the consumer-facing pullback surface. Since the construction used only the cited budget, non-escape, terminal-coherence, and classifier-determinacy rows, no quotient stream equality, selected limit, host real equality, ambient completion, metric-completeness datum, countable-choice row, Classical row, or standard bridge row can be imported into the reflected route. □

Theorem 126.561 (StreamName finite-request common-refinement exactness)**.** *Let Q and Q' be accepted finite* $\mathsf{StreamName}^{\uparrow}$ *requests. Suppose both are read by the* $\mathsf{Real}^{\uparrow}$ *endpoint section and by the* $\mathsf{RegSeqRat}^{\uparrow}$ *window-budget section. Suppose further that they agree on a displayed common refinement of the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius budget rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then Q and Q' factor through the same terminal four-face refinement packet

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Conversely, every such displayed four-face refinement induces the same terminal public row for the two accepted requests. This exactness statement contains no quotient stream equality, no selected limit, no host real equality, no ambient or metric-completeness datum, no countable-choice row, no Classical row, no aggregate formalstatus *row, and no standard bridge row.*

Proof. First apply Definition 126.556 to Q and Q'. The $\mathsf{StreamName}^{\uparrow}$ finite window, DyadicRatCore endpoint and radius budget, RegSeqRat regularity and readback, RealUp seal, and displayed support rows are the section-budget rows themselves.

Next use Definition 126.557. The Real endpoint reading cannot add quotient stream equality, selected limits, host real equality, ambient completion, metric-completeness data, countable choice, Classical data, an aggregate status row, or a standard bridge row to the common refinement.

Now compare the sibling faces. DyadicRatCore exactness is supplied by Definition 291.66 and Definition 291.28; RegSeqRat exactness is supplied by Definition 301.69; and the RealUp face is

supplied by Definition 38.457. These results put the dyadic budget, regularity readback, and Real seal on the same displayed finite four-face packet.

Finally apply Definition 126.559 to the two refined requests. Since the four faces and the five support rows agree, the terminal public row is the same. Conversely, reading any displayed four-face refinement through the same cited exactness results recovers exactly those section rows, so terminal coherence sends the refinement back to the same public row. □

Theorem 126.562 (StreamName finite-request cover gluing)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of* $\mathsf{StreamName}^{\uparrow}$ *requests. Suppose each $\mathcal{R}_i$ reads both as a* $\mathsf{Real}^{\uparrow}$ *endpoint finite-request section and as a* $\mathsf{RegSeqRat}^{\uparrow}$ *window-budget section. Suppose also that every displayed pairwise overlap agrees on the rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Then the finite cover glues to one terminal four-face packet

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

over the finite union of the requests, together with only the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. The glued packet contains no quotient stream equality, no quotient equality of Cauchy presentations, no host sequence equality, no selected limit, no host real equality, no ambient or metric-completeness datum, no countable-choice row, no Classical row, and no standard bridge row.*

Proof. For each member of the finite family, apply Definition 126.554 to read it as a Real endpoint finite-request section. Apply Definition 126.555 to the same member to read it as the RegSeqRat window-budget section using the same StreamName, DyadicRatCore, RegSeqRat, RealUp, and displayed support rows.

On a displayed pairwise overlap, the hypotheses identify the BHist, hsame, Cont, Pkg, NameCert, DyadicRatCore, RegSeqRat, and RealUp rows seen from the two requests. Apply Definition 126.559 to each side of the overlap. The two readings therefore land on the same terminal public row, namely the four-face packet

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Now pass from pairwise agreement to finite-cover compatibility. On every triple overlap, use Definition 126.549 to identify the shared StreamName source surface, and use Definition 38.191 for the corresponding RealUp finite-window consumer surface. Thus the pairwise terminal rows satisfy the cocycle condition needed to paste a finite cover.

Finally paste the finite family by finite induction over the request inventory. The singleton case is the terminal packet just constructed. In the induction step, glue the next request along its displayed overlaps; the pairwise terminal coherence gives the common boundary row, and the triple-overlap cocycles make this boundary independent of the order in which overlaps are consumed.

The exclusion surface is inherited from Definition 126.557 and from the non-escape clause of Definition 126.559. Since every gluing step reads only displayed finite rows, no quotient stream equality, quotient Cauchy-presentation equality, host sequence equality, selected limit, host real equality, ambient or metric-completeness datum, countable-choice row, Classical row, or standard bridge row is introduced by the finite cover. □

Theorem 126.563 (StreamName finite-request subcover terminal invariance)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of* $\mathsf{StreamName}^{\uparrow}$ *requests satisfying the hypotheses of Definition 126.562. Let $J \subseteq I$ be a finite subfamily such that every request in $I \setminus J$ has the same terminal four-face packet as the retained subfamily on every displayed overlap. Then deleting the requests indexed by $I \setminus J$ leaves the same terminal packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

over the retained finite request cover, with the same displayed support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The retained terminal packet still contains no quotient stream equality, no quotient equality of Cauchy presentations, no host sequence equality, no selected limit, no host real equality, no ambient or metric-completeness datum, no countable-choice row, no Classical row, and no standard bridge row.

Proof. Apply Definition 126.562 to the full finite family. This produces one terminal four-face packet over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with only the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

On each displayed overlap between a discarded request and the retained subfamily, apply Definition 126.559. The overlap has the same StreamName, DyadicRatCore, RegSeqRat, RealUp, and displayed support rows on both sides, so the discarded request and the retained cover land on the same terminal public row.

It remains to see that the order of deletion is irrelevant. For any three requests meeting on a displayed overlap, use Definition 126.549 for the shared StreamName source surface and Definition 38.191 for the RealUp finite-window consumer surface. These cocycles are the same compatibility data used in Definition 126.562, so removing discarded requests in any finite order preserves the boundary row already seen by the retained subfamily.

The remaining finite cover is therefore pasted with the same terminal packet as the full cover. Its exclusion surface is inherited from the non-escape clause of Definition 126.559 and from Definition 126.562: every step reads only the displayed finite BEDC rows. Thus no quotient stream equality, quotient Cauchy-presentation equality, host sequence equality, selected limit, host real equality, ambient or metric-completeness datum, countable-choice row, Classical row, or standard bridge row appears after the subcover is retained. □

Theorem 126.564 (StreamName finite-request Real seal cocycle determinacy)**.** *Let $\mathcal{R}_0, \mathcal{R}_1, \mathcal{R}_2$ be three finite* $\mathsf{StreamName}^{\uparrow}$ *requests satisfying the hypotheses of Definition 126.562. Suppose that every pairwise overlap among the three requests exposes the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Then the Real-facing seal row determined on the triple overlap is independent of the order in which the pairwise overlaps are consumed. Equivalently, the two finite overlap-consumption paths*

$$(\mathcal{R}_0 \cap \mathcal{R}_1) \cap \mathcal{R}_2 \quad \textit{and} \quad \mathcal{R}_0 \cap (\mathcal{R}_1 \cap \mathcal{R}_2)$$

repack the same terminal Real seal row through the finite BEDC support rows. This determinacy asserts only the displayed finite-request surface: it adds no quotient stream equality, no host sequence equality, no selected limit, no ambient or metric-completeness datum, no countable-choice row, no Classical row, and no standard bridge row.

Proof. Start with the three pairwise overlaps. On each pair, apply Definition 126.559. The shared StreamName, DyadicRatCore, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows force both requests in the pair to land on the same terminal four-face packet.

The possible ambiguity is only the order in which the three pairwise overlaps are consumed. Use Definition 126.549 to identify the StreamName source surface on the triple overlap, and use Definition 38.191 to identify the corresponding RealUp finite-window consumer surface. These two cocycles make the left-associated and right-associated overlap readings carry the same source row and the same Real-facing consumer row.

Finally repack that common terminal row through the displayed finite BEDC support data. Since the repacking reads only BHist, hsame, Cont, Pkg, and NameCert, it cannot introduce quotient stream equality, host sequence equality, selected limits, ambient or metric-completeness data, countable choice, Classical rows, or standard bridge rows. The Real-facing seal row on the triple overlap is therefore determined independently of the overlap-consumption order. □

Theorem 126.565 (StreamName finite-request cover CauchyLimitSeal stability)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of* $\mathsf{StreamName}^{\uparrow}$ *requests satisfying the hypotheses of Definition 126.562. Suppose also that each $\mathcal{R}_i$ is consumed by the terminal* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route of Definition 386.118. Then the cover determines the same glued four-face packet through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},\quad \mathsf{CauchyLimitSeal}^{\uparrow}.$$

The CauchyLimitSeal consumer reads the glued StreamName schedule, RegSeqRat source, DyadicRatCore ledger, RealUp seal, and displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows without changing the glued packet. It adds no quotient stream equality, selected host limit, host real equality, hidden tail oracle, ambient completeness, metric-completeness datum, countable-choice row, Classical row, or standard bridge row.*

Proof. First apply Definition 126.562. The finite family has one glued four-face packet over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with only the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For each member of the finite family, apply Definition 386.118. Its terminal seal consumer must pass through the same scheduled $\mathsf{StreamName}^{\uparrow}$ row, then the displayed $\mathsf{RegSeqRat}^{\uparrow}$ source, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row. Thus the consumer cannot select a second schedule or replace the finite cover by an external endpoint.

On overlaps, apply Definition 386.49. The seal route first factors through the finite-window meet surface before reading the seal packet, so the pairwise and triple-overlap compatibilities already used by the glued cover are the boundary seen by the CauchyLimitSeal consumer.

Therefore the CauchyLimitSeal read is a terminal consumer of the glued packet, not an additional gluing coordinate. The non-escape clauses in the cited StreamName and CauchyLimitSeal rows rule out quotient stream equality, selected host limits, host real equality, hidden tail oracles, ambient completeness, metric-completeness data, countable-choice rows, Classical rows, and standard bridge rows. □

Theorem 126.566 (StreamName finite-request section status pullback)**.** *Let $\mathcal{R}$ be an accepted finite-request* $\mathsf{StreamName}^{\uparrow}$ *section that is consumed by both the terminal* $\mathsf{Real}^{\uparrow}$ *route and the terminal* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route. Then the Phase Real and Completion status read pulls back to the same four local records*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Each face keeps its own closurestatus row and its own formalstatus row, as read through the two-axis discipline of section 9467.2. The pullback exports no quotient stream equality, selected limit, host real equality, ambient completeness, metric-completeness datum, countable-choice row, Classical row, aggregate formalstatus row, or standard bridge row.

Proof. First apply Definition 126.556. The accepted section has exactly the displayed finite support over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so every downstream consumer must read the same section budget and cannot add another face to the packet.

Next apply Definition 126.557 and Definition 126.558. The terminal $\mathsf{Real}^{\uparrow}$ route therefore consumes the accepted StreamName section through the same scheduled row, dyadic ledger, regular source, and Real seal, with no escape to a selected host limit or host real equality.

Now apply Definition 126.565. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer reads the same finite-request surface as a terminal seal route. Its seal read is a consumer of the four-face packet, not a new completion coordinate or a replacement for the Real-facing row.

Finally read both consumers through section 9467.2. That discipline keeps the paper closure axis, Lean verification axis, and bridge status attached to each face separately. Hence the Phase Real and Completion status read pulls back only to the four local records named above, and it cannot export quotient stream equality, selected limits, host real equality, ambient or metric-completeness data, countable-choice rows, Classical rows, aggregate formalstatus rows, or standard bridge rows. □

Theorem 126.567 (StreamName finite-request phase-exit sufficiency)**.** *An accepted finite-request* $\mathsf{StreamName}^{\uparrow}$ *section that exposes exactly the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the shared BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows is sufficient for the current Phase Real and Completion exit read. Conversely, every current Phase Real and Completion exit read pulls back to such an accepted finite-request* $\mathsf{StreamName}^{\uparrow}$ *section.*

The sufficiency and pullback contain only the displayed section packet and the four local face records. They do not assert quotient stream equality, selected limits, host real equality, ambient completeness, metric-completeness, countable choice, an aggregate formalstatus row, or standard bridge rows.

Proof. For sufficiency, apply Definition 126.556. The accepted section has exactly the four named faces and the shared BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows, so the section supplies the finite budget required by the StreamName side of the exit read.

Next apply Definition 126.558. The terminal consumers of that section must pass through the same scheduled StreamName row, dyadic ledger, regular-rational source, and Real-facing seal. Apply Definition 126.592 to identify that terminal surface with the four-face packet visible to the roadmap criterion.

Finally apply Definition 38.733. Its certificate accepts precisely the four-object surface over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with the displayed BEDC support rows. Hence the accepted finite-request section is sufficient for the current Phase Real and Completion exit read.

For the converse, start from any current Phase Real and Completion exit read and apply Definition 38.733. The read is a four-object certificate over the same dyadic, StreamName, RegSeqRat, and Real faces, with only the shared BEDC support rows.

Now apply Definition 126.566. The roadmap status read pulls back to the accepted finite-request $\mathsf{StreamName}^{\uparrow}$ section carrying those four local records. The pullback keeps the closurestatus and formalstatus rows componentwise rather than forming an aggregate row.

The exclusion clauses come from the same budget exactness, terminal coherence, status pullback, four-face completeness, and Real exit-certificate results. Together they leave no coordinate for quotient stream equality, selected limits, host real equality, ambient or metric-completeness, countable choice, aggregate formalstatus, or standard bridge rows. □

126.41 StreamName finite-request RealUp seal lock

Theorem 126.568 (StreamName finite request section RealUp seal lock)**.** *Any finite request section packet accepted by* $\mathsf{StreamName}^{\uparrow}$ *and consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity ledger, componentwise* hsame *transport, the displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *rows. The seal lock exports no quotient stream, no host real equality, no ambient completion point, and no* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Start with the finite request section packet of Definition 126.554 and Definition 126.555. These results make the accepted request a finite StreamName section whose public rows are the schedule, endpoint, readback, budget, transport, continuation, package, and local naming rows.

Next use the RegSeqRat-to-RealUp handoff rows of Definition 301.22, Definition 301.52, and Definition 301.141. They place the Real seal behind the same regularity ledger and finite request rows rather than behind a host sequence equality or selected completed limit.

Then compose with the DyadicRatCore endpoint and radius ledger reads recorded by Definition 301.5, Definition 301.13, and Definition 301.69. The endpoint and radius rows are therefore the displayed dyadic rows carried by the finite section, not independent ambient metric data.

Finally apply the non-escape exclusions of Definition 126.557 and Definition 126.536. Since the composed route has coordinates only for the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity ledger, hsame, Cont, Pkg, and $\mathsf{NameCert}$, it cannot export quotient streams, host real equality, ambient completion points, or RealUp completeness data. □

Theorem 126.569 (StreamName finite request Real seal totality)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *request consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal is exhausted by the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. There is no additional request coordinate outside these rows.*

Proof. Apply Definition 126.568. It already factors the accepted finite request section through the StreamName schedule rows, the DyadicRatCore endpoint-radius ledger, the RegSeqRat regularity ledger, componentwise hsame transport, Cont, Pkg, and local $\mathsf{NameCert}$.

It remains only to name the terminal seal face. The same theorem places the accepted request behind the $\mathsf{RegSeqRat}^{\uparrow}$-to-$\mathsf{Real}^{\uparrow}$ seal, while Definition 38.713 identifies that seal read with the four displayed object faces and the same support rows. Therefore the finite request has no coordinate beyond the schedule, endpoint, radius, regularity, readback, seal, and support rows listed in the statement. □

Theorem 126.570 (StreamName request section non-escape boundary)**.** *The finite request section of Definition 126.568 does not read a quotient stream, host sequence equality, selected limit, host*

real equality, ambient completion point, countable-choice row, metric-completeness row, or $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. First apply Definition 126.569. The visible packet is exhausted by the finite StreamName schedule, DyadicRatCore endpoint-radius rows, RegSeqRat regularity and readback rows, the RealUp seal row, and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Now use Definition 126.557. That boundary excludes quotient streams, host equalities, selected limits, ambient completion points, and RealUp completeness data from the request section. The totality packet has no row for countable choice or metric completeness either, so those rows cannot be read from the section. □

Theorem 126.571 (StreamName open-phase request handoff)**.** *The finite request section is precisely the local handoff from* $\mathsf{StreamName}^{\uparrow}$ *through* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *to* $\mathsf{Real}^{\uparrow}$*: its terminal packet is the four-face route with* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Proof. Start with Definition 126.568. It places the finite request inside the local $\mathsf{StreamName}^{\uparrow}$ section consumed by the $\mathsf{RegSeqRat}^{\uparrow}$-to-$\mathsf{Real}^{\uparrow}$ seal. Then use Definition 38.713 to read that seal as a terminal four-face packet.

Next apply Definition 126.500. The four faces are exactly $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and the only support rows are BHist, hsame, Cont, Pkg, and NameCert.

Finally apply Definition 126.557. It prevents the handoff from carrying quotient streams, selected limits, host real equality, ambient completion points, countable choice, metric completeness, or a RealUp completeness datum. Hence the section is exactly the local open-phase handoff through the displayed four faces and support rows. □

Theorem 126.572 (StreamName finite request Real seal classifier exactness)**.** *For a finite request section consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal, acceptance by the seal-facing classifier is necessary and sufficient for factorization through exactly the visible* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The classifier accepts no quotient stream equality, host real equality, selected limit, choice datum, ambient completion, metric-completeness row, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. For necessity, start from an accepted seal-facing request. Apply Definition 126.568 to factor the request through the finite StreamName section consumed by the Real seal, and then apply Definition 126.569. The accepted coordinates are exhausted by the schedule, endpoint, radius, regularity, readback, seal, and displayed support rows.

For sufficiency, suppose a finite section already factors through exactly those rows. Use Definition 126.571 to read the packet as the local handoff from $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$. Then Definition 126.500 identifies the same packet as the four-object Real-completion exit route, so the seal-facing classifier accepts it.

Finally apply Definition 126.570. The non-escape boundary rules out quotient stream equality, host real equality, selected limits, choice data, ambient completion, metric-completeness rows, and any second $\mathsf{Real}^{\uparrow}$ seal coordinate. Thus the displayed four faces and support rows are not merely sufficient witnesses for acceptance; they are the exact classifier surface. □

Theorem 126.573 (StreamName finite request Real seal common-refinement lock)**.** *Let* $\mathcal{R}$ *and* $\mathcal{S}$ *be two finite request sections consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal and accepted by the*

seal-facing classifier. Suppose that their displayed rows agree on the $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, the componentwise* hsame *rows, the displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows. Then* $\mathcal{R}$ *and* $\mathcal{S}$ *determine the same finite seal-facing packet. No quotient stream, selected limit, choice datum, ambient completion, metric-completeness row, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate can separate the two accepted requests.*

Proof. Apply Definition 126.572 to $\mathcal{R}$ and to $\mathcal{S}$. Since both requests are accepted, each factors through exactly the displayed StreamName schedule rows, DyadicRatCore endpoint-radius rows, RegSeqRat regularity and readback rows, the RealUp seal row, and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Next use Definition 126.571 for each section. Both presentations are therefore the same four-object route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ once the displayed rows in the hypothesis are identified.

Apply Definition 126.559 to the two presentations, and then apply Definition 126.562 to the finite two-member cover $\{\mathcal{R}, \mathcal{S}\}$. The common displayed rows are precisely the overlap data required by the gluing theorem, so the two accepted sections collapse to one terminal seal-facing packet.

Finally apply Definition 126.570. The common packet has no row for quotient streams, selected limits, choice data, ambient completion, metric completeness, or a second RealUp seal coordinate. Hence no non-displayed coordinate can distinguish the two accepted seal-facing requests. □

126.42 StreamName RegSeqRat Real seal handoff

Theorem 126.574 (StreamName RegSeqRat Real seal handoff)**.** *Let* W *be a finite-window packet accepted by* $\mathsf{StreamName}^{\uparrow}$*. Suppose each point row of* W *is certified by* $\mathsf{DyadicRatCore}^{\uparrow}$*, adjacent windows satisfy the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity budget, and the displayed support rows are exactly the finite-window* BHist *rows, componentwise* hsame *transport,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row. Then* W *reaches the* $\mathsf{Real}^{\uparrow}$ *seal boundary through the existing finite-window route, the* $\mathsf{RegSeqRat}^{\uparrow}$ *pointwise handoff, and the Real completion sibling route. The handoff exports no quotient stream equality, selected limit, host real equality, or ambient completeness datum.*

Proof. First read the finite-window packet through the hub routes. The finite-window budget and finite-request section rows expose the StreamName schedule, point rows, transport rows, continuation routes, package provenance, and local naming surface before any real-seal consumer is reached.

Next apply the RegSeqRat pointwise handoff. The DyadicRatCore-certified point rows and the adjacent-window regularity budget place the packet inside the displayed $\mathsf{RegSeqRat}^{\uparrow}$ regularity ledger rather than inside quotient stream equality or a selected host sequence.

Then compose with the Real completion sibling route. That route consumes the finite StreamName window and the RegSeqRat regularity ledger as the source face of the $\mathsf{Real}^{\uparrow}$ seal boundary.

The non-escape statement follows from the visible coordinate list. Since the packet contains only finite-window rows, DyadicRatCore point certificates, RegSeqRat regularity rows, the RealUp seal face, hsame, Cont, Pkg, and NameCert, it has no coordinate for quotient stream equality, selected limits, host real equality, or ambient completeness. □

Theorem 126.575 (StreamName RegSeqRat Real tail-section pullback)**.** *Let U and V be two finite tail-section requests of the same accepted* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose the point rows displayed by U and V are* $\mathsf{DyadicRatCore}^{\uparrow}$*-certified, the adjacent windows in both requests satisfy the* $\mathsf{RegSeqRat}^{\uparrow}$ *budget, and each request reaches the* $\mathsf{Real}^{\uparrow}$ *seal boundary through the handoff of Definition 126.574. Then U and V determine the same seal-visible source exactly when their visible rows admit a common finite pullback over the displayed StreamName window, the DyadicRatCore endpoint and radius ledger, the RegSeqRat regularity and classifier rows, componentwise* hsame *transports,* Cont *replay rows,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *rows. This pullback exports no quotient stream equality, selected limit, host real equality, or ambient completeness datum.*

Proof. For the forward direction, apply Definition 126.574 to each request. The seal-visible source of either request is read only through the finite StreamName window, the DyadicRatCore point certificates, the RegSeqRat budget rows, the transport and replay rows, provenance, and local naming.

Use the RegSeqRat common-window surface and the tail-selector rows to compare the two finite requests before the $\mathsf{Real}^{\uparrow}$ seal is read. Since the accepted StreamName packet is the same, the overlap is a pullback of displayed rows rather than a comparison of host sequences.

For the reverse direction, start with the common finite pullback. Its projections recover the visible rows of U and V, including the endpoint and radius ledger, regularity/classifier data, hsame transports, Cont replay, Pkg provenance, and local $\mathsf{NameCert}$ rows.

Composing each projection with the seal handoff gives the same $\mathsf{Real}^{\uparrow}$ seal-visible source. The coordinate inventory excludes quotient stream equality, selected limits, host real equality, and ambient completeness, so equality at the seal is exactly the displayed finite pullback condition. □

Theorem 126.576 (StreamName RegSeqRat Real seal correspondence)**.** *Let W be a finite-window packet accepted by* $\mathsf{StreamName}^{\uparrow}$*. Suppose each point row of W is certified by* $\mathsf{DyadicRatCore}^{\uparrow}$*, the adjacent-window rows satisfy the* $\mathsf{RegSeqRat}^{\uparrow}$ *budget, and the displayed support rows are the finite-window* BHist *rows, componentwise* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. A seal-visible source section determined by W is the same as the seal-visible source section of the corresponding public finite* $\mathsf{RegSeqRat}^{\uparrow}$ *request exactly when both sections factor through the ordered four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

with the same visible BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. This correspondence exports no quotient stream equality, host real equality, selected limit, choice datum, ambient completeness datum, metric-completeness row, or second seal coordinate.*

Proof. First apply Definition 126.574 to read the accepted $\mathsf{StreamName}^{\uparrow}$ window at the $\mathsf{Real}^{\uparrow}$ seal boundary. The handoff exposes only the finite StreamName window, the DyadicRatCore point certificates, the RegSeqRat adjacent-window budget, and the listed support rows.

Next apply Definition 301.139 to the corresponding public finite $\mathsf{RegSeqRat}^{\uparrow}$ request. Its source section displays the same schedule, dyadic ledger, classifier and regularity rows, componentwise hsame transports, Cont replay rows, Pkg provenance, and local $\mathsf{NameCert}$ surface.

For the forward direction, compose these two readings with Definition 301.141. A seal-visible source section coming from W therefore restricts to the same finite request source section precisely when the public request and the StreamName packet share the displayed rows of the four-face route.

For the reverse direction, start with a common ordered route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. The finite request source section repacks along the StreamName handoff, and Definition 38.713 identifies the resulting packet as the same terminal-budget Real seal read.

The non-escape clause is the coordinate inventory of the cited routes. None of them contains a row for quotient stream equality, host real equality, selected limits, choice, ambient completeness, metric-completeness data, or a second seal coordinate, so the correspondence is exactly the equality of the displayed finite BEDC surface. □

126.43 StreamName finite-request section pullback

Theorem 126.577 (StreamName finite-request section pullback)**.** *Every finite request section that faces* $\mathsf{Real}^{\uparrow}$ *through the* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal pulls back to the same displayed* $\mathsf{StreamName}^{\uparrow}$ *section schedule, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback surface, the same componentwise* hsame *rows, the same displayed* Cont *routes, the same* Pkg *provenance, and the same local* NameCert *rows. Thus a RealUp-facing request has no route around the displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{RegSeqRat}^{\uparrow}$ *rows.*

Proof. Start with the finite endpoint section of Definition 126.554. It reads the RealUp-facing request as a finite $\mathsf{StreamName}^{\uparrow}$ section whose visible coordinates are the endpoint, certified observation, support, and local naming rows.

Next apply Definition 126.555. The $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{DyadicRatCore}^{\uparrow}$ budget rows consumed by the same request are not independent rows; they are the window-budget face of the same finite section.

Now use Definition 126.568 and Definition 126.569. The $\mathsf{RegSeqRat}^{\uparrow}$-to-$\mathsf{Real}^{\uparrow}$ seal is exhausted by the displayed StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity/readback surface, and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Finally compare with the Real-side route. Apply Definition 38.698 to repack the RealUp-facing request as the same finite packet, and apply Definition 38.713 to rule out a second terminal-budget face. The pullback is therefore the displayed StreamName, DyadicRatCore, RegSeqRat, and support-row section already named above. □

Theorem 126.578 (StreamName RegSeqRat Real finite-request section lock)**.** *Let* $\mathcal{R}$ *and* $\mathcal{S}$ *be two presentations of a* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal over the same finite request. The presentations agree exactly when their displayed section rows agree: the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback surface, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *rows. No further RealUp-facing coordinate can distinguish the two presentations.*

Proof. For the forward direction, read both presentations through Definition 126.577. Since the finite request is the same, the pullback exposes the same StreamName schedule, DyadicRatCore ledger, RegSeqRat surface, and BEDC support rows for both presentations.

For the reverse direction, suppose the displayed section rows agree. Apply Definition 126.571 to each presentation. Both seal presentations are then the same local handoff through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

It remains to see that the Real-facing seal cannot add a separating row. Use Definition 126.568 to place each presentation behind the same finite section, and use Definition 126.569 together with Definition 38.713 to exhaust the terminal seal surface by those rows. Hence agreement of the displayed section rows is both necessary and sufficient. □

Theorem 126.579 (StreamName finite-request section classifier pullback)**.** *Let Q and Q' be RealUp-facing finite requests on the terminal L10* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *route. Suppose that the two requests display the same* $\mathsf{StreamName}^{\uparrow}$ *section schedule, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback surface, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same support rows* BHist*, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. Then Q and Q' pull back to the same finite carrier verdict and the same classifier verdict on that terminal four-face route.*

The pullback uses only the displayed four faces and the named support rows. It exports no quotient stream equality, no host sequence equality, no selected limit, no ambient completeness row, no countable-choice row, and no bridge row.

Proof. First apply Definition 126.577 to both Q and Q'. The two RealUp-facing requests are read through the displayed StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity/readback surface, RealUp seal boundary, and support rows named in the hypotheses.

Next use Definition 126.578. Since those displayed rows agree, the two seal presentations have the same finite request section at the terminal route.

Now apply Definition 126.587. The common finite section fixes the carrier verdict and classifier verdict read by the $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ four-face route, so there is no second classifier route for either request.

Finally apply Definition 126.584. The common verdict is supported only by the displayed faces and support rows, and the excluded quotient stream equality, host sequence equality, selected limit, ambient completeness, countable-choice, and bridge rows are not part of the pullback. □

Theorem 126.580 (StreamName finite-request cofinal section)**.** *Let Q_0 and Q_1 be terminal L10 finite requests on the* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *route. Suppose the two requests have a common finite observation bound for their StreamName windows, DyadicRatCore endpoint-radius ledgers, RegSeqRat readbacks, Real seal boundaries, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. Then there is a common* $\mathsf{StreamName}^{\uparrow}$ *finite-request section S refining both Q_0 and Q_1. The section S carries the same DyadicRatCore endpoint-radius ledger, RegSeqRat readback, Real seal boundary, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *rows as its two terminal restrictions.*

The cofinal section is a finite readback object on the displayed L10 route. It does not introduce quotient streams, selected limits, countable choice, host sequence equality, ambient completion points, or a detached $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. First apply Definition 126.577 to the two terminal requests and the common finite observation bound. This places both requests inside one displayed StreamName section with the same dyadic, regular-rational, Real-seal, transport, replay, provenance, and local naming rows.

Next use Definition 126.578. The lock keeps the RegSeqRat readback and Real seal boundary attached to the same finite section, so refining the StreamName schedule cannot add quotient stream equality, a selected limit, or an ambient completion point.

Now apply Definition 126.579. The classifier verdict of each terminal restriction is read from the same four-face section, hence the common section refines both requests without changing the DyadicRatCore endpoint-radius ledger or the RegSeqRat readback.

Finally use the Real terminal-budget exhaustion supplied by Definition 38.713. Since every terminal Real request has already spent its budget on the displayed finite faces and support rows, the common refinement is cofinal among such finite requests and has no coordinate for quotient streams, selected limits, countable choice, or Real completeness. □

Theorem 126.581 (StreamName finite-request section pullback exactness)**.** *Let Q and Q' be RealUp-facing finite requests on the terminal L10* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *route. The two requests determine the same finite carrier verdict and the same classifier verdict if and only if their displayed four-face pullbacks agree on the* $\mathsf{StreamName}^{\uparrow}$ *section schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback surface, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the support rows* BHist*, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

This equivalence is internal to the finite terminal packet. It excludes quotient streams, host sequence equality, selected limits, ambient completeness, countable choice, metric-completeness rows, and bridge rows.

Proof. For the forward direction, assume that Q and Q' determine the same finite carrier verdict and classifier verdict. Apply Definition 126.579 to read each verdict through the displayed terminal four-face route, and apply Definition 126.578 to lock the two seal presentations to the same finite request section.

The lock identifies exactly the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity/readback surface, RealUp seal boundary, and support rows named in the statement. Hence the displayed four-face pullbacks agree on every coordinate available to the finite verdict.

For the reverse direction, assume that the displayed four-face pullbacks agree on those rows. Use Definition 126.577 to identify both requests with the same finite section on the terminal L10 route. The classifier pullback theorem then reads that common section as the same finite carrier verdict and the same classifier verdict.

Finally use Definition 126.584. It rules out off-route separating coordinates: no quotient stream, host sequence equality, selected limit, ambient completeness, countable-choice row, metric-completeness row, or bridge row can distinguish the two requests once the displayed finite packet agrees. □

Theorem 126.582 (StreamName finite-request section kernel pullback)**.** *Every accepted finite-request section whose terminal face is consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *route pulls back to the same finite* BHist *window rows, componentwise* hsame *classifier rows, displayed* Cont *replay rows, and local* NameCert *rows exposed by its* $\mathsf{StreamName}^{\uparrow}$ *section. The pullback cannot introduce a host selector, quotient stream equality, selected limit, ambient completion coordinate, countable-choice row, metric-completeness row, or bridge row.*

Equivalently, the kernel-visible part of any such request is exactly the finite terminal packet named by the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity and readback surface, RealUp seal boundary, BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

Proof. Apply Definition 126.581. It reduces kernel agreement for the terminal finite request to agreement of the displayed four-face pullback: the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity and readback surface, RealUp seal boundary, and the named support rows.

Next use Definition 126.583. It shows that accepted cofinal refinements preserve the finite carrier verdict and classifier verdict when those displayed rows are preserved, so the terminal consumer sees the same kernel window rows.

Finally apply Definition 126.584. The nonescape clause removes every off-route coordinate listed in the statement, leaving only the finite BHist, hsame, Cont, Pkg, and local NameCert rows already visible in the pullback. □

Theorem 126.583 (StreamName finite-request section cofinal verdict invariance)**.** *Let Q and Q' be RealUp-facing finite requests on the terminal L10 route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*. Suppose that Q' is obtained from Q by an accepted cofinal refinement preserving the displayed* $\mathsf{StreamName}^{\uparrow}$ *section schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and readback surface, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the support rows* BHist*, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. Then Q and Q' determine the same finite carrier verdict and the same classifier verdict on the terminal four-face route.*

This invariance is only a finite-request statement. It exports no quotient stream equality, no host sequence equality, no selected limit, no ambient completeness row, no countable-choice row, no metric-completeness row, and no bridge row.

Proof. Apply Definition 126.581. It is enough to identify the displayed four-face pullbacks for Q and Q': the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity and readback surface, RealUp seal boundary, and named BEDC support rows.

The accepted cofinal refinement preserves the displayed StreamName section. Use Definition 126.597 to read this preservation as equality of the finite section restrictions seen by the terminal request.

For the RegSeqRat-to-Real part, apply Definition 301.244. The compatible refinement composition transports the RegSeqRat regularity/readback surface together with the RealUp-facing seal boundary, so the refined request has the same terminal four-face display.

Now use Definition 126.578. The lock prevents the seal presentation from adding a distinguishing coordinate once the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, and support rows agree.

Finally apply Definition 126.584. The excluded quotient stream equality, host sequence equality, selected limit, ambient completeness, countable-choice, metric-completeness, and bridge rows therefore cannot separate the finite carrier verdict or the classifier verdict. □

Theorem 126.584 (StreamName finite-request section nonescape)**.** *The finite-request section pullback of Definition 126.577 exports no quotient stream equality, no host sequence equality, no selected limit, no host real equality, no countable-choice row, no ambient completion, no metric-completeness row, and no* $\mathsf{Real}^{\uparrow}$ *completeness datum. Its public surface is only the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity/readback surface, and the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

Proof. First apply Definition 126.577. The RealUp-facing request has already been pulled back to the displayed StreamName, DyadicRatCore, RegSeqRat, and support-row section.

Next apply Definition 126.568. The seal lock blocks quotient stream equality, host real equality, ambient completion points, and RealUp completeness data from the seal presentation.

Now use Definition 126.569 and Definition 126.571. These results exhaust the open-phase handoff by the four displayed faces and the support rows, leaving no coordinate for host sequence equality, selected limits, countable choice, or a metric-completeness row.

Finally apply the Real-side finite-request route Definition 38.698 and the terminal-budget exhaustion of Definition 38.713. They confirm that any RealUp-facing consumer reads the same finite packet rather than an ambient completion or completeness datum. □

Theorem 126.585 (StreamName finite-request terminal support minimality)**.** *Every accepted* $\mathsf{Real}^{\uparrow}$*-facing finite request on the* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *route has minimal public support exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius*

ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ *regularity/readback surface, the terminal* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Removing any one of these faces prevents the existing classifier pullback, exactness, kernel pullback, and nonescape route from being invoked as a public finite-request certificate.

The support is minimal only for this displayed route. It does not assert a host sequence equality, quotient stream equality, selected limit, countable-choice schedule, metric-completeness row, ambient completion point, or independent $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Apply Definition 126.581. The accepted request is exact only when the StreamName schedule, DyadicRatCore endpoint-radius ledger, RegSeqRat regularity/readback surface, Real seal boundary, and support rows are all present in the same finite section.

Next use Definition 126.582. The kernel part of the route identifies the displayed support rows as the public source of transport, replay, provenance, and local naming. Removing any one of those rows breaks the kernel pullback rather than producing a smaller accepted certificate.

Finally apply Definition 126.584. Since the route exports none of the excluded host, quotient, choice, completion, or Real completeness coordinates, no omitted face can be recovered from an ambient object outside the displayed finite support. □

126.44 StreamName finite-section pullback exactness

Theorem 126.586 (StreamName finite-section pullback exactness)**.** *Let Q be an accepted finite request section of a* $\mathsf{StreamName}^{\uparrow}$ *packet. If the finite windows of Q agree with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback used by the current* $\mathsf{Real}^{\uparrow}$ *seal, then Q determines the same terminal four-face route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*. The support of this route is only the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. It exports no quotient stream, selected limit, host sequence equality, ambient completeness row, countable-choice row, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFiniteSectionPullbackExactness`

Proof. First apply Definition 126.577. The accepted request section is already pulled back to the displayed $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint-radius ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ regularity and readback surface, and the support rows BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Next use Definition 126.449. Since the finite windows agree with the DyadicRatCore ledger and the RegSeqRat readback used by the current RealUp seal, terminality identifies the resulting route with the unique four-face route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Now apply Definition 126.605. The RealUp seal remains on the public finite rows and therefore cannot add a quotient stream, selected limit, host sequence equality, or ambient completeness coordinate to the section.

Finally use Definition 126.610. It exhausts carrier, classifier, stability, ledger, and non-escape obligations by the same four faces and the displayed support rows, leaving no countable-choice row or standard bridge row to export. □

Theorem 126.587 (StreamName finite-section classifier determinacy)**.** *Let Q and Q' be accepted finite request sections of a current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose that Q and Q' have the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the same* $\mathsf{Real}^{\uparrow}$ *seal boundary. Then the carrier verdict and*

classifier verdict read at the terminal $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *four-face route are the same for* Q *and* Q'*.*

The common route is supported only by the displayed BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It contains no quotient stream equality, selected limit, host sequence equality, ambient completeness row, countable-choice row, or standard bridge row.*

Proof. Apply Definition 126.586 first to Q and then to Q'. Each accepted section is read through the same StreamName finite window, DyadicRatCore ledger, RegSeqRat readback row, RealUp seal boundary, and displayed support rows.

Next use Definition 126.449. The shared four faces identify the terminal finite BEDC route for both sections, so a carrier or classifier verdict has no second terminal route on which to vary.

Now apply Definition 126.605. The RealUp seal remains public over the finite route and cannot contribute a hidden quotient stream, selected limit, host sequence equality, or ambient completeness coordinate that would separate the two sections.

Finally use Definition 126.610. Carrier, classifier, stability, ledger, and non-escape obligations are exhausted by the shared four faces together with the displayed BHist, hsame, Cont, Pkg, and NameCert rows. Hence the two accepted sections have the same carrier and classifier verdicts at the terminal route, with no countable-choice or bridge row left outside that support. □

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFiniteSectionClassifierDeterminacy`

Theorem 126.588 (StreamName finite-section pasting exactness)**.** *Let* Q_0 *and* Q_1 *be accepted finite request sections of a current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet, and suppose their finite windows have an accepted overlap* Q_{01}*. If* Q_0 *and* Q_1 *agree on* Q_{01} *in the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows, then the pasted finite section determines the same terminal four-face route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Re}$ *and the same public classifier verdict as its two restrictions.*

The pasted route exports no quotient stream, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Proof. Apply Definition 126.586 first to Q_0 and then to Q_1. Each restriction is pulled back to its displayed StreamName finite window, DyadicRatCore ledger row, RegSeqRat readback row, RealUp seal boundary, and support rows.

On the accepted overlap Q_{01}, apply Definition 126.587. The overlap hypotheses identify the four visible faces and the displayed support rows, so the two restrictions have one carrier verdict and one public classifier verdict at the common terminal route.

Now paste the finite windows along that overlap. Since both restrictions are already pullbacks of the same four-face data on Q_{01}, the pasted section has no additional face from which a second terminal route could be read.

Finally apply Definition 126.589. Every Real-facing or completion-facing consumer of the pasted section is locked to the same StreamName, DyadicRatCore, RegSeqRat, and RealUp faces. Thus the public classifier verdict and the terminal four-face route are the same on the pasted section and on its two restrictions, while the excluded quotient, host-equality, limit-selection, completeness, choice, and bridge coordinates remain unavailable. □

Theorem 126.589 (StreamName Real-RegSeq-Dyadic finite lock)**.** *Let* Q *be an accepted finite request section of a current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose that*

Q exposes the same $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *seal boundary as the terminal four-face route. Then every* $\mathsf{Real}^{\uparrow}$*-facing and completion-facing consumer reads the same finite lock through exactly those four faces and the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The lock contains no quotient stream, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamNameFiniteSectionRealRegSeqDyadicLock`

Proof. First use Definition 126.586. The accepted section Q is already pulled back to the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{Real}^{\uparrow}$ seal boundary, and the displayed support rows.

Next apply Definition 126.587. Any accepted request section exposing those same four faces has the same carrier and classifier verdict at the terminal route, so no Real-facing or completion-facing consumer can split the finite lock by rereading one face.

Now use Definition 126.504. It identifies every downstream Real or completion read with the terminal finite pullback once the four faces and support rows agree.

Finally combine this terminal pullback with Definition 126.610. The handoff exhausts carrier, classifier, stability, ledger, and non-escape obligations through the same BHist, hsame, Cont, Pkg, and NameCert rows. The excluded quotient, host-equality, limit-selection, completeness, countable-choice, and bridge coordinates therefore have no row from which a consumer could read them. □

Theorem 126.590 (StreamName finite-section terminal coverage)**.** *Every displayed terminal four-face lock for the current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet is realized by an accepted finite request section. More explicitly, suppose the displayed lock consists of a* $\mathsf{StreamName}^{\uparrow}$ *finite window, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, a* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the support rows* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert*. Then there is an accepted finite request section Q whose exposed terminal route is exactly that lock, and every Real-facing or completion-facing consumer reads Q through those rows.*

The realized section contains no quotient stream, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Proof. First apply Definition 126.504. The displayed four faces and their BHist, hsame, Cont, Pkg, and NameCert rows form the terminal pullback surface consumed by the Real and completion endpoints.

Next use Definition 126.586 to read that terminal surface as a finite request-section surface of the same packet. The exactness clause supplies the accepted finite section Q whose exposed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces are the displayed lock.

Apply Definition 126.587 to this section. Determinacy makes the carrier and classifier verdicts of Q unique at the displayed terminal route, so no consumer can choose a different finite section with the same four faces but a different public verdict.

Finally use Definition 126.610. The handoff routes all carrier, classifier, stability, ledger, and non-escape obligations through the same support rows. Thus quotient streams, host sequence equality, selected limits, ambient completeness, metric-completeness data, countable-choice rows, and bridge rows remain outside the realized finite section. □

Theorem 126.591 (StreamName terminal face iff)**.** *Let Q and Q' be accepted finite request sections of the current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet. The public finite-section carrier verdicts and classifier verdicts of Q and Q' agree if and only if Q and Q' expose the same*

terminal four-face route consisting of the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows.*

This criterion contains no quotient stream, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, countable-choice row, or standard bridge row.*

Proof. For the forward direction, assume that the public carrier and classifier verdicts of Q and Q' agree. Apply Definition 126.587 to read both verdicts at the terminal finite route determined by the visible faces.

Next apply Definition 126.589. The agreed verdicts cannot be reread through any Real-facing or completion-facing coordinate outside the $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal, and the displayed support rows.

Now use Definition 126.504. It recovers the common four-face terminal pullback from the agreed verdicts and the visible BHist, hsame, Cont, Pkg, and NameCert rows.

For the reverse direction, assume that Q and Q' expose the same terminal four-face route with the displayed support rows. By Definition 126.586, each section is pulled back to exactly that visible route.

Finally apply Definition 126.449. The two pullbacks have no second terminal face on which the carrier or classifier could vary, so their public finite-section carrier verdicts and classifier verdicts agree. The excluded quotient, host-equality, limit-selection, completeness, choice, metric-completion, and bridge coordinates are not part of the route in either direction. □

Theorem 126.592 (StreamName four-face terminal completeness)**.** *For a current L10 Phase Real and Completion terminal read of* $\mathsf{StreamName}^{\uparrow}$*, completeness for the present open exit surface is exactly factorization through the four visible faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$ *together with the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Conversely, any accepted read exposing those four faces and those support rows supplies the full carrier, classifier, stability, ledger, and non-escape surface available to the current Phase Real and Completion route. This completeness assertion excludes quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.

Proof. For necessity, start with a complete terminal read of the current open exit surface. By Definition 126.586, its accepted finite section is pulled back to the StreamName finite window, the DyadicRatCore ledger, the RegSeqRat readback, the RealUp seal boundary, and the displayed support rows.

Next apply Definition 126.587 and Definition 126.589. These results make the carrier and classifier verdicts determinate at the same four-face finite lock for every Real-facing or completion-facing consumer.

For sufficiency, suppose an accepted read exposes the four visible faces and the displayed BHist, hsame, Cont, Pkg, and NameCert rows. Use Definition 126.504 to identify that packet with the terminal finite pullback for the current Real and Completion boundary.

Finally apply Definition 126.610. The handoff fills exactly the carrier, classifier, stability, ledger, and non-escape obligations from those rows. Since the terminal pullback has no coordinate for quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, or standard bridge data, those excluded surfaces are not part of the completeness claim. □

Theorem 126.593 (StreamName finite-section terminal reflection)**.** *Let Q be an accepted finite request section of a current L10 Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *packet. Then Q supplies the current Phase Real and Completion public reflection surface exactly when every visible row of Q factors through the four faces* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *together with the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The reflected surface contains precisely the carrier, classifier, stability, ledger, and non-escape data readable through those rows. It contains no quotient stream, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Proof. For the forward direction, suppose Q supplies the current Phase Real and Completion public reflection surface. Apply Definition 126.586. The accepted section is pulled back to the StreamName finite window, the DyadicRatCore ledger, the RegSeqRat readback, the RealUp seal boundary, and the displayed support rows.

Next use Definition 126.587. The carrier and classifier verdicts are fixed by that four-face route, so the public reflection surface has no second verdict outside the displayed support.

Apply Definition 126.588 to any two visible restrictions of the reflected finite section. On their accepted overlap, the pasted section retains the same terminal route and the same public classifier verdict, so local visible rows cannot introduce an additional reflection face.

Now apply Definition 126.589. Every Real-facing and completion-facing consumer of Q is locked to the same four faces and support rows. Hence quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows have no coordinate in the reflected surface.

For the reverse direction, suppose every visible row of Q factors through exactly the four faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows. By Definition 126.592, those rows supply the full carrier, classifier, stability, ledger, and non-escape surface available to the current Phase Real and Completion route.

The same theorem also excludes every non-public row listed above. Therefore the factorized finite section supplies exactly the current public reflection surface, with no quotient, host-equality, limit-selection, completeness, choice, metric-completion, or bridge data added beyond the four-face terminal support. □

Theorem 126.594 (StreamName finite-section descent gluing)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose that every accepted overlap Q_{ij} has the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows when read from Q_i and from Q_j. Then the family descends to one public reflection surface over the four-face route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *whose restrictions are the given local sections.*

Conversely, any public reflection surface over that four-face route restricts to accepted local finite sections whose pairwise overlaps agree on exactly the same finite-window, ledger, readback, seal, BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Both directions exclude quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Proof. For descent, paste the finite family by induction on its finite index set. The two-section step is exactly Definition 126.588: the pairwise overlap agreement keeps the StreamName finite

window, the DyadicRatCore ledger, the RegSeqRat readback, the RealUp seal boundary, and the displayed support rows fixed while the pasted section keeps the same public classifier verdict.

At each induction step, use Definition 126.592. The rows retained by the pasted section are already sufficient for the carrier, classifier, stability, ledger, and non-escape surface of the current Phase Real and Completion route, so no further face is available to distinguish the next local section from the accumulated paste.

Apply Definition 126.593 to the final pasted finite section. It turns the completed four-face factorization into the public reflection surface over $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$. The Real, RegSeq, and Dyadic handoff rows used above keep every read on the L10 four-object packet and leave no quotient-stream, selected-limit, host-equality, ambient completeness, metric-completion, countable-choice, or bridge coordinate to export.

For restriction, start with a public reflection surface over the same four-face route. By Definition 126.593, every visible row of that surface factors through the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal boundary, and displayed support rows. Restricting those rows to any finite local window gives an accepted local section, and restricting them to a pairwise overlap gives the same rows from both sides. □

Theorem 126.595 (StreamName finite-section tail-window terminal equivalence)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections, and let*

$$\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_n$$

be a finite chain of $\mathsf{StreamName}^{\uparrow}$ *tail-window coverage packets over the same public endpoints and the same accepted* RegSeqRat *spine. Suppose each Q_i and each $\mathcal{P}_j$ displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then the public reflection surface produced by finite-section descent gluing and the terminal read produced by tail-window cover-chain coverage are the same four-face terminal route through* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqR}$ *with the same carrier and the same classifier verdict.*

Conversely, any terminal tail-window read over this four-face route restricts to compatible accepted finite sections whose overlaps display exactly those finite-window, ledger, readback, seal, BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Both directions exclude quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Proof. For the finite-section side, apply Definition 126.594. The accepted local sections glue to one public reflection surface over the four-face route because their overlaps carry the same StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal boundary, and displayed support rows.

Apply Definition 126.593 to that glued surface. The result is a terminal public reflection surface on the current Phase Real and Completion route. By Definition 126.587, the carrier and classifier verdict of this surface are already determined by the displayed four-face rows.

For the tail-window side, use Definition 126.232. Every packet in the cover chain induces the same consumer-facing finite source surface. Then apply Definition 126.233 to identify the terminal RealUp read with exactly that common source surface.

It remains to compare the two terminal surfaces. The common rows assumed for the Q_i and the $\mathcal{P}_j$ are the rows named by Definition 126.589; hence both constructions factor through the same StreamName, DyadicRatCore, RegSeqRat, and RealUp faces, and no additional carrier or classifier coordinate is available on either side.

For the converse, start with a terminal tail-window read over the same four-face route. By Definition 126.232 and Definition 126.233, it is covered by one common finite source surface. Restricting that surface to the finite windows selected by the accepted current Phase Real and Completion requests gives finite sections whose overlaps inherit the same displayed rows.

Finally apply Definition 126.594 to these restricted sections and Definition 126.587 to their visible classifier rows. The resulting finite-section surface is the same terminal four-face route as the original tail-window read, and the boundary exclusions above leave no quotient stream, selected limit, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, or standard bridge row to distinguish them. □

Theorem 126.596 (StreamName cofinal-tail refinement invariance)**.** *Let $\{Q_i\}_{i\in I}$ and $\{R_k\}_{k\in K}$ be finite families of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose both families refine a common cofinal tail-window cover chain*

$$\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_n$$

over the same public endpoints and the same accepted RegSeqRat *spine. Assume that every Q_i, every R_k, and every $\mathcal{P}_j$ displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows on each accepted overlap. Then the finite-section descent gluing surface of $\{Q_i\}_{i\in I}$ and the finite-section descent gluing surface of $\{R_k\}_{k\in K}$ determine the same four-face terminal route through* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*, with the same carrier and the same classifier verdict.*

This comparison is internal to the four visible faces. It excludes quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.

Proof. Apply Definition 126.594 to $\{Q_i\}_{i\in I}$. The overlap hypotheses paste the family to one public reflection surface over the StreamName, DyadicRatCore, RegSeqRat, and RealUp faces, while retaining exactly the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Apply the same descent-gluing theorem to $\{R_k\}_{k\in K}$. Since this second family refines the same cofinal tail-window cover chain and carries the same visible rows on accepted overlaps, its glued surface has the same public four-face data as the first glued surface.

Now use Definition 126.595 for each glued surface against the shared tail-window cover chain. Both glued surfaces identify with the same terminal tail-window read over the current Phase Real and Completion route. Hence their carriers and classifier verdicts are the carriers and verdicts of that shared terminal read.

Finally invoke Definition 126.589. The lock keeps the comparison on the displayed StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal boundary, and support rows. Therefore no quotient stream equality, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row can enter the invariance claim. □

Theorem 126.597 (StreamName finite-section restriction exactness)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose that every accepted overlap Q_{ij} displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows when read*

from either side. For every finite subfamily $J \subseteq I$, the restriction $\{Q_j\}_{j\in J}$ has as its descent-gluing surface exactly the terminal four-face route obtained by applying Definition 126.594 to the restricted data.

The route is the same public route through $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *and has the same carrier and classifier verdict as the tail-window terminal read determined by the ambient family. The restriction excludes quotient stream equality, selected limits, host real equality, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Proof. Restrict the finite family to J. Every accepted overlap in the restricted family is an accepted overlap in the ambient family, so the StreamName finite-window row, DyadicRatCore ledger row, RegSeqRat readback row, RealUp seal boundary, and displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows are inherited without adding any new coordinate.

Apply Definition 126.594 to the restricted family. The result is a public reflection surface over the four-face route $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$, and its local restrictions are precisely the selected sections $\{Q_j\}_{j\in J}$.

Compare this surface with the ambient terminal route by Definition 126.595. Both the ambient family and the restricted family read the same finite-window, ledger, readback, seal, and support rows into the tail-window terminal surface, so their carriers and classifier verdicts are the same terminal carrier and verdict.

Now use Definition 126.596. The restricted family is a finite refinement of the same cofinal tail-window data after dropping unused local sections, and the overlap rows retained above are exactly the rows required for the invariance comparison.

Finally apply Definition 126.589. The lock identifies the only Real-facing and completion-facing rows available to the restricted surface: the StreamName finite window, the DyadicRatCore ledger, the RegSeqRat readback, the RealUp seal boundary, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows. Hence quotient stream equality, selected limits, host real equality, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows have no place in the restricted descent-gluing surface. □

Theorem 126.598 (StreamName finite-section cover descent classifier reflection)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose that every accepted overlap displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows from either side. Then the descent-gluing surface for the cover is the unique public classifier reflection surface for the family.*

Concretely, every finite restriction of the cover has the same carrier verdict and the same classifier verdict as the glued surface, and every Real-facing or completion-facing consumer factors through the same four-face route $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*. The claim excludes quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Proof. First apply Definition 126.594 to the whole finite cover. The accepted-overlap hypotheses paste the local sections into a single public surface over the displayed StreamName, DyadicRatCore, RegSeqRat, and RealUp faces, with the stated BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows as its only support data.

Next apply Definition 126.597 to each finite subfamily. Every restriction inherits the same overlap rows, so its descent-gluing surface is the restricted instance of the same public four-face route and carries the same terminal carrier and classifier verdict.

Now compare refinements by Definition 126.596. Any consumer that sees the family through a finer finite tail-window cover still reads the same StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal boundary, and support rows, so the route available to the consumer is unchanged.

Finally use Definition 126.587 and Definition 126.589. Determinacy makes the carrier and classifier verdicts unique on the public surface, while the lock confines all Real-facing and completion-facing uses to the four visible faces. Hence no quotient stream equality, host sequence equality, selected limit, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row is part of the classifier reflection surface. □

Theorem 126.599 (StreamName common-refinement classifier uniqueness)**.** *Let $\{Q_i\}_{i\in I}$ and $\{R_j\}_{j\in J}$ be finite families of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose that they admit a certified finite common refinement $\{S_k\}_{k\in K}$ with refinement maps $a : K \to I$ and $b : K \to J$. For every $k \in K$, the row S_k restricts to the rows $Q_{a(k)}$ and $R_{b(k)}$, and every accepted overlap in the refinement displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows when read through either cover. Then the cover-descent classifier reflection surface determined by $\{Q_i\}_{i\in I}$ and the cover-descent classifier reflection surface determined by $\{R_j\}_{j\in J}$ are the same public four-face classifier surface.*

Equivalently, the two presentations have the same carrier verdict and the same classifier verdict on the visible route $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*. The comparison refuses quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Proof. Apply Definition 126.598 to the cover $\{Q_i\}_{i\in I}$. Apply the same theorem to the cover $\{R_j\}_{j\in J}$. The hypotheses give public classifier reflection surfaces for both covers over the same four visible faces and the same support rows.

Now apply Definition 126.596 to the certified common refinement $\{S_k\}_{k\in K}$. Each refined row restricts to the corresponding row of both covers, and every accepted refined overlap reads the same finite window, ledger, readback, seal boundary, BHist, hsame, Cont, Pkg, and NameCert rows. Thus the two cover surfaces compare through the same cofinal tail-window surface.

It remains to identify the public verdicts. Use Definition 126.587 on the two surfaces transported to the refinement surface, and use Definition 126.589 to keep the carrier and classifier reads on the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, and RealUp seal boundary.

The resulting comparison is therefore a comparison of the same public four-face classifier surface, not a comparison of quotient streams or host sequences. The lock also excludes selected limits, ambient Real completeness, metric-completeness data, countable-choice rows, and standard bridge rows from the common-refinement uniqueness claim. □

Theorem 126.600 (StreamName finite-section cover descent normal form)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose that a public cover-descent surface restricts to these sections, and that each restriction and each accepted overlap displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, the displayed* BHist*, and the componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then the surface is equivalent, as a public cover-descent reflection surface, to the canonical normal form consisting exactly of*

the finite family rows, the accepted overlap compatibility rows, the common-refinement classifier surface, the four-face consumer route $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*, and the nonescape exclusions for quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable choice, and standard bridge rows.*

Conversely, any such finite family rows together with accepted overlap compatibility rows, the common-refinement classifier surface, the four-face consumer route, and the same nonescape exclusions construct a public cover-descent reflection surface with those restrictions.

Proof. Proceed by induction on the finite cover. In the empty and singleton cases the normal form is the displayed restriction row itself, with no hidden consumer route beyond the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, and RealUp seal boundary.

For the induction step, separate the last accepted section from the already glued subcover. Apply Definition 126.594 to paste the subcover surface and the last section along their accepted overlaps. The induction hypothesis identifies the subcover surface with its finite family rows, overlap rows, four-face route, and nonescape exclusions, so the glued surface has no additional support row available.

Next apply Definition 126.597 to the glued surface and to every finite subfamily obtained during the induction. Each restriction reads the same finite-window, ledger, readback, seal boundary, BHist, hsame, Cont, Pkg, and NameCert rows; hence the public surface is determined by the displayed cover data and not by a chosen enumeration of the family.

Now use Definition 126.598 to package the glued data as a cover-descent classifier reflection surface. Apply Definition 126.599 to compare any two presentations through their finite common refinement. The comparison identifies the common-refinement classifier surface as the unique classifier component of the normal form.

Finally apply Definition 126.589. The lock keeps every Real-facing and completion-facing consumer on the four visible faces, so quotient stream equality, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, countable-choice rows, and standard bridge rows cannot enter the public reflection surface.

For the converse direction, start with the finite family rows and accepted overlap compatibility rows. The same descent-gluing theorem constructs the public surface, classifier reflection supplies the classifier row, and common-refinement uniqueness makes the construction independent of the finite presentation. The lock then supplies exactly the stated nonescape exclusions, which is the required public cover-descent reflection surface. □

Theorem 126.601 (StreamName finite-section cover-descent support minimality)**.** *Let* $\{Q_i\}_{i\in I}$ *be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections satisfying the overlap hypotheses of Definition 126.600. Then the canonical cover-descent normal form is accepted exactly on the four visible faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

Deleting any one visible face or any one displayed support row prevents the same carrier verdict and the same classifier verdict from being presented to Real-facing or completion-facing consumers. No quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, countable-choice row, standard bridge row, aggregate formalstatus row, or bridge row can replace the deleted coordinate.*

Proof. Apply Definition 126.600. The cover-descent surface reduces to the finite family rows, the accepted overlap compatibility rows, the common-refinement classifier surface, and the four-face consumer route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

On that normal form, apply Definition 126.662. Its terminal support packet is accepted exactly on the four visible faces and the displayed BHist, componentwise hsame, Cont, Pkg, and NameCert rows, and deletion of any one of these coordinates loses the same Real-facing or completion-facing carrier and classifier verdicts.

It remains to exclude substitute coordinates. Use Definition 126.589 on the same normal-form route. The lock keeps every consumer read on the finite StreamName window, DyadicRatCore ledger, RegSeqRat readback, and Real seal boundary, so quotient stream equality, host sequence equality, selected limits, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, countable-choice rows, standard bridge rows, aggregate formalstatus rows, and bridge rows cannot restore the deleted face or support row. □

126.45 StreamName finite-section reindex gluing

Theorem 126.602 (StreamName finite-section reindex gluing)**.** *Let Q and Q' be accepted current Phase Real and Completion finite request sections of a* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose that a certified* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex route transports the finite window of Q to the finite window of Q', and suppose that after this transport the two sections agree on the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then Q and Q' determine the same terminal four-face route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *and the same public carrier and classifier verdict at that route.*

The glued route remains finite and displayed. It contains no quotient stream, selected limit, host equality, countable-choice row, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, aggregate status row, or standard bridge row.*

Proof. First apply Definition 126.639. The certified finite-window reindex route, together with the transported BHist, Cont, Pkg, and NameCert rows and the hsame compatibility, identifies the two finite observation sections after transport.

Next use Definition 126.642. The transported finite observation section reaches exactly the four terminal faces $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$, with the same DyadicRatCore ledger, RegSeqRat readback, RealUp seal boundary, and displayed support rows.

Now apply Definition 126.586 to Q and to Q'. Pullback exactness reads both accepted request sections through the same four-face finite route once the endpoint-radius ledger, regularity rows, readback rows, seal boundary, and displayed support rows have been transported to agreement.

Finally apply Definition 126.587. The common four-face route leaves no second public carrier surface or classifier surface on which the verdict could vary. The exclusion clauses follow from the same finite support: the construction never exports a quotient stream, selected limit, host equality, countable-choice row, metric-completeness row, ambient Real completeness row, aggregate status row, or standard bridge row. □

Theorem 126.603 (StreamName finite-section reindex gluing is choice-free)**.** *The gluing construction of Definition 126.602 remains inside the displayed finite windows of the participating* $\mathsf{StreamName}^{\uparrow}$ *packets. It uses only the certified* ProbeBundle *windows, pointwise classifier rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows attached to the two finite request sections and their reindex route.*

Consequently the gluing cannot select host indices, quotient streams, selected limits, countable-choice schedules, ambient metric-completeness witnesses, ambient $\mathsf{Real}^{\uparrow}$ *completeness rows, aggregate status rows, or standard bridge credentials.*

Proof. Start with Definition 126.602. Its hypotheses already name the certified finite-window reindex route and the displayed agreement of the endpoint-radius ledger, regular readback, Real seal, BHist, hsame, Cont, Pkg, and NameCert support rows.

Use Definition 126.639. The transported section is determined by the inspected ProbeBundle windows and pointwise classifier rows, so the construction has no coordinate from which to choose a host index or a second stream representative.

The final route is then read by Definition 126.642. The only terminal faces are $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, Re and they are reached through the same displayed finite windows.

Since the carrier rows used in the proof are exactly the local transport, replay, provenance, and naming rows, no quotient stream, selected limit, countable-choice schedule, ambient completeness witness, aggregate status row, or bridge credential is introduced. □

Theorem 126.604 (StreamName finite-section reindex cocycle)**.** *Let Q_0, Q_1, and Q_2 be accepted current Phase Real and Completion finite request sections of a* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose that certified* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes transport the finite window of Q_0 to the finite window of Q_1 and the finite window of Q_1 to the finite window of Q_2. Suppose also that the two transported sections agree on the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then the direct composite route from Q_0 to Q_2 determines the same terminal four-face route* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *and the same public carrier and classifier verdict as the two-step route through Q_1.*

The cocycle comparison remains finite and displayed. It contains no quotient stream, selected limit, host equality, countable-choice row, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, aggregate status row, or standard bridge row.*

Proof. First apply Definition 126.602 to the overlap from Q_0 to Q_1 and again to the overlap from Q_1 to Q_2. The shared endpoint-radius ledger, readback rows, regularity rows, seal boundary, and displayed BHist, hsame, Cont, Pkg, and NameCert rows give the two adjacent finite gluing identifications.

Next use Definition 126.641. The certified two-step finite-window route and the direct composite route from Q_0 to Q_2 present the same public reindexing data, so the intermediate section Q_1 cannot contribute a second terminal presentation.

Now apply Definition 126.642. Both the two-step route and the direct composite route reach exactly the same four terminal faces $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$, with no extra face and with the same displayed support rows.

Finally apply Definition 126.587. Since the terminal four-face route is common, the public carrier and classifier verdict read from the composite route agrees with the verdict read from the two-step route. The non-escape exclusions are inherited from the finite displayed routes used in the two gluing steps: no quotient stream, selected limit, host equality, countable choice, metric completeness, ambient Real completeness, aggregate status row, or standard bridge row is introduced. □

126.46 StreamName RegSeqRat Real public seal boundary

Theorem 126.605 (StreamName-RegSeqRat-Real public seal no-quotient boundary)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *seal route exported from the* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff and consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *factors through the finite* BHist *rows, pointwise* hsame *rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows already exposed by Definition 126.79, Definition 126.83, and Definition 126.112.*

The handoff exports no quotient stream equality, selected limit, host real equality, ambient completeness claim, or open-cover compactness claim.

Proof. First apply Definition 126.79. It identifies the public StreamName source surface as a finite-window packet: the selected history rows, the finite ProbeBundle ledger, membership rows, unary-history rows, and the visible BHist, hsame, Cont, Pkg, and NameCert support.

Next apply Definition 126.83. The RegSeqRat consumer reads the same finite packet through the regular-sequence seal route, so the Real-facing seal is reached through the displayed finite rows and their provenance rather than through a hidden stream equality or a chosen completed value.

Finally apply Definition 126.112. That boundary keeps the RealUp seal at the finite-window interface and excludes quotient streams, selected limits, host real equality, and ambient completeness data. The sibling L10 consumers chapter 301, chapter 291, and chapter 38 therefore receive only the displayed finite rows and local certificates, not an open-cover compactness claim. □

Theorem 126.606 (StreamName-RegSeqRat-Real public seal finite-section determinacy)**.** *Let $\mathcal{S}_0$ and $\mathcal{S}_1$ be public* $\mathsf{Real}^{\uparrow}$ *seal routes exported from the* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff and consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*. Suppose they display the same* $\mathsf{StreamName}^{\uparrow}$ *finite section, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the same local* $\mathsf{Real}^{\uparrow}$ *finite-section readback, and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then $\mathcal{S}_0$ and $\mathcal{S}_1$ determine the same finite public seal section.

This determinacy is only a statement about the public finite section of the BEDC ledger. It does not assert quotient-stream equality, selected limits, host real equality, countable choice, ambient completeness, an aggregate formalstatus row, bridge rows, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 126.586 and Definition 126.589. The common StreamName finite section is pulled back to the same DyadicRatCore ledger, RegSeqRat readback, local Real seal row, and displayed support rows.

Next apply Definition 301.237. Since the two routes expose the same StreamName window, dyadic ledger, RegSeqRat regularity and classifier rows, local Real readback, and support rows, they come from one common finite RegSeqRat source section.

Now apply Definition 38.720. The local Real readback of each route is accepted exactly through the same ordered four-face packet over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The two public seal routes are therefore projections of one finite BEDC ledger. Projecting that ledger to the public seal coordinate gives the same finite public seal section for $\mathcal{S}_0$ and $\mathcal{S}_1$, and the excluded quotient, limit, host-equality, choice, completeness, aggregate status, and bridge coordinates have no displayed row from which to vary. □

Theorem 126.607 (StreamName-RegSeqRat-Real public seal window induction)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *seal section exported from a* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff and consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *is generated by induction over the displayed finite rows. The generating rows are precisely the visible* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the local* $\mathsf{Real}^{\uparrow}$ *readback row, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The induction step appends one visible window row and preserves the same public seal section exactly when the finite-section determinacy hypotheses of Definition 126.606 are preserved.

The generated section contains no quotient stream equality, selected limit, host real equality, countable choice, metric-completeness datum, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. The base section is the empty displayed window together with its finite support rows. Apply Definition 126.605. It identifies the public seal boundary as a route through the finite BHist, hsame, Cont, Pkg, and NameCert rows and supplies no quotient, limit, host-equality, choice, completeness, or bridge coordinate.

For the induction step, append one visible $\mathsf{StreamName}^{\uparrow}$ window row and its matching dyadic, RegSeqRat, local Real, and support rows. Apply Definition 126.586 and Definition 126.589 to transport the appended window through the same finite four-face packet.

Next apply Definition 301.237. The RegSeqRat consumer sees only the displayed window, ledger, regularity, classifier, readback, and support rows, so the source section after the append is the unique finite source section with those rows.

Finally apply Definition 38.720 and then Definition 126.606. The local Real readback is accepted through the same ordered four-face packet, and determinacy says that preserving the displayed finite rows preserves the same public seal section. Since every step appends only such rows, the whole public section is generated by the stated finite-window induction. □

Theorem 126.608 (StreamName-RegSeqRat-Real public seal support intersection)**.** *Let* $\mathcal{S}_0$ *and* $\mathcal{S}_1$ *be public* $\mathsf{Real}^{\uparrow}$ *seal routes exported from the* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff and consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*. Suppose their visible rows agree on the* $\mathsf{StreamName}^{\uparrow}$ *finite section, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the local* $\mathsf{Real}^{\uparrow}$ *readback, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then $\mathcal{S}_0$ *and* $\mathcal{S}_1$ *have the same finite support intersection inside the public seal table. Any disagreement in that intersection either deletes one of the displayed rows or introduces a coordinate outside the public table exposed by the seal route.*

The assertion is only about the common finite support of the two displayed routes. It does not identify quotient streams, select limits, assert host real equality, add bridge rows, or invoke ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 126.605. It identifies the public seal inventory as exactly the displayed finite-window rows, dyadic ledger rows, RegSeqRat regularity and classifier rows, local Real readback, and the support rows BHist, hsame, Cont, Pkg, and NameCert.

Next apply Definition 126.606. The hypotheses say that the two routes agree on every row that can appear in the public seal section, so projecting either route to the visible support table gives the same finite section.

Finally apply Definition 126.607. Appending visible rows preserves the section precisely when the displayed window, ledger, classifier, readback, and support rows are preserved. Thus a proposed difference in the support intersection has only two possibilities: it removes a displayed row already fixed by the common section, or it names a coordinate that the no-quotient boundary says is not in the public seal table. □

Theorem 126.609 (StreamName-RegSeqRat-Real public seal support union)**.** *Let* $\mathcal{S}_0$ *and* $\mathcal{S}_1$ *be public* $\mathsf{Real}^{\uparrow}$ *seal routes exported from* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoffs and consumed by* $\mathsf{RegSeqRat}^{\uparrow}$*. Suppose the two routes agree on their finite support intersection in the sense of Definition 126.608. Then their displayed union is again the same finite public seal section exactly*

when the union contains only the $\mathsf{StreamName}^{\uparrow}$ *window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the local* $\mathsf{Real}^{\uparrow}$ *readback rows, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The union row contains no quotient stream equality, selected limit, host real equality, countable choice, metric or ambient completeness coordinate, aggregate formalstatus row, or bridge row.

Proof. First apply Definition 126.608. The two public routes agree on the overlap of their displayed finite supports, so the proposed union has a common boundary along the rows already visible in both sections.

For the forward direction, apply Definition 126.605. A union that is again a public seal section must still factor through the finite-window inventory: StreamName rows, dyadic ledger rows, RegSeqRat regularity and classifier rows, local Real readback rows, and the support rows BHist, hsame, Cont, Pkg, and NameCert. The same boundary excludes quotient streams, selected limits, host real equality, countable choice, completeness coordinates, aggregate formalstatus data, and bridge rows.

For the reverse direction, assume the displayed union contains only those public rows. Apply Definition 126.607 to generate the union by adjoining the visible window rows one at a time. At each adjoining step the overlap condition supplies the fixed intersection, and Definition 126.606 identifies the resulting display as the same finite public seal section.

Thus the finite-cover gluing route has exactly one admissible public union: the union of the displayed StreamName, DyadicRatCore, RegSeqRat, local Real, and support rows. Any extra coordinate would lie outside the no-quotient public boundary, while omitting one of the displayed rows would break the finite-window induction step or the common support intersection. □

126.47 StreamName RegSeqRat Dyadic Real obligation handoff

Theorem 126.610 (StreamName RegSeqRat Dyadic Real obligation handoff)**.** *Let U be an accepted L10 consumer whose four visible faces are a* $\mathsf{StreamName}^{\uparrow}$ *finite window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and a* $\mathsf{Real}^{\uparrow}$ *seal boundary. Then every carrier, classifier, stability, ledger, and non-escape obligation for U factors through those four faces together with the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows. No quotient stream equality, host sequence equality, selected limit, ambient completeness row, metric-completeness datum, or bridge row is exported by this handoff.*

Proof. First use open-phase terminal exactness, Definition 126.419. It places every seal-facing L10 read on the ordered StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal route, with the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply the terminal factorization and boundary theorems, Definition 126.422 and Definition 126.423. They make the four-face route the consumer contract for seal reads and refuse quotient streams, host sequence equality, selected limits, ambient Real completeness, metric-completeness data, and bridge rows as alternate factors.

Now use the DyadicRatCore window handoff supplied by Definition 126.442 and the DyadicRegSeq route factorization of Definition 126.444. These keep the observation ledger and readback row on the same finite StreamName window instead of on a detached host sequence or selected limit.

Finally combine the ledger coverage of Definition 126.420 with the public seal no-quotient boundary of Definition 126.605. The resulting surface is exactly the four visible faces and their displayed support rows, so carrier, classifier, stability, ledger, and non-escape obligations have no remaining source outside that handoff. □

Theorem 126.611 (StreamName RegSeqRat Dyadic Real obligation terminality)**.** *Let U be an accepted L10 consumer whose visible faces are exactly a* $\mathsf{StreamName}^{\uparrow}$ *finite window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and a* $\mathsf{Real}^{\uparrow}$ *seal boundary. Then the carrier, classifier, stability, ledger, and non-escape obligations form the terminal finite* BEDC *interface for that read. Every downstream consumer factors through the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows; and two accepted presentations of the same read are the same whenever those rows agree componentwise. This terminal interface exports no quotient stream equality, host sequence equality, selected limit, ambient completeness row, metric-completeness datum, bridge row, trichotomy row, open-cover compactness row, or choice datum.*

Proof. Begin with the four-face obligation handoff of Definition 126.610. It already places the carrier, classifier, stability, ledger, and non-escape obligations on the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal boundary, supported only by the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

The terminal seal exactness of Definition 126.419 fixes the ordered route through those four faces. The Real-RegSeq factorization of Definition 126.422 and the seal-boundary theorem Definition 126.423 make any accepted downstream consumer read the same finite packet rather than a detached stream, host sequence, limit, completeness assertion, or bridge row.

It remains to exclude an additional source row between the dyadic ledger and the regular-rational readback. Use the window anchor Definition 126.442 together with the Dyadic-RegSeq route factorization Definition 126.444. These results pin every observation and tolerance coordinate to the same finite StreamName window before the RegSeqRat and RealUp consumers can inspect it.

Finally apply the ledger coverage theorem Definition 126.420 and the public seal no-quotient boundary Definition 126.605. Coverage says every public coordinate of the packet is one of the displayed faces or support rows, while the no-quotient boundary excludes quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, and bridge rows as alternate public data.

Trichotomy, open-cover compactness, and choice data are not among the displayed rows and cannot enter through any of the preceding terminal routes. Hence no fifth source row remains: every downstream consumer factors through the listed finite interface, and componentwise agreement of those rows identifies the two accepted consumer presentations. □

Theorem 126.612 (StreamName RegSeqRat Dyadic Real four-face exactness)**.** *An accepted L10 seal-facing read is admissible exactly when its public carrier, classifier, stability, ledger, and non-escape obligations factor through the four displayed faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$*, together with the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. Conversely, any packet with precisely those four faces and no quotient-stream, host-sequence, selected-limit, ambient-completeness, metric-completeness, bridge, trichotomy, open-cover compactness, or choice row supplies the admissible public interface for the same L10 seal-facing read.*

Proof. For the forward direction, start with Definition 126.610. It places the carrier, classifier, stability, ledger, and non-escape obligations on the StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal boundary.

Apply Definition 126.611 and Definition 126.419. These make the same four faces terminal for the accepted read and keep every support coordinate among the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert rows.

It remains to exclude alternate public data. Use Definition 126.605 and Definition 126.444. The first refuses quotient streams, host sequence equality, selected limits, ambient completeness, metric-completeness data, and bridge rows; the second pins the dyadic ledger and regular-rational readback to the same finite StreamName route. Trichotomy, open-cover compactness, and choice rows have no coordinate in that route.

For the reverse direction, suppose a packet displays exactly those four faces and support rows and contains none of the excluded rows. Repack the StreamName, RegSeqRat, DyadicRatCore, and RealUp coordinates through terminality. The no-quotient boundary supplies the non-escape clause, and the route factorization supplies the finite dyadic-readback ledger. The resulting packet is therefore the admissible public interface for the L10 seal-facing read. □

Theorem 126.613 (StreamName L10 four-face exit gate)**.** *An accepted L10 seal-facing read satisfies the current Phase Real and Completion exit gate exactly when its public surface factors through the four displayed faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with displayed* BHist *rows, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. This gate exports no quotient stream, host sequence equality, selected limit, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or choice row.*

Proof. For the forward direction, apply the obligation handoff theorem Definition 126.610. It places every carrier, classifier, stability, ledger, and non-escape obligation on the StreamName finite window, RegSeqRat readback row, DyadicRatCore observation ledger, and RealUp seal boundary, with only the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert support rows.

Next apply terminality, Definition 126.611. Terminality says that every downstream consumer of the same accepted read factors through those rows and that componentwise agreement of the rows identifies accepted presentations. Hence the exit surface has no fifth source row.

The four-face exactness theorem Definition 126.612 supplies the converse direction. Any packet displaying precisely the StreamName, RegSeqRat, DyadicRatCore, and RealUp faces with the listed support rows is the admissible public interface for the same L10 seal-facing read.

Finally combine the exclusion clauses in those three results. Quotient streams, host sequence equality, selected limits, ambient completeness, metric-completeness, bridges, trichotomy, open-cover compactness, and choice rows are not coordinates of the displayed terminal packet. The Lean route names `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectExitRoute` and `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectTerminalPullback` identify the corresponding formalization touchpoints for this four-face route. □

Theorem 126.614 (StreamName L10 four-face exit gate reindex stability)**.** *Let U be an accepted L10 seal-facing read satisfying the four-face exit gate of Definition 126.613. Suppose U is transported along a support-row-preserving public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex route. Then the transported read satisfies the same exit gate over the same visible faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, with the same displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows. The reindexed gate exports no quotient streams, host sequence equality, selected limits, ambient completeness, metric completeness, bridge rows, trichotomy, open-cover compactness, or choice.*

Proof. Start with the original gate, Definition 126.613. It identifies the accepted read with the four visible faces and the displayed BHist, hsame, Cont, Pkg, and local NameCert support rows, and it excludes all non-displayed source rows.

Transport that terminal surface along the certified public reindex route by Definition 126.647. Support-row preservation keeps the finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal on the same public route.

Next apply the pullback statement, Definition 126.648. It says that a reindexed terminal packet whose four faces and support rows agree is read through the same finite four-face surface, not through the shape of the reindexer or a hidden host coordinate.

Finally use the converse admissibility direction of Definition 126.612. Since the transported packet displays exactly the same four faces and the same support rows, it is again an admissible L10 seal-facing read satisfying the exit gate. The exclusion list is preserved because none of quotient streams, host sequence equality, selected limits, ambient completeness, metric completeness, bridge rows, trichotomy, open-cover compactness, or choice is a coordinate of that transported packet. □

Theorem 126.615 (StreamName L10 four-face ordered exit gate)**.** *An accepted Phase Real and Completion seal-facing read satisfies the public L10 exit gate only when its four visible faces are read along the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The $\mathsf{StreamName}^{\uparrow}$ *finite window is read first, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger is anchored to that window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback is read from those anchored rows, and the* $\mathsf{Real}^{\uparrow}$ *seal is read last. Merely listing the four faces does not satisfy the gate if the route permutes them, detaches the dyadic ledger from the StreamName window, reads the RegSeqRat row before the ledger, or bypasses directly to the RealUp seal. The ordered gate exports no quotient stream, host sequence equality, selected limit, choice row, metric-completeness row, bridge row, or ambient Real-completeness row.*

Proof. First apply the four-face exit gate, Definition 126.613. It identifies the accepted seal-facing public surface with the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and with the displayed BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows.

Next read the gateway order from Definition 126.488. In that gateway the finite source is consumed as $S \longrightarrow D \longrightarrow R \longrightarrow E$: the StreamName finite window precedes the DyadicRatCore ledger, the RegSeqRat readback is available only from the paired window-and-ledger route, and the RealUp seal is available only after that readback.

Apply terminality, Definition 126.487. Since every terminal Real-completion route factors through the same four-face packet and support rows, a consumer cannot satisfy the public gate by permuting the faces, skipping the dyadic ledger, detaching the RegSeqRat row from the anchored ledger, or jumping directly from the StreamName window to the RealUp seal.

Finally use the reindex stability theorem, Definition 126.614. It preserves the same displayed faces and support rows under support-row-preserving public reindexing, so the order-sensitive gate is stable under finite-window transport while retaining the exclusions of quotient streams, host sequence equality, selected limits, choice, metric completeness, bridges, and ambient Real completeness. □

Theorem 126.616 (StreamName L10 ordered exit composition determinacy)**.** *Let U and V be accepted Phase Real and Completion seal-facing reads whose public surfaces both satisfy the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume that the two-step read $U \to V$ and a certified composite route both preserve the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support rows. Then the two-step read and the certified composite expose the same terminal* $\mathsf{Real}^{\uparrow}$ *seal surface exactly when they agree*

on the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. This determinacy exports no quotient stream, selected limit, choice datum, metric-completeness row, bridge row, or ambient Real-completeness row.*

Proof. For the forward direction, apply the four-face exit gate Definition 126.613. It identifies each accepted public surface with the same four visible faces and with only the displayed BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows.

Next use reindex stability, Definition 126.614. The two-step read and the certified composite preserve the support rows by hypothesis, so transporting along either route keeps the same finite StreamName window, DyadicRatCore tolerance ledger, RegSeqRat readback row, and RealUp seal row.

Now apply the ordered exit gate, Definition 126.615. Since both routes read the faces in the order $\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$, the terminal Real seal is reached only after the same anchored ledger and readback rows. Agreement on those four rows therefore forces the two terminal seal exposures to coincide.

For the reverse direction, suppose the two-step read and the certified composite expose the same terminal $\mathsf{Real}^{\uparrow}$ seal surface through the ordered route and preserved support rows. Terminality in the four-face gate leaves no fifth coordinate from which they could differ, so any disagreement must already appear on the StreamName window, DyadicRatCore ledger, RegSeqRat readback, or RealUp seal row. Hence equality of the terminal exposure is equivalent to componentwise agreement on those four rows.

The exclusion clauses are inherited from the three gate theorems just used. Quotient streams, selected limits, choice data, metric-completeness rows, bridge rows, and ambient Real-completeness rows are not coordinates of either accepted ordered route, so they cannot witness a distinct composite exit surface. □

Theorem 126.617 (StreamName L10 ordered exit face-status readback)**.** *Let U be an accepted Phase Real and Completion seal-facing read whose public surface satisfies the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then every seal-facing read of closure-status, formal-status, Lean-target, and bridge-status data for U is facewise: the StreamName entry is read from the $\mathsf{StreamName}^{\uparrow}$ *chapter face, the dyadic ledger entry from the* $\mathsf{DyadicRatCore}^{\uparrow}$ *chapter face, the regular-rational readback entry from the* $\mathsf{RegSeqRat}^{\uparrow}$ *chapter face, and the terminal seal entry from the* $\mathsf{Real}^{\uparrow}$ *chapter face. The ordered route creates no route-level closure-status row, formal-status row, Lean target, bridge row, quotient stream, selected limit, choice datum, metric-completeness row, or ambient Real-completeness claim.*

Proof. Apply the ordered exit gate, Definition 126.615. It fixes the only admissible read order as $\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ and places the public exit surface on those four visible faces with their displayed BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows.

Next apply ordered composition determinacy, Definition 126.616. If two accepted seal-facing reads preserve those support rows, their terminal exposure is determined exactly by agreement on the four face rows. Hence a status reader cannot obtain an additional row from the route composite itself; any such row would distinguish two composites with identical face data.

It remains to identify the status sources. Use Definition 126.507, Definition 291.112, Definition 38.833, and Definition 38.834, together with the terminal pullback formalization touchpoint `BEDC.Derived.StreamNameUp.StreamNameRealCompletionFourObjectTerminalPullback`. They

keep closure-status, formal-status, Lean-target, and bridge-status reads attached to the object faces that expose them, rather than to the ordered path between the faces.

The exclusion list follows from the same gate and determinacy results. Quotient streams, selected limits, choice data, metric-completeness rows, bridge rows, route-level Lean targets, and ambient Real-completeness claims are not coordinates of the four-face packet, so the ordered route supplies no credential beyond the four facewise chapter reads. □

Theorem 126.618 (StreamName L10 four-face terminal coherence)**.** *Let U be an accepted Phase Real and Completion seal-facing read whose public surface follows the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the terminal public credential for U is exactly the componentwise agreement of the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row, together with the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows. No route-level closure-status row, formal-status row, Lean target, bridge row, quotient stream, selected limit, choice datum, metric-completeness row, or ambient Real-completeness claim is a fifth coordinate of that credential.*

Proof. First apply the four-face exit gate, Definition 126.613. It identifies the admissible public surface with the four visible object faces and with only the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert support rows.

Next use reindex stability, Definition 126.614. Any support-row-preserving finite-window transport preserves the same four object faces and the same support rows, so terminal agreement cannot depend on the presentation of the public route.

Apply the ordered exit gate, Definition 126.615. The order

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

forces the tolerance ledger to be anchored to the StreamName finite window, the RegSeqRat readback to be read from the anchored rows, and the RealUp seal to be read last.

Now apply ordered composition determinacy, Definition 126.616. It makes equality of the terminal seal exposure equivalent to componentwise agreement on the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback row, and RealUp seal row, with the displayed support rows preserved.

Finally use face-status readback, Definition 126.617. Closure-status, formal-status, Lean-target, and bridge-status data remain attached to the four object faces rather than to the route composite, while quotient streams, selected limits, choice data, metric-completeness rows, and ambient Real-completeness claims are excluded by the same status-axis noncollapse. Hence the four object faces are jointly exact, and no route-level credential supplies a fifth coordinate. □

Theorem 126.619 (StreamName L10 ordered exit common-refinement naturality)**.** *Let U and V be accepted Phase Real and Completion seal-facing reads whose public surfaces follow the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume that U and V admit a support-row-preserving common finite-window refinement W. Thus the transports from U to W and from V to W preserve the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support. Then the transported terminal public credentials of U and V over W agree if and only if the two transported reads agree on the four face rows over W: the*

$\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. This comparison exports no quotient stream, selected limit, choice datum, metric-completeness row, route-level formal-status row, route-level Lean target, route-level bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First transport both accepted reads to the common finite-window refinement. Apply reindex stability, Definition 126.614, separately to the $U \to W$ and $V \to W$ transports. The support-row-preserving hypothesis keeps the same displayed BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support, so both transported reads still present only the four object faces over W.

For the forward direction, suppose the transported terminal public credentials agree over W. Apply ordered exit composition determinacy, Definition 126.616, to the two transported ordered routes. Since the terminal exposure has no coordinate other than the ordered four-face packet and the displayed support rows, equality of the terminal credential forces agreement of the $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and $\mathsf{Real}^{\uparrow}$ seal row over the common refinement.

For the reverse direction, assume those four transported face rows agree over W. Apply Definition 126.616 again to identify the terminal exposure from the componentwise four-face data. Then use terminal coherence, Definition 126.618, to repack that componentwise agreement as equality of the transported terminal public credentials.

It remains to keep the status and bridge data from becoming an additional comparison coordinate. Use face-status readback, Definition 126.617. Closure-status, formal-status, Lean-target, and bridge-status entries remain facewise along the ordered route, so the common refinement compares only the four object rows and their displayed support.

The exclusion clauses follow from the same three inputs. Quotient streams, selected limits, choice data, metric-completeness rows, route-level formal-status rows, route-level Lean targets, route-level bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not produced by the support-row-preserving transports and are not fifth coordinates of the terminal credential. □

Theorem 126.620 (StreamName L10 ordered exit zigzag confluence)**.** *Let $U_0, \ldots, U_n$ be a finite zigzag of accepted Phase Real and Completion seal-facing reads, each of whose public surfaces follows the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume that every adjacent edge between U_i and U_{i+1} is witnessed by a support-row-preserving common finite-window refinement, preserving the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support. Then the endpoints U_0 and U_n expose the same terminal public credential along the zigzag if and only if every adjacent comparison agrees on the four face rows: the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row, over the displayed support. The zigzag comparison exports no quotient stream, selected limit, countable choice datum, metric-completeness datum, aggregate formal-status row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Proceed by induction on the finite zigzag. The empty and one-node cases are immediate from terminal coherence, Definition 126.618, since there is no adjacent comparison and the terminal credential is exactly the four-face packet with its displayed support.

For the induction step, split the zigzag as an initial finite zigzag from U_0 to U_k followed by one adjacent common-refinement edge from U_k to U_{k+1}. Apply the induction hypothesis to the initial zigzag. This identifies endpoint agreement from U_0 to U_k with agreement on all adjacent four-face rows in that initial segment.

Now apply common-refinement naturality, Definition 126.619, to the final edge between U_k and U_{k+1}. It identifies agreement of the transported terminal credentials on that edge with agreement of the StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback row, and RealUp seal row over the common finite-window refinement.

For the forward direction, endpoint equality across the whole zigzag restricts to the initial endpoint comparison and to the final adjacent edge. The induction hypothesis gives the four-face agreements in the initial segment, while common-refinement naturality gives the four-face agreement on the last edge.

For the reverse direction, assume every adjacent comparison agrees on the four face rows. The induction hypothesis gives terminal credential equality from U_0 to U_k, and common-refinement naturality gives terminal credential equality from U_k to U_{k+1}. Compose these equalities using ordered exit composition determinacy, Definition 126.616, and repack the componentwise data by terminal coherence, Definition 126.618.

Finally apply face-status readback, Definition 126.617. Status and bridge reads remain attached to the four object faces at every node and every adjacent refinement, so the finite zigzag creates no aggregate formal-status row, aggregate bridge row, or standard bridge row. Quotient streams, selected limits, countable choice data, metric-completeness data, and ambient $\mathsf{Real}^{\uparrow}$ completeness are likewise absent from the ordered route and therefore cannot become confluence coordinates. □

Theorem 126.621 (StreamName L10 ordered exit zigzag terminality)**.** *Let $U_0, \ldots, U_n$ be a finite zigzag of accepted Phase Real and Completion seal-facing reads, each of whose public surfaces follows the ordered route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume that every adjacent edge between U_i and U_{i+1} is witnessed by a support-row-preserving common finite-window refinement, and that every adjacent comparison agrees on the four face rows: the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. Then the whole zigzag determines a unique terminal public credential, namely the credential determined exactly by the common StreamName finite window, DyadicRatCore tolerance ledger, RegSeqRat readback row, RealUp seal row, displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support. This terminal packet contains no quotient stream, selected limit, countable choice datum, metric-completeness datum, aggregate formal-status row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Induct on the finite zigzag. In the empty and one-node cases, terminal coherence, Definition 126.618, identifies the only public credential with the displayed four-face packet and its support rows.

For the induction step, split the zigzag as an initial zigzag from U_0 to U_k followed by one adjacent edge from U_k to U_{k+1}. Apply the induction hypothesis to obtain the unique terminal credential for the initial zigzag. Apply common-refinement naturality, Definition 126.619, to the final edge, so the final adjacent four-face agreement transports the same credential across the common finite-window refinement.

Next use zigzag confluence, Definition 126.620. It upgrades adjacent agreement on the four face rows to endpoint agreement for the whole finite zigzag, so there is only one candidate terminal public credential compatible with all adjacent refinements.

Finally apply terminal coherence and face-status readback, Definition 126.618 and Definition 126.617. Terminal coherence identifies the unique credential with the common StreamName

finite window, DyadicRatCore tolerance ledger, RegSeqRat readback row, RealUp seal row, displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert support. Face-status readback keeps status and bridge data attached to the four object faces, so quotient streams, selected limits, countable choice data, metric-completeness data, aggregate formal-status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness cannot become extra terminal coordinates. □

126.48 StreamName terminal window fusion

Theorem 126.622 (StreamName Real-completion terminal-window fusion)**.** *Every accepted Phase Real and Completion read through*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

is determined by the fused terminal window consisting of the StreamName finite request window, the $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Equivalently, two accepted reads with the same fused terminal window have the same public classifier surface and the same terminal factorization through the four Real and Completion exit faces.

The fused packet exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. Begin with the four-object exit route of Definition 126.500. It identifies every accepted current read with the four displayed faces and with only the BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply the terminal pullback and terminal exactness results, Definition 126.504 and Definition 126.505. These results say that agreement on the StreamName finite request window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the RealUp seal, and the displayed support rows is precisely the terminal boundary for public acceptance.

Now transport this terminal boundary to the classifier surface. Use Definition 126.514: once the fused terminal window agrees componentwise, the public classifier has no second coordinate on which to distinguish the two reads.

It remains to bind the dependency and handoff rows. The dependency exactness theorem Definition 126.518 names the same four faces as necessary and sufficient, while Definition 126.519 reads the StreamName finite-window handoff, DyadicRatCore ledger handoff, and RegSeqRat-to-Real seal as route witnesses for those existing rows.

Finally apply the no-choice route factorization, Definition 126.522. It removes every attempted selector, quotient, completeness, metric, choice, or bridge coordinate from the packet. Therefore the fused terminal window determines the accepted Phase Real and Completion read exactly through the four displayed exit faces and the five displayed support rows. □

Theorem 126.623 (StreamName terminal fusion common-refinement stability)**.** *Let* $\mathcal{W}_L$ *and* $\mathcal{W}_R$ *be accepted Phase Real and Completion reads whose* $\mathsf{StreamName}^{\uparrow}$ *finite windows admit a certified common refinement* $\mathcal{R}$*. Suppose the refinement transports the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the same* $\mathsf{Real}^{\uparrow}$ *seal, and the same displayed support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the fused terminal-window packet read through $\mathcal{W}_L$ is the same packet read through $\mathcal{W}_R$. In particular the public classifier surface is unchanged by passing to $\mathcal{R}$ and restricting back to either selected window.

The stability statement adds no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. First read the common refinement at the StreamName boundary. Apply Definition 126.308 and Definition 126.234. The refinement $\mathcal{R}$ supplies one finite-window classifier, one ProbeBundle row, the same InBundle membership rows, the same selected histories, and the same displayed hsame/Cont/Pkg ledger rows for both selected windows.

Next pass from the source tuple to the Real and Completion exit packet. Use Definition 126.240: every downstream RegSeqRat handoff and every finite-window $\mathsf{Real}^{\uparrow}$ handoff read from $\mathcal{R}$ factors through that common source tuple. The hypotheses identify the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal, and local NameCert rows as the same transported data on the two restrictions.

Now apply the terminal pullback theorem Definition 126.504. Since the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ and the displayed support rows agree after transport along $\mathcal{R}$, the two accepted reads determine the same terminal finite BEDC pullback. The terminal-window fusion theorem Definition 126.622 repacks this pullback as one fused terminal-window packet.

Finally transport the equality of terminal packets to the public classifier surface by Definition 126.514. The no-choice route factorization Definition 126.522 removes every selector, quotient, completeness, metric, choice, and bridge coordinate, so a common refinement cannot create a second public presentation of the same terminal route. □

Theorem 126.624 (StreamName terminal fusion common-tail Real boundary pullback)**.** *Let $\mathcal{W}$ be an accepted Phase Real and Completion read, and let its fused terminal window be transported through a* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail window packet with common refinement W_*. The transported fused terminal packet determines exactly the same public* $\mathsf{Real}^{\uparrow}$ *seal boundary as the common-tail Real boundary equivalence of Definition 301.186.*

Equivalently, two such transported reads have the same public classifier surface if and only if they agree on the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, and the displayed rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

No quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row is part of this pullback boundary.*

Proof. First use Definition 126.623. The common refinement makes the selected $\mathsf{StreamName}^{\uparrow}$ finite windows one fused terminal packet after the shared $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback rows, the $\mathsf{Real}^{\uparrow}$ seal, and the displayed support rows have been transported through W_*.

Next apply Definition 301.186. The common-tail packet and the finite-request $\mathsf{Real}^{\uparrow}$ seal boundary determine one another exactly on the StreamName schedule and refinement rows, the dyadic endpoint-radius-distance ledger, the RegSeqRat classifier and regularity rows, the Real seal-source rows, and the displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Now compare this boundary with the four-face public interface. By Definition 38.775, those same finite rows form the public pullback surface over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Thus the common-tail presentation cannot add or remove a public row from the fused terminal presentation.

Finally transport the shared four-face surface to the public classifier by Definition 126.514. Agreement on the displayed rows is therefore sufficient for public classifier agreement, and any public classifier agreement reads back to the same displayed rows through the common-tail Real boundary equivalence. The no-choice factorization of Definition 126.522 excludes selectors, quotient stream equality, host sequence equality, chosen limits, completeness, metric-completeness data, countable choice, and bridge rows from serving as another boundary coordinate. □

Theorem 126.625 (StreamName terminal fusion finite-request section exactness)**.** *Let $\mathcal{W}$ be an accepted fused terminal-window packet for the* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$ *route, and view its terminal request as a finite-request section. Then the displayed rows of $\mathcal{W}$ are exactly the finite-request section pullback rows: the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Conversely, any finite-request section carrying precisely those displayed rows determines the same fused terminal-window packet on the public terminal four-face route.

This identification exports no quotient stream equality, no host sequence equality, no selected limit, no ambient completeness row, no metric-completeness data, no countable-choice row, and no bridge row.

Proof. For the forward direction, first read $\mathcal{W}$ through Definition 126.622. The fused terminal packet is exhausted by the finite StreamName window, the DyadicRatCore ledger, the RegSeqRat readback, the Real seal, and the displayed $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ support rows.

Next view the same request as a finite-request section and apply Definition 126.577. This identifies the section with the same StreamName finite schedule, DyadicRatCore endpoint, radius, and distance ledger, RegSeqRat classifier and regularity/readback rows, Real seal-source rows, and support provenance.

For the reverse direction, start with a finite-request section carrying those rows. Apply Definition 126.579 to recover the public carrier and classifier verdict on the terminal four-face route. Then apply Definition 126.624 to repack the same row family as the common-tail Real boundary of one fused terminal packet.

Finally use Definition 126.584. It removes quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, countable choice, and bridge rows from the section surface. Hence the finite-request section and the fused terminal-window packet are interchangeable exactly on the displayed BEDC-visible L10 rows. □

Theorem 126.626 (StreamName terminal fusion source exhaustion)**.** *Every accepted current Phase Real and Completion read whose terminal request is presented as a fused* $\mathsf{StreamName}^{\uparrow}$ *window factors through exactly the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and exactly the support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Conversely, a terminal request carrying those four faces and those five support rows determines the same public finite-request section as the fused terminal window presentation.

The source-exhaustion statement exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness data, no countable-choice row, and no bridge row.*

Proof. First apply Definition 126.622. It identifies an accepted current read with the fused terminal packet over the StreamName finite request window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the Real seal, and the displayed support rows.

Next apply Definition 126.625. The finite-request section exposes exactly the same four faces and exactly the same BHist/hsame/Cont/Pkg/NameCert support rows, and no further public row is available on the section surface.

For the reverse direction, start with a terminal request carrying the displayed faces and support rows. Use Definition 126.624 to read those rows as the common-tail $\mathsf{Real}^{\uparrow}$ boundary of the fused terminal presentation, and then read the resulting packet back through finite-request section exactness.

Finally apply Definition 126.522. Quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, countable choice, and bridge rows have no coordinate in the route, so the four displayed faces and the five support rows exhaust the accepted current source. □

Theorem 126.627 (StreamName terminal-window fusion reindexing compatibility)**.** *Let* $\mathcal{W}_0$ *and* $\mathcal{W}_1$ *be accepted Phase Real and Completion terminal-window packets. Suppose they differ only by a certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex route, and suppose that route transports componentwise the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows, and the public endpoint rows. Then* $\mathcal{W}_0$ *and* $\mathcal{W}_1$ *determine the same fused terminal-window packet and the same public four-face route through*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Conversely, any fused terminal-window packet transported by the certified identity reindexer or by a composable certified reindexer reads back to the same public finite observation section. The compatibility claim introduces no quotient stream equality, host sequence equality, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, or standard bridge row.*

Proof. First identify the finite public section. Apply Definition 126.639 to the two displayed $\mathsf{StreamName}^{\uparrow}$ finite-window packets. The certified reindex route supplies the hsame-compatible map, the common endpoint rows, and the componentwise transport of the displayed BHist, Cont, Pkg, and NameCert rows, so both packets expose one public finite observation section.

Next carry that section to the terminal L10 route. Use Definition 126.642. The transported finite section presents the same $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal as the terminal Phase Real and Completion route.

Now repack the transported rows as a fused terminal packet. Apply Definition 126.622 to read the common four-face route as one fused terminal-window packet, and apply Definition 126.626 to see that no source coordinate remains beyond the four faces and the displayed BHist/hsame/Cont/Pkg/NameCert support rows.

For the converse, read an identity-reindexed or composably reindexed fused packet through the same terminal coverage theorem. Identity and composable certified reindexers return the same

finite observation section before fusion, and the fusion and source-exhaustion theorems repack exactly that section as the same public terminal route.

The exclusions follow because every step is confined to the displayed finite-window route, the transported tolerance ledger, the readback rows, the seal row, and the named support rows. None of the cited results exports quotient stream equality, host sequence equality, selected limits, countable-choice data, ambient completeness, metric-completeness data, or a standard bridge row. □

Theorem 126.628 (StreamName terminal fusion finite-cover cocycle exactness)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows. Suppose the pairwise windows $\mathcal{W}_{ij}$ and triple windows $\mathcal{W}_{ijk}$ carry the pasted-source hypotheses for finite StreamName–*$\mathsf{RegSeqRat}^{\uparrow}$ *covers, each local terminal fused packet transports through a* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail packet, and every local handoff row consumes the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger together with the same* $\mathsf{Real}^{\uparrow}$ *seal-source row.*

Then the family pastes to one terminal fused packet exactly when the pairwise restrictions expose the same common-tail Real boundary. The pasted packet has precisely the visible rows

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

where the $\mathsf{StreamName}^{\uparrow}$ *rows are the given finite windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows are the endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *rows are the common-tail classifier and regularity rows, and the* $\mathsf{Real}^{\uparrow}$ *row is the seal-source row. Its only support provenance is*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The exactness claim exports no quotient stream equality, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no countable-choice row, and no standard bridge row.*

Proof. First build the finite StreamName source surface. Apply Definition 126.551 to the certified windows and their pairwise and triple overlap data. This produces one pasted finite source whose support rows remain the displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Next transport every local fused packet through the common-tail boundary. By Definition 301.186, the $\mathsf{RegSeqRat}^{\uparrow}$ common-tail classifier and regularity rows expose exactly the same Real seal-source boundary as the dyadic endpoint, radius, and distance ledger carried by the local handoff rows.

Now apply Definition 38.774. The common-tail Real boundary is therefore the cocycle condition for pasting the local $\mathsf{Real}^{\uparrow}$ seal-source rows across the finite cover, and the shared $\mathsf{DyadicRatCore}^{\uparrow}$ ledger prevents a second radius or distance coordinate from entering the seal.

Finally use Definition 126.624. It identifies agreement of the pairwise common-tail Real boundaries with agreement of the terminal fused StreamName packet on the four visible faces and the five support rows. Hence the local terminal fused packets paste to one terminal fused packet exactly in the stated case, while quotient stream equality, host sequence equality, chosen limits, completeness, metric-completeness data, countable choice, and bridge rows remain outside the boundary. □

Theorem 126.629 (StreamName terminal fusion cocycle section descent)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows satisfying the pasted-source hypotheses of Definition 126.628. Assume each local fused terminal packet is carried through the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and regularity rows, and the same* $\mathsf{Real}^{\uparrow}$ *seal-source row. Then pairwise common-tail* $\mathsf{Real}^{\uparrow}$ *boundary agreement is equivalent to descent of the local fused terminal packets to one finite-request section.*

The descended section has exactly the visible rows consisting of the $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source row, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

It exports no quotient stream equality, no host sequence equality, no selected limit, no countable-choice row, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, and no standard bridge row.*

Proof. For the descent direction, apply Definition 126.628. The pairwise common-tail $\mathsf{Real}^{\uparrow}$ boundary agreement is exactly the cocycle condition for the certified local terminal packets to paste to one fused terminal packet over the finite family.

Next read the pasted terminal packet as a finite request. Use Definition 126.577. The pullback exposes precisely the StreamName windows, the DyadicRatCore endpoint-radius-distance ledger, the RegSeqRat classifier and regularity rows, the Real seal-source row, and the displayed $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ support rows. Thus the pasted packet descends to one finite-request section with no further public coordinate.

For the reverse direction, start with such a finite-request section. The section pullback gives the same displayed rows on every local window, and Definition 301.186 identifies those rows with the common-tail $\mathsf{Real}^{\uparrow}$ boundary read by the RegSeqRat classifier and regularity data.

Finally apply Definition 38.774 and then Definition 126.624. The first theorem reads the shared boundary as the finite-cover seal pasting criterion, while the second reads it back as agreement of the local fused StreamName terminal packets on exactly the visible rows and the five support rows. The excluded quotient, host-sequence, selected-limit, choice, completeness, metric-completeness, and bridge rows therefore cannot be part of the descent datum. □

Theorem 126.630 (StreamName terminal fusion refinement invariance)**.** *Let* $\{\mathcal{W}_i\}_{i\in I}$ *be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows satisfying the hypotheses of Definition 126.629. Suppose* $\{\mathcal{R}_a\}_{a\in A}$ *is a certified finite refinement of that family whose restrictions preserve the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and regularity rows, the same* $\mathsf{Real}^{\uparrow}$ *seal-source row, and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the finite-request section descended from the refined family is the same section descended from the original family. Consequently the public terminal fused packet over the four faces

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

is unchanged by passing to the certified refinement and restricting back to the original cover.

The invariant packet exports no quotient stream equality, no host sequence equality, no selected limit, no countable-choice row, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, and no standard bridge row.*

Proof. First compare each original window with its refined restrictions. Apply Definition 126.623. The preserved endpoint-radius-distance ledger, common-tail classifier and regularity rows, seal-source row, and displayed support rows make every restriction read the same terminal fused packet as the original window from which it is certified.

Next verify the cocycle on the refined cover. Use Definition 301.190 to identify the triple-overlap RegSeqRat common-tail rows, and then apply Definition 126.628. The pairwise common-tail $\mathsf{Real}^{\uparrow}$

boundary condition for the refined windows is therefore the same finite-cover cocycle condition as for the original family.

Now descend both finite covers. By Definition 126.629, the original family and the certified refinement each produce one finite-request section carrying exactly the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Finally restrict the refined section back along the refinement maps. The common-refinement stability already identifies every restricted local terminal packet with its original local packet, while the finite-cover cocycle exactness identifies the pasted packet by precisely those rows. Hence the two descended sections are the same finite-request section, and the public terminal fused packet is invariant under the certified refinement. Since all steps read only the visible four faces and the five support rows, quotient stream equality, host sequence equality, selected limits, choice, completeness, metric-completeness data, and bridge rows remain outside the interface. □

Theorem 126.631 (StreamName terminal fusion phase-exit consumer readback)**.** *Let $\mathcal{W}$ be an accepted fused StreamName terminal-window packet over*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

with support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

If a same-route RealCompletionExactBoundaryUp *face is supplied for the four roadmap faces of $\mathcal{W}$, then $\mathcal{W}$ determines the same five-face consumer readback as an accepted* $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer: the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* RealCompletionExactBoundaryUp *local records, together with the supporting* BHist*, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{PhaseRealCompletionExit}^{\uparrow}}$ *rows.*

Conversely, any accepted $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer displaying precisely those five local records and those support rows restricts along the four roadmap faces to the fused StreamName finite-window packet carried by $\mathcal{W}$.*

The comparison exports no quotient stream equality, no selected limit, no host completeness row, no countable-choice row, no metric-completeness row, no aggregate formalstatus row, no bridge token, and no fused completion witness.

Proof. For the forward direction, first apply Definition 126.626. It reads the accepted fused terminal-window packet through exactly the four roadmap faces and the displayed BHist/hsame/Cont/Pkg/NameCe support rows.

Next apply Definition 126.625. The same row family is the finite-request section surface, so supplying RealCompletionExactBoundaryUp on that same finite route adds the fifth local face without changing the four-face StreamName packet.

Finally apply Definition 1327.24. Its consumer theorem reads exactly the five local records and the same support rows, with the exact-boundary face constrained to the four roadmap faces. Thus the fused terminal packet determines the phase-exit consumer readback.

For the reverse direction, start with an accepted $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ consumer displaying those five local records. The facewise readback theorem identifies the first four records as the dyadic, stream, regular-rational, and real faces on the same finite route as the exact-boundary face.

Discard the exact-boundary face and keep the displayed support rows. By source exhaustion and finite-request section exactness, those four roadmap faces and support rows are precisely the fused StreamName finite-window packet. The excluded quotient, selected-limit, host-completeness,

choice, metric-completeness, aggregate-status, bridge, and fused-witness rows therefore cannot supply another consumer coordinate. □

Theorem 126.632 (StreamName terminal fusion phase-exit refinement readback invariance)**.** *Let* $\{\mathcal{W}_i\}_{i\in I}$ *be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows satisfying the hypotheses of Definition 126.629, and let* $\{\mathcal{R}_a\}_{a\in A}$ *be a certified finite refinement preserving the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and regularity rows, the same* $\mathsf{Real}^{\uparrow}$ *seal-source row, and the same support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Assume moreover that the original descended packet and the refined descended packet are supplied with a same-route $\mathsf{RealCompletionExactBoundaryUp}$ *face for their four roadmap faces. Then the accepted* $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer readback obtained from the refined fused terminal packet is the same five-face readback as the one obtained from the original fused terminal packet: the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{RealCompletionExactBoundaryUp}$ *local records, together with the supporting* BHist, *componentwise* hsame, *displayed* Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{PhaseRealCompletionExit}^{\uparrow}}$ *rows.*

The comparison exports no quotient stream equality, no host sequence equality, no selected limit, no countable-choice row, no ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, no metric-completeness datum, no aggregate formalstatus row, no bridge token, and no fused completion witness.*

Proof. First apply Definition 126.630. The certified refinement preserves exactly the endpoint-radius-distance ledger, common-tail classifier and regularity rows, seal-source row, and displayed support rows used by the descent theorem. Hence the original cover and the refined cover descend to the same finite-request section and to the same public fused terminal packet over the four faces.

Next read the original presentation as a phase-exit consumer. Apply Definition 126.631 to the original fused packet and its same-route $\mathsf{RealCompletionExactBoundaryUp}$ face. The theorem returns precisely the five local records and the displayed $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}_{\mathsf{PhaseRealCompletionExit}^{\uparrow}}$ support rows.

Apply the same consumer-readback theorem to the refined presentation. The first step identifies the refined four-face fused packet with the original four-face fused packet, and the hypothesis supplies the same-route $\mathsf{RealCompletionExactBoundaryUp}$ face. Therefore the refined presentation reads back the same five local records and the same support rows.

The no-quotient, no-choice, no-host-completeness, no-metric-completeness, no-aggregate-status, no-bridge, and no-fused-witness exclusions are inherited from the refinement-invariance and phase-exit consumer-readback theorems. Since both applications use only the visible four roadmap faces, the exact boundary face on that route, and the five displayed support rows, no additional consumer coordinate is available. □

Theorem 126.633 (StreamName terminal fusion universal consumer normal form)**.** *Let* $\mathcal{W}$ *be an accepted terminal fused StreamName packet supplied with a same-route* $\mathsf{RealCompletionExactBoundaryUp}$ *face, so that it is readable as an accepted terminal* $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer. Every downstream consumer of this terminal Phase Real and Completion packet that preserves BEDC-visible public rows factors through the four roadmap faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

on that route, the same-route $\mathsf{RealCompletionExactBoundaryUp}$ *face, and the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Equivalently, once the four roadmap faces, the exact-boundary face on that route, and the displayed support rows are fixed, the consumer readback is in normal form: two presentations with the same displayed rows give the same downstream consumer readback.

This normal form exports no quotient stream equality, no host sequence equality, no selected limit, no ambient completeness row, no metric-completeness datum, no countable-choice row, no bridge token, no aggregate formalstatus row, and no fused completion witness.

Proof. First reduce the terminal packet to its source rows. By Definition 126.626, an accepted terminal fused StreamName packet is exhausted by the four roadmap faces and the displayed BHist/hsame/Cont/Pkg/NameCert support rows. Thus a BEDC-visible downstream consumer cannot read an additional StreamName-side coordinate before the phase-exit face is attached.

Next attach the same-route exact-boundary face and read the result as a phase-exit consumer. Apply Definition 126.631. The consumer readback consists of the four roadmap records, the RealCompletionExactBoundaryUp face constrained to that route, and the same support rows; the excluded quotient, limit, choice, completeness, aggregate status, bridge, and fused-witness rows are not part of the exported interface.

It remains to check independence from presentation. If two terminal presentations display the same four roadmap faces, the same exact-boundary face on that route, and the same support rows, then apply Definition 126.632 to any certified common refinement between them. The refined and original presentations give the same five-face phase-exit consumer readback, hence the same downstream readback for every row-preserving consumer.

Finally identify the roadmap substrate. By Definition 126.613, the only roadmap faces available to the terminal route are $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. The four-face route supplies the roadmap substrate, while the phase-exit consumer readback retains the RealCompletionExactBoundaryUp face as a constrained fifth local record. Combining that gate with source exhaustion, phase-exit readback, and refinement readback invariance gives the stated universal normal form. □

Theorem 126.634 (StreamName terminal fusion universal consumer reflection)**.** *Let $\mathcal{W}$ and $\mathcal{W}'$ be accepted terminal fused StreamName packets whose four roadmap faces are supplied with same-route* RealCompletionExactBoundaryUp *faces, and suppose their row-preserving terminal* $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer readbacks agree. Then the displayed terminal rows of the two packets agree: the four roadmap faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},$$

the same-route RealCompletionExactBoundaryUp *face, and the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

are the same on both terminal presentations.

Thus consumer equivalence for accepted terminal fused StreamName packets is reflected exactly by the BEDC-visible four-face terminal surface and its exact-boundary support. Quotient stream equality, selected limits, host sequence equality, ambient completeness, metric-completeness, countable choice, aggregate formalstatus, bridge token, and fused completion witness cannot witness consumer equality.

Proof. First put each terminal packet in universal consumer normal form. Apply Definition 126.633 to $\mathcal{W}$ and to $\mathcal{W}'$. Every row-preserving terminal consumer of either packet factors through its four roadmap faces, same-route RealCompletionExactBoundaryUp face, and displayed BHist/hsame/Cont/Pkg/NameCert rows.

Next read both normal forms through the phase-exit interface. By Definition 126.631, the terminal $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ consumer readback is exactly the five local faces together with the displayed support rows. Since the two consumer readbacks agree by hypothesis, the five local records and support rows named by that theorem agree.

It remains to rule out hidden witnesses. Source exhaustion, Definition 126.626, identifies the StreamName terminal packet before the exact-boundary attachment with only the four roadmap faces and the displayed support rows.

Finally apply the no-choice route factorization, Definition 126.522. It removes quotient stream equality, selected limits, host sequence equality, ambient completeness, metric-completeness, countable choice, aggregate formalstatus, bridge token, and fused completion witness from the terminal route. Therefore no excluded coordinate can account for the common consumer readback, and the agreement reflects back exactly to the displayed terminal rows. □

Theorem 126.635 (StreamName terminal fusion four-face exit status equivalence)**.** *Let $\mathcal{W}$ and $\mathcal{W}'$ be accepted terminal fused StreamName packets whose four roadmap faces are supplied with same-route* $\mathsf{RealCompletionExactBoundaryUp}$ *faces. Row-preserving terminal* $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer equivalence between $\mathcal{W}$ and $\mathcal{W}'$ holds if and only if their terminal presentations agree on the four roadmap faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},$$

on the same-route exact-boundary face, and on the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Thus the terminal exit status for the four-object Real-completion route is exactly the equality class of these BEDC-visible rows.

The equivalence has no further coordinates: aggregate formalstatus, bridge token, quotient stream equality, selected limits, host sequence equality, ambient completeness, metric completeness, countable choice, and fused completion witnesses are not part of the exit-status comparison.

Proof. Assume first that the displayed terminal rows agree. Put each packet in normal form by Definition 126.633. Since the two packets have the same four roadmap faces, the same same-route $\mathsf{RealCompletionExactBoundaryUp}$ face, and the same $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ support rows, the normal forms determine the same row-preserving terminal $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ consumer readback.

For the reverse direction, assume that the row-preserving terminal consumer readbacks agree. Apply Definition 126.634. The reflection theorem reads the common consumer back to equality of the four roadmap faces, the same-route exact-boundary face, and the displayed support rows.

It remains to identify the allowed surface. Source exhaustion, Definition 126.626, says that the accepted terminal fused StreamName packet supplies no StreamName-side coordinate beyond the four roadmap faces and the displayed $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ rows. The four-face exit gate, Definition 126.613, fixes the roadmap surface as $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while Definition 126.631 records the same-route $\mathsf{RealCompletionExactBoundaryUp}$ face as the constrained local readback for that route.

Finally apply the no-choice route factorization, Definition 126.522. The aggregate formalstatus, bridge token, quotient stream equality, selected limits, host sequence equality, ambient completeness, metric completeness, countable choice, and fused completion witness are not consumer coordinates on this terminal route. Therefore the two implications above form the exact four-face exit status equivalence. □

Theorem 126.636 (StreamName terminal fusion support minimality)**.** *Let $\mathcal{W}$ be an accepted terminal fused StreamName packet. Deleting any one roadmap face*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

or any one displayed support row

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

destroys the accepted terminal packet. Equivalently, no proper subpacket of these four faces and five support rows carries the same terminal $\mathsf{PhaseRealCompletionExit}^{\uparrow}$ *consumer readback.*

There is no replacement row for the missing support: quotient stream equality, selected limits, countable choice, a metric-completeness row, and bridge rows are outside the accepted terminal surface.

Proof. The terminal-window fusion theorem Definition 126.622 constructs the accepted packet from exactly the four Real-completion faces and the displayed support rows. Thus each listed coordinate is part of the packet admitted by the terminal fusion surface.

Finite-request section exactness, Definition 126.625, shows that each terminal request is read through the displayed finite section, so deleting one face or support row removes a row needed by some accepted finite request. Source exhaustion, Definition 126.626, then rules out any additional StreamName-side coordinate from filling the gap.

Finally apply the four-face exit status equivalence Definition 126.635. The terminal consumer status is exactly the equality class of the four roadmap faces, the same-route exact-boundary face, and the displayed support rows. A proper subpacket therefore cannot have the same accepted terminal status, and the excluded quotient, choice, metric-completeness, and bridge coordinates cannot provide a substitute. □

Theorem 126.637 (StreamName terminal window fusion nonescape)**.** *Let $\mathcal{W}$ be an accepted fused terminal* $\mathsf{StreamName}^{\uparrow}$ *window consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *on the L10 four-face route. Then every such consumer preserves the displayed finite request section, the reindex gluing row, the terminal fusion row, and the support-minimality row. Its readable surface is exactly*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

No consumer of the fused terminal window obtains a selected limit, quotient stream equality, host sequence equality, countable-choice schedule, metric-completeness datum, bridge row, fused completion witness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness field from the fusion packet.*

Proof. Begin with the finite request section. Apply Definition 126.625. Every terminal request read by the RegSeqRat and Real consumers is already a displayed section of the fused StreamName packet.

Next apply the reindex and fusion rows. The terminal-window fusion theorem Definition 126.622 keeps the reindexed requests on the same four roadmap faces and the same displayed support, while the universal consumer readback of Definition 126.631 identifies the RegSeqRat and Real-facing reads with that fused terminal surface.

Now use Definition 126.636. Since removing any roadmap face or support row destroys the accepted terminal packet, every consumer that still reads the fused window must preserve those rows rather than replacing them by an external coordinate.

Finally combine source exhaustion with the four-face exit status equivalence. The exhaustion theorem leaves no additional StreamName-side coordinate, and Definition 126.635 identifies the terminal consumer status with the same four faces and support rows. Thus selected limits, quotient stream equality, host sequence equality, choice schedules, metric-completeness data, bridge rows, fused completion witnesses, and ambient Real completeness fields cannot escape through the terminal fusion packet. □

Theorem 126.638 (StreamName RegSeqRat Real budget cocycle)**.** *Let $\mathcal{W}$ be an accepted terminal finite* $\mathsf{StreamName}^{\uparrow}$ *window on the L10 four-face route. Suppose its* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and downstream* $\mathsf{Real}^{\uparrow}$ *seal are read through the same displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget row and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the terminal window, the RegSeqRat readback, and the Real seal form one budget cocycle: after terminal fusion, none of the three faces can be independently reindexed away from the shared budget row.

The cocycle exposes no quotient stream equality, selected limit, host sequence equality, countable-choice schedule, metric-completeness datum, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness field.*

Proof. Begin with Definition 126.622. It constructs the terminal packet from the StreamName finite request window, the DyadicRatCore tolerance ledger, the RegSeqRat readback, the Real seal, and the displayed support rows.

Next apply Definition 126.623 and Definition 126.631. The common refinement and terminal consumer readback keep the RegSeqRat-facing and Real-facing reads on the same fused terminal surface.

Use Definition 126.636. Since deleting the budget-facing support or any of the four roadmap faces destroys the accepted packet, no separate reindexing row can replace the shared dyadic budget after the fusion is read.

Finally apply Definition 126.637. The terminal consumer has no selected limit, quotient stream equality, host sequence equality, choice schedule, metric-completeness datum, bridge row, or ambient Real-completeness coordinate, so the shared budget row is the only readable route through the StreamName, RegSeqRat, and Real faces. □

Theorem 126.639 (StreamName finite-window reindex determinacy)**.** *Let W_0 and W_1 be accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets. Suppose their reindex maps are* hsame*-compatible, their certified endpoint rows are identical, and their displayed* BHist*,* Cont*,* Pkg*, and* NameCert *support rows transport componentwise across the same reindex route. Then W_0 and W_1 determine the same public finite observation section.*

The determinacy statement is internal to the displayed StreamName packet. It does not use quotient stream equality, host sequence equality, selected limits, countable choice, or a completion row.

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameWindowReindexDeterminacy`

Proof. First read both packets through the transported finite-window endpoint package of Definition 126.32. The shared endpoint rows and the hsame-compatible reindex route place both packets on the same finite endpoint surface.

Next apply successor projection determinacy, Definition 126.299. It prevents the reindex route from creating two public successor projections once endpoint rows and support rows have been identified.

Finally use terminal window fusion, Definition 126.622. The fused terminal packet has no extra coordinate beyond the finite window, endpoint data, and displayed support rows, so both accepted packets export the same public finite observation section. □

Theorem 126.640 (StreamName public reindexing identity law)**.** *For every public* StreamName$^{\uparrow}$ *finite-window packet over a* ProbeBundle*, the certified identity reindexer preserves the displayed* RatStreamNameFiniteWindowClassifier*,* UnaryHistory *observation rows,* InBundle *membership rows, pointwise rational classifier rows,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The resulting public finite observation section is the same section read through the identity route.*

This identity law is a statement about the public finite-window packet only. It does not introduce quotient stream equality, host sequence equality, selected limits, countable choice, a completion row, or a standard bridge row.

Proof. Read the packet through the public finite-window interface and the public reindexing obligation of Definition 126.317. On an identity reindexer, every certified UnaryHistory observation remains the displayed observation, and every InBundle row is read from the same ProbeBundle.

The pointwise rational classifier, hsame comparison, Cont route, Pkg provenance, and local NameCert row therefore reappear as the same displayed rows. No extra endpoint, quotient representative, or host-index coordinate is available in the public obligation surface.

Apply Definition 126.639 to the original packet and to the identity-reindexed packet. The hypotheses are exactly the shared endpoint rows, the identity hsame route, and the componentwise agreement of the displayed support rows, so the exported public finite observation section is unchanged. □

Theorem 126.641 (StreamName public reindexing associative law)**.** *Let r and s be composable certified unary reindexers displayed over public* StreamName$^{\uparrow}$ *finite-window packets. The two-step packet obtained by reindexing along r and then along s exposes the same public finite-window section as the single packet obtained by the composite reindexer. The common section has the same* RatStreamNameFiniteWindowClassifier*,* UnaryHistory *ledger,* InBundle *transport, pointwise rational classifier rows,* hsame *comparisons, composed* Cont *route, displayed* Pkg *provenance, and local* NameCert *rows.*

The law is confined to the finite public surface. It does not claim quotient stream equality, host sequence equality, selected limits, countable choice, completion data, or a standard bridge row.

Proof. First apply the public reindexing obligation of Definition 126.317 to the r leg and then to the s leg. The two applications list only the certified UnaryHistory observations, InBundle membership rows, pointwise rational classifier rows, hsame comparisons, Cont routes, Pkg provenance, and local naming rows displayed by the finite packets.

Next use the finite-window reindexing composition theorem, Definition 126.304. It identifies the two restricted finite BHist packets with the packet obtained by restricting once along the composite reindexer, with the classifier, endpoint, hsame, and finite ledger rows merely repacked over the target ProbeBundle.

Finally apply Definition 126.639 to the two-step packet and the composite packet. Their reindex maps are hsame-compatible, their endpoint rows agree, and their displayed BHist, Cont, Pkg, and NameCert rows transport componentwise, so the exported public finite observation section is the same. □

Theorem 126.642 (StreamName reindex terminal coverage)**.** *A certified public* StreamName$^{\uparrow}$ *finite-window reindex route preserves exactly the terminal four-face L10 exit route. Namely, if*

an accepted reindex route transports the public finite window together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows, then the transported exit packet exposes the same* StreamName$^{\uparrow}$ *window, the same* DyadicRatCore$^{\uparrow}$ *ledger, the same* RegSeqRat$^{\uparrow}$ *readback, and the same* Real$^{\uparrow}$ *seal as its terminal Phase Real and Completion route.*

Conversely, any terminal four-face route transported by the identity certified reindexer or by composable certified reindexers reads the same public finite observation section. The coverage is confined to the finite route and excludes quotient stream equality, host sequence equality, selected limits, countable choice, ambient Real$^{\uparrow}$ *completeness, metric completeness, and standard bridge rows.*

Lean4 ✓ `BEDC.Derived.StreamNameUp.StreamnameReindexTerminalCoverage`

Proof. Start with the public finite-window section. The determinacy theorem, Definition 126.639, says that matching endpoint rows, hsame-compatible reindex maps, and componentwise transported BHist, Cont, Pkg, and NameCert rows determine one public finite observation section.

For the identity route, apply Definition 126.640. It keeps the displayed finite window, unary-history ledger, bundle membership, rational classifier, hsame, Cont, Pkg, and local NameCert rows unchanged, so the terminal packet is read from the same public section.

For composable certified routes, apply Definition 126.641. The two-step and composite reindexings expose the same finite section, hence they present the same support rows to the exit boundary.

Finally use Definition 126.449 and Definition 126.450. Terminality fixes the four faces once the StreamName window, DyadicRatCore ledger, RegSeqRat readback, RealUp seal, and support rows agree, while readback says every terminal exit read factors through exactly those rows. Thus transported identity and composable routes cover precisely the finite four-face exit route, with no additional quotient, host, limit, choice, completeness, or bridge coordinate. □

Theorem 126.643 (StreamName finite-window reindex stability)**.** *Let R be an accepted public* StreamName$^{\uparrow}$ *finite-window reindex route. Suppose R preserves the endpoint rows, unary observation rows,* InBundle *membership rows, pointwise rational classifier rows, componentwise* hsame *comparisons, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of the finite packet. Then R preserves the public finite observation section presented to downstream* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumers.*

The preserved section is exactly the displayed StreamName window with its endpoint, bundle, rational classifier, transport, replay, provenance, and naming rows. It exposes no quotient stream equality, host sequence equality, selected limit, countable choice, ambient Real completeness, metric-completeness data, or standard bridge row.

Proof. Apply finite-window reindex determinacy, Definition 126.639. The preserved endpoint rows, unary observations, bundle membership, pointwise rational classifiers, and support rows determine one public finite observation section.

Use the public identity law, Definition 126.640, to identify unchanged windows with the same displayed section. This accounts for trivial reindex legs without adding host sequence equality.

Next apply the public associative law, Definition 126.641. Composable certified reindex routes therefore present the same finite section after repacking their displayed support rows.

Finally use terminal coverage, Definition 126.642. The downstream RegSeqRat$^{\uparrow}$ readback and Real$^{\uparrow}$ seal consume only that public finite section and its support rows, so the excluded quotient, choice, limit, completeness, metric, and bridge coordinates cannot alter the consumer-facing section. □

Theorem 126.644 (StreamName public reindexing section cancellation)**.** *Let R_0 and R_1 be certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes displayed over the same* ProbeBundle*. Suppose they expose the same public finite observation section, the same endpoint rows, and the same displayed* BHist*, and suppose their componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows agree over that section. Then every terminal Phase Real and Completion consumer reads the same four-face route through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *from R_0 and R_1.*

Thus the consumer cannot distinguish the two routes by reindexer shape, host sequence equality, quotient stream equality, selected limits, countable choice, ambient completeness, metric completeness, or a standard bridge row. The visible data are exactly the displayed finite section, endpoint rows, and support rows.

Proof. First apply Definition 126.639 to the two certified routes. The shared endpoint rows, the common displayed ProbeBundle, the displayed BHist, and the componentwise hsame, Cont, Pkg, and local NameCert support rows identify the public finite observation section read by the two packets.

The identity and composite presentations do not add observable data. Apply Definition 126.640 to any identity leg and Definition 126.641 to any composite presentation. Both laws reduce the public presentation back to the same finite section with the same displayed support rows.

Finally apply Definition 126.642 and Definition 126.622. Terminal coverage says every accepted reindex route reaches the same four-face exit surface once the finite section and support rows agree, while terminal window fusion carries that agreement through the $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal. Hence the terminal consumer reads one route, independent of the certified reindexer shape and of the excluded quotient, host, limit, choice, completeness, or bridge coordinates. □

Theorem 126.645 (StreamName public reindexing cancellation boundary)**.** *Let R_0 and R_1 be certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes displayed over a finite* ProbeBundle*, and suppose both feed the same terminal Phase Real and Completion four-face route. Then any public distinction between R_0 and R_1 must appear in one of the displayed finite observation section rows:*

$$\mathsf{RatStreamNameFiniteWindowClassifier},\quad \mathsf{ProbeBundle},\quad \mathsf{InBundle},\quad \mathsf{UnaryHistory},$$

the pointwise $\mathsf{Rat}^{\uparrow}$ *classifier rows, the endpoint* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance rows, or the local* NameCert *rows.*

If all those rows agree, then downstream $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers receive the same terminal route through*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

The boundary contains no quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, or standard bridge row.*

Proof. First use Definition 126.639. The finite window classifier, bundle membership, unary-history display, endpoint hsame data, displayed Cont routes, Pkg provenance, and local NameCert rows are exactly the public rows from which a certified reindex packet is read.

Next apply the identity and associativity laws, Definition 126.640 and Definition 126.641. Identity legs and composite presentations cannot create an additional visible distinction beyond the same finite observation rows.

Now use Definition 126.642. Every certified public reindex route that reaches the terminal Phase Real and Completion surface is read through the four displayed faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no extra quotient, host, selector, choice, completeness, metric, or bridge coordinate.

Finally apply Definition 126.644. Once the listed finite rows agree, section cancellation identifies the terminal read of R_0 and R_1. The terminal four-face readback used by Definition 126.646 then passes the same route to downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, so any remaining public distinction would have had to occur in the displayed finite rows already listed. □

Theorem 126.646 (StreamName reindex finite-cover terminal descent)**.** *Let $\{\mathcal{W}_i\}_{i\in I}$ be a finite family of certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packets, each equipped with a certified public reindex route to the terminal Phase Real and Completion surface. Suppose that on every overlap the reindexed packets expose the same public finite observation section, the same endpoint rows, the same displayed* BHist*, and the same componentwise* hsame, Cont, Pkg*, and local* $\mathsf{NameCert}$ *support rows. Suppose also that the associated local terminal packets satisfy the common-tail* $\mathsf{Real}^{\uparrow}$ *boundary agreement hypotheses of Definition 126.628.*

Then the reindexed family descends to one finite-request section on the terminal four-face route

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

The descended section has only the displayed finite StreamName windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source row, and the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

It does not assert quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or standard bridge rows.*

Proof. First compare the overlap reads after reindexing. Apply Definition 126.644 to each pair of certified overlap routes. The shared finite observation section, endpoint rows, displayed BHist, and componentwise $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ support rows identify the terminal read on the four visible faces.

Next keep the identified reads inside the public terminal surface. By Definition 126.642, every accepted reindex route exposes exactly the $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal, with no additional quotient, host, selector, choice, completeness, metric, or bridge coordinate.

Now use the assumed common-tail $\mathsf{Real}^{\uparrow}$ boundary agreement. Apply Definition 126.628 to read that boundary agreement as the finite-cover cocycle condition for the local terminal fused packets on the same four-face surface.

Finally apply Definition 126.629. The cocycle condition descends the local terminal packets to one finite-request section, and the descent theorem lists exactly the displayed StreamName, DyadicRatCore, RegSeqRat, Real, and support rows. Thus the reindex data contribute only the public finite sections already cancelled above. □

Theorem 126.647 (StreamName reindex four-face exit naturality)**.** *Let R be a support-row-preserving certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex route, displayed over a finite* $\mathsf{ProbeBundle}$*, from a local StreamName window to the terminal Phase Real and Completion exit surface. Suppose*

the route preserves the public finite observation section, the endpoint rows, the displayed BHist*, and the componentwise support rows*

$$\mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then transport along R is natural at the terminal exit surface: the source read and the transported read have the same visible four-face Phase Real and Completion surface, namely

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},$$

and the only support rows visible to every terminal consumer are

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

No additional coordinate is transported or identified. In particular, the naturality statement does not assert quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, or any standard bridge row.*

Proof. First read R through the public finite observation section. By Definition 126.639, preservation of the finite section, endpoint rows, displayed BHist, and componentwise hsame/Cont/Pkg/NameCert support rows fixes the public data seen before and after the certified reindex route.

Next place that fixed public section on the terminal route. Apply Definition 126.642. The route reaches exactly the four visible faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with the listed support rows and with no quotient, host, selector, choice, completeness, metric, or bridge coordinate added to the surface.

The certified route shape itself is immaterial to the terminal consumer. Use Definition 126.644 to compare any two presentations of the same preserved section; section cancellation keeps the terminal read invariant under reindexer shape.

Finally apply Definition 126.646 to the singleton finite family determined by R. Finite-family descent says the terminal section remains a section on the same four-face surface with exactly the same support rows. Hence support-row-preserving certified reindex transport is natural for the terminal Phase Real and Completion exit surface, and it carries none of the excluded quotient, host, limit, choice, completeness, metric, or bridge data. □

Theorem 126.648 (StreamName terminal reindex four-face pullback)**.** *Let R_0 and R_1 be certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes into the terminal Phase Real and Completion exit boundary. Assume both routes preserve the same public finite observation section, the same endpoint rows, the same displayed* BHist*, and the same componentwise support rows*

$$\mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Assume also that the local NameCert *support used by each route is the same finite support read over the preserved section. Then R_0 and R_1 determine the same terminal pullback over the four visible faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Conversely, every terminal pullback produced by such a support-row-preserving reindex route is read from exactly the public finite observation section, the endpoint rows, displayed BHist*, componentwise* hsame/Cont/Pkg *rows, and local* NameCert *support listed above.*

The assertion is only about this four-face terminal pullback. It does not assert quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or standard bridge rows.*

Proof. First apply Definition 126.647 separately to R_0 and R_1. Each route has the same transported terminal exit surface, and that surface has exactly the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces with the listed support rows.

Next compare the two route presentations at the public section. By Definition 126.644, the common finite observation section, endpoint rows, displayed BHist, and componentwise $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ support cancel the reindexer shape. Thus the two routes expose the same terminal read before any four-face packaging is imposed.

Now keep that read inside the terminal surface. Use Definition 126.642 to see that no fifth face or hidden support coordinate is present: the route contributes precisely the StreamName, DyadicRatCore, RegSeqRat, Real, and local support rows named in the statement.

Finally apply Definition 126.646 to the singleton finite family determined by either route. Singleton descent identifies the finite-family terminal section with the same four-face terminal pullback, so R_0 and R_1 give one pullback over the shared rows.

For the converse direction, start with any terminal pullback produced by a support-row-preserving reindex route of the stated kind. The same terminal coverage theorem lists all rows from which it can be read, and the singleton descent theorem repacks those rows without adding quotient, host, selector, choice, completeness, metric, or bridge data. Hence the pullback is read from exactly the public section, endpoint rows, displayed BHist, componentwise $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}$ rows, and local $\mathsf{NameCert}$ support. □

Theorem 126.649 (StreamName reindex tail-window terminal equivalence)**.** *Let $\mathcal{F}$ be a finite family of accepted current Phase Real and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections, all displayed over the same public endpoints and the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *spine. Let $\mathcal{W}$ be a finite chain of* $\mathsf{StreamName}^{\uparrow}$ *tail-window coverage packets over those endpoints and that spine, and let R be a support-row-preserving certified public* $\mathsf{StreamName}^{\uparrow}$ *reindex route for the family. Assume that R preserves the public finite observation section, the endpoint rows, the displayed* BHist*, and the componentwise support rows*

$$\mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then reindexing along R preserves the equivalence between the finite-section descent-gluing public reflection surface of $\mathcal{F}$ and the tail-window terminal read of $\mathcal{W}$. Both sides are identified by the same four-face terminal route

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

with the same carrier rows, the same local $\mathsf{NameCert}$ *support, and the same classifier verdict.*

This equivalence is confined to the displayed public terminal surface. It does not assert quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, or standard bridge rows.*

Proof. First place the certified reindex route on the public finite observation section. By Definition 126.648, the reindexed route is read through exactly the same finite section, endpoints, displayed BHist, componentwise $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}$ rows, and local $\mathsf{NameCert}$ support as the original route.

Next descend the reindexed finite family. Apply Definition 126.646 to the family carried by R. The descent-gluing surface remains a finite terminal public reflection surface over the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, with no extra quotient, host, selector, choice, completeness, metric, or bridge coordinate.

Now compare that descended surface with the tail-window terminal read. Use Definition 126.595 for the finite request sections and tail-window coverage packets over the shared public endpoints and accepted $\mathsf{RegSeqRat}^{\uparrow}$ spine. This identifies the descent-gluing public reflection surface with the terminal read of the tail-window chain, preserving the displayed carrier rows, local $\mathsf{NameCert}$ support, and classifier verdict.

Finally keep the comparison inside the four visible faces. By Definition 126.642, the certified public reindex route has no access to a fifth coordinate: the only terminal faces are $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and the excluded quotient, host, limit, choice, completeness, metric, and bridge data remain outside the assertion. Hence certified reindexing preserves the tail-window terminal equivalence for the finite descent-gluing surface. □

Theorem 126.650 (StreamName public reindex zigzag normal form)**.** *Let Z be a finite zigzag of support-row-preserving certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes whose visible endpoints are the same public finite observation sections and whose spine row is the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback. Suppose every leg of Z preserves the displayed public finite section, endpoint rows, displayed* BHist*, and the componentwise support rows*

$$\mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then Z determines one terminal four-face packet over

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with exactly those displayed BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows.*

Conversely, any two displayed public finite-window sections over the same public endpoints and accepted $\mathsf{RegSeqRat}^{\uparrow}$ *spine that determine the same terminal four-face pullback are connected by a finite zigzag of support-row-preserving certified public reindex routes. The assertion is confined to the displayed public terminal surface. It excludes quotient stream equality, host sequence equality, selected limits, countable choice, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, standard bridge rows, and any aggregate status row.*

Proof. Start with the forward direction. Insert certified identity legs where a zigzag endpoint is repeated and compose adjacent forward-facing legs whenever their endpoints match. The identity insertion is harmless by Definition 126.640, and the collapse of a two-leg presentation to its composite is harmless by Definition 126.641.

Whenever two neighboring presentations expose the same public finite section, use Definition 126.644. This removes the reindexer shape from the terminal consumer and leaves only the displayed finite section, endpoint rows, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support.

The remaining finite family of displayed sections is then descended by Definition 126.646. The descent surface is a finite terminal public reflection surface with no added quotient, host, selector, choice, completeness, metric, bridge, or aggregate coordinate.

Finally apply Definition 126.648 and Definition 126.649. The first theorem reads every normalized reindex presentation through the same four visible faces, and the second identifies the finite-section descent surface with the tail-window terminal read over the shared accepted $\mathsf{RegSeqRat}^{\uparrow}$ spine. Hence the whole zigzag determines one terminal four-face packet with the displayed support rows named in the statement.

For the converse direction, begin with two displayed public finite-window sections that have the same terminal four-face pullback. Read both sections through Definition 126.648; the common pullback lists exactly the shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and the displayed support rows.

Use Definition 126.649 to place both sections on the same tail-window terminal read, then apply Definition 126.646 to repack that read as a finite public family. Identity legs connect each section to its displayed occurrence in the family, associative composition joins consecutive legs, and section cancellation identifies parallel displayed sections. These legs form the required support-row-preserving finite zigzag. □

Theorem 126.651 (StreamName reindex support-row necessity)**.** *A certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex route feeds the terminal four-face Phase Real and Completion route if and only if the same public finite observation section displays the* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal, and the shared support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Here hsame *is componentwise,* Cont *is displayed on the same preserved finite section,* Pkg *records the route provenance visible to the terminal consumer, and* NameCert *is the local certificate support for that section.*

No quotient stream equality, host sequence equality, selected limit, countable choice datum, ambient $\mathsf{Real}^{\uparrow}$ *completeness assumption, metric-completeness assumption, or standard bridge row can replace any of these displayed support rows in the terminal route.*

Proof. For the forward direction, start with a certified public $\mathsf{StreamName}^{\uparrow}$ finite-window reindex route feeding the terminal four-face surface. Apply Definition 126.642. The coverage theorem restricts every such terminal read to the four visible faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the displayed BHist, componentwise hsame, displayed Cont, Pkg, and local NameCert rows.

Now compare the certified route with its terminal pullback presentation. Use Definition 126.648. The pullback inventory says that the terminal route is read from exactly the public finite observation section, endpoint rows, displayed BHist, componentwise hsame/Cont/Pkg rows, and local NameCert support. Thus feeding the terminal four-face route forces the displayed window, ledger, readback, seal, and support rows named in the statement.

For the reverse direction, assume the public finite observation section already displays the four faces and the listed support rows. Apply Definition 126.647 to transport the section along the certified public reindex route without changing the visible terminal surface.

Then apply Definition 126.650. The normal form theorem packs any finite support-row-preserving presentation over the same public endpoints and accepted $\mathsf{RegSeqRat}^{\uparrow}$ spine into one terminal four-face packet. Hence the displayed support rows are sufficient for the certified route to feed the terminal Phase Real and Completion route.

Finally rule out substitutions. By Definition 126.645, cancellation is confined to the preserved public section and its displayed support rows, while the terminal pullback inventory just cited lists no quotient stream, host equality, selected-limit, choice, ambient-completeness, metric-completeness, or bridge coordinate. None of those external rows can replace a required support row in the four-face route. □

Theorem 126.652 (StreamName reindex bundle naturality)**.** *Let* B *be a* ProbeBundle *indexing a public* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet, and let* $B' \subseteq B$ *be a displayed sub-bundle with its* InBundle *rows. Any certified reindex route on* B *that preserves* UnaryHistory *observation rows,* InBundle *membership rows, pointwise rational classifier rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *support commutes with restriction to* B'*.*

Equivalently, restricting the public finite observation section to B' and then reindexing produces the same displayed finite section as reindexing on B and then restricting to B'. The common section exposes exactly the same $\mathsf{StreamName}^{\uparrow}$ *windows, pointwise rational classifier rows, support rows, and NameCert provenance, and exports no quotient stream equality, host sequence equality, selected limit, countable choice datum, ambient* $\mathsf{Real}^{\uparrow}$ *completeness assumption, metric-completeness assumption, or standard bridge row.*

Proof. First apply the finite-window reindex determinacy already displayed in this chapter. Since the route preserves UnaryHistory observations, InBundle rows, pointwise classifiers, and the structural support rows, both composites are certified presentations of the same public finite observation section over the same endpoints.

Next use the public identity and associative laws for reindexing. Identity legs identify the displayed restriction of B to B', and associativity compares the route that restricts before reindexing with the route that restricts after reindexing as two factorizations of one certified finite section.

Finally apply Definition 126.651. The terminal section can use only the displayed window, classifier, hsame, Cont, Pkg, and NameCert rows. Thus the two restricted packets have the same public finite observation section, and no off-table quotient, selector, choice, completeness, metric, or bridge row can distinguish them. □

Theorem 126.653 (StreamName terminal four-face support minimality)**.** *Let U be an accepted current Phase Real and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Then the public terminal surface of U is accepted exactly through the four visible faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$ *together with the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows.*

Moreover, this support is minimal for the accepted public verdict: deleting any one of the four faces, or deleting any one of the displayed support rows, prevents the resulting packet from presenting the same carrier verdict and the same classifier verdict to Real-facing or completion-facing consumers. The minimality claim uses no quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus row, or bridge row.*

Proof. First build the public classifier surface. Apply Definition 126.598 to the accepted terminal request section and its finite cover, then compare any two public presentations with Definition 126.599. These results place the carrier and classifier verdicts on the same visible StreamName, DyadicRatCore, RegSeqRat, and Real faces over the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next lock the StreamName side to the dyadic, regular-rational, and Real sides. The theorem Definition 126.589 says that a Real-facing or completion-facing read of the terminal request section can use only the finite StreamName window, the DyadicRatCore ledger, the RegSeqRat readback, the Real seal boundary, and the same support rows. Thus a packet with one visible face or one support row removed is no longer the packet seen by those consumers.

Now read the same packet from the RegSeqRat terminal boundary. By Definition 301.239, terminal acceptance is equivalent to the presence of exactly the four displayed faces with the shared support rows. By Definition 301.237, any accepted consumer with the same public verdict has the same finite RegSeqRat source. Hence removing a face or support row removes the witness needed to identify the source that presents that verdict.

Finally pass through the Real dependency lattice. The exit totality theorem Definition 38.468 sends every current Phase Real and Completion terminal read through the ordered four-face route

and the displayed support rows. Combining this totality with the classifier reflection and source-uniqueness steps gives the stated minimality: the public carrier and classifier verdicts survive exactly on the four-face support surface and not on any shorter packet.

The exclusion list follows from the same route description. None of the cited surfaces contains a coordinate for quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, aggregate formalstatus, or bridge rows, so those objects cannot replace a missing visible face or support row. □

Theorem 126.654 (StreamName terminal support defect localization)**.** *Let U be an accepted current Phase Real and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Suppose a public terminal presentation of U fails to preserve at least one of the carrier verdict, the classifier verdict, or the consumer-facing terminal route supplied by Definition 126.653. Then the failure is witnessed on one of the four visible faces* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*, or on one of the displayed support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Consequently, quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, aggregate formalstatus, and bridge rows cannot be the carrier of such a defect.*

Proof. The minimality theorem Definition 126.653 identifies the only support surface that presents the accepted carrier verdict and classifier verdict to Real-facing and completion-facing consumers. Therefore any loss of one of those verdicts, or of the displayed terminal route, must remove something from that support surface.

The readback theorem Definition 126.450 sends the public exit of an accepted terminal request through the same StreamName, DyadicRatCore, RegSeqRat, and Real faces. The Real-side localization theorem Definition 38.838 says that an L10 exit failure is detected on a displayed face or support row rather than on a hidden quotient, limit, choice, completeness, aggregate-status, or bridge coordinate.

Combining these two route descriptions with the two-axis roadmap discipline gives the advertised referee check. The theory axis records which face or support row carries the terminal evidence, while the verification axis records whether that row has been checked; neither axis turns the excluded quotient, limit, completeness, choice, aggregate formalstatus, or bridge rows into support for the StreamName terminal verdict. □

Theorem 126.655 (StreamName terminal support defect pullback)**.** *Let U and V be accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose a consumer-visible terminal presentation detects a carrier defect, a classifier defect, or a terminal route defect on one of the visible faces* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*, or on one displayed support row* BHist*, componentwise* hsame*,* Cont*,* Pkg*, or local* NameCert*. Then the defect pulls back to a finite request-section mismatch: it is witnessed by the finite-section pullback, by the Real-seal lock, by window reindex determinacy, or by the terminal-window fusion source and reindexing compatibility surfaces.*

Consequently excluded coordinates such as quotient stream equality, host sequence equality, selected limits, countable choice, metric completeness, aggregate formalstatus, bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ *completeness cannot serve as a defect carrier and cannot serve as a repair coordinate for the terminal request section consumed by the L10 Real route.*

Proof. First localize the visible failure. Apply Definition 126.654. The carrier, classifier, or route defect is already forced onto one of the four visible faces or onto one displayed BHist, hsame, Cont, Pkg, or NameCert support row.

Now pass from the terminal presentation to the finite request section. Apply Definition 126.577. The visible StreamName terminal read is pulled back to the finite window and request rows that the Phase $\mathsf{Real}^{\uparrow}$ route actually consumes. If the detected defect lies on the Real boundary of that read, apply Definition 126.568; the Real seal identifies the same finite request section rather than a separate ambient completion coordinate.

It remains to account for presentations that differ by window transport. Apply Definition 126.639. The certified reindexing data preserve the finite observation section, so a defect surviving consumer-visible reindexing is still a mismatch of the same finite request rows.

Finally use the fused terminal-window surface. The source-exhaustion theorem Definition 126.626 shows that an accepted terminal-window packet has no source beyond the displayed four-face section and support rows. The reindexing compatibility theorem Definition 126.627 keeps that source fixed under the allowed window transport. Thus every visible support defect pulls back to the finite request-section evidence listed in the statement.

The exclusion clause follows because none of the pullback, seal-lock, determinacy, source-exhaustion, or compatibility surfaces exports a coordinate for quotient stream equality, host sequence equality, selected limits, countable choice, metric completeness, aggregate formalstatus, bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Such data therefore cannot carry the detected defect and cannot repair the finite section consumed by the L10 Real route. □

Theorem 126.656 (StreamName terminal support removal witness)**.** *Let U be an accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Delete from the public terminal support of U either one visible face among* $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$*, or one displayed support row among* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$*. Then the shortened request section cannot present the same carrier verdict, classifier verdict, and consumer-facing terminal route as U.*

The lost verdict is witnessed as a finite request-section mismatch. If the removed coordinate is the finite $\mathsf{StreamName}^{\uparrow}$ *window or one of its displayed request rows, the witness is the finite-section pullback. If the removed coordinate is the* $\mathsf{Real}^{\uparrow}$ *terminal boundary, the witness is the Real-seal lock. If the removed coordinate is a transported window row, the witness is window reindex determinacy. If the removed coordinate is part of the fused terminal-window source, the witness is the terminal-window fusion surface.*

No quotient stream equality, host sequence equality, selected limit, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric completeness, aggregate formalstatus row, or bridge row can repair the shortened section or replace the finite witness.*

Proof. Begin with the deletion. By Definition 126.653, every visible face and every displayed support row named in the statement is a required coordinate of the accepted terminal packet. Removing one of them therefore loses the public carrier verdict, the public classifier verdict, or the consumer-facing route.

Next localize the loss. Apply Definition 126.654. The failure cannot be carried by an off-route equality, a selected limit, a choice row, a completeness row, an aggregate verification row, or a bridge row. It is located on the deleted face or support row itself.

Now pull the localized failure back to finite BEDC data. Use Definition 126.655. A missing StreamName window or displayed request row is read by the finite-section pullback. A missing Real terminal boundary is read by the Real-seal lock. A missing transported window row is read by window reindex determinacy. A missing coordinate from the fused terminal source is read by the terminal-window fusion source and reindexing compatibility surfaces.

These four witness surfaces exhaust the repair options available to the terminal request section. Since none of them exports quotient stream equality, host sequence equality, selected limits, countable choice, ambient Real completeness, metric completeness, aggregate formalstatus rows, or bridge rows, the shortened section has a finite request-section mismatch and no excluded coordinate can repair it. □

Theorem 126.657 (StreamName terminal four-face support exhaustion)**.** *Let U be an accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. A consumer-visible support coordinate of U is accepted if and only if it is one of the four terminal faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, or one of the displayed rows* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$*.*

Consequently the accepted support of U has no coordinate for quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, or bridge rows. None of these excluded data can be accepted as a substitute support coordinate for the terminal request section.*

Proof. For the reverse direction, the displayed four faces and support rows are accepted by the terminal packet described in Definition 126.653. That theorem already identifies the visible StreamName, DyadicRatCore, RegSeqRat, and Real faces together with the BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows as the public terminal surface of U.

For the forward direction, let a consumer-visible support coordinate be accepted by the current Phase Real and Completion terminal request section. Apply Definition 126.589. The consumer read is locked to the finite StreamName window, the DyadicRatCore ledger, the RegSeqRat readback, the Real seal boundary, and the same displayed support rows.

Next read the coordinate through the RegSeqRat terminal boundary. By Definition 301.239, terminal acceptance is exactly the four-face packet with those displayed rows. By Definition 301.237, an accepted consumer with the same public verdict has the same finite RegSeqRat source, so no second RegSeqRat-facing support source is available.

Finally pass to the Real exit route. Theorem Definition 38.468 sends every current Phase Real and Completion terminal read through the ordered $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ route and the displayed support rows. Therefore every accepted consumer-visible support coordinate is one of exactly those faces or rows.

The excluded objects are not coordinates of that route. Quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, aggregate formalstatus rows, and bridge rows occur in neither the StreamName lock, the RegSeqRat exactness and uniqueness surface, nor the Real exit-totality route. Hence none of them is an accepted support coordinate for U. □

Theorem 126.658 (StreamName terminal four-face support transport stability)**.** *Let U and V be accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose their consumer-visible terminal reads expose the same four visible faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and suppose their displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support rows agree after componentwise transport and replay. Then U and V present the same consumer-visible terminal support packet.*

The transport cannot introduce quotient stream equality, host sequence equality, a selected limit, countable choice, metric-completeness data, an aggregate formalstatus row, a bridge row, or an ambient $\mathsf{Real}^{\uparrow}$ *completeness row. The transported packet remains exactly the same four-face BEDC support surface seen by Real-facing and completion-facing consumers.*

Proof. First classify the accepted coordinates. Apply Definition 126.657 to both terminal request sections. Every consumer-visible support coordinate of either section is therefore one of the four displayed faces or one of the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Next use the minimal support theorem. By Definition 126.653, no visible face and no displayed support row can be deleted or substituted while preserving the same Real-facing and completion-facing carrier and classifier verdicts. Since the hypotheses identify the four faces and replay the support rows componentwise, the two sections have the same StreamName-side public surface.

Now pass through the RegSeqRat terminal route. The exactness theorem Definition 301.239 reads the common displayed faces as one terminal RegSeqRat four-face packet, and Definition 301.237 rules out a second RegSeqRat source section with the same public verdict. Thus the transported RegSeqRat component is the same finite source record.

Finally read the common packet through the Real L10 exit lattice. The theorem Definition 38.468 sends every accepted current Phase Real and Completion terminal read through the ordered $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ route with the displayed support rows. The two transported presentations therefore determine the same terminal support packet, and the exhaustion theorem excludes every off-route coordinate listed in the statement. □

Theorem 126.659 (StreamName terminal route facewise conservativity)**.** *Let U be an accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section, and let P be a consumer-visible terminal presentation of U. Suppose P preserves the accepted carrier verdict, the accepted classifier verdict, and the consumer-facing terminal route of U. Then P restricts facewise to the same terminal* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces as U, and to the same displayed* BHist, *componentwise* hsame, Cont, Pkg, *and local* NameCert *support rows.*

No quotient stream equality, host sequence equality, selected limit, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness datum, aggregate formalstatus row, or bridge row can serve as a substitute coordinate for this conservative terminal presentation.*

Proof. First exhaust the coordinates that a preserved terminal verdict can use. By Definition 126.657, every accepted consumer-visible support coordinate of U is one of the four displayed faces or one of the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert rows.

Assume contrapositively that P does not restrict facewise to this displayed support. Then it either omits one displayed face or row, or it replaces one of them by an off-route coordinate. The defect localization theorem Definition 126.654 forces such a failure to appear on a visible face or displayed support row whenever the carrier verdict, classifier verdict, or terminal route is not preserved.

The hypotheses say that P preserves exactly those three consumer-visible outputs. Hence no such localized defect is available. The exhaustion theorem also says that quotient equality, host sequence equality, selected limits, choice, completeness, aggregate formalstatus, and bridge rows are not accepted support coordinates, so none of them can repair the missing facewise evidence.

It remains to identify the preserved presentation. Read P and U as two accepted terminal presentations with the same visible faces and componentwise replayed support rows. The transport stability theorem Definition 126.658 therefore identifies their consumer-visible terminal support packets. Thus preserving the accepted carrier verdict, classifier verdict, and terminal route is conservative exactly on the four BEDC-visible faces and displayed support rows listed in the statement. □

Theorem 126.660 (StreamName terminal support replay induction)**.** *Let U and V be accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose the replay from U to V begins with the same finite* $\mathsf{StreamName}^{\uparrow}$ *window, and then replays in order the*

DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$ *visible faces together with the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows. Then finite induction over this ordered support list determines one consumer-visible terminal support packet.*

The induction uses only those displayed faces and rows. It does not use quotient stream equality, host sequence equality, selected limits, countable choice, ambient Real$^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, or bridge rows.*

Proof. Start with the displayed finite StreamName$^{\uparrow}$ window. The minimality theorem Definition 126.653 supplies the base: this window is a required support coordinate and cannot be replaced by any off-route equality, limit, completeness, formalstatus, or bridge datum.

For the induction step, assume the replayed prefix has already determined the same terminal support prefix. Adding the next displayed row preserves determinacy because minimality forbids deleting that row or substituting a different support coordinate while keeping the same Real-facing and completion-facing verdicts.

At the RegSeqRat$^{\uparrow}$ step, the exactness theorem Definition 301.239 identifies the replayed prefix as the terminal four-face RegSeqRat packet. The source uniqueness theorem Definition 301.237 then rules out a second finite RegSeqRat source with the same public verdict.

At the final Real$^{\uparrow}$ step, theorem Definition 38.468 sends every accepted current Phase Real and Completion terminal read through the ordered StreamName$^{\uparrow}$–DyadicRatCore$^{\uparrow}$–RegSeqRat$^{\uparrow}$–Real$^{\uparrow}$ route and the displayed support rows. Thus the induction has exhausted the full terminal route.

By Definition 126.657, every accepted consumer-visible support coordinate is one of these four faces or displayed rows. The componentwise replay hypotheses therefore give exactly the transport hypotheses of Definition 126.658, which concludes that U and V present one terminal support packet. □

Theorem 126.661 (StreamName terminal support Real-seal minimality)**.** *Let U be an accepted current Phase* Real$^{\uparrow}$ *and Completion terminal* StreamName$^{\uparrow}$ *request section. The public Real-facing seal route exported by U is minimal on the displayed* Real$^{\uparrow}$ *seal face and on the support rows* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert*. Deleting the* Real$^{\uparrow}$ *seal face, or deleting any one of those displayed support rows, prevents the same public Real-facing seal route from being exported.*

The lost route cannot be restored by quotient stream equality, host sequence equality, selected limits, countable choice, ambient Real$^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, or bridge rows.*

Proof. Begin with the terminal four-face support minimality theorem Definition 126.653. It identifies the accepted public verdict with the visible StreamName$^{\uparrow}$–DyadicRatCore$^{\uparrow}$–RegSeqRat$^{\uparrow}$–Real$^{\uparrow}$ route and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Now specialize to the Real-seal coordinate. The open-phase four-face readback Definition 126.450 and the Real-seal lock Definition 126.568 place the terminal Real$^{\uparrow}$ seal after the finite StreamName window, DyadicRatCore ledger, and RegSeqRat readback. Removing that seal therefore removes the public Real-facing endpoint of the route rather than merely changing a presentation of it.

For a displayed support row, apply the defect-localization theorem Definition 126.654. A deleted BHist, hsame, Cont, Pkg, or NameCert row is detected on the same support surface that carries the terminal route, so the export no longer presents the same Real-facing seal route.

Finally use the same open-phase readback lemmas together with minimality. The excluded coordinates are not faces or support rows of the four-face route, and defect localization does not let them carry the missing seal or support coordinate. Hence they cannot restore the deleted Real-seal route. □

Theorem 126.662 (StreamName finite-cover terminal support minimality)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections. Suppose every accepted overlap displays the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *support rows when read through either local section. Then the cover-descent terminal support packet for the family is accepted exactly on those four visible faces and displayed support rows.*

Moreover, deleting any one visible face or any one displayed support row prevents the resulting cover packet from presenting the same carrier verdict and the same classifier verdict to Real-facing or completion-facing consumers. This finite-cover minimality claim uses no quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, or bridge rows.*

Proof. First form the cover surface. Apply Definition 126.598 to the finite family. The accepted-overlap hypotheses place the carrier verdict and classifier verdict on the common StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, Real seal boundary, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next compare all choices of cover presentation. The common-refinement theorem Definition 126.599 says that any certified finite refinement reads the same public four-face classifier surface. Thus the cover-descent terminal packet is independent of the chosen finite presentation once the displayed overlap rows agree.

Now work on each terminal section. For every $i \in I$, Definition 126.653 says that the local terminal packet is accepted exactly on the four visible faces and the displayed support rows, and that deleting any one of these coordinates loses the same Real-facing or completion-facing verdict. Therefore a shorter cover packet would already be shorter on some accepted local section or accepted overlap.

It remains to pass from local minimality to cover minimality. Use Definition 126.660 on the ordered list consisting of the StreamName finite window, the DyadicRatCore ledger, the RegSeqRat readback, the Real seal boundary, and the displayed support rows. The induction transports the local terminal packets through the cover in the same order and gives one consumer-visible terminal support packet.

Finally rule out substitutes for the missing coordinate. The exactness theorem Definition 301.239 identifies the RegSeqRat terminal boundary with precisely the four-face support packet, while Definition 301.237 rules out a second finite RegSeqRat source with the same public verdict. The Real exit totality theorem Definition 38.468 then forces every accepted Phase Real and Completion terminal read through the same ordered route.

The coordinates listed outside the statement are absent from that route. Hence quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, aggregate formalstatus rows, and bridge rows cannot supply the deleted face or support row, and cannot preserve the same carrier and classifier verdicts. □

Theorem 126.663 (StreamName finite-cover terminal support defect localization)**.** *Let $\{Q_i\}_{i\in I}$ be a finite family of accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections satisfying the accepted-overlap hypotheses of Definition 126.662. Suppose a cover-descent terminal support packet for the family fails to preserve the carrier verdict, the classifier verdict, or the consumer-facing terminal route presented by that finite cover. Then the failure is witnessed on one local face among* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, or on one displayed support row among* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert*.*

The witness is componentwise on one accepted local section or accepted overlap. Quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, and bridge rows cannot serve as the defect carrier and cannot serve as the repair coordinate for the cover-descent terminal packet.*

Proof. First fix the cover support. By Definition 126.662, the finite cover presents its terminal support packet exactly on the StreamName finite-window face, the DyadicRatCore ledger face, the RegSeqRat readback face, the Real seal face, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Now restrict the failed cover presentation to one accepted local section or accepted overlap where the carrier verdict, classifier verdict, or terminal route is lost. Apply Definition 126.654 on that local section. The local theorem places the defect on one of the four visible faces or on one displayed support row, and excludes quotient, host-sequence, limit, choice, completeness, aggregate-status, and bridge coordinates.

It remains to show that this local witness is still the cover witness. Use Definition 126.660 on the ordered cover support list. The induction transports the local localization through the StreamName window, DyadicRatCore ledger, RegSeqRat readback, Real seal boundary, and displayed support rows without adding any off-route coordinate.

At the RegSeqRat face, Definition 301.239 identifies the transported boundary with the terminal four-face support packet, and Definition 301.237 rules out a second finite RegSeqRat source with the same public verdict. Thus a RegSeqRat defect cannot be repaired by changing quotient equality, selected limits, or ambient completeness data.

Finally Definition 38.468 sends every accepted current Phase Real and Completion terminal read through the same ordered $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ exit route. The cover-descent packet therefore has no remaining coordinate outside the four faces and displayed rows on which a carrier verdict, classifier verdict, or consumer-facing terminal route defect could live. □

Theorem 126.664 (StreamName finite-cover terminal support removal witness)**.** *Let* $\{Q_i\}_{i\in I}$ *be a finite family of accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion* $\mathsf{StreamName}^{\uparrow}$ *request sections satisfying the accepted-overlap hypotheses of Definition 126.662. Delete from the cover-descent terminal support packet either one visible face among* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, or one displayed support row among* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$*. Then the shortened cover packet cannot present the same carrier verdict, classifier verdict, and consumer-facing terminal route as the original finite cover.*

The lost verdict is witnessed on one accepted local section or accepted overlap. Quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate formalstatus rows, and bridge rows cannot replace the deleted face or displayed row and cannot repair the cover-descent packet.*

Proof. Start with the finite cover support. By Definition 126.662, every visible face and displayed row named in the statement is a required coordinate of the cover-descent terminal packet. Deleting one of those coordinates therefore removes data needed by the accepted carrier verdict, classifier verdict, or consumer-facing terminal route.

Now localize the loss. Apply Definition 126.663 to the shortened cover packet. The defect is witnessed on one accepted local section or accepted overlap, and it lies on a visible $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ face or on one displayed BHist, hsame, Cont, Pkg, or local $\mathsf{NameCert}$ row.

On that local section, use Definition 126.656. The local deletion already prevents presentation of the same carrier verdict, classifier verdict, and consumer-facing terminal route, with the witness read as a finite request-section mismatch.

It remains to transport the local loss back through the cover. Use Definition 126.660 on the ordered cover support list. The induction replays the local witness through the StreamName finite window, DyadicRatCore ledger, RegSeqRat readback, Real seal boundary, and displayed support rows, so the cover cannot regain the lost terminal packet from another section of the same family.

Finally rule out substitutes. The exactness theorem Definition 301.239 identifies the RegSeqRat boundary with precisely the four-face terminal support packet, and Definition 301.237 rules out a second finite RegSeqRat source with the same public verdict. The Real exit totality theorem Definition 38.468 sends every accepted current Phase Real and Completion terminal read through the same ordered route.

Thus quotient stream equality, host sequence equality, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, aggregate formalstatus rows, and bridge rows are off-route for this finite cover. They cannot supply the deleted coordinate and cannot preserve the same carrier verdict, classifier verdict, and consumer-facing terminal route. □

126.49 StreamName Finite-Cover Support Removal Global Obstruction

This finite-cover support surface is the $\mathsf{StreamName}^{\uparrow}$-side read of the L10 route through chapter 291, chapter 301, and chapter 38: those sibling chapters supply the dyadic ledger, regular-sequence readback, and terminal $\mathsf{Real}^{\uparrow}$ seal faces consumed by the theorems in this file.

Theorem 126.665 (StreamName finite-cover support removal global obstruction)**.** *Let $\{Q_i\}_{i\in I}$ be an accepted finite cover of current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request sections feeding the DyadicRatCore–RegSeqRat–Real four-face route. Suppose the accepted overlaps display the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source, and the same* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows. If one displayed local support row is deleted from any member Q_j, then the cover-descent terminal support packet cannot present the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source.*

The obstruction is global over the finite cover: quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, bridge rows, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or a replacement regularity selector cannot supply the deleted row or restore the same cover-descent source.*

Proof. First restrict to the member where the deletion occurs. The local removal witness theorem Definition 126.656 says that deleting a displayed BHist, hsame, Cont, Pkg, or local NameCert row from the accepted terminal packet loses the carrier verdict, classifier verdict, or consumer-facing terminal route of that local section.

Next descend through the finite cover. Apply Definition 126.662. The cover-descent terminal packet is accepted exactly on the common $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces together with the displayed support rows on the accepted overlaps. Therefore a local deletion in Q_j is not confined to a private presentation choice; it removes one coordinate of the cover support itself.

Now localize the resulting cover defect. By Definition 126.663, a failure of the cover-descent carrier verdict, classifier verdict, or terminal route is witnessed on one accepted local section or

accepted overlap, and the witness lies on a displayed face or support row. In the present case the witness is the deleted local support row, so the cover cannot still present the same $\mathsf{Real}^{\uparrow}$ seal-visible source.

Finally rule out hidden replacement data. The selector nonchoice theorem Definition 126.343 prevents the $\mathsf{RegSeqRat}^{\uparrow}$ regularity row from re-entering as a hidden selector, host function, countable-choice witness, quotient representative, selected limit, ambient completeness coordinate, or independent completed-real carrier. Together with the exclusion clauses in the finite-cover minimality and defect localization theorems, this leaves no quotient equality, limit, choice, metric-completeness datum, aggregate formalstatus row, bridge row, ambient $\mathsf{Real}^{\uparrow}$ completeness principle, or replacement selector able to supply the missing row. □

Theorem 126.666 (StreamName finite-cover support invariance under refinement)**.** *Let $\{Q_i\}_{i\in I}$ and $\{R_k\}_{k\in K}$ be accepted finite covers of the same current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Suppose they admit an accepted common refinement $\{S_\ell\}_{\ell\in L}$, and that after pullback to the refinement the two covers agree on the four visible faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and on the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows. If one displayed local support row is deleted in either original cover, then every accepted refinement-equivalent presentation fails to present the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source.*

Equivalently, changing the finite-cover presentation cannot hide the missing support row. Quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, bridge rows, ambient $\mathsf{Real}^{\uparrow}$ *completeness, and replacement regularity selectors are not refinement coordinates for restoring that source.*

Proof. Pull both finite covers to the accepted common refinement $\{S_\ell\}_{\ell\in L}$. By hypothesis the pullbacks display the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and the same BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows. Thus the deleted row is a deleted coordinate of the refined cover support, not merely a feature of one presentation.

Apply Definition 126.662 to the refined cover. The accepted terminal support packet on the refinement is accepted exactly on the four visible faces and the displayed support rows. Deleting one displayed local support row therefore removes a coordinate needed for the same carrier verdict, classifier verdict, and terminal route.

Next localize the failure with Definition 126.663. The defect is witnessed on one accepted refined local section or accepted refined overlap, and it lies on a visible face or on a displayed support row. In this case the witness is the deleted local support row transported to the common refinement.

Finally apply Definition 126.665 on the refined presentation. The theorem rules out quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, bridge rows, ambient $\mathsf{Real}^{\uparrow}$ completeness, and replacement regularity selectors as substitute coordinates. Hence no presentation whose support agrees after refinement can present the same $\mathsf{Real}^{\uparrow}$ seal-visible source after the row is missing. □

Theorem 126.667 (StreamName finite-cover support preservation exactness)**.** *Let $\{Q_i\}_{i\in I}$ and $\{R_k\}_{k\in K}$ be accepted finite covers of the same current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Suppose they admit an accepted common refinement $\{S_\ell\}_{\ell\in L}$, and that on every accepted refined member and accepted refined overlap the two pullbacks preserve the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source, and the same displayed* BHist*, componentwise*

hsame, Cont, Pkg, *and local* NameCert *support rows. Then the two finite-cover terminal support packets present the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source after descent.*

The exactness criterion has no further coordinates. It does not assume or produce quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or replacement regularity selectors.*

Proof. Apply Definition 126.662 to the accepted common refinement. The accepted terminal support packet is identified by the four visible faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert rows on refined members and overlaps. By hypothesis the two pullbacks preserve exactly these rows, so their refined support packets expose the same seal-visible source.

It remains to exclude a hidden local defect. Use Definition 126.663 contrapositively: if the descended packets failed to present the same $\mathsf{Real}^{\uparrow}$ seal-visible source, the failure would be witnessed on some accepted refined member or accepted refined overlap, and the witness would lie on one of the displayed visible faces or support rows. Each such row is preserved by hypothesis, so no such local witness exists.

Finally compare with the negative boundary supplied by Definition 126.666. If one displayed row were missing, refinement would detect the loss and the same seal-visible source could not be presented. Since no row is missing, the complete finite L10 route is precisely the four visible faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with their displayed local support, and no quotient equality, selected limit, choice principle, metric-completeness datum, bridge row, ambient completeness principle, or replacement selector is an extra coordinate. □

Theorem 126.668 (StreamName finite-cover support preservation reflection)**.** *Let* $\{Q_i\}_{i\in I}$ *and* $\{R_k\}_{k\in K}$ *be accepted finite covers of the same current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section. Suppose they admit an accepted common refinement* $\{S_\ell\}_{\ell\in L}$*, and suppose the descended finite-cover terminal support packets present the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source. Then, after pullback to the accepted common refinement, the two presentations agree on the four visible faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and on the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

The reflection direction has exactly the same boundary as the exactness direction. It reflects only the finite-cover L10 support rows and does not reflect quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, aggregate formalstatus rows, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or replacement regularity selectors.*

Proof. Argue contrapositively on the accepted common refinement. Suppose that after pullback the two presentations differ on one of the four visible faces or on one displayed BHist, componentwise hsame, Cont, Pkg, or local NameCert row.

By Definition 126.663, the changed or missing displayed row localizes a finite-cover terminal defect on some accepted refined member or accepted refined overlap. The defect is not an invisible presentation choice: it lies on one of the rows from which the refined terminal support packet reads its carrier verdict, classifier verdict, or consumer-facing terminal route.

Apply Definition 126.665 to that localized support defect. A refined presentation with such a defect cannot present the same $\mathsf{Real}^{\uparrow}$ seal-visible source merely by deleting, changing, or omitting the displayed row. The obstruction also rules out quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, aggregate formalstatus rows, ambient $\mathsf{Real}^{\uparrow}$ completeness, and replacement regularity selectors as substitute coordinates for the defective row.

Finally use Definition 126.666. Passing between the original finite covers and the accepted common refinement cannot hide the localized defect or convert it into the same descended $\mathsf{Real}^{\uparrow}$

seal-visible source. Therefore the assumed sameness of the descended source forces agreement, after pullback, on all four visible faces and on the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert rows.

Together with Definition 126.667, this gives the bidirectional finite-cover support criterion for the L10 StreamName exit: preserving exactly the displayed finite support yields the same descended $\mathsf{Real}^{\uparrow}$ source, and the same descended $\mathsf{Real}^{\uparrow}$ source reflects preservation of exactly that displayed finite support. □

Theorem 126.669 (StreamName finite-cover support bicriterion)**.** *Let $\{Q_i\}_{i\in I}$ and $\{R_k\}_{k\in K}$ be accepted finite covers of the same current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion terminal* $\mathsf{StreamName}^{\uparrow}$ *request section, and suppose that they admit an accepted common refinement $\{S_\ell\}_{\ell\in L}$. The descended finite-cover terminal support packets present the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source if and only if, after pullback to the accepted common refinement, the two presentations agree on the four visible faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *and on the displayed* BHist, *componentwise* hsame, Cont, Pkg, *and local* NameCert *rows.*

This bicriterion is only a criterion for the finite-cover L10 support surface. It excludes quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, aggregate formalstatus rows, ambient $\mathsf{Real}^{\uparrow}$ *completeness, and replacement regularity selectors; none of these is an additional coordinate of the descended support packet, and none is recovered from the agreement assertion.*

Proof. For the forward direction, assume the descended finite-cover terminal support packets present the same $\mathsf{Real}^{\uparrow}$ seal-visible source. Apply Definition 126.668. It reflects that sameness back to agreement, after pullback to the accepted common refinement, on the four visible faces and on the displayed BHist, componentwise hsame, Cont, Pkg, and local NameCert rows.

For the reverse direction, assume agreement after pullback on exactly those visible faces and displayed support rows. Apply Definition 126.667. The exactness theorem descends that preserved finite support to the same $\mathsf{Real}^{\uparrow}$ seal-visible source for the two finite-cover terminal support packets.

Finally record the boundary of the equivalence. The exactness direction does not add quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, ambient $\mathsf{Real}^{\uparrow}$ completeness, or replacement regularity selectors, and the reflection direction does not reflect quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, aggregate formalstatus rows, ambient $\mathsf{Real}^{\uparrow}$ completeness, or replacement regularity selectors. Therefore the criterion binds only the displayed finite-cover support rows and has no hidden coordinate beyond them. □

126.50 StreamName finite-window diagonal section

Theorem 126.670 (StreamName finite-window diagonal section)**.** *Every finite diagonal section read by a* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer and then by a* $\mathsf{Real}^{\uparrow}$ *seal factors through the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window request. The displayed route is the finite window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget row, the* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows. The section exports no quotient stream equality, quotient equality of Cauchy presentations, selected limit, host real equality, countable-choice row, metric-completeness datum, or ambient completion coordinate.*

Proof. Start with the finite-window budget handoff of Definition 126.390. It places every $\mathsf{RegSeqRat}^{\uparrow}$ regularity row, dyadic tolerance row, and $\mathsf{Real}^{\uparrow}$ seal row behind the same displayed StreamName finite observation-budget surface.

Next apply the finite-request section packet of Definition 126.554 and Definition 126.555. These results package the endpoint, readback, budget, StreamName window, hsame, Cont, Pkg, and local NameCert rows as one finite request section rather than as separate diagonal sources.

Use the RegSeqRat handoff of Definition 126.574. The diagonal read reaches the $\mathsf{Real}^{\uparrow}$ seal only after the finite StreamName window and the RegSeqRat readback have been transported by hsame and replayed by Cont through the displayed support rows.

Finally apply the Real seal non-escape boundary of Definition 126.557 and the finite request seal lock of Definition 126.568. They exclude quotient streams, quotient Cauchy-presentation equality, selected limits, host real equality, countable choice, metric completeness, and ambient completion from the route. Thus the diagonal section is exactly the finite StreamName request transported and replayed through the listed BEDC rows. □

Theorem 126.671 (StreamName finite-window nested-refinement induction)**.** *Let*

$$W_0, W_1, \ldots, W_k$$

be an accepted finite chain of $\mathsf{StreamName}^{\uparrow}$ *windows such that each successor row* W_{i+1} *refines the previous window* W_i *by retaining the displayed pointwise rational observations and only appending later finite requests. Then the whole chain preserves the displayed pointwise rational observations, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row exposed by* W_0*. The induction exports no quotient stream equality, selected limit, host sequence equality, countable-choice schedule, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Proceed by induction on the finite refinement chain.

The base chain has only W_0. The conclusion is exactly the local finite-window diagonal section of Definition 126.670: the displayed observations, transport, replay, provenance, and local NameCert rows are already present, and no excluded coordinate is available.

For the successor step, assume the claim for the chain ending at W_i and read the accepted refinement row from W_i to W_{i+1}. The finite-window pullback of Definition 126.555 keeps the old rational observations visible inside the later window, while the reindexing route of Definition 126.390 places the same $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers behind that retained window surface.

Transport is componentwise. The hsame row of the successor refinement agrees with the previously displayed observations on the old window and only names the appended finite requests separately. The displayed Cont replay and Pkg provenance therefore compose along the same finite route, and the local $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ row remains the one read by the refined window chain.

Finally, Definition 126.557 and Definition 126.568 exclude quotient streams, selected limits, host sequence equality, countable choice, and ambient Real completeness at each successor stage. The finite induction therefore preserves exactly the listed StreamName rows for the whole chain. □

126.51 StreamName L10 gateway obligation surface

Theorem 126.672 (StreamName L10 gateway NameCert obligation surface)**.** *Every L10 gateway read exported by a* $\mathsf{StreamName}^{\uparrow}$ *packet is pinned to a finite* BHist *observation window before it can be consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$*. The public route consists of the finite StreamName carrier rows of Definition 126.1, the certificate fields of Definition 126.13, the finite request sections of Definition 126.554 and Definition 126.555, the terminal Real seal locks of Definition 126.568 and Definition 126.605, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows.*

The gateway exports no quotient stream equality, host sequence equality, selected limit, countable-choice row, metric-completeness datum, or ambient completion coordinate.

Proof. Read the carrier and certificate fields first. The StreamName packet exposes unary finite observations, bundle membership rows, pointwise rational classifier rows, transport rows, replay rows, provenance rows, and local naming rows; it does not expose a host sequence.

Next apply the finite request sections. They package endpoint, window, RegSeqRat budget, dyadic tolerance, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows as one finite gateway request.

Finally use the terminal seal locks. They force every Real-facing read to pass through the finite request section before the $\mathsf{Real}^{\uparrow}$ seal is available, and they refuse quotient streams, selected limits, host real equality, countable choice, metric completeness, and ambient completion. □

Theorem 126.673 (StreamName L10 gateway window reindex stability)**.** *Let W_0 and W_1 be accepted $\mathsf{StreamName}^{\uparrow}$ finite-window packets that are related by a certified reindex route. If their displayed endpoint rows, pointwise classifier rows, BHist support, hsame comparisons, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows transport componentwise, then every L10 gateway read through W_0 determines the same public finite observation section as the corresponding read through W_1.*

The stability statement is internal to the finite StreamName gateway. It does not assert quotient stream equality, host sequence equality, selected limits, countable choice, completion data, or a standard bridge row.

Proof. Start with finite-window reindex determinacy, Definition 126.639. Its hypotheses identify the endpoint rows, reindex route, and displayed support rows that determine a public finite observation section.

Use the public reindexing identity and associative laws, Definition 126.640 and Definition 126.641. They show that certified identity routes and composable certified routes preserve the displayed classifier, unary observation, bundle-membership, hsame, Cont, Pkg, and local naming rows.

Apply the terminal coverage theorem, Definition 126.642. Since the transported packets expose the same public finite observation section, every L10 gateway read reaches the same four-face route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no quotient, host, limit, choice, completion, or bridge coordinate. □

Theorem 126.674 (StreamName L10 gateway Real-RegSeqRat handoff)**.** *Every Real-facing L10 gateway read of a $\mathsf{StreamName}^{\uparrow}$ packet factors through the finite route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

The handoff uses finite observation windows, regular rational readback, dyadic budget rows, terminal real seal locks, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}$ rows. It does not export quotient stream equality, quotient equality of Cauchy presentations, selected limits, host real equality, countable choice, metric completeness, or ambient completion.

Proof. Begin with the L10 gateway factorization of Definition 126.347. It places the StreamName point rows, unary observations, bundle ledger, regular source row, dyadic observation ledger, finite tail witness, finite approximation row, and $\mathsf{Real}^{\uparrow}$ seal row on one displayed route.

Next use the RegSeqRat handoff and finite-window diagonal section, Definition 126.574 and Definition 126.670. They ensure that the Real-facing read is not detached from the same finite StreamName request.

The terminal Real seal locks then close the route. By Definition 126.568 and Definition 126.605, a consumer receives only the finite observation, regular-rational, dyadic-budget, and Real-seal rows, not quotient equality, selected limits, host equality, choice, completion, or a standard bridge. □

Theorem 126.675 (StreamName L10 face-window realization)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$ *L10 gateway packet consumed as Phase Real and Completion evidence realizes each finite request window through four displayed faces: the* $\mathsf{StreamName}^{\uparrow}$ *finite section, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. These four faces are carried together with componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows.*

The realization exports no quotient stream, selected limit, quotient equality of Cauchy presentations, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or host completion coordinate.*

Proof. Start with the L10 gateway obligation surface of Definition 126.672. It pins every gateway request to finite StreamName carrier rows, finite request sections, dyadic tolerance data, regular-rational readback, terminal Real locks, componentwise transport, replay, provenance, and local naming.

Apply the reindex-stability theorem, Definition 126.673. Certified reindex routes preserve the endpoint rows, pointwise classifier rows, BHist support, hsame comparisons, Cont routes, Pkg provenance, and local NameCert rows, so the same finite request window can be read through its transported public section.

Finally use the Real-RegSeqRat handoff of Definition 126.674. It orders the request through the StreamName finite section, RegSeqRat readback, DyadicRatCore budget, and Real seal before any Phase Real or Completion consumer sees evidence. Since each cited route refuses quotient streams, selected limits, countable choice, and ambient Real completeness, the four-face realization has the same refusal surface. □

Theorem 126.676 (StreamName finite request obligation surface)**.** *A finite request section of an accepted* $\mathsf{StreamName}^{\uparrow}$ *packet must expose the requested index, opened* BHist *window, point certificate row, pointwise classifier row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer may read the stream. The downstream consumer receives only that finite request surface, not quotient stream equality, host sequence equality, selected limits, countable choice, or ambient Real completeness.*

Proof. Start with the finite request vocabulary already used by the StreamName child files. A request section names one index, opens the corresponding finite BHist window, and records the point certificate and pointwise classifier rows attached to that window.

The structural rows then keep the request local. The hsame row transports the opened window and classifier componentwise, the Cont row replays the finite request, and the Pkg and NameCert rows record provenance and local naming.

Only after these rows are visible may the $\mathsf{RegSeqRat}^{\uparrow}$ route of chapter 301 read exactly the finite request rows as a regular rational source, and only after that downstream handoff may a $\mathsf{Real}^{\uparrow}$ consumer inspect a seal route. Since the section contains no quotient stream equality, host sequence equality, selected limit, choice, or ambient completeness coordinate, those data cannot enter through the finite request surface. □

126.52 Pointwise Certified Source

Definition 126.677 (Pointwise certified NameCert source)**.** *A pointwise certified NameCert source for* $\mathsf{StreamName}^{\uparrow}$ *is a finite packet*

$$W = (I, S, B, H, C, P, N)$$

where I is the requested index ledger, S is the certified stream source row, B is the opened BHist *window at I, H is componentwise* hsame *transport for the point row and classifier row, C is displayed* Cont *replay for the finite request, P is* Pkg *provenance over the StreamName, DyadicRatCore, RegSeqRat, and Real routes, and N is the local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row.*

The classifier reads only the displayed point row and the opened finite window. It exposes no quotient stream equality, host sequence equality, selected limit, countable-choice row, or $\mathsf{Real}^{\uparrow}$ *completeness assertion.*

Theorem 126.678 (Pointwise classifier stability)**.** *Let $W_0 = (I_0, S_0, B_0, H_0, C_0, P_0, N_0)$ and $W_1 = (I_1, S_1, B_1, H_1, C_1, P_1, N_1)$ be pointwise certified NameCert sources for* $\mathsf{StreamName}^{\uparrow}$*. If a displayed* hsame *route transports the requested index ledger, source row, opened* BHist *window, point classifier row, replay row, provenance row, and local naming row from W_0 to W_1, then every pointwise classifier read accepted at W_0 is accepted at W_1 with the transported finite request surface.*

The transported read remains a StreamName finite-window read that may be consumed by $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *only through their existing NameCert routes. It does not become quotient stream equality, a selected limit, host real equality, or a completeness principle.*

Proof. Start with the carrier rows of Definition 126.677. The pointwise source has only the requested index ledger, certified stream row, opened BHist window, transport row, replay row, provenance row, and local naming row available.

Use the displayed hsame route to move each row componentwise. The point certificate and classifier row are transported together with the opened window, so no host sequence or quotient stream coordinate is introduced during the comparison.

Replay the transported request with the Cont row. The replay keeps the request inside the same finite StreamName surface, after which Pkg provenance records the permitted sibling route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Since the packet contains no selected limit, host equality, countable choice, or completeness row, stability cannot export one. □

Theorem 126.679 (Constant certified point stream)**.** *For a constant rational point displayed as a* $\mathsf{StreamName}^{\uparrow}$ *pointwise certified source, every accepted finite request section opens the same point row, the same* BHist *window shape, the same pointwise classifier row, the same* hsame *transport, the same* Cont *replay, the same* Pkg *provenance, and the same local* NameCert *row. The resulting constant stream is a certified point stream for the L10 route through* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, not a host sequence equality or quotient stream representative.*

Proof. Project the pointwise source of Definition 126.677. Constancy is recorded as a displayed point row inside the finite request surface, so every request opens a finite BHist window of the same certificate shape.

Transport identical requests by the hsame row and replay them by the Cont row. These rows preserve the point certificate, classifier row, provenance, and local naming row without adding any host function or quotient coordinate.

Finally read the downstream route only through Pkg provenance. The consumer may pass the certified point stream to $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ as finite NameCert data, while selected limits, host real equality, countable choice, and $\mathsf{Real}^{\uparrow}$ completeness remain absent. □

Theorem 126.680 (Pointwise constant finite request section)**.** *A constant rational point displayed as a pointwise certified* $\mathsf{StreamName}^{\uparrow}$ *NameCert source determines, for every accepted finite request, the same requested index ledger, certified source row, opened* BHist *window, point classifier row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row. These rows form the finite request section available to any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer before that consumer can read the constant point stream.*

Proof. Use the pointwise certified source of Definition 126.677. Its displayed packet already separates the index ledger, certified source row, opened history window, transport row, replay row, provenance row, and local naming row from any downstream completion-facing interpretation.

Apply Definition 126.679. Constancy identifies the rational point row across accepted requests only inside the finite request surface, so the same classifier row and the same opened BHist window are replayed for each request.

The section handed to $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ is therefore exactly the displayed row package. Since neither Definition 126.677 nor Definition 126.679 supplies quotient stream equality, a selected limit, countable choice, or $\mathsf{Real}^{\uparrow}$ completeness, no downstream consumer can read such data from the constant section. □

Theorem 126.681 (Pointwise source reindex cofinality)**.** *Every accepted pointwise certified* $\mathsf{StreamName}^{\uparrow}$ *source whose finite request section is transported along a displayed unary reindexing row still factors through the same pointwise source, componentwise classifier, and local* $\mathsf{NameCert}$ *rows before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer may read it. The reindexed request may change the displayed finite ledger index, but it does not export quotient stream equality, host function equality, a selected infinite tail, countable choice, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Project the packet of Definition 126.677. The only available data are the requested index ledger, certified stream source row, opened BHist window, componentwise transport, replay, provenance, and local naming row.

Apply Definition 126.678 to the unary reindexing row. The classifier is transported componentwise with the opened finite window, so the target request remains a pointwise certified StreamName request rather than a host-level stream comparison.

The constant-section route of Definition 126.680 supplies only the base case in which the reindexing row leaves the displayed point fixed. General reindexing is therefore cofinal only through the same finite source, classifier, and NameCert rows.

The downstream consumer can then read the reindexed section through Pkg provenance toward $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$. Since no coordinate in the source supplies quotient equality, host function equality, an infinite tail selector, countable choice, or completeness, none is exported by the handoff. □

Theorem 126.682 (Pointwise map composition finite-window stability)**.** *Let* $W = (I, S, B, H, C, P, N)$ *be an accepted pointwise certified* $\mathsf{StreamName}^{\uparrow}$ *NameCert source. Suppose a displayed finite map row* M *is carried in the same packet, with its finite graph, source and target index ledgers, opened* BHist *window, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *row all displayed before the request is handed to any downstream consumer. Then the composed finite-window read along* M *still factors through the original pointwise source classifier and local naming row before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer can read it.*

The composed read remains a finite StreamName request surface. It exports no quotient stream equality, no host function equality, no selected infinite tail, no countable-choice row, and no ambient $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Project the source packet of Definition 126.677. The displayed map row contributes only a finite graph, the two finite ledgers, the opened history window, componentwise transport, replay, provenance, and the local naming row, so the composed request has no hidden host-level stream data.

Apply Definition 126.678 to transport the opened window and classifier row across the displayed graph of M. Then apply Definition 126.681 to keep the target request inside the same finite pointwise source surface after the ledger has been mapped.

The consumer route is therefore read only through the existing Pkg provenance. Since neither the source packet nor the displayed map row supplies quotient stream equality, host function equality, a selected infinite tail, countable choice, or $\mathsf{Real}^{\uparrow}$ completeness, the composed finite-window handoff cannot export any of them. □

126.53 Finite Observation Section Cofinality

Theorem 126.683 (StreamName finite observation section cofinality)**.** *Every finite observation request on a pointwise certified* $\mathsf{StreamName}^{\uparrow}$ *source factors through a finite section window that is cofinal for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *handoff reads. Concretely, after the request opens its index ledger, certified source row, finite* BHist *window, pointwise classifier row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, any later regular-rational or real-seal consumer may refine the request only by another finite section window over the same StreamName source. The handoff exposes finite BHist, hsame, Cont, and Pkg rows rather than quotient stream equality, selected limits, host real equality, or ambient completeness.*

Proof. Start with Definition 126.678. It keeps every accepted pointwise classifier read attached to the requested index ledger, certified source row, opened BHist window, transport row, replay row, provenance row, and local naming row.

Use Definition 126.680 for the section shape. The finite request section is the row package visible to $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers before either consumer can read a constant or regular point stream.

Now pass to the RegSeqRat and Real handoff files already carried by the StreamName hub. Their handoff reads consume finite windows and terminal seal rows through the same displayed StreamName source, so a larger downstream request is represented by a finite refinement of the same section window.

Thus the finite section windows are cofinal for the L10 handoff route. Since each step is expressed through BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, no quotient stream equality, selected limit, host real equality, or ambient completeness principle is introduced. □

Theorem 126.684 (StreamName finite observation section functoriality)**.** *Let S be a certified* $\mathsf{StreamName}^{\uparrow}$ *source and let*

$$U \longrightarrow V \longrightarrow W$$

be two composable finite observation-section refinements over S. If both refinements preserve the index ledger, finite BHist *windows, pointwise classifier rows,* hsame *transport,* Cont *replay,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{StreamName}^{\uparrow}}$ *rows, and the* $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *handoff surface, then their composite is again a finite observation-section refinement over S preserving exactly those rows. The composite introduces no quotient stream equality, selected limit, countable-choice row, host real equality, or ambient completeness principle.*

Proof. Apply finite observation section cofinality, Definition 126.683, to the source S and to each displayed refinement. Both arrows are finite section refinements over the same certified source, so their source row and index ledger are already fixed before any downstream consumer reads the handoff.

Use diagonal coherence, Definition 126.686, to compare the middle section V with the source and target windows. The comparison supplies a common finite section in which the classifier rows, BHist windows, hsame transports, Cont replays, Pkg rows, and local naming rows remain attached to S.

Now apply section induction, Definition 126.687, along the finite spine obtained by concatenating the two refinement traces. Monotone extension, Definition 126.688, identifies the old rows inside the concatenated section, so composition changes only the appended finite request rows.

The RegSeqRat and Real handoff surface is therefore preserved by the composite finite section. Since each cited step is expressed only through finite observation rows and their displayed transport, replay, provenance, and NameCert data, the composite has no coordinate for quotient streams, selected limits, countable choice, host real equality, or ambient completeness. □

Theorem 126.685 (StreamName finite observation section public cofinality)**.** *Every public* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *handoff read through* $\mathsf{StreamName}^{\uparrow}$ *factors through the finite observation section package of Definition 126.683. Any later refinement remains a finite section refinement over the same certified StreamName source, with the same index ledger, finite* BHist *window, pointwise classifier row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row.*

The public handoff surface therefore exports finite sections only. It contains no quotient stream equality, selected limit, countable-choice row, host real equality, or ambient completeness principle.

Proof. Start with finite observation section cofinality, Definition 126.683. It already states that finite observation requests cofinally cover the RegSeqRat and Real handoff reads over the displayed StreamName source.

Apply pointwise classifier stability, Definition 126.678. The classifier row, finite BHist window, transport row, replay row, provenance row, and local naming row remain attached to the same source when the handoff is refined.

The RegSeqRat and Real handoff inputs consume exactly those finite section rows before reading regular rational or real-seal data. Hence a public handoff cannot bypass the finite observation package; it may only request a larger finite section over the same source.

Since the route never introduces quotient streams, selected limits, countable choice, host real equality, or ambient completeness, the public cofinality interface is the same finite-section interface already witnessed locally. □

Theorem 126.686 (StreamName finite observation diagonal coherence)**.** *Let two finite observation section refinements read the same certified* $\mathsf{StreamName}^{\uparrow}$ *source before a* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *handoff. Then they admit a common finite refinement over that source whose pointwise classifier row, finite* BHist *window,* hsame *transport row,* Cont *replay row,* Pkg *provenance row, and local* NameCert *row still factor through the same public RegSeqRat and Real handoff surface. The common refinement synchronizes the two observations without adding quotient stream equality, selected limits, countable choice, host real equality, or ambient completeness.*

Proof. Apply finite observation section cofinality, Definition 126.683, to each refinement. Both observations are finite section windows over the same certified StreamName source, so their downstream reads are represented by finite windows in the same index ledger.

Use public cofinality, Definition 126.685, for the handoff surface. The RegSeqRat and Real consumers see only the finite section package, so a section large enough to contain both windows is again a public handoff refinement over the same source.

Finally apply pointwise classifier stability, Definition 126.678. It keeps the classifier row, BHist window, hsame transport, Cont replay, Pkg provenance, and local NameCert row attached to the common source after the finite window is enlarged.

Thus the two observations have a diagonal finite refinement that preserves exactly the rows visible to the RegSeqRat and Real handoff route. Since no step introduces a quotient stream, a selected limit, countable choice, host real equality, or ambient completeness, the synchronized refinement remains a finite-means StreamName observation. □

Theorem 126.687 (StreamName finite observation section induction)**.** *Every finite chain of accepted* $\mathsf{StreamName}^{\uparrow}$ *observation-section refinements over a pointwise certified source is generated from the empty request section by finitely many successor steps. Each successor step opens one finite* BHist *window, preserves the pointwise classifier row for the same certified source, and replays through the displayed* hsame*,* Cont*,* Pkg*, and local* NameCert *rows before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *handoff reads the section. Consequently every finite handoff-facing chain is represented by a finite section trace over the same StreamName source, not by quotient stream equality, selected limits, countable-choice rows, host real equality, or ambient completeness.*

Proof. The empty request section is the base surface supplied by finite observation section cofinality, Definition 126.683. It exposes only the index ledger, certified source row, and the finite row package visible to later RegSeqRat and Real consumers.

For the successor step, open the next finite BHist window over the same certified StreamName source. Pointwise classifier stability keeps the classifier row attached to that source, and the cofinality theorem keeps the opened window inside the same hsame, Cont, Pkg, and local NameCert replay package.

For two successor choices at the same finite stage, use diagonal coherence, Definition 126.686. It supplies a common finite refinement that preserves the displayed rows and synchronizes the observations without changing the public handoff surface.

Finally use public cofinality, Definition 126.685, to pass the finished finite chain to a $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer. The consumer reads only the finite section trace just generated, so the construction never introduces quotient stream equality, selected limits, countable choice, host real equality, or ambient completeness. □

Theorem 126.688 (StreamName finite observation section monotone extension)**.** *Let an accepted finite observation section over a certified* $\mathsf{StreamName}^{\uparrow}$ *source be enlarged by additional certified unary indices. Then every window, bundle-membership row,* hsame *comparison,* Cont *replay,* Pkg *provenance row, and local* NameCert *row already admitted on the old section remains unchanged on that old section. The enlarged section only appends finite request rows; it does not reinterpret earlier observations, replace the source classifier, or introduce quotient stream equality, selected limits, countable choice, host real equality, or ambient completeness.*

Proof. Induct over the appended finite request spine. In the empty case the enlarged section is the original section, so the old windows, membership rows, transports, replays, provenance rows, and local naming rows are identical by carrier projection.

For the successor step, add one certified unary index to the already enlarged section. Finite observation section cofinality, Definition 126.683, keeps the appended request inside a finite section window over the same certified StreamName source.

Use diagonal coherence, Definition 126.686, to compare the old section with the one-step enlargement. The common refinement restricts back to the old window rows and preserves the same pointwise classifier, hsame transport, Cont replay, Pkg provenance, and local NameCert rows there.

Finally apply section induction, Definition 126.687, to iterate this argument over the whole appended spine. Each step changes only the newly appended finite request row, so every previously admitted row remains fixed on the old section. □

Theorem 126.689 (StreamName finite-window handoff for constructive IVT moduli)**.** *Every accepted* ConstructiveIVTModulus$^{\uparrow}$ *bisection request opens only finitely many* StreamName$^{\uparrow}$ *observation windows before* RegSeqRat$^{\uparrow}$ *readback and the terminal* Real$^{\uparrow}$ *seal. The handoff reads the located interval source, opposite-sign witnesses, finite bisection schedule, and dyadic tolerance ledger of the modulus carrier, then opens exactly the endpoint and midpoint windows requested by that finite schedule. It does not claim a completed stream, selected branch, quotient equality, host root selector, countable choice, or ambient completeness.*

Proof. Project the ConstructiveIVTModulus$^{\uparrow}$ carrier. Its bisection schedule and tolerance ledger are finite rows, so they determine a bounded list of endpoint and midpoint observations.

Apply the StreamName$^{\uparrow}$ finite-window discipline already used by the L10 countable-name gateway. Each observation is a displayed window request in the carrier route, and no completed stream object is produced.

The same windows are then repacked by the RegSeqRat$^{\uparrow}$ readback row and only afterward reach the Real$^{\uparrow}$ seal. Since the carrier has no selected branch, quotient-equality, root-selection, choice, or completeness coordinate, the finite-window handoff is the full exported StreamName boundary. □

Theorem 126.690 (StreamName finite-request cover pullback)**.** *Let a* ConstructiveIVTModulus$^{\uparrow}$ *carrier open a finite family of endpoint or midpoint requests during its bisection schedule. Then that family pulls back to a finite* StreamName$^{\uparrow}$ *cover whose* RegSeqRat$^{\uparrow}$ *readback rows and terminal* Real$^{\uparrow}$ *seal row are unchanged from the original modulus carrier. The pullback only records the displayed request windows, dyadic tolerance rows, regular-rational readback rows, terminal seal,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows; it does not add completed streams, selected branches, quotient equality, countable choice, or ambient completeness.*

Proof. Project the finite bisection schedule from the ConstructiveIVTModulus$^{\uparrow}$ carrier. Its endpoint and midpoint requests form a bounded list because the carrier stores a finite schedule and a displayed dyadic tolerance ledger.

Apply Definition 126.689 to each request in that list. Each endpoint or midpoint observation is therefore represented by a finite StreamName$^{\uparrow}$ window, with no completed stream or branch selector produced.

Collect the resulting windows into one finite cover indexed by the request list. The cover uses the same dyadic tolerance rows as the original schedule, so the RegSeqRat$^{\uparrow}$ readback rows are the same rows already present in the carrier.

Finally repack the unchanged readbacks into the original terminal Real$^{\uparrow}$ seal row, carrying along the same hsame, Cont, Pkg, and local NameCert data. Since no coordinate of the carrier stores quotient equality, countable choice, or ambient completeness, the finite cover is only the pullback of the displayed StreamName windows. □

Theorem 126.691 (StreamName pointwise classifier induction)**.** *Let W be an accepted finite unary window for a* $\mathsf{StreamName}^{\uparrow}$ *packet. Suppose every displayed index in W carries pointwise classifier evidence, and suppose the window, classifier rows,* BHist *observations,* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows are transported together through the existing finite-window handoff surface. Then the whole finite window has a classified* $\mathsf{StreamName}^{\uparrow}$ *read. The classified read remains a finite observation packet; it exports no quotient stream equality, selected limit, host real equality, countable-choice schedule, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Induct on the finite unary window W. In the initial case, the window contains only the first displayed observation, so the pointwise classifier evidence at that observation gives the classified StreamName read after the local BHist, hsame, Cont, Pkg, and NameCert rows are projected.

For the successor step, assume the shorter window has already been classified. Add one displayed observation at the successor index, together with its pointwise classifier evidence.

Apply the finite-window transport route to keep the previously classified prefix and the new observation in the same hsame and Cont packet. Then use the pointwise handoff rows to attach the new classifier evidence to the enlarged window without changing the source StreamName packet.

The resulting packet classifies the enlarged finite window through exactly the displayed observations, classifier rows, transport rows, replay rows, provenance, and local naming data. Since the induction never introduces an infinite representative, quotient equality, a selected limit, countable choice, or ambient completeness coordinate, none is exported by the classified read. □

Theorem 126.692 (StreamName finite-prefix pointwise classifier induction)**.** *Let $F = (k, W, D, R, H, C, P, N)$ be an accepted* $\mathsf{FinitePrefixStream}^{\uparrow}$ *carrier whose displayed prefix windows carry pointwise* $\mathsf{StreamName}^{\uparrow}$ *classifier evidence at every displayed index. Then every displayed prefix index $i \leq k$ has a classified* $\mathsf{StreamName}^{\uparrow}$ *read obtained through exactly the finite* BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of F.*

The classified prefix read does not export quotient stream equality, selected tails, countable choice, host real equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or bridge checking.*

Proof. Apply Definition 7253.4 to the accepted carrier F. For each displayed $i \leq k$, the observation route is forced through the corresponding StreamName window row in W, the matching dyadic tolerance row in D, the RegSeqRat handoff row in R, and the structural rows H, C, P, N.

Now apply Definition 126.691 to the finite StreamName window exposed at that index. The assumed pointwise classifier evidence supplies the classifier row, while the observation induction supplies the finite BEDC support rows needed to transport and replay it.

Combining the two routes gives a classified StreamName read at each displayed prefix index. Since both cited routes are finite-window routes and neither has a coordinate for quotient streams, selected tails, countable choice, host real equality, ambient Real completeness, or bridge checking, the combined prefix classifier read exports none of those objects. □

Theorem 126.693 (StreamName pointwise finite-window induction)**.** *Let W be a certified finite observation section for a* $\mathsf{StreamName}^{\uparrow}$ *packet, displayed as a UnaryHistory window with its* BHist *observations, pointwise classifier rows, successor-window projection rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *data. Suppose a finite-window predicate is stable under pointwise classifier transport and under successor-window projection along the displayed UnaryHistory section. If the predicate holds at the initial displayed observation, then it holds on every certified finite observation section of W.*

The induction is internal to the displayed UnaryHistory window. It does not export host $\mathsf{Nat}^{\uparrow}$ *induction as a public primitive, quotient stream equality, selected tails, countable choice, host real equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or bridge checking.*

Proof. Start with the carrier definition of $\mathsf{StreamName}^{\uparrow}$ and read the certified observation section as a finite UnaryHistory packet. The initial displayed observation is covered by the assumed base evidence together with the local BHist, hsame, Cont, Pkg, and NameCert rows.

For the successor step, apply the pointwise classifier induction of Definition 126.691 to transport the predicate across the classifier row attached to the newly displayed observation. Then use finite observation section cofinality from Definition 126.683 to keep the enlarged section inside the certified observation surface.

The successor-window projection determinacy of Definition 126.299 identifies the predecessor section and the enlarged section as the displayed UnaryHistory step named by the certificate. Thus the predicate is propagated only through public finite-window rows.

Iterating over the displayed UnaryHistory constructors gives the claim for every certified finite observation section. The argument never exposes host $\mathsf{Nat}^{\uparrow}$ induction as part of the public certificate and never adds quotient streams, selected tails, countable choice, host real equality, ambient Real completeness, or bridge data. □

Theorem 126.694 (StreamName pointwise tail-section induction bridge)**.** *Let* $\mathcal{T}$ *be a certified* $\mathsf{StreamName}^{\uparrow}$ *tail section consumed by a downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *or finite-window* $\mathsf{Real}^{\uparrow}$ *handoff. Suppose a finite-window predicate is stable under pointwise classifier transport, successor-window projection, and finite observation-section cofinal refinement over the displayed* BHist *observations, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. If the predicate holds at the initial displayed observation of the source window, then it holds on every certified finite tail section of* $\mathcal{T}$ *that is consumed by the handoff.*

The conclusion is a tail-section handoff statement over the same certified source window. It does not introduce quotient stream equality, selected limit data, countable choice, host sequence equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or bridge checking.*

Proof. Apply the pointwise finite-window induction theorem Definition 126.693 to the certified source window. This propagates the predicate across every displayed finite observation section using only pointwise classifier transport and successor-window projection.

Next use finite observation-section cofinality, Definition 126.683. The tail section read by the downstream $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ handoff is a finite cofinal refinement of the same displayed source, not a new stream object or a chosen external tail.

Finally apply the public cofinality and monotone-extension rows attached to the handoff. They identify the consumed tail section as a finite refinement over the same BHist, hsame, Cont, Pkg, and local NameCert support rows. The predicate therefore reaches every certified tail section consumed by the handoff while staying inside the finite public packet. □

Theorem 126.695 (StreamName terminal-window inhabited section)**.** *Every accepted terminal* $\mathsf{StreamName}^{\uparrow}$ *finite window consumed by a downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *handoff has an inhabited displayed UnaryHistory section. Its initial observation, successor projection, pointwise classifier rows, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows are all visible in the consumed finite window.*

The inhabited section is a finite public section of the displayed terminal window. It is not obtained from quotient stream equality, a selected tail, countable choice, host sequence equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or bridge checking.*

Proof. Apply Definition 126.693 to the terminal finite window with the predicate saying that the current displayed section has a visible initial observation, successor projection interface, classifier row, and structural support. The base row is the initial displayed observation of the UnaryHistory window.

For the consumed terminal tail, apply Definition 126.694. It transports the same predicate from the source window to every finite tail section read by the downstream $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ handoff.

The resulting section is inhabited because the initial observation survives the tail-section handoff and every successor projection is displayed as a finite UnaryHistory row. The support rows are exactly the visible BHist, hsame, Cont, Pkg, and local NameCert rows named by the two induction theorems, so no quotient stream equality, selected tail, countable choice, or ambient Real completeness is introduced. □

Theorem 126.696 (StreamName finite-stream forward route)**.** *Every finite* $\mathsf{StreamName}^{\uparrow}$ *observation section first consumes the finite-stream packet of chapter 5916 before it is reindexed as pointwise StreamName window data. The route reads the finite request list, displayed observation window, componentwise* hsame *transport, finite* Cont *replay,* Pkg *provenance, and local* NameCert *row from the* $\mathsf{FiniteStream}^{\uparrow}$ *packet, then repacks those rows as the pointwise StreamName window surface used by downstream* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumers. It exports no infinite stream equality, no selected limit, and no ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with the finite-stream packet cited in chapter 5916. Its public rows are finite request, finite observation, transport, replay, provenance, and local naming data.

The StreamName observation section only reindexes those displayed finite rows as pointwise window data. The reindexing changes the consumer-facing window name but does not add a quotient stream, a hidden selector, or an infinite equality principle.

Consequently every downstream read through $\mathsf{StreamName}^{\uparrow}$ still factors through the same finite packet. Since the input has no coordinate for selected limits or ambient $\mathsf{Real}^{\uparrow}$ completeness, the StreamName route exports none. □

Theorem 126.697 (StreamName finite-stream forward preservation)**.** *The finite-stream-to-*$\mathsf{StreamName}^{\uparrow}$ *route of Definition 126.696 preserves the finite request list, displayed observation window, componentwise* hsame *rows, finite* Cont *replay,* Pkg *provenance, and local* NameCert *rows when the resulting observation section is consumed by* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *handoff packets. Each downstream consumer may refine the observation only through a finite* $\mathsf{StreamName}^{\uparrow}$ *section window over the same finite-stream source, and no consumer obtains infinite stream equality, quotient stream equality, selected limits, countable choice, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness from the route.*

Proof. Start with the forward route, Definition 126.696. It repacks the finite-stream request list, finite observation window, componentwise transport, replay, provenance, and local naming rows as a pointwise StreamName window without adding an infinite equality coordinate.

Apply finite observation section cofinality, Definition 126.683, to the resulting StreamName window. Any RegSeqRat or Real consumer sees only a finite section refinement over the same certified source, with the same displayed support rows.

The DyadicRatCore handoff reads the same terminal tolerance surface through those finite StreamName windows before it reaches the RegSeqRat and Real faces. Hence its consumer-facing data is also bounded by the preserved finite request, observation, transport, replay, provenance, and naming rows.

Thus all three downstream packets consume the same finite support supplied by the original finite-stream packet. Since the route and its finite observation refinements never add infinite stream equality, quotient stream equality, selected limits, countable choice, or ambient Real completeness, preservation holds at the handoff surface. □

Theorem 126.698 (StreamName finite-stream forward composition)**.** *Two consecutive finite-stream-to-*$\mathsf{StreamName}^{\uparrow}$ *forward routes compose into one finite observation section. The composite section preserves the finite request lists, displayed observation windows, componentwise* hsame *rows, finite* Cont *replay,* Pkg *provenance, and local* NameCert *rows from the two input sections, and it remains the finite* $\mathsf{StreamName}^{\uparrow}$ *window surface consumed by downstream* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *packets.*

The composed route exports no infinite stream equality, quotient stream equality, selected limit, countable-choice schedule, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 126.696 to the first finite-stream packet. It repacks the initial request list, observation window, transport, replay, provenance, and local naming rows as a pointwise $\mathsf{StreamName}^{\uparrow}$ observation section.

Apply the same route to the second finite-stream packet, whose source begins at the terminal finite section displayed by the first route. The shared endpoint is identified by componentwise hsame transport and replayed by the displayed Cont rows, so the two sections meet inside finite observation data.

Use finite observation section cofinality, Definition 126.683, to concatenate the consecutive request windows into a single finite $\mathsf{StreamName}^{\uparrow}$ section over the same certified source. The Pkg and NameCert rows are inherited from the two input packets as provenance and local naming for the composed section.

Finally apply preservation, Definition 126.697. Downstream $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers therefore see the composite as one finite-window route and receive no infinite stream equality, quotient stream equality, selected limits, countable choice, or ambient Real completeness. □
