The totally-bounded interface $\mathsf{TotallyBounded}^{\uparrow}$ packages a metric carrier admitting, for every $\varepsilon > 0$, an explicit finite ε-net. It depends on $\mathsf{NameCert}_{\mathsf{Met}^{\uparrow}}$ (chapter 57) and is the prerequisite for $\mathsf{NameCert}_{\mathsf{CompactMetric}^{\uparrow}}$ (chapter 129).

127.1 Carrier definition

Definition 127.1 (Singleton metric totally-bounded instance)**.** *The singleton metric totally-bounded instance is the* $\mathsf{Met}^{\uparrow}$ *carrier on histories*

$$T_{\mathsf{e}}(x) := \mathsf{hsame}(x, \mathsf{e}).$$

Its classifier is

$$x \sim_T y \quad \Longleftrightarrow \quad T_{\mathsf{e}}(x) \wedge T_{\mathsf{e}}(y) \wedge \mathsf{hsame}(x, y),$$

and its distance witness is the concrete metric row

$$d_T(x, y, \delta) := \mathsf{MetricDistanceWitness}(x, y, \delta).$$

For every positive tolerance history ε, the finite net is the one-point closed bundle $\mathsf{Bcons}(\mathsf{e}, \mathsf{Bnil})$ *with ledger center* e*. The bundle membership row is the head* $\mathsf{InBundle}$ *constructor, and the coverage ledger for a carried point x uses the empty-distance witness* $\mathsf{MetricDistanceWitness}(x, \mathsf{e}, \mathsf{e})$ *together with the carried endpoint row $T_{\mathsf{e}}(x)$.*

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedUpTasteGate single carrier alignment ChapterTasteGa`

Theorem 127.2 (Singleton metric totally-bounded laws)**.** *The instance of Definition 127.1 satisfies the concrete finite-net laws required by* $\mathsf{TotallyBounded}^{\uparrow}$*:* e *inhabits the carrier, the unique net center* e *lies in the carrier, every carried point is covered by that center at empty distance, the net witness is stable under the singleton classifier $\sim_T$, and the coverage row is compatible with metric empty-distance exactness from Definition 57.7.*

Proof. Carrier inhabitation and center membership are both the reflexive hsame row on e. Thus the ledger center named by the one-point $\mathsf{ProbeBundle}$ is accepted by T_{e}.

For coverage, fix a carried point x. The row $T_{\mathsf{e}}(x)$ is exactly $\mathsf{hsame}(x, \mathsf{e})$, so the singleton classifier records $x \sim_T \mathsf{e}$ using the carried endpoint row, reflexivity of e, and the same endpoint hsame witness.

Apply Definition 57.7 to identify the empty-distance metric row with the two endpoint classifiers to e. This packages $\mathsf{MetricDistanceWitness}(x, \mathsf{e}, \mathsf{e})$ as the coverage witness for the unique center, and the head $\mathsf{InBundle}$ constructor records that the center belongs to $\mathsf{Bcons}(\mathsf{e}, \mathsf{Bnil})$.

Stability under $\sim_T$ follows by unpacking the classifier on the source and target endpoints. Both histories classify with e, so the empty-distance exactness row supplies the same metric coverage after transport, and the closed bundle branch is unchanged. □

Lean4 (definition) `BEDC.Derived.TotallyBoundedUp.SingletonMetricTotallyBoundedInstance`
Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.SingletonMetricTotallyBounded laws`

The ten-field fit is: traditional target total boundedness by finite ε-nets; BEDC source $\mathsf{Met}^{\uparrow}$ over BHist; carrier T_{e}; classifier $\sim_T$; stability from hsame and $\mathsf{MetricDistanceWitness}$ empty-distance exactness; ledger one center and one $\mathsf{ProbeBundle}$ branch; core theorem Definition 127.2; exactness singleton coverage; standard bridge terminal metric space; status $\mathsf{ProofTarget}$.

Definition 127.3 (Totally bounded ProbeBundle net carrier)**.** *Let X be a metric BEDC carrier whose distance rows are encoded by* $\mathsf{MetricDistanceWitness}$*. A totally bounded ProbeBundle net carrier at tolerance history ε is the history relation*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$$

whose accepted row consists only of BHist *ledger data:*

1. *a positive* $\mathsf{NameCert}_{\mathsf{Rat}^{\uparrow}}$ *tolerance history ε;*
2. *a closed* $\mathsf{ProbeBundle}$ *$\mathcal{P}$ of center names;*
3. *for every probe row* $\mathsf{InBundle}(p, \mathcal{P})$*, a center history c_p admitted by the metric carrier X;*
4. *for every such bundled probe, a positive* $\mathsf{NameCert}_{\mathsf{Rat}^{\uparrow}}$ *radius history r_p;*
5. *for every source-point history x admitted by X, a bundled probe row* $\mathsf{InBundle}(p, \mathcal{P})$*, a distance history d_p, and a row* $\mathsf{MetricDistanceWitness}(x, c_p, d_p)$ *whose* $\mathsf{Rat}^{\uparrow}$ *comparison ledger certifies $d_p \leq \varepsilon$.*

The finite carrier is the closed $\mathsf{ProbeBundle}$ *inductive together with the displayed* $\mathsf{InBundle}$ *coverage rows. It is not an external enumeration of centers, and no host-level list is exposed as certificate data.*

Lean4 (definition) `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet`

Theorem 127.4 (Totally bounded ProbeBundle net coverage stability)**.** *Let X be a metric BEDC carrier with* $\mathsf{MetricDistanceWitness}$ *classifier transport. Suppose*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$$

holds. If the tolerance history ε, the bundled center histories c_p, the positive radius histories r_p, and all displayed distance histories d_p are transported by hsame*, and if the positive-tolerance, positive-radius, and bound comparisons are transported by the* $\mathsf{Rat}^{\uparrow}$ *classifier, then the same* $\mathsf{ProbeBundle}$ *$\mathcal{P}$ with the transported ledgers is again a valid totally bounded net for the transported tolerance history.*

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet coverage hsame transport`

Proof. Proceed by induction on the closed ProbeBundle spine. In the Bnil case there is no bundled probe row to transport, and any accepted coverage row is absent by inversion on InBundle.

For a cons bundle $\mathsf{Bcons}(p, \mathcal{P}_0)$, the head probe is handled by the head constructor of InBundle and the tail probes are handled by the induction hypothesis through the tail constructor. The center history and the positive radius history attached to each case are moved along the supplied hsame rows, while the $\mathsf{Rat}^{\uparrow}$ classifier transports positivity of the radius ledger.

Now fix a transported source-point history x'. The original coverage row for an hsame representative x supplies a bundled probe p, a center c_p, and a distance row $\mathsf{MetricDistanceWitness}(x, c_p, d_p)$ with $d_p \leq \varepsilon$. Metric hsame transport carries this row to $\mathsf{MetricDistanceWitness}(x', c'_p, d'_p)$ for the transported center and distance histories.

It remains to repack the bound. The $\mathsf{Rat}^{\uparrow}$ classifier transports the comparison $d_p \leq \varepsilon$ to the comparison $d'_p \leq \varepsilon'$, and the same $\mathsf{InBundle}(p, \mathcal{P})$ constructor records that the chosen probe still belongs to the finite carrier. Thus the transported ledgers satisfy the carrier relation for the same closed bundle. □

127.2 The certificate

Theorem 127.5 (TotallyBoundedUp ProbeBundle NameCert target)**.** *The carrier of Definition 127.3, the classifier given by transported tolerance and bundled ledger histories, the coverage-stability theorem Definition 127.4, and the ledger policy that records the tolerance,* ProbeBundle, InBundle *membership rows, center histories, positive radius histories,* MetricDistanceWitness *rows, and* $\mathsf{Rat}^{\uparrow}$ *bound rows form the paper-level* NameCert *target for* $\mathsf{TotallyBounded}^{\uparrow}$ *over a* $\mathsf{Met}^{\uparrow}$ *carrier.*

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet name certificate`

Proof. The source field is the underlying $\mathsf{Met}^{\uparrow}$ carrier together with its accepted point histories and metric-distance classifier. The pattern field is the relation $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$ for each positive $\mathsf{Rat}^{\uparrow}$ tolerance history.

The classifier acts on the visible tolerance and on every bundled ledger row: centers, radii, distance histories, and comparison proofs are transported by the displayed hsame and $\mathsf{Rat}^{\uparrow}$ classifier rows. The finite part of the certificate is unchanged because $\mathcal{P}$ is the closed ProbeBundle inductive and membership is witnessed by InBundle constructors.

The stability obligation is exactly Definition 127.4. The ledger policy records the same rows named in the carrier definition, so source soundness, pattern soundness, classifier stability, and ledger soundness are all witnessed by the displayed carrier and stability theorem. This is the required current paper target for $\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}$. □

Theorem 127.6 (Totally bounded ProbeBundle net tolerance weakening)**.** *Let X be a metric BEDC carrier whose distance rows are encoded by* MetricDistanceWitness*, and write $\delta \leq_{\mathsf{Rat}^{\uparrow}} \eta$ for a visible non-strict* $\mathsf{Rat}^{\uparrow}$ *comparison ledger. Suppose*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$$

holds in the sense of Definition 127.3. If ε' is a positive $\mathsf{NameCert}_{\mathsf{Rat}^{\uparrow}}$ *tolerance history and $\theta : \varepsilon \leq_{\mathsf{Rat}^{\uparrow}} \varepsilon'$ is supplied, then the row $net_{\varepsilon'}$ obtained from net by reusing the same closed* ProbeBundle *spine, bundled centers, radius histories,* InBundle *rows, source-point probe selections,*

and MetricDistanceWitness *rows, and by replacing each displayed bound* $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon$ *with its transitive composite* $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon'$*, satisfies*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon', \mathcal{P}, net_{\varepsilon'}).$$

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet tolerance weakening`

Proof. Unpack the accepted row for *net*. It contains the positive tolerance row for ε, the closed ProbeBundle carrier $\mathcal{P}$, the center and positive-radius ledgers attached to each bundled probe, and, for each source-point history x carried by X, a bundled probe p, a distance history d, a row $\mathsf{MetricDistanceWitness}(x, c_p, d)$, and a comparison ledger $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon$.

To build the row at ε', use the supplied positive tolerance row for ε'. The closed bundle, the InBundle membership rows, the center histories, and the radius histories are copied verbatim from *net*. These clauses of Definition 127.3 do not mention the upper tolerance except through its positivity row.

Now fix a carried source-point history x. Read from *net* the same bundled probe p, the same center c_p, the same distance history d, and the same metric row $\mathsf{MetricDistanceWitness}(x, c_p, d)$. The original coverage comparison gives $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon$. Compose this comparison on the right with $\theta : \varepsilon \leq_{\mathsf{Rat}^\uparrow} \varepsilon'$ by the transitivity field of the non-strict $\mathsf{Rat}^\uparrow$ comparison ledger. The resulting row is $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon'$.

Thus every source point keeps its original bundled probe and metric-distance witness, while only the final rational upper-bound ledger is weakened from ε to ε'. All fields required by the totally bounded ProbeBundle net carrier are therefore present for $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon', \mathcal{P}, net_{\varepsilon'})$. □

Definition 127.7 (Subcarrier-restricted TotallyBounded ProbeBundle net)**.** *Let* $X : \mathsf{BHist} \to \mathsf{Prop}$ *be a metric BEDC carrier with* MetricDistanceWitness *rows, and let* $Y : \mathsf{BHist} \to \mathsf{Prop}$ *be a subcarrier of* X *with inclusion*

$$\iota_Y : \forall y : \mathsf{BHist}.\ Y(y) \to X(y).$$

Given a row

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$$

in the sense of Definition 127.3, the subcarrier-restricted row

$$\mathsf{TotallyBoundedProbeBundleNet}_{X \downarrow Y}(\varepsilon, \mathcal{P}, net|_Y)$$

keeps the positive tolerance history, the closed ProbeBundle $\mathcal{P}$*, every bundled center history* c_p *carried by* X*, every positive radius history* r_p*, and every* $\mathsf{InBundle}(p, \mathcal{P})$ *row from net, while replacing the source-point coverage clause by the same clause quantified only over histories carried by* Y*.*

Lean4 (definition) `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNetSubcarrierRestriction`

Theorem 127.8 (Totally bounded ProbeBundle net subcarrier restriction)**.** *Let* X *be a metric BEDC carrier whose distance rows are encoded by* MetricDistanceWitness*, and let* Y *be a classifier-stable subcarrier of* X*. Thus there are rows*

$$\iota_Y : \forall y : \mathsf{BHist}.\ Y(y) \to X(y)$$

and

$$\sigma_Y : \forall y y' : \mathsf{BHist}.\ Y(y) \to y \sim_X y' \to Y(y'),$$

where $\sim_X$ is the metric classifier of Definition 57.4. If

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$$

holds, then the row obtained by restricting only the source-point coverage quantifier satisfies

$$\mathsf{TotallyBoundedProbeBundleNet}_{X\downarrow Y}(\varepsilon, \mathcal{P}, net|_Y).$$

Moreover, if every bundled center is also carried by Y,

$$\forall p : \mathsf{BHist}.\ \mathsf{InBundle}(p, \mathcal{P}) \to Y(c_p),$$

then the same restricted row is an ordinary $\mathsf{TotallyBoundedProbeBundleNet}(Y, \varepsilon, \mathcal{P}, net|_Y)$ *for the induced metric subcarrier.*

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet subcarrier restriction`

Proof. Unpack the accepted row for $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}, net)$ using Definition 127.3. It supplies the positive $\mathsf{NameCert}_{\mathsf{Rat}^\uparrow}$ tolerance history ε, the closed $\mathsf{ProbeBundle}$ spine $\mathcal{P}$, the bundled center histories c_p carried by X, the positive radius histories r_p, and the coverage row for every source-point history carried by X.

The subcarrier-restricted row keeps all bundle-indexed data unchanged. The positive tolerance row, the closed bundle spine, the $\mathsf{InBundle}(p, \mathcal{P})$ witnesses, the ambient center rows $X(c_p)$, and the radius rows are exactly the rows already present in *net*. These clauses do not inspect whether the covered source point is taken from X or from the subcarrier Y.

It remains to verify coverage for a carried point of Y. Fix $y : \mathsf{BHist}$ with $Y(y)$. The inclusion row gives $X(y)$. Applying the coverage clause of *net* to this ambient source point gives a bundled probe p, a membership row $\mathsf{InBundle}(p, \mathcal{P})$, a distance history d_p, a metric row

$$\mathsf{MetricDistanceWitness}(y, c_p, d_p),$$

and a rational comparison ledger

$$d_p \leq_{\mathsf{Rat}^\uparrow} \varepsilon.$$

The restricted row uses precisely these witnesses for the same point y. Thus every Y-carried point is covered by the same closed bundle $\mathcal{P}$ with the same distance and bound ledgers.

The classifier-stability row σ_Y records that the induced carrier is a legitimate classifier-stable subcarrier: replacing a Y-carried endpoint by an ambient-classified endpoint keeps it in Y. No center or distance ledger is altered by this restriction step.

If the additional center-carrier rows $\forall p.\ \mathsf{InBundle}(p, \mathcal{P}) \to Y(c_p)$ are supplied, then the only remaining difference between the relative row and the ordinary $\mathsf{TotallyBoundedProbeBundleNet}$ row over Y disappears. Replace each ambient center clause $X(c_p)$ by the supplied subcarrier center clause $Y(c_p)$, and keep the same positive tolerance, bundle spine, radius rows, coverage witnesses, metric-distance rows, and rational bound ledgers. These are exactly the fields required for $\mathsf{TotallyBoundedProbeBundleNet}(Y, \varepsilon, \mathcal{P}, net|_Y)$. □

Lemma 127.9 (ProbeBundle append membership row separation)**.** *Let $\mathcal{P}_X$ and $\mathcal{P}_Y$ be closed* $\mathsf{ProbeBundle}$ *spines. For every probe history p, a visible membership row*

$$\mathsf{InBundle}(p, \mathsf{bundleAppend}(\mathcal{P}_X, \mathcal{P}_Y))$$

determines either a left membership row $\mathsf{InBundle}(p, \mathcal{P}_X)$ *or a right membership row* $\mathsf{InBundle}(p, \mathcal{P}_Y)$*. Conversely, every left or right membership row injects into the appended bundle. The alternatives are row alternatives: if the same probe name occurs on both sides, the left and right ledger branches remain distinct membership rows.*

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet append membership separation`

Proof. Induct on the closed spine $\mathcal{P}_X$. If $\mathcal{P}_X = \mathsf{Bnil}$, then $\mathsf{bundleAppend}(\mathsf{Bnil}, \mathcal{P}_Y)$ is $\mathcal{P}_Y$. Thus an appended membership row is exactly a right membership row, and the converse right injection is the identity. There is no left membership row in the empty bundle.

For the cons case write $\mathcal{P}_X = \mathsf{Bcons}(q, \mathcal{P}_0)$. A membership row in

$$\mathsf{InBundle}(p, \mathsf{bundleAppend}(\mathsf{Bcons}(q, \mathcal{P}_0), \mathcal{P}_Y))$$

is either the head equality row $p = q$ or a tail row in $\mathsf{bundleAppend}(\mathcal{P}_0, \mathcal{P}_Y)$. The head equality gives the left membership row in $\mathsf{Bcons}(q, \mathcal{P}_0)$. For a tail row, apply the induction hypothesis. A left-tail result is reinserted by the tail constructor of $\mathsf{InBundle}$ for $\mathsf{Bcons}(q, \mathcal{P}_0)$, and a right result remains a right membership row in $\mathcal{P}_Y$.

The converse injections are obtained by the same constructors. A left head row maps to the appended head row. A left tail row first injects into $\mathsf{bundleAppend}(\mathcal{P}_0, \mathcal{P}_Y)$ by the induction hypothesis and then into the appended cons tail. A right row first injects into $\mathsf{bundleAppend}(\mathcal{P}_0, \mathcal{P}_Y)$ and then into the appended cons tail. This proves both directions and keeps duplicated probe names separated by their visible branch rows. □

Theorem 127.10 (Finite union of totally bounded ProbeBundle nets)**.** *Let $X, Y : \mathsf{BHist} \to \mathsf{Prop}$ be metric BEDC carriers over the same* $\mathsf{MetricDistanceWitness}$ *rows and the same metric classifier of Definition 57.4. Define the union carrier by*

$$(X \cup Y)(z) :\Longleftrightarrow X(z) \vee Y(z).$$

Assume

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_X, net_X) \quad \textit{and} \quad \mathsf{TotallyBoundedProbeBundleNet}(Y, \varepsilon, \mathcal{P}_Y, net_Y)$$

in the sense of Definition 127.3. Let

$$\mathcal{P}_{X \cup Y} := \mathsf{bundleAppend}(\mathcal{P}_X, \mathcal{P}_Y).$$

Then the union carrier $X \cup Y$ carries a totally bounded ProbeBundle net at the same tolerance ε with probe bundle $\mathcal{P}_{X \cup Y}$. Its ledger $net_{X \cup Y}$ is obtained by reading each appended membership row through Definition 127.9: left rows use the corresponding fields of net_X, and right rows use the corresponding fields of net_Y.

Proof. Unpack the two accepted rows by Definition 127.3. The row net_X supplies a positive $\mathsf{NameCert}_{\mathsf{Rat}^\uparrow}$ tolerance history ε, the closed bundle $\mathcal{P}_X$, center histories, positive radius histories, and coverage rows for all points carried by X. The row net_Y supplies the same fields over Y and $\mathcal{P}_Y$ at the same tolerance history. Use either positive-tolerance row for the union net.

The finite carrier of the union net is the closed spine $\mathsf{bundleAppend}(\mathcal{P}_X, \mathcal{P}_Y)$. Since $\mathsf{bundleAppend}$ is generated by recursion on the left closed $\mathsf{ProbeBundle}$ spine, the result is again a closed $\mathsf{ProbeBundle}$.

Fix an appended probe row

$$\alpha : \mathsf{InBundle}(p, \mathcal{P}_{X \cup Y}).$$

By Definition 127.9, α is read as either a left row $\alpha_X : \mathsf{InBundle}(p, \mathcal{P}_X)$ or a right row $\alpha_Y : \mathsf{InBundle}(p, \mathcal{P}_Y)$. In the left case, copy from net_X the center history, positive radius history, and center-carrier row attached to α_X; the center is carried by $X \cup Y$ by the left union injection. In the right case, copy the corresponding fields from net_Y and use the right union injection. If the same

probe name appears in both bundles, these are still two ledger branches selected by the visible membership row, so no side-disjointness assumption is required.

It remains to verify coverage. Let z be a history carried by $X \cup Y$. If $X(z)$ holds, the coverage clause of net_X supplies a probe p, a row $\mathsf{InBundle}(p, \mathcal{P}_X)$, a center history, a distance history d, a metric row

$$\mathsf{MetricDistanceWitness}(z, c_p, d),$$

and a rational comparison ledger $d \leq_{\mathsf{Rat}^\uparrow} \varepsilon$. Inject the left membership row into $\mathsf{InBundle}(p, \mathcal{P}_{X \cup Y})$ using Definition 127.9, and keep the same center, distance, metric witness, and bound ledger. The center-carrier row is promoted from X to $X \cup Y$ by the left union injection.

If $Y(z)$ holds, apply the same argument to net_Y, inject the right membership row into the appended bundle, and promote the center-carrier row by the right union injection. Thus every source point of $X \cup Y$ is covered by a bundled center in $\mathcal{P}_{X \cup Y}$ at distance bounded by the same tolerance ε. All fields required by Definition 127.3 are present for

$$\mathsf{TotallyBoundedProbeBundleNet}(X \cup Y, \varepsilon, \mathcal{P}_{X \cup Y}, net_{X \cup Y}).$$

□

Lean4 ✓ `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet finite union`

Theorem 127.11 (TotallyBoundedUp compact-metric component bridge)**.** *Let X be a certified metric carrier, and suppose that each positive* $\mathsf{Rat}^\uparrow$ *tolerance history ε is assigned a row*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$$

as in Definition 127.3. This family supplies exactly the totally-bounded component required by

$$\mathsf{CompactMetricCertificate}(X)$$

in Definition 129.1: the exported carrier is the same carrier X; the finite carrier at tolerance ε is the closed ProbeBundle *spine $\mathcal{P}_\varepsilon$; membership is read only through rows of* InBundle*; coverage is witnessed by the displayed* MetricDistanceWitness *rows in net_ε; and every bound is one of the displayed* $\mathsf{Rat}^\uparrow$ *comparison ledgers against ε.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.TotallyBoundedCompactMetric component bridge`

Proof. The carrier component is fixed before the net is read. By Definition 129.1, the compact-metric certificate asks for a totally-bounded field over the same certified metric carrier X. By Definition 127.5, each accepted $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ row exports the same target carrier X, so no carrier translation or quotienting step is present.

The finite component is the closed probe spine already carried by the totally-bounded row. The unpacking specified in Definition 127.3 exposes $\mathcal{P}_\varepsilon$ as a closed ProbeBundle, and every center or probe lookup is keyed by a visible InBundle row. Thus the compact-metric field consumes the bundle ledger rather than an ambient finite set or an untracked list of representatives.

The coverage and bound components are also copied without changing their meaning. For each point history carried by X, Definition 127.4 keeps the coverage witness stable under the stated metric carrier interface: the same center row, the same MetricDistanceWitness distance row, and the same $\mathsf{Rat}^\uparrow$ comparison ledger against ε are the rows consumed by the totally-bounded clause of $\mathsf{CompactMetricCertificate}(X)$.

Therefore the bridge row contributes only the totally-bounded component named in Definition 129.1. It does not assert open-cover compactness, does not select a finite subcover, and does not introduce any host-level choice principle. □

Closure status for $\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}$.

Constructive story: A totally bounded metric carrier is built by taking an already certified $\mathsf{Met}^{\uparrow}$ carrier and, for each positive $\mathsf{Rat}^{\uparrow}$ tolerance history ε, displaying a closed finite ProbeBundle of center names with membership rows, center histories, radius histories, distance witnesses, and rational bound ledgers. A row is admitted only when every carried source point is assigned one of those bundled probes and a visible MetricDistanceWitness whose distance is classified below ε; data lacking the positive tolerance, closed bundle, center carrier row, membership constructor, or comparison ledger is outside the carrier. Two such net rows are the same when the tolerance and every visible center, radius, distance, and comparison row transport through hsame and the $\mathsf{Rat}^{\uparrow}$ classifier while the same closed bundle spine keeps its membership branches visible. The source is the underlying metric carrier and its point-distance certificate, the pattern is the finite-net coverage package, and the ledger records the tolerance, bundle, membership, centers, radii, coverage distances, and rational inequalities without replacing them by an external finite set. The five name-certificate obligations follow because the singleton carrier at e gives an inhabited example, history-equality and rational classification supply reflexive, symmetric, and transitive comparison, and coverage stability repacks any classified representative as an accepted net. A history package h lies in the signature gap of a $\mathsf{TotallyBounded}^{\uparrow}$ token p when the source-domain accepts its metric carrier and finite-net row, the signature relation pairs that row with an answer net and evidence ledger, and the token-introduction relation names the answer as p; unfolded, the same ProbeBundle centers cover each source point at the positive tolerance encoded by p. The chapter registers this ProbeBundle-net construction under the name $\mathsf{TotallyBounded}^{\uparrow}$; the compact-metric component bridge reads the same finite ledgers downstream, with no open-cover compactness, finite-subcover choice, sequential compactness, or host-level list of centers introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper scope binds the exported ProbeBundle-net NameCert target over $\mathsf{Met}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$, coverage transport, tolerance weakening, subcarrier restriction, append membership separation, finite union, the $\mathsf{CompactMetric}^{\uparrow}$ component bridge of Definition 127.11, and the consumer references from $\mathsf{CompactMetric}^{\uparrow}$ and the compact uniform-continuity capstone.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.TotallyBoundedUp.TotallyBoundedProbeBundleNet\_name\_certificate`

Bridge status: paperBridge

Not claimed: Open-cover compactness, sequential compactness, finite-subcover choice, and bridgeChecked verification are not claimed.

Upgrade path: Only bridgeChecked audit coverage can strengthen the verification axis; the chapter claims no open-cover compactness or sequential compactness principle.

Chapter 128

A Concrete Naming Certificate for $\mathsf{CompleteMetric}^{\uparrow}$

The complete-metric interface $\mathsf{CompleteMetric}^{\uparrow}$ packages a metric carrier in which every regular Cauchy sequence converges to an explicit limit with explicit modulus. It is the L10 sub-milestone certified by the real-completeness capstone (chapter 9238) and the substrate for $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$.

$\mathsf{CompleteMetric}^{\uparrow}$ consumes the $\mathsf{Met}^{\uparrow}$ distance-witness and classifier rows of chapter 57 before adding limit-witness data, so its completion surface is a metric-carrier extension rather than a kernel-only float.

128.1 Carrier definition

Definition 128.1 (Singleton complete metric instance)**.** *The singleton complete metric instance is the metric carrier on histories*

$$C_{\mathsf{e}}(x) := \mathsf{hsame}(x, \mathsf{e}).$$

Its classifier is

$$x \sim_C y \quad \Longleftrightarrow \quad C_{\mathsf{e}}(x) \wedge C_{\mathsf{e}}(y) \wedge \mathsf{hsame}(x, y).$$

A regular Cauchy name for this carrier is a stream of observed histories γ whose every observed history γ_n is carried by C_{e}, together with the regularity ledger asserting that every displayed pair γ_m, γ_n admits the empty-distance metric row $\mathsf{MetricDistanceWitness}(\gamma_m, \gamma_n, \mathsf{e})$ *after transport along their carried endpoint rows. The limit selector sends every such name to* e*. Its modulus is the empty history, and its convergence distance witness at every observation is* $\mathsf{MetricDistanceWitness}(\gamma_n, \mathsf{e}, \mathsf{e})$*.*

Lean4 (definition) `BEDC.Derived.CompleteMetricUp.CompleteMetricSingletonCarrier`
Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricSingleton semantic name certificate`

Definition 128.2 (Complete metric limit witness)**.** *Let X be a certified metric carrier over* BHist*, with point classifier, distance rows encoded by* $\mathsf{MetricDistanceWitness}$*, and the* $\mathsf{Rat}^{\uparrow}$ *comparison*

ledgers used for visible tolerances. A complete metric limit witness for a regular Cauchy stream name s is the BEDC relation

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$$

whose accepted row consists of the following ledgers:

1. *a* $\mathsf{StreamName}^{\uparrow}$ *regular Cauchy stream name s whose observations are carried by X;*
2. *an explicit modulus history μ certifying the regular Cauchy bound for s at each positive* $\mathsf{Rat}^{\uparrow}$ *tolerance;*
3. *a limit history ℓ carried by X;*
4. *for every positive tolerance history ε, a threshold observation history N_ε displayed by μ;*
5. *for every observation history n beyond N_ε, a distance history $d_{n,\varepsilon}$ together with the row* $\mathsf{MetricDistanceWitness}(s($ *and a* $\mathsf{Rat}^{\uparrow}$ *comparison ledger certifying $d_{n,\varepsilon} \le \varepsilon$.*

The witness is therefore a finite-schema history package: the carrier, stream, modulus, limit, metric-distance rows, and rational comparisons are all visible BEDC ledgers, while convergence is recorded by the family of displayed late-observation bounds.

128.2 The certificate

Theorem 128.3 (Singleton complete metric laws)**.** *The instance of Definition 128.1 satisfies the complete-metric laws required by* $\mathsf{CompleteMetric}^{\uparrow}$*: every C_{e} regular Cauchy name converges to the selected limit* e*, the selected limit is stable under the classifier $\sim_C$, any two displayed limits are* hsame*, and the convergence ledger is compatible with metric empty-distance exactness from Definition 57.7. This construction is the* $\mathsf{CompleteMetric}^{\uparrow}$ *companion to Definition 127.2.*

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.SingletonCompleteMetric laws`

Proof. Unfold C_{e}. Each observed history γ_n of a regular Cauchy name comes with a carried endpoint row $\mathsf{hsame}(\gamma_n, \mathsf{e})$. The selected limit e is carried by reflexivity of hsame, and the empty modulus asks for no additional history beyond this endpoint ledger.

For convergence, apply Definition 57.7 to the endpoint rows $\mathsf{hsame}(\gamma_n, \mathsf{e})$ and $\mathsf{hsame}(\mathsf{e}, \mathsf{e})$. This identifies the empty-distance metric row $\mathsf{MetricDistanceWitness}(\gamma_n, \mathsf{e}, \mathsf{e})$ with the classifier data already carried by the stream observation and the selected limit.

Stability under $\sim_C$ is obtained by unpacking the classifier. A transported candidate limit is carried by C_{e}, hence it is hsame to e. Transitivity of hsame transports the convergence ledger from

e to that candidate, while the empty-distance exactness theorem supplies the same metric row after the endpoint transport.

Finally, suppose ℓ_1 and ℓ_2 are two displayed limits for the same regular Cauchy name. Each displayed limit is carried by C_{e}, so $\mathsf{hsame}(\ell_1, \mathsf{e})$ and $\mathsf{hsame}(\ell_2, \mathsf{e})$ hold. Symmetry and transitivity of hsame give $\mathsf{hsame}(\ell_1, \ell_2)$, proving uniqueness of displayed limits inside the singleton classifier. □

Theorem 128.4 (Complete metric limit witness stability)**.** *Let X be a certified metric carrier with* $\mathsf{StreamName}^{\uparrow}$ *observation transport,* $\mathsf{MetricDistanceWitness}$ *transport, and* $\mathsf{Rat}^{\uparrow}$ *comparison transport. If*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$$

holds, and if the stream observations of s, the modulus history μ, the limit history ℓ, every displayed threshold, and every displayed distance history are transported by hsame *together with the corresponding* $\mathsf{Rat}^{\uparrow}$ *positivity and comparison rows, then the transported ledgers form a complete metric limit witness*

$$\mathsf{CompleteMetricLimitWitness}(X, s', \mu', \ell', L')$$

for the transported regular Cauchy stream name s' and transported limit history ℓ'.

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness hsame transport`

Proof. Unpack the witness row. The stream component is pointwise: for each certified observation history, $\mathsf{StreamName}^{\uparrow}$ transport carries the observed history $s(n)$ to the corresponding observed history $s'(n')$, and the regular Cauchy modulus row is moved along the supplied hsame history for μ.

Fix a positive tolerance history ε' transported from ε. The threshold ledger N_ε is carried to $N'_{\varepsilon'}$, and the $\mathsf{Rat}^{\uparrow}$ classifier transports the positivity row for the tolerance together with the order row expressing that an observation is late enough.

For such a late transported observation, the original witness supplies $\mathsf{MetricDistanceWitness}(s(n), \ell, d_{n,\varepsilon})$ and the bound $d_{n,\varepsilon} \le \varepsilon$. Metric-distance transport moves this row to

$$\mathsf{MetricDistanceWitness}(s'(n'), \ell', d'_{n',\varepsilon'}).$$

The remaining ledger is the comparison. Apply the $\mathsf{Rat}^{\uparrow}$ classifier transport to the displayed bound and repack the result as $d'_{n',\varepsilon'} \le \varepsilon'$. Since every field of the carrier row has been transported and the quantification over late observations is preserved pointwise, the transported package is again a complete metric limit witness. □

Theorem 128.5 (CompleteMetricUp limit witness NameCert target)**.** *Let X be a certified* $\mathsf{Met}^{\uparrow}$ *carrier over* BHist*. The carrier of Definition 128.2, the classifier given by transported stream observations, modulus histories, limit histories, threshold ledgers, distance histories, and* $\mathsf{Rat}^{\uparrow}$ *comparison rows, the stability theorem Definition 128.4, and the ledger policy recording* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{MetricDistanceWitness}$ *rows, and* $\mathsf{Rat}^{\uparrow}$ *bounds form the paper-level* $\mathsf{NameCert}$ *target for* $\mathsf{CompleteMetric}^{\uparrow}$ *over X.*

Proof. The source object is the certified metric carrier X together with its $\mathsf{Met}^{\uparrow}$ point classifier and distance-row interface. The BEDC pattern is the regular Cauchy stream name s, the modulus history μ, the carried limit history ℓ, and the family L of late-observation bound ledgers in Definition 128.2.

The classifier is the componentwise transport relation on this package. It requires transported $\mathsf{StreamName}^{\uparrow}$ observations, transported modulus and limit histories, transported threshold histories for each positive tolerance, transported distance histories, and transported $\mathsf{Rat}^{\uparrow}$ positivity and comparison rows. These are exactly the histories named in the public complete-metric witness.

For the stability field, apply Definition 128.4. It takes a displayed complete metric limit witness and the componentwise classifier data just listed, then repacks them as a complete metric limit witness for the transported stream and transported limit.

The ledger policy is therefore visible and finite-schema: it records $\mathsf{StreamName}^{\uparrow}$ observation rows, $\mathsf{MetricDistanceWitness}$ rows from late observations to the selected limit, and $\mathsf{Rat}^{\uparrow}$ comparison rows showing that each displayed distance is below the requested positive tolerance. The remaining entries of the ten-field template are inherited from the same metric carrier: target name $\mathsf{CompleteMetric}^{\uparrow}$, carrier X, exactness by metric endpoint transport, and no separate standard bridge. Thus the listed fields assemble the paper-level $\mathsf{NameCert}$ target for $\mathsf{CompleteMetric}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness name certificate`

Theorem 128.6 (Complete metric limit witness uniqueness)**.** *Let X be a separated certified $\mathsf{Met}^{\uparrow}$ carrier over BHist with point classifier $\sim_X$. Assume the metric certificate supplies symmetry, the triangle comparison row, the positive-half $\mathsf{Rat}^{\uparrow}$ comparison ledger, and zero-distance exactness in the following ledger form: if carried histories a, b have, for every positive $\mathsf{Rat}^{\uparrow}$ tolerance ε, a distance history e_ε with*

$$\mathsf{MetricDistanceWitness}(a, b, e_\varepsilon) \quad \textit{and} \quad e_\varepsilon \le \varepsilon,$$

then $a \sim_X b$. If two displayed complete-metric limit witnesses converge the same regular Cauchy stream name s,

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu_0, \ell_0, L_0) \quad \textit{and} \quad \mathsf{CompleteMetricLimitWitness}(X, s, \mu_1, \ell_1, L_1),$$

then their limit histories are point-classifier equal:

$$\ell_0 \sim_X \ell_1.$$

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness singleton uniqueness`

Proof. Unpack the two rows of Definition 128.2. The rows state that ℓ_0 and ℓ_1 are carried by X, and that each positive $\mathsf{Rat}^{\uparrow}$ tolerance supplies a threshold after which the observations of the same stream s are within that tolerance of the displayed limit.

Fix a positive tolerance ε. Choose its positive half ρ_ε together with the comparison ledger $\rho_\varepsilon + \rho_\varepsilon \le \varepsilon$. The first limit witness supplies a threshold N^0_ρ such that every observation n beyond it has a distance row

$$\mathsf{MetricDistanceWitness}(s(n), \ell_0, d^0_{n,\rho}) \quad \text{with} \quad d^0_{n,\rho} \le \rho_\varepsilon.$$

The second witness supplies a threshold N^1_ρ such that every observation n beyond it has a distance row

$$\mathsf{MetricDistanceWitness}(s(n), \ell_1, d^1_{n,\rho}) \quad \text{with} \quad d^1_{n,\rho} \le \rho_\varepsilon.$$

The common-tail ledger of the regular $\mathsf{StreamName}^{\uparrow}$ component gives an observation n_ε beyond both thresholds.

Apply metric symmetry to the first displayed distance row at n_ε, obtaining the same bound for a row from ℓ_0 to $s(n_\varepsilon)$. Apply the triangle comparison row to this symmetric row and to the second displayed row from $s(n_\varepsilon)$ to ℓ_1. This produces a distance history e_ε with

$$\mathsf{MetricDistanceWitness}(\ell_0, \ell_1, e_\varepsilon)$$

and a comparison ledger

$$e_\varepsilon \leq d^0_{n_\varepsilon,\rho} + d^1_{n_\varepsilon,\rho}.$$

The two convergence bounds and the half-tolerance comparison compose in $\mathsf{Rat}^\uparrow$ to give

$$e_\varepsilon \leq \varepsilon.$$

Since ε was an arbitrary positive $\mathsf{Rat}^\uparrow$ tolerance, the pair ℓ_0, ℓ_1 has displayed distance below every positive tolerance. The zero-distance exactness field of the separated metric carrier therefore returns $\ell_0 \sim_X \ell_1$. □

Theorem 128.7 (Complete metric limit witness tolerance weakening)**.** *Let X be a certified $\mathsf{Met}^\uparrow$ carrier over BHist whose distance rows are encoded by $\mathsf{MetricDistanceWitness}$, and write $\delta \leq_{\mathsf{Rat}^\uparrow} \eta$ for a visible non-strict $\mathsf{Rat}^\uparrow$ comparison ledger. Suppose*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$$

holds in the sense of Definition 128.2. Let Θ be a visible weakening ledger such that, for every positive target tolerance history η, it supplies a positive source tolerance history ε_η and a comparison ledger

$$\theta_\eta : \varepsilon_\eta \leq_{\mathsf{Rat}^\uparrow} \eta.$$

Define L^Θ at η by reusing the branch of L at ε_η: the same threshold N_{ε_η} displayed by μ, the same late-observation distance histories d_{n,ε_η}, and the same rows

$$\mathsf{MetricDistanceWitness}(s(n), \ell, d_{n,\varepsilon_\eta}),$$

while replacing each displayed bound

$$d_{n,\varepsilon_\eta} \leq_{\mathsf{Rat}^\uparrow} \varepsilon_\eta$$

by its transitive composite with θ_η. Then

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L^\Theta)$$

holds for the weakened tolerance ledger family.

Proof. Unpack the accepted row for $\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$ using Definition 128.2. It supplies the carried stream name, the modulus history μ, the carried limit history ℓ, and, for every positive source tolerance history ε, a threshold N_ε displayed by μ. For every observation history n beyond that threshold, it also supplies a distance history $d_{n,\varepsilon}$, a row

$$\mathsf{MetricDistanceWitness}(s(n), \ell, d_{n,\varepsilon}),$$

and a rational comparison ledger

$$d_{n,\varepsilon} \leq_{\mathsf{Rat}^\uparrow} \varepsilon.$$

Fix a positive target tolerance history η. The weakening ledger Θ supplies a positive source tolerance ε_η and the comparison row $\theta_\eta : \varepsilon_\eta \leq_{\mathsf{Rat}^\uparrow} \eta$. Read the original witness at that source

tolerance. The threshold N_{ε_η}, the late-observation predicate, the distance history d_{n,ε_η}, and the metric-distance row from $s(n)$ to ℓ are copied unchanged into the target branch.

Only the final upper-bound comparison is altered. For each late observation, the source branch gives

$$d_{n,\varepsilon_\eta} \leq_{\mathsf{Rat}^\uparrow} \varepsilon_\eta.$$

Composing this row on the right with $\theta_\eta : \varepsilon_\eta \leq_{\mathsf{Rat}^\uparrow} \eta$ by transitivity of the non-strict $\mathsf{Rat}^\uparrow$ comparison ledger gives

$$d_{n,\varepsilon_\eta} \leq_{\mathsf{Rat}^\uparrow} \eta.$$

This argument is pointwise in the target tolerance history η. Hence every positive target tolerance has a displayed threshold and every late observation has a displayed metric-distance row bounded by that target tolerance. The carrier, stream, modulus, limit, threshold, and distance ledgers are exactly the rows required by Definition 128.2, so the repacked family L^Θ is a complete metric limit witness for the same stream, modulus, and limit. □

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness tolerance weakening`

Theorem 128.8 (CompleteMetricUp limit-witness standard bridge)**.** *The public* $\mathsf{CompleteMetric}^\uparrow$ *limit-witness interface of Definition 128.2 and Definition 128.5 admits a conservative standard interpretation as explicit Bishop complete-metric convergence data over the same* BHist *carrier. Under this bridge, a BEDC row*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$$

is read as the displayed datum consisting of the stream s, modulus μ, limit ℓ, the convergence rows

$$\mathsf{MetricDistanceWitness}(s(n), \ell, d_{n,\varepsilon}),$$

positive denominator and budget rows for the $\mathsf{Rat}^\uparrow$ *tolerances, tolerance weakening rows, and separated-limit uniqueness. Conversely, any displayed standard convergence datum with exactly these BEDC rows and no additional host primitive repacks as*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L).$$

The bridge asserts only this bidirectional reading of the displayed convergence rows. It does not assert RealUp completeness, Banach completion, compactness, operation descent, host-level quotient equality, or choice.

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness standard bridge row package`

Proof. For the forward reading, start with the public row $\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$. The NameCert target Definition 128.5 identifies the carrier, classifier, and ledger policy: the stream observations, modulus history, carried limit, threshold histories, distance histories, and $\mathsf{Rat}^\uparrow$ comparison rows are exactly the public fields of the witness.

Unpacking Definition 128.2 therefore gives the Bishop-style convergence data without changing carrier. For each positive tolerance history ε, the package supplies a threshold displayed by μ; for each late observation it supplies the metric-distance row from $s(n)$ to ℓ and the rational budget row $d_{n,\varepsilon} \leq_{\mathsf{Rat}^\uparrow} \varepsilon$. The positive-denominator and budget readbacks are part of the same visible $\mathsf{Rat}^\uparrow$ ledger surface.

The standard bridge fields are conservative because their stability and comparison behavior are already supplied inside the public interface. Definition 128.4 transports the whole package along

hsame-compatible stream, modulus, limit, threshold, distance, and rational comparison rows. Definition 128.7 supplies the tolerance-weakening component by repacking source tolerance branches through displayed $\mathsf{Rat}^{\uparrow}$ comparison rows. For separated carriers, Definition 128.6 gives the uniqueness of the displayed limit in the point classifier.

For the reverse reading, assume a displayed Bishop complete-metric convergence datum over the same BHist carrier whose entries are precisely the stream s, modulus μ, limit ℓ, positive tolerance rows, thresholds, late-observation metric-distance rows, and $\mathsf{Rat}^{\uparrow}$ budget rows just listed. Place those rows in the five fields of Definition 128.2: stream, modulus, carried limit, tolerance thresholds, and late-observation distance comparisons. Since no extra host equality, quotient, compactness, completion, or selection principle is used, the repacked object is exactly $\mathsf{CompleteMetricLimitWitness}(X, s, \mu, \ell, L)$.

Thus encode and decode are identity-on-rows readings of the same finite BEDC ledger surface. Their round trips are immediate row repackings, theorem preservation is limited to stability, uniqueness, and tolerance weakening as cited above, and the no-host-leak condition holds at paper level because the bridge introduces no public carrier or theorem field beyond those BEDC rows. □

Lean4 ✓ `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness standard bridge`

Closure status for $\mathsf{NameCert}_{\mathsf{CompleteMetric}^{\uparrow}}$.

Constructive story: A complete metric witness is generated over an already certified $\mathsf{Met}^{\uparrow}$ carrier by displaying a regular $\mathsf{StreamName}^{\uparrow}$ Cauchy stream, a modulus history, a carried limit history, and for every positive $\mathsf{Rat}^{\uparrow}$ tolerance a threshold with late-observation distance and bound ledgers. The carrier accepts exactly those packages whose observations stay in the metric carrier and whose late observations have visible MetricDistanceWitness rows to the proposed limit below the requested tolerance; a stream without its modulus, carried limit, threshold row, distance row, or rational comparison is not part of the surface. The classifier is componentwise transport of the stream observations, modulus, limit, thresholds, distances, and rational comparisons by hsame and the $\mathsf{Rat}^{\uparrow}$ classifier, so two witnesses are identified only when the displayed convergence ledger can be repacked field by field. The source is the metric carrier with its stream observations, the pattern is explicit Cauchy convergence to a named limit, and the ledger keeps the observation rows, modulus, thresholds, late distances, and tolerance budgets visible rather than forming a completion quotient. The five name-certificate obligations are supplied by the singleton carrier at e for inhabitation, by the equivalence laws of history-equality and rational comparison for the classifier, and by limit-witness stability for closure under classified replacements. A package h lies in the signature gap of a $\mathsf{CompleteMetric}^{\uparrow}$ token p when the source-domain accepts its regular stream and limit witness, the signature relation pairs it with an answer convergence package and evidence ledger, and the token-introduction relation names that answer as p; concretely, p records the same stream, modulus, limit, and late-distance bounds. The standard bridge reads this finite ledger as Bishop-style complete-metric convergence data and reads it back without adding choice, host completion, quotient equality, compactness, or Banach structure; the chapter registers the construction under the name $\mathsf{CompleteMetric}^{\uparrow}$.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompleteMetric}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature CompleteMetricUp paper-side boundary is bound to the limit-witness NameCert target, the singleton complete metric instance, the singleton limit-selector readback, separated-limit uniqueness, tolerance weakening, StreamNameUp observations, MetricDistanceWitness convergence rows, RatUp comparison ledgers, and the displayed standard bridge for the same finite ledger surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompleteMetric}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.CompleteMetricUp.CompleteMetricLimitWitness\_name\_certificate`

Bridge status: paperBridge

Not claimed: RealUp completeness, Banach completion, compactness, operation descent, host-level quotient equality, choice, or bridgeChecked verification.

Upgrade path: Only a stronger verification grade requires bridgeChecked audit verification for the paper bridge; no further paper closure grade is asserted here.

Chapter 129

A Concrete Naming Certificate for $\mathsf{CompactMetric}^{\uparrow}$

The compact-metric interface $\mathsf{CompactMetric}^{\uparrow}$ packages a metric carrier that is both totally bounded and complete in the senses of $\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}$ (chapter 127) and $\mathsf{NameCert}_{\mathsf{CompleteMetric}^{\uparrow}}$ (chapter 128). It is the metric form of compactness used by the Heine–Cantor capstone (chapter 9237).

129.1 Carrier definition

Definition 129.1 (Compact metric certificate carrier)**.** *Let X be a certified metric carrier over* BHist*. The compact metric certificate carrier*

$$\mathsf{CompactMetricCertificate}(X)$$

is the conjunction of the following BEDC certificate fields:

1. *a* $\mathsf{Met}^{\uparrow}$ *carrier and distance package for X, with distance rows encoded by* $\mathsf{MetricDistanceWitness}$ *and classifier transport on point histories;*
2. *for every positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history ε, a* $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ *package of Definition 127.5;*
3. *for every regular Cauchy* $\mathsf{StreamName}^{\uparrow}$ *stream name s whose observations are carried by X, a complete metric limit witness* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$ *as in Definition 128.2.*

Thus compactness is represented by the metric carrier, the finite ProbeBundle-net family at each visible positive tolerance, and the explicit limit-witness family for all regular Cauchy streams. No external compact set or host-level subsequence principle is part of the carrier.

Lean4 (definition) `BEDC.Derived.CompactMetricUp.CompactMetricCertificateCarrier`

129.2 The certificate

Theorem 129.2 (Compact metric carrier obligation)**.** *Let X carry the compact metric certificate relation of Definition 129.1. Then the public carrier row for* $\mathsf{CompactMetric}^{\uparrow}$ *is exactly the underlying* $\mathsf{Met}^{\uparrow}$ *carrier: the same* BHist *point histories are accepted, the same point classifier is used, the displayed distance rows are the inherited* $\mathsf{MetricDistanceWitness}$ *rows, and distance-transport is the*

hsame-*stable transport row supplied by the metric certificate. In the ten-field* NameCert *roadmap template this fixes the source, carrier, classifier, stability, and metric ledger entries before the* TotallyBounded$^{\uparrow}$ *and* CompleteMetric$^{\uparrow}$ *fields are read.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate metric distance transport`

Proof. Unpack the first field of Definition 129.1. It is a Met$^{\uparrow}$ package over BHist, so it already names the accepted point histories, their point classifier, and the distance witness relation used for every metric comparison.

No compact-specific carrier is introduced at this stage. The CompactMetric$^{\uparrow}$ carrier copies those point histories and copies the point classifier, so classifier transport is the same hsame row that the metric certificate uses on endpoints.

It remains to record the ledger surface. Each distance claim exposed by the compact certificate is a MetricDistanceWitness row inherited from Met$^{\uparrow}$, and distance transport is precisely the inherited hsame-stable metric transport. These rows give the carrier, classifier, distance witness, and distance-transport obligations required by the NameCert template. □

Theorem 129.3 (Compact metric finite-net obligation)**.** *Let X carry the compact metric certificate relation of Definition 129.1. For every positive* Rat$^{\uparrow}$ *tolerance history ε, the* TotallyBounded$^{\uparrow}$ *field supplies a closed* ProbeBundle *net with center histories, positive radius histories, bundle-membership rows, metric coverage rows, and rational comparison ledgers. These center, radius, coverage, and ledger rows are stable under* hsame *and the* Rat$^{\uparrow}$ *classifier by Definition 127.4, and they form the finite-net carrier, classifier-stability, and ledger obligations for* CompactMetric$^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricTotallyBoundedNet obligation`

Proof. Fix a positive Rat$^{\uparrow}$ tolerance history ε. The second field of Definition 129.1 gives a TotallyBoundedProbeBundleNet$(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ row, where $\mathcal{P}_\varepsilon$ is a closed ProbeBundle and membership is witnessed internally by InBundle constructors.

Unpacking that row gives the finite-net carrier: each bundled probe has a center history carried by the metric source, a positive radius history, and a coverage ledger saying that every carried point has a bundled center within the displayed tolerance. The ledger rows are exactly the tolerance history, center histories, radius histories, membership constructors, MetricDistanceWitness rows, and Rat$^{\uparrow}$ bound comparisons.

Apply Definition 127.4. It transports the positive tolerance, bundled centers, radii, metric distances, and bound comparisons along hsame and the Rat$^{\uparrow}$ classifier while keeping the same closed ProbeBundle carrier. Therefore the finite-net family supplies the required classifier-stability and ledger obligations for the compact metric certificate. □

Theorem 129.4 (Compact metric complete-limit obligation)**.** *Let X carry the compact metric certificate relation of Definition 129.1. For every regular* StreamName$^{\uparrow}$ *Cauchy stream name s whose observations are carried by X, the* CompleteMetric$^{\uparrow}$ *field supplies a* CompleteMetricLimitWitness$(X, s, \mu_s, \ell_s, L_s)$ *row. This row records the stream, modulus, limit classifier, threshold histories, late-observation distance rows, and* Rat$^{\uparrow}$ *comparison ledgers, and it is stable under stream transport, modulus transport, and limit-classifier transport by Definition 128.4. These rows form the complete-limit carrier, classifier-stability, and ledger obligations for* CompactMetric$^{\uparrow}$*.*

Proof. Fix a regular StreamName$^{\uparrow}$ Cauchy stream name s whose observations lie in the inherited Met$^{\uparrow}$ carrier. The third field of Definition 129.1 provides a complete metric limit witness for s, with explicit modulus history μ_s, carried limit history ℓ_s, and late-observation ledger family L_s.

Unpack the witness. Its carrier data are the observed stream histories, the modulus, the limit history, and the displayed threshold histories. Its ledger data are the MetricDistanceWitness rows from late observations to the limit and the corresponding $\mathsf{Rat}^{\uparrow}$ comparisons against each positive tolerance.

Apply Definition 128.4. Stream transport moves the observed histories, modulus transport moves the Cauchy threshold rows, and limit classifier transport moves ℓ_s while preserving the late-distance witnesses and rational bounds. Thus every regular Cauchy stream receives a transported limit-witness package, giving the complete metric part of the $\mathsf{CompactMetric}^{\uparrow}$ NameCert surface. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCompleteLimit obligation`

Theorem 129.5 (Compact metric package from total boundedness and completeness)**.** *For a certified metric carrier X, the three fields of Definition 129.1 form the paper-level* NameCert *target for* $\mathsf{CompactMetric}^{\uparrow}$*. The classifier is inherited from the* $\mathsf{Met}^{\uparrow}$ *point and distance classifier; the totally-bounded field is stable by Definition 127.4; and the complete-metric field is stable by Definition 128.4.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate hsame transport`
Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricSingleton certificate package`

Proof. Start with the metric carrier field. It supplies the source object, point classifier, distance rows, and metric-distance transport used by both subcertificates, so the public $\mathsf{CompactMetric}^{\uparrow}$ carrier can use the same histories and the same MetricDistanceWitness ledger policy.

For total boundedness, fix a transported positive tolerance history. The certificate carrier provides the corresponding closed ProbeBundle net, its bundled center histories, positive radius histories, membership rows, distance witnesses, and rational comparison ledgers. Apply Definition 127.4 to transport this finite-net row along the metric and $\mathsf{Rat}^{\uparrow}$ classifier data.

For completeness, fix a transported regular Cauchy stream name whose observations are carried by X. The certificate carrier supplies the modulus history, limit history, threshold ledgers, and late-observation distance bounds. Apply Definition 128.4 to transport these rows pointwise and recover the displayed limit witness for the transported stream.

The ledger policy for $\mathsf{CompactMetric}^{\uparrow}$ is exactly the union of these three visible packages: metric carrier data, ProbeBundle-net data at each positive tolerance, and complete-limit data for each regular Cauchy stream. Since each component has classifier transport and the shared source classifier is the metric one, the assembled fields satisfy the paper-level NameCert target for $\mathsf{CompactMetric}^{\uparrow}$. □

Theorem 129.6 (Compact metric certificate scope)**.** *For a certified metric carrier X, the source, carrier, classifier, stability, ledger, exactness, and status fields of* $\mathsf{CompactMetricCertificate}(X)$ *are exactly the fields exposed in Definition 129.1: the* $\mathsf{Met}^{\uparrow}$ *carrier and* MetricDistanceWitness *rows, the* TotallyBoundedProbeBundleNet *rows at positive* $\mathsf{Rat}^{\uparrow}$ *tolerances, and the* CompleteMetricLimitWitness *rows for regular Cauchy* $\mathsf{StreamName}^{\uparrow}$ *stream names.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate scope`

Proof. Unpack the three displayed fields of Definition 129.1. The first field supplies the source object, carrier predicate, point-history classifier, distance witness classifier, and exactness ledger used by the compact-metric package.

The second field supplies, for each visible positive tolerance, a closed ProbeBundle net together with its membership, center, radius, distance, and $\mathsf{Rat}^{\uparrow}$ comparison ledgers. Its stability clause is precisely Definition 127.4.

The third field supplies, for each regular Cauchy stream name, the modulus, limit, late-observation threshold, and distance-bound ledgers. Its stability clause is precisely Definition 128.4. There is no fourth field in the displayed carrier, so the compact-metric certificate scope is exactly this metric, finite-net, and limit-witness surface. □

Theorem 129.7 (Compact metric component stability)**.** *Let X be a certified metric carrier equipped with the* $\mathsf{Met}^{\uparrow}$ *point and distance classifier. Suppose the tolerance histories, stream observations, moduli, limit histories, distance histories, and every displayed comparison ledger in* $\mathsf{CompactMetricCertificate}(X)$ *are transported by* hsame *together with the* $\mathsf{Rat}^{\uparrow}$ *classifier. Then the transported rows again assemble a compact-metric certificate over the transported carrier, component by component.*

Proof. Start with the shared metric carrier. The transported point histories and distance rows remain under the same $\mathsf{Met}^{\uparrow}$ classifier, so both subcertificates read the same carrier predicate and the same MetricDistanceWitness transport policy.

For the finite-net component, fix a transported positive tolerance history. Apply Definition 127.4 to the corresponding TotallyBoundedProbeBundleNet row. This preserves the closed ProbeBundle spine, the visible coverage rows, and the $\mathsf{Rat}^{\uparrow}$ bounds against the transported tolerance.

For the complete-limit component, fix a transported regular Cauchy stream name. Apply Definition 128.4 to the corresponding CompleteMetricLimitWitness row. This preserves the modulus, transported limit, late-observation thresholds, metric distance rows, and $\mathsf{Rat}^{\uparrow}$ bounds for the transported stream.

Repack the three transported components using Definition 129.5. Since both subcertificates share the transported metric carrier classifier, their ledgers combine into a single transported $\mathsf{CompactMetric}^{\uparrow}$ certificate. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate component stability`

Theorem 129.8 (Compact metric downstream consumer boundary)**.** *Downstream* $\mathsf{ContinuousMap}^{\uparrow}$ *and Heine–Cantor consumers of* $\mathsf{CompactMetricCertificate}(X)$ *may use only the metric carrier, the finite* ProbeBundle*-net family, and the complete-limit family exposed by the compact-metric certificate. The certificate does not expose open-cover compactness, sequential compactness, or choice-based subsequence extraction.*

Proof. Read the exported ledger union from Definition 129.5. The public package contains metric carrier data, one finite ProbeBundle-net row for each positive tolerance, and one complete-limit witness row for each regular Cauchy stream name.

A $\mathsf{ContinuousMap}^{\uparrow}$ consumer can therefore inspect point histories, distance rows, finite net membership rows, and explicit limit-witness rows. A Heine–Cantor consumer can use the same rows to combine total boundedness, continuity control, and completeness through explicit certificates.

The same exported union contains no row naming open covers, no row selecting a finite subcover, no row asserting sequential compactness for arbitrary sequences, and no row extracting a subsequence by host-level choice. The negative boundary recorded in the $\mathsf{CompactMetric}^{\uparrow}$ closure status is therefore a consequence of the displayed certificate surface. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricDownstreamConsumer boundary`

Theorem 129.9 (Compact metric uniform modulus consumer route)**.** *Any* $\mathsf{UniformModulus}^{\uparrow}$ *or compact-uniform-continuity consumer reading a* $\mathsf{CompactMetric}^{\uparrow}$ *source must factor through the certified* $\mathsf{Met}^{\uparrow}$ *distance rows, the* $\mathsf{TotallyBounded}^{\uparrow}$ *finite* ProbeBundle*-net rows, the* $\mathsf{CompleteMetric}^{\uparrow}$ *limit-witness rows, and the* $\mathsf{Rat}^{\uparrow}$ *tolerance comparison ledgers already exposed by Definition 129.1. The consumer route may not replace those rows by open-cover compactness, sequential compactness, or a choice-based finite-subcover principle.*

Proof. First read the metric source. By Definition 129.2, every compact-metric consumer begins with the same $\mathsf{Met}^{\uparrow}$ carrier and the same MetricDistanceWitness ledgers.

Next read the finite-net component. The Definition 129.3 supplies, for each positive $\mathsf{Rat}^{\uparrow}$ tolerance, the displayed ProbeBundle net, membership rows, center rows, radius rows, metric coverage rows, and rational comparison ledgers used by a uniform-modulus request.

Finally read the complete-limit component and the public boundary. The Definition 129.4 supplies the $\mathsf{CompleteMetric}^{\uparrow}$ limit-witness rows for regular Cauchy streams, while Definition 129.7 transports all component rows under the same classifier. The exclusion clause is exactly Definition 129.8: the exported surface contains no open-cover, sequential-compactness, or choice-based subcover row. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCarrier uniform window consumer route`

Public export and downstream consumption

Definition 129.10 (Compact metric public interface)**.** *For a certified metric carrier X, the public compact-metric interface*

$$\mathsf{CompactMetricPublic}(X)$$

is the exported package consisting exactly of the three visible fields of Definition 129.1: the $\mathsf{Met}^{\uparrow}$ *carrier, classifier, and distance rows; the* $\mathsf{TotallyBounded}^{\uparrow}$ *positive-tolerance* ProbeBundle*-net selector $\varepsilon \mapsto (\mathcal{P}_\varepsilon, net_\varepsilon)$; and the* $\mathsf{CompleteMetric}^{\uparrow}$ *regular-Cauchy limit-witness selector $s \mapsto (\mu_s, \ell_s, L_s)$. No open-cover compactness witness, subsequence selector, or host-level compact-object predicate is part of* $\mathsf{CompactMetricPublic}(X)$*.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricTasteGate single carrier alignment`

Theorem 129.11 (Compact metric public interface stability)**.** *For a certified metric carrier X, the package* $\mathsf{CompactMetricPublic}(X)$ *is transported by the inherited metric classifier. The metric carrier and distance rows are carried by the* $\mathsf{Met}^{\uparrow}$ *classifier data; each positive-tolerance finite-net row is transported by Definition 127.4; and each regular-Cauchy limit-witness row is transported by Definition 128.4.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricPublicInterface stability`

Proof. Apply Definition 129.5 to view $\mathsf{CompactMetricPublic}(X)$ as the visible export of $\mathsf{CompactMetricCertificate}(X)$ The inherited metric classifier transports the carrier histories and distance rows, so the public metric field has the same source classifier as the certificate package.

For the totally-bounded selector, fix a transported positive $\mathsf{Rat}^{\uparrow}$ tolerance history. The certificate supplies the matching closed ProbeBundle net and its distance and comparison ledgers, and Definition 127.4 transports that whole row.

For the complete-metric selector, fix a transported regular Cauchy stream name. The certificate supplies the modulus, limit history, threshold rows, and late-observation distance bounds, and Definition 128.4 transports the displayed limit witness. These three transported fields are precisely $\mathsf{CompactMetricPublic}(X)$. □

Theorem 129.12 (Compact metric downstream consumption bridge)**.** *Any downstream* $\mathsf{ContinuousMap}^{\uparrow}$ *or Heine–Cantor argument whose compact input requirements are a metric carrier, explicit finite nets at positive rational tolerances, and regular-Cauchy limit witnesses may consume exactly the three fields of* $\mathsf{CompactMetricPublic}(X)$*. Such an argument gains no additional open-cover compactness principle and no subsequence principle from the compact-metric input.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricPublicInterface downstream consumption bridge`

Proof. Unpack Definition 129.10. A request for the carrier, classifier, or distance rows is routed to the $\mathsf{Met}^{\uparrow}$ field. This is the same metric source used by the total-boundedness and completeness clauses, so no extra carrier equivalence is introduced.

A request for a finite net at a positive rational tolerance is routed to the $\mathsf{TotallyBounded}^{\uparrow}$ selector $\varepsilon \mapsto (\mathcal{P}_\varepsilon, net_\varepsilon)$. Its centers, membership rows, distance witnesses, and rational comparison ledgers are the rows supplied by the certificate carrier.

A request for a limit witness for a regular Cauchy stream is routed to the $\mathsf{CompleteMetric}^{\uparrow}$ selector $s \mapsto (\mu_s, \ell_s, L_s)$. The modulus, limit history, threshold ledger, and late-distance bounds are exactly the rows available to the downstream proof.

The public interface has no fourth field. Therefore a downstream $\mathsf{ContinuousMap}^{\uparrow}$ or Heine–Cantor proof that uses $\mathsf{CompactMetricPublic}(X)$ consumes only metric rows, positive-tolerance ProbeBundle nets, and regular-Cauchy limit witnesses. □

Theorem 129.13 (CompactMetricUp metric source scope)**.** *For every certified metric carrier* X *equipped with* $\mathsf{CompactMetricCertificate}(X)$*, the public* $\mathsf{CompactMetric}^{\uparrow}$ *certificate exposes the same* $\mathsf{Met}^{\uparrow}$ *source carrier, point classifier, and* $\mathsf{MetricDistanceWitness}$ *rows used by the totally-bounded and complete-metric fields. The finite-net family and the complete-limit family are therefore both read over one metric classifier scope, with no independent carrier or distance package.*

Proof. Project the first field of Definition 129.1. It is already the $\mathsf{Met}^{\uparrow}$ carrier and distance package for X, so it supplies the source history object, point classifier, and distance-witness ledger rows.

The remaining certificate fields are indexed by the same carrier X and use the same point histories when they mention net centers, stream observations, and limit histories. Repack these rows under the projected classifier scope. This gives the displayed $\mathsf{CompactMetric}^{\uparrow}$ source data consumed by both the totally-bounded and complete-metric obligations. □

Theorem 129.14 (CompactMetricUp finite-net family coverage)**.** *For every certified metric carrier* X*, every* $\mathsf{CompactMetricCertificate}(X)$*, and every positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history* ε*, the certificate projects a* $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ *package. This package is stable under the metric carrier classifier and rational tolerance classifier transport of Definition 127.5 and Definition 127.4.*

Proof. Fix the positive tolerance row ε. Project the second field of Definition 129.1; it supplies the displayed $\mathsf{TotallyBoundedProbeBundleNet}$ package at that tolerance, including the ProbeBundle centers, membership rows, distance witnesses, and rational comparison ledgers.

The package is a $\mathsf{NameCert}_{\mathsf{TotallyBounded}^{\uparrow}}$ target by Definition 127.5. Apply Definition 127.4 to transport the net along the shared metric classifier and the transported positive $\mathsf{Rat}^{\uparrow}$ tolerance. The resulting row is the finite-net family coverage exported by the $\mathsf{CompactMetric}^{\uparrow}$ certificate. □

Theorem 129.15 (CompactMetricUp complete-limit family coverage)**.** *For every certified metric carrier* X*, every* $\mathsf{CompactMetricCertificate}(X)$*, and every regular* $\mathsf{StreamName}^{\uparrow}$ *Cauchy stream name* s *whose observations are carried by* X*, the certificate projects a* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$ *as in Definition 128.2. This witness is stable under classifier transport by Definition 128.4.*

Proof. Fix the regular Cauchy stream name s and its carrier row over X. Project the third field of Definition 129.1; it gives the modulus history, limit history, threshold ledgers, and late-observation distance bounds that form the displayed $\mathsf{CompleteMetricLimitWitness}$.

Apply Definition 128.4 pointwise to the stream observations, the modulus, the proposed limit, and the late-bound ledger rows. The transported rows again satisfy Definition 128.2, so the complete-limit family is available as a separate $\mathsf{CompactMetric}^{\uparrow}$ obligation site. □

Theorem 129.16 (Compact metric public downstream coverage)**.** *Let X be a certified metric carrier equipped with* $\mathsf{CompactMetricCertificate}(X)$*. Every accepted local consumer of the public packet* $\mathsf{CompactMetricPublic}(X)$ *is exhausted by the following visible rows:*

1. *the* $\mathsf{Met}^{\uparrow}$ *carrier, classifier, and* $\mathsf{MetricDistanceWitness}$ *rows;*
2. *for each positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history ε, the finite* $\mathsf{ProbeBundle}$ *alternatives $\mathcal{P}_\varepsilon$, the* $\mathsf{InBundle}(p, \mathcal{P}_\varepsilon)$ *membership rows, the coverage rows in net_ε, and the displayed* $\mathsf{Rat}^{\uparrow}$ *comparison ledgers;*
3. *for each carried regular Cauchy* $\mathsf{StreamName}^{\uparrow}$ *stream name s, the modulus, limit history, threshold ledger, late-distance rows, and* $\mathsf{Rat}^{\uparrow}$ *comparison rows of* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$*.*

Consequently an open-cover compactness witness, finite-subcover selector, subsequence selector, or host-level compact-object predicate is not an accepted downstream alternative for the public compact-metric packet.

Proof. Unpack Definition 129.10. The public packet has one metric field, one positive-tolerance finite-net selector, and one regular-Cauchy limit-witness selector. Thus a local consumer accepted by this packet must ask for a row through one of these three displayed selectors.

The first selector is the inherited $\mathsf{Met}^{\uparrow}$ field, so carrier, classifier, and distance requests are exhausted by the point-history classifier and the $\mathsf{MetricDistanceWitness}$ ledger rows. By Definition 129.11, transport of this part is still the inherited metric transport; no independent carrier or distance package is introduced.

For a positive $\mathsf{Rat}^{\uparrow}$ tolerance history ε, apply Definition 129.14. The selected finite-net row is

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon).$$

Hence the finite alternatives available to a downstream consumer are exactly the bundled probes in the closed $\mathsf{ProbeBundle}$ spine $\mathcal{P}_\varepsilon$, read through their $\mathsf{InBundle}(p, \mathcal{P}_\varepsilon)$ membership rows. The same theorem identifies the coverage surface: every admitted source point is handled by a listed bundled center, a displayed metric-distance row in net_ε, and a displayed $\mathsf{Rat}^{\uparrow}$ comparison ledger against ε. Stability of the public interface keeps this finite-net row under the same metric carrier classifier and the same rational-tolerance classifier, so transport does not create an additional alternative.

For a carried regular Cauchy stream name s, the third public selector is the complete-limit row

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s).$$

By Definition 129.11, its admissible transport is precisely the componentwise complete-metric stability row. Thus a limit consumer can read only the named modulus, limit history, threshold rows, late-distance witnesses, and rational comparison ledgers already displayed in that witness.

These three cases exhaust the public packet. The defining export contains no fourth selector, and the two stability clauses cited above transport only the metric, finite-net, and limit-witness rows. Therefore open-cover compactness, finite-subcover selection, subsequence selection, and host-level compact-object predicates remain outside the accepted BEDC packet for $\mathsf{CompactMetricPublic}(X)$. □

Definition 129.17 (Public CompactMetricUp export source)**.** *For a certified metric carrier X, the public* $\mathsf{CompactMetric}^{\uparrow}$ *export source is the same shared carrier used in Definition 129.1: the* $\mathsf{Met}^{\uparrow}$ *point carrier and distance package for X, together with the* $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ *family for every positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history ε, and the* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$ *family for every regular Cauchy* $\mathsf{StreamName}^{\uparrow}$ *stream name s carried by X.*

The public surface exposes exactly these three component families as the compact-metric constructor source. It does not add an open-cover selector, subsequence extractor, or external compact set; downstream consumers receive the finite-net and complete-limit rows already certified by the component NameCerts.

Lean4 (definition) `BEDC.Derived.CompactMetricUp.CompactMetricPublicExportSource`

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricPublicExportSource component rows`

Theorem 129.18 (Public compact-metric constructor package)**.** *The export source of Definition 129.17 produces the public compact-metric constructor package for* $\mathsf{CompactMetric}^{\uparrow}$*. The package has the same metric carrier, the same positive-tolerance* ProbeBundle *net family, and the same regular-Cauchy limit-witness family as Definition 129.5; classifier transport is inherited componentwise from the metric, totally-bounded, and complete-metric certificates. The natural formal target name for this constructor package is* `BEDC.Derived.CompactMetricUp.CompactMetricPublicConstructor_pack`

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricPublicConstructor package`

Proof. Project the metric field from Definition 129.5. This gives the public source carrier, the point classifier, the distance rows, and the MetricDistanceWitness ledgers used by the constructor package.

For each positive $\mathsf{Rat}^{\uparrow}$ tolerance history ε, project the totally-bounded field. The projected row is already the closed ProbeBundle net $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$, and its stability is the componentwise transport supplied by Definition 127.4.

For each regular Cauchy $\mathsf{StreamName}^{\uparrow}$ stream name s, project the complete-metric field. The projected row is the limit witness $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$, transported by Definition 128.4.

Repack these three projected component families under the shared metric classifier. Since the public export source contains no additional fields, the componentwise transports assemble directly into the public $\mathsf{CompactMetric}^{\uparrow}$ constructor package. □

Theorem 129.19 (Heine–Cantor consumer bridge for CompactMetricUp)**.** *Let*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$$

be a metric $\mathsf{ContinuousMap}^{\uparrow}$ *consumer whose source metric carrier is the same BEDC carrier X as the export source of Definition 129.17. Then the public* $\mathsf{CompactMetric}^{\uparrow}$ *export supplies the compact finite-net input and complete-limit input required by the Heine–Cantor capstone Definition 9237.6. The finite-net input is the positive-tolerance* $\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$ *family, and the complete-limit input is the regular-Cauchy* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$ *family; both are consumed over the same metric distance rows as the continuous-map source certificate. The natural formal target name for this consumer bridge is* `BEDC.Derived.CompactMetricUp.CompactMetric`

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricHeineCantor consumer bridge`

Proof. Read the continuous-map source through Definition 130.29. The consumer therefore uses a categorical graph row, a modulus witness, and a MetricDistanceWitness row over the displayed source carrier.

Identify this source carrier with the metric carrier in the public CompactMetric$^{\uparrow}$ export. The metric classifier then transports the continuous-map distance row and the compact-metric distance row to the same BEDC history relation.

For a positive tolerance history ε, pass the exported ProbeBundle net family to the finite-cover input of the Heine–Cantor construction. This is exactly the located finite-net datum used by Definition 9237.3 and Definition 9237.4.

For a regular Cauchy stream name s, pass the exported complete-limit witness to the complete metric input. The capstone proof may then consume finite-net coverage and complete-limit convergence over the same source metric, so the uniform-modulus ledger is obtained from the public CompactMetric$^{\uparrow}$ export rather than from a private component package. □

Theorem 129.20 (Public compact-metric export surface)**.** *For a certified metric carrier X equipped with* CompactMetricCertificate(X)*, the public* CompactMetric$^{\uparrow}$ *surface exports exactly the metric carrier and distance rows of X, every finite-net row*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon),$$

and every complete-limit row

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s).$$

It does not export an open-cover compactness principle, a subsequence selection principle, or any host-level compact set predicate.

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate public export surface`

Proof. Project the carrier definition of Definition 129.1. The first component is the same Met$^{\uparrow}$ carrier, classifier, and distance witness family, so the public metric rows are copied without changing their histories or classifier ledgers.

For each positive tolerance history ε, the second component gives the displayed TotallyBoundedProbeBundleNet row. Its classifier transport and coverage stability are exactly the rows supplied by Definition 127.4.

For each regular Cauchy stream name s, the third component gives the displayed CompleteMetricLimitWitness row. Its stability is the componentwise transport supplied by Definition 128.4. Since the definition has no further compactness field, the public surface consists precisely of these metric, total-bounded, and complete subcertificates. □

Theorem 129.21 (Continuous-map consumption boundary)**.** *Any* ContinuousMap$^{\uparrow}$ *construction consuming a public* CompactMetric$^{\uparrow}$ *certificate may use only the exported metric classifier, the exported distance witnesses, and the finite* TotallyBoundedProbeBundleNet *rows. It receives no open-cover row, no subsequence compactness row, and no unlisted compact-set eliminator from* CompactMetricCertificate(X)*.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate continuousmap consumption boundary`

Proof. By Definition 129.20, the visible public rows are exactly the metric carrier rows, the finite ProbeBundle-net family, and the complete-limit family. The continuous-map interface can therefore read the point classifier, distance witnesses, and finite-net center and coverage ledgers directly from the exported certificate.

The same projection also proves the boundary. The certificate carrier in Definition 129.1 contains no open-cover predicate, no subsequence selector, and no compact-set eliminator. Hence a $\mathsf{ContinuousMap}^{\uparrow}$ argument consuming this public surface must factor through the displayed metric and total-bounded rows rather than through any classical compactness principle. □

Theorem 129.22 (Heine–Cantor input boundary)**.** *The compact-uniform-continuity capstone may consume a public* $\mathsf{CompactMetric}^{\uparrow}$ *certificate by using the finite* ProbeBundle*-net family together with continuous pointwise modulus ledgers to assemble a uniform-modulus ledger. Completeness enters only through the named* $\mathsf{CompleteMetric}^{\uparrow}$ *limit-witness field* $\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$.

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate heine cantor input boundary`

Proof. Start from the public export theorem. For each positive tolerance, the $\mathsf{CompactMetric}^{\uparrow}$ surface supplies the finite TotallyBoundedProbeBundleNet row, including bundled centers, membership rows, distance witnesses, and rational comparison ledgers. Apply Definition 127.4 to transport these rows along the metric classifier data used by the capstone.

The continuous input contributes pointwise modulus ledgers at the exported centers. The finite net supplies only finitely many such center rows, so the capstone can combine their visible tolerance ledgers into one uniform-modulus ledger without invoking open covers or subsequences.

Completeness is used only at the point where a regular Cauchy stream requires a named limit witness. That row is exactly the CompleteMetricLimitWitness exported from the certificate, with transport governed by Definition 128.4. No additional compactness principle is consumed. □

Theorem 129.23 (Compact metric carrier-field projection)**.** *Let X be a certified metric carrier equipped with* $\mathsf{CompactMetricCertificate}(X)$*. Then the compact-metric certificate exposes the same* $\mathsf{Met}^{\uparrow}$ *point carrier, the same* MetricDistanceWitness *distance rows, and the same point-classifier transport consumed by Definition 129.5.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate metric field projection`

Proof. Unpack Definition 129.1. Its first field is the metric carrier interface for X, including the accepted point histories, the distance package, and the classifier transport on point histories.

Repack exactly this field as the metric face of the compact-metric certificate. No total-bounded net row or complete-limit row is used in this projection, so the exported carrier, distance ledger, and classifier data are the same rows used by the bundled package theorem. □

Theorem 129.24 (Compact metric total-bounded-field projection)**.** *Let X be a certified metric carrier equipped with* $\mathsf{CompactMetricCertificate}(X)$*. For every positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history ε, the certificate exposes a face*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon)$$

stable under $\mathsf{Rat}^{\uparrow}$ *tolerance transport and metric classifier transport, with coverage stability supplied by Definition 127.4.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate total bounded field projection`

Proof. Unpack the second field of Definition 129.1 at the chosen positive tolerance history ε. It provides the closed ProbeBundle spine $\mathcal{P}_\varepsilon$, the net ledger net_ε, and the BEDC rows recording centers, membership, distance witnesses, and rational bounds against ε.

To transport this face, move the tolerance through the $\mathsf{Rat}^{\uparrow}$ classifier and move the point, center, and distance histories through the metric classifier. Apply Definition 127.4 to repack the transported coverage row, while the closed ProbeBundle carrier and its InBundle membership constructors remain the displayed finite spine. □

Theorem 129.25 (Compact metric complete-field projection)**.** *Let X be a certified metric carrier equipped with* $\mathsf{CompactMetricCertificate}(X)$*. Every regular Cauchy* $\mathsf{StreamName}^{\uparrow}$ *stream s carried by X exposes a face*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s),$$

and this face is stable under hsame *transport of the stream, modulus, and limit, with stability supplied by Definition 128.4.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate complete field projection`

Proof. Unpack the third field of Definition 129.1 at the regular Cauchy stream name s. It provides the modulus history μ_s, the limit history ℓ_s, and the late-observation ledger family L_s recording the displayed MetricDistanceWitness rows and $\mathsf{Rat}^{\uparrow}$ bounds.

Under hsame transport of the stream observations, the modulus, and the limit, the component rows are carried pointwise. Apply Definition 128.4 to repack the transported threshold ledgers, distance witnesses, and comparison rows as the same complete-limit face for the transported stream data. □

Theorem 129.26 (CompactMetric metric source obligation)**.** *Let X be a compact-metric certificate carrier in the sense of Definition 129.1. Its metric source projection is exactly the displayed* $\mathsf{Met}^{\uparrow}$ *carrier on X: the point classifier, the* MetricDistanceWitness *distance rows, and classifier transport are the ones supplied by the metric carrier field. The source projection contains no open-cover predicate, ambient compact subset predicate, finite-subcover principle, or host compactness assertion.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricCertificate metric source obligation`

Proof. Read the first field of Definition 129.1. It is already the certified $\mathsf{Met}^{\uparrow}$ source for X, with the point classifier, the distance rows, and the transport rule for those rows displayed before the totally-bounded and complete-metric fields are considered.

Now apply Definition 129.5. The package theorem uses that metric source as the public classifier for $\mathsf{CompactMetric}^{\uparrow}$, so the source field of the ten-field NameCert template is filled by the same carrier and the same MetricDistanceWitness ledger. Since the carrier definition lists only metric data, ProbeBundle nets, and limit witnesses, no open-cover or host compact-set row can be projected from this source. □

Theorem 129.27 (CompactMetric ProbeBundle net-family obligation)**.** *Let X be a compact-metric certificate carrier. For every carried positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history ε, the totally-bounded component supplies the existing package*

$$\mathsf{TotallyBoundedProbeBundleNet}(X, \varepsilon, \mathcal{P}_\varepsilon, net_\varepsilon).$$

Transport of this family is exactly the componentwise transport provided by Definition 127.4.

Proof. Unpack the second field of Definition 129.1. For each positive tolerance history it gives a closed ProbeBundle spine $\mathcal{P}_\varepsilon$, center histories, membership rows, distance witnesses, and $\mathsf{Rat}^\uparrow$ comparison ledgers in the package named in the statement.

The transport clause is then read through Definition 127.4. That theorem keeps the same metric carrier interface and transports the tolerance, membership, center, distance, and rational-bound rows along the source classifiers.

Finally repack these rows into the $\mathsf{CompactMetric}^\uparrow$ ten-field NameCert template by Definition 129.5. The resulting obligation is only the tolerance-indexed finite-net family; it does not add a finite-subcover choice principle or any open-cover surface. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricProbeBundleNetFamily obligation`

Theorem 129.28 (CompactMetric limit-witness family obligation)**.** *Let X be a compact-metric certificate carrier. Every carried regular Cauchy* $\mathsf{StreamName}^\uparrow$ *stream s has the complete-metric witness*

$$\mathsf{CompleteMetricLimitWitness}(X, s, \mu_s, \ell_s, L_s)$$

of Definition 128.2. Transport of these witnesses is the pointwise transport supplied by Definition 128.4.

Proof. Unpack the third field of Definition 129.1. For a carried regular Cauchy stream it supplies the modulus history μ_s, the carried limit history ℓ_s, the threshold rows, the late-observation distance rows, and the $\mathsf{Rat}^\uparrow$ budget comparisons required by Definition 128.2.

Apply Definition 128.4 to the displayed stream, modulus, limit, threshold, distance, and rational comparison rows. The transport remains internal to the same metric carrier classifier and does not use a host completion or a choice of subsequence.

Repack the transported witness through Definition 129.5. This fills the complete-metric part of the ten-field NameCert template for $\mathsf{CompactMetric}^\uparrow$ while leaving all convergence data visible as the limit-witness ledger. □

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricLimitWitnessFamily obligation`

Theorem 129.29 (CompactMetric ledger exactness obligation)**.** *For a compact-metric certificate carrier X, the* $\mathsf{CompactMetric}^\uparrow$ *ledger is exactly the union of the metric-distance rows of* $\mathsf{Met}^\uparrow$*, the tolerance-indexed finite-net rows of* $\mathsf{TotallyBounded}^\uparrow$*, and the regular-stream limit-witness rows of* $\mathsf{CompleteMetric}^\uparrow$*. Coverage, soundness, and completeness for the exported certificate are read componentwise over these three sources.*

Lean4 ✓ `BEDC.Derived.CompactMetricUp.CompactMetricLedger exactness obligation`

Proof. Start from the carrier inventory in Definition 129.1. It lists one metric source field, one ProbeBundle-net family indexed by positive $\mathsf{Rat}^\uparrow$ tolerances, and one limit-witness family indexed by carried regular Cauchy streams. These are the only rows available to the compact-metric package.

Coverage is componentwise. The metric source covers point classification and distance witnessing; the totally-bounded component covers each carried point by a bundled center at a displayed tolerance; and the complete-metric component covers each carried regular Cauchy stream by its displayed limit witness.

Soundness is also componentwise. Metric rows are compared by the $\mathsf{Met}^\uparrow$ classifier, finite-net rows by Definition 127.4, and limit rows by Definition 128.4. Each comparison stays inside the classifier and ledger named by its source component.

Completeness follows by repacking all three inventories through Definition 129.5. Any exported compact-metric row therefore comes from one of the displayed metric, finite-net, or limit-witness rows, and every such row is accepted by the ten-field NameCert template for CompactMetric$^{\uparrow}$. □

Closure status for NameCert$_{\text{CompactMetric}^{\uparrow}}$.

Constructive story: A compact metric carrier is assembled by keeping one certified Met$^{\uparrow}$ carrier and attaching exactly two visible families to it: a TotallyBounded$^{\uparrow}$ ProbeBundle net at every positive Rat$^{\uparrow}$ tolerance and a CompleteMetric$^{\uparrow}$ limit witness for every carried regular StreamName$^{\uparrow}$ Cauchy stream. A row is admitted only when the metric carrier, finite-net family, and limit-witness family are all present over the same point histories; open covers, subsequence selections, or ambient compact subsets are not carrier data. The classifier is inherited componentwise from the metric point classifier, the ProbeBundle-net transport rows, and the complete-limit transport rows, so two compact-metric packages agree only by transporting those displayed metric, net, and convergence ledgers. The source is the shared metric carrier, the pattern is the conjunction of total boundedness and completeness, and the ledger is the union of distance rows, positive-tolerance finite-net rows, membership and coverage rows, regular-stream moduli, carried limits, and late-observation bounds. The five name-certificate obligations are obtained by the singleton compact metric package for inhabitation, by the equivalence behavior of the inherited classifiers, and by the component-stability theorems that repack transported finite-net and limit-witness rows under the same metric carrier. A package h lies in the signature gap of a CompactMetric$^{\uparrow}$ token p when the source-domain accepts its metric carrier with both component families, the signature relation pairs that triple with an answer compact-metric package and evidence ledger, and the token-introduction relation names the answer as p; unfolded, p encodes precisely the metric rows, tolerance-indexed nets, and Cauchy-limit witnesses. The public bridge lets continuous-map and Heine–Cantor consumers read the same finite-net and complete-limit data, and the chapter registers this componentwise construction under CompactMetric$^{\uparrow}$ without adding open-cover compactness, sequential compactness, products, or function-space compactness.

Theory closure: TheoryGate(NameCert$_{\text{CompactMetric}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper scope consists of the public compact-metric export surface, the public compact-metric constructor package, the Heine–Cantor consumer bridge, the metric/ProbeBundle/limit-witness projections, and the ledger exactness obligation.

Formal verification: FormalStatus(NameCert$_{\text{CompactMetric}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CompactMetricUp.CompactMetricSingleton\_certificate\_package`

Bridge status: paperBridge

Not claimed: Open-cover compactness, sequential compactness without explicit data, Tychonoff-style products, or compactness of function spaces.

Upgrade path: No stronger theory-closure grade is claimed here; bridgeChecked remains the Lean-side bridge verification target.

The ContinuousMap$^{\uparrow}$ entry point reads its metric distance witness through chapter 57, its pointwise-modulus rows through chapter 59, and its categorical graph and composition rows through chapter 61; compact-uniform consumers read the resulting horizontal lattice through the child files below.

Chapter 130

A Metric-Carrier Interface for $\mathsf{ContinuousMap}^{\uparrow}$

The continuous-map interface $\mathsf{ContinuousMap}^{\uparrow}$ packages a function between metric carriers together with a pointwise modulus of continuity. It depends on $\mathsf{NameCert}_{\mathsf{Met}^{\uparrow}}$ (chapter 57) and lifts $\mathsf{NameCert}_{\mathsf{CFun}^{\uparrow}}$ (chapter 59) to general L10 metric carriers.

130.1 Carrier definition

Definition 130.1 (ContinuousMap carrier)**.** *For histories* $source, map, target, modulus, cert, dist$: BHist, $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, dist)$ *is the conjunction of the continuous-function carrier* $\mathsf{ContinuousFunctionCarrier}(source, map, target, modulus, cert)$ *and the metric distance witness* $\mathsf{MetricDistanceWitness}(source, target, dist)$.

Lean4 (definition) `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier`

Theorem 130.2 (ContinuousMap carrier category-metric decomposition)**.** *For histories* $source, map, target, modu$ BHist, *the carrier splits exactly into a categorical hom row, a target-side continuous-modulus row, and a metric-distance row:*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$$
$$\iff \mathsf{CategoryHomCarrier}(source, target, map) \wedge \mathsf{ContinuousModulusWitness}(target, modulus, cert) \wedge \mathsf{MetricD}$$

Proof. For the forward direction, unpack $\mathsf{ContinuousMapCarrier}$ into its continuous-function component and its metric-distance component. The continuous-function fields provide unary source, target, and map histories together with the graph continuation, hence the displayed $\mathsf{CategoryHomCarrier}(source, target$ The same continuous-function component also exposes the target-modulus continuation, which is precisely $\mathsf{ContinuousModulusWitness}(target, modulus, cert)$. The remaining projection is the displayed metric-distance witness.

For the reverse direction, unpack the category hom row into unary source, target, and map histories plus the graph continuation. Unpack the modulus row into unary target, modulus, and certificate histories plus the terminal continuation. These two rows rebuild $\mathsf{ContinuousFunctionCarrier}(source, map, tar$ and pairing that carrier with the supplied $\mathsf{MetricDistanceWitness}(source, target, distance)$ gives the claimed $\mathsf{ContinuousMapCarrier}$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier category metric decomposition`

The ten-field fit is: traditional target continuous maps as categorical morphisms with a metric ledger; BEDC source CategoryUp/ContinuousUp/MetricUp/ContinuousMapUp; carrier ContinuousMapCarrier; classifier hsame; stability inherited from CategoryHomCarrier, ContinuousModulusWitness, and MetricDistanceWitness ledger map, modulus, certificate, and distance histories; core theorem Theorem 130.2; exactness the displayed equivalence; standard bridge is deferred; status ProofTarget.

Theorem 130.3 (ContinuousMap visible-context category-metric decomposition)**.** *For histories* $p, q, source, map, target, modulus, cert, distance$: BHist*, the displayed carrier with visible continuous-function context and prefixed metric ledger is equivalent to unary context evidence together with the central categorical, continuity, and metric rows:*

$$\mathsf{ContinuousMapCarrier}(p \cdot source, map, p \cdot target, modulus \cdot q, (p \cdot cert) \cdot q, p \cdot distance)$$
$$\iff \mathsf{UnaryHistory}(p) \wedge \mathsf{UnaryHistory}(q) \wedge \mathsf{CategoryHomCarrier}(source, target, map) \wedge \mathsf{ContinuousModulusWitn}$$

Proof. For the forward direction, unpack ContinuousMapCarrier into its visible continuous-function component and its metric-distance component. Apply Definition 59.169 to the function row to recover unary evidence for p and q together with the central continuous-function carrier.

Apply Definition 59.139 to that central carrier. Its graph row is exactly $\mathsf{CategoryHomCarrier}(source, target, map)$ and its target-modulus row is $\mathsf{ContinuousModulusWitness}(target, modulus, cert)$. Apply Definition 57.11 to the metric row to read back the central $\mathsf{MetricDistanceWitness}(source, target, distance)$.

For the reverse direction, start with the two unary context histories, the central categorical row, the target-modulus witness, and the central metric witness. The categorical row supplies the graph continuation and unary source, target, and map histories.

The modulus row supplies the unary modulus and certificate histories plus the certificate continuation, so the central continuous-function carrier is reassembled.

Apply Definition 59.169 from right to left to restore the visible source, target, modulus, and certificate ledgers. Apply Definition 57.11 from right to left to restore the prefixed metric ledger, and pair the two rows into the displayed ContinuousMapCarrier. □

The ten-field fit is: traditional continuous maps carried with explicit visible context on the continuous-function row and an exposed metric ledger; BEDC source CategoryUp/ContinuousUp/MetricUp/Continuo carrier ContinuousMapCarrier; classifier hsame; stability from visible continuous-function context, category hom readback, modulus readback, and metric prefix exactness; ledger visible contexts, map, modulus, certificate, and distance histories; core theorem Theorem 130.3; exactness the displayed equivalence; standard bridge is deferred; status ProofTarget.

Theorem 130.4 (ContinuousMap canonical distance carrier)**.** *For histories* $source, map, target, modulus, cert$: BHist*, the carrier with canonical distance ledger* $\mathsf{append}(source, target)$ *is exactly the underlying continuous-function carrier:*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, \mathsf{append}(source, target)) \iff \mathsf{ContinuousFunctionCarrier}($$

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier canonical distance iff`

Proof. The forward direction projects the function-carrier component. Conversely, the function carrier supplies unary source and target histories; unary append closure and the reflexive continuation equation build the canonical metric distance witness. □

Theorem 130.5 (ContinuousMap carrier empty distance exactness)**.** *For histories* $source, map, modulus, cert$: BHist*,*

$$\mathsf{ContinuousMapCarrier}(source, map, \mathsf{e}, modulus, cert, \mathsf{e})$$
$$\iff \mathsf{UnaryHistory}(source) \wedge \mathsf{UnaryHistory}(map) \wedge \mathsf{UnaryHistory}(modulus) \wedge source \sim \mathsf{e} \wedge map \sim \mathsf{e} \wedge cert \sim m$$

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty distance exact`

Proof. Unpack the carrier into the continuous-function row and the metric-distance row. Empty distance forces the source endpoint to be e, while the continuous-function graph row into e forces the map component to be e. The remaining certificate row is the left-unit continuation from e to $modulus$, hence $cert \sim modulus$. Conversely, the displayed unary and boundary data build the two continuation rows and the empty-distance metric witness directly. □

Theorem 130.6 (ContinuousMap empty map with empty distance)**.** *For histories source, modulus, and cert, the empty graph map at the source together with an empty metric distance witness is exact for the source being empty and the modulus ledger being certified:*

$$\mathsf{ContinuousFunctionCarrier}(source, \mathsf{e}, source, modulus, cert) \wedge \mathsf{MetricDistanceWitness}(source, source, \mathsf{e})$$
$$\iff \mathsf{ContinuousModulusWitness}(source, modulus, cert) \wedge \mathsf{hsame}(source, \mathsf{e}).$$

Proof. From the carrier, unpack the target-certificate continuation and the unary source and modulus ledgers; unary continuation closure supplies the certificate ledger, hence the displayed modulus witness. The empty-distance witness forces the source endpoint to be empty. Conversely, the modulus witness builds the empty-map identity carrier, and the empty source endpoint builds the empty metric distance witness. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty map empty distance iff`

Theorem 130.7 (ContinuousMap empty certificate exactness)**.** *For histories* $source, map, target, modulus, dist$: BHist,

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, \mathsf{e}, dist)$$

holds exactly when

$$source\mathsf{hsamee}, \quad map\mathsf{hsamee}, \quad target\mathsf{hsamee}, \quad modulus\mathsf{hsamee}, \quad dist\mathsf{hsamee}.$$

Proof. The function-carrier half gives empty source, map, target, and modulus by the empty-certificate theorem for $\mathsf{ContinuousFunctionCarrier}$. With source and target reduced to e, the metric-distance continuation is compared with the right unit continuation, forcing the displayed distance to be empty. The reverse direction reassembles the function witness and the empty distance witness after the five endpoint equalities are exposed. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty cert iff`

Theorem 130.8 (Empty identity maps reflect metric witnesses)**.** *For histories* $x, y, x', y', d, m_x, m_y, c_x, c_y$: BHist, *if* $\mathsf{ContinuousFunctionCarrier}(x, \mathsf{e}, x', m_x, c_x)$ *and* $\mathsf{ContinuousFunctionCarrier}(y, \mathsf{e}, y', m_y, c_y)$ *are empty-map continuous carriers, then every displayed metric witness* $\mathsf{MetricDistanceWitness}(x', y', d)$ *reflects to a source-side witness* $\mathsf{MetricDistanceWitness}(x, y, d)$.

Proof. The empty-map carrier readback identifies x' with x and y' with y. Unary endpoint membership and the continuation field of the metric witness transport along these two hsame witnesses, while the distance history is held fixed. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty identity metric witness reflects`

Theorem 130.9 (Empty identity maps transport metric witnesses exactly)**.** *For histories* $x, y, x', y', d, m_x, m_y, c_x, c$ BHist*, if* ContinuousFunctionCarrier$(x, \mathsf{e}, x', m_x, c_x)$ *and* ContinuousFunctionCarrier$(y, \mathsf{e}, y', m_y, c_y)$ *are empty-map continuous carriers, then the image-side and source-side metric witnesses are equivalent:*

$$\mathsf{MetricDistanceWitness}(x', y', d) \iff \mathsf{MetricDistanceWitness}(x, y, d).$$

Proof. For the forward direction, apply Theorem 130.8 to the two empty-map continuous carriers and the displayed image-side metric witness.

For the reverse direction, apply Theorem 59.13 to the two carriers. It reads back $x'\mathsf{hsame}x$ and $y'\mathsf{hsame}y$; symmetry orients these witnesses as $x\mathsf{hsame}x'$ and $y\mathsf{hsame}y'$. Combine them with reflexivity $d\mathsf{hsame}d$ and apply Theorem 57.347 to transport the source-side metric fields. Repacking those transported unary fields and the transported continuation ledger gives MetricDistanceWitness(x', y', d). □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty identity metric witness iff`

The ten-field fit is: traditional target empty continuous-map metric readback, BEDC source ContinuousMapUp, carrier ContinuousFunctionCarrier, classifier hsame, empty-map graph ledger e, distance ledger d, metric certificate MetricDistanceWitness, core theorem Theorem 130.9, exactness the displayed iff, and downstream consumer compact-continuous metric readback.

Theorem 130.10 (Empty identity maps preserve metric result determinacy)**.** *For histories* $x, y, x', y', d, d', m_x, m_y$ BHist*, if the two endpoints are carried by empty continuous maps, then an image-side metric witness* MetricDistanceWitness(x', y', d) *and a source-side metric witness* MetricDistanceWitness(x, y, d') *have* hsame *distance results.*

Proof. First reflect the image-side witness through the empty continuous maps to get MetricDistanceWitness(x, y, d). Metric witness result determinacy at reflexive source endpoints then compares the two displayed distance histories. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty identity metric result deterministic`

Theorem 130.11 (ContinuousMap empty-target metric rebased carrier)**.** *For histories* $source, modulus, cert, dist,$ *suppose*

ContinuousFunctionCarrier$(source, \mathsf{e}, source, modulus, cert)$, MetricDistanceWitness$(source, \mathsf{e}, dist)$, Cont(

Then the metric distance ledger itself supports the empty-map continuous function carrier

$$\mathsf{ContinuousFunctionCarrier}(dist, \mathsf{e}, dist, modulus, cert').$$

Proof. Unpack the continuous-function carrier and the metric distance witness. The metric witness supplies unary membership of $dist$, while the continuous carrier supplies unary membership of $modulus$. The empty map is unary, the right-unit continuation gives Cont$(dist, \mathsf{e}, dist)$, and the displayed continuation gives the terminal certificate row. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty target metric rebased carrier`

Theorem 130.12 (ContinuousMap empty-target metric certificate determinacy)**.** *For histories* $source, modulus, cert, dist, cert',$ *suppose*

ContinuousFunctionCarrier$(source, \mathsf{e}, source, modulus, cert)$, MetricDistanceWitness$(source, \mathsf{e}, dist)$, Cont(

Then the original continuous-function certificate and the metric-rebased certificate classify together:

$$\mathsf{hsame}(cert, cert').$$

Proof. The empty-right metric witness identifies *dist* with *source* while preserving the unary distance ledger. The original carrier supplies the continuation $\mathsf{Cont}(source, modulus, cert)$; transporting the source side across the metric identification and comparing it with $\mathsf{Cont}(dist, modulus, cert')$ gives $\mathsf{hsame}(cert, cert')$ by continuation determinacy under hsame. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap empty target metric cert deterministic`

Theorem 130.13 (ContinuousMap target, certificate, and distance determinacy)**.** *For histories source, map, target, target′, modulus, cert, cert′, distance, and distance′, two concrete continuous-map carriers with the same source, map, and modulus determine the target, certificate, and distance ledgers up to* hsame*:*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance) \Longrightarrow \mathsf{ContinuousMapCarrier}(source, map, targe$$
$$\Longrightarrow \mathsf{hsame}(target, target') \wedge \mathsf{hsame}(cert, cert') \wedge \mathsf{hsame}(distance, distance') \wedge \mathsf{Cont}(source, target, distance).$$

Proof. The continuous-function components have the same source, map, and modulus, so continuous-function target-certificate determinacy gives $\mathsf{hsame}(target, target')$ and $\mathsf{hsame}(cert, cert')$. The two metric distance witnesses then share source histories and target histories up to hsame; metric result determinacy identifies *distance* and *distance′*. The continuation ledger $\mathsf{Cont}(source, target, distance)$ is the final field of the left metric distance witness. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier target cert distance deterministic`

Theorem 130.14 (ContinuousMap carrier canonical distance exactness)**.** *For histories source, map, target, modul* BHist*, the concrete continuous-map carrier is exactly the continuous-function carrier together with the canonical source-target distance classifier:*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance) \Longleftrightarrow \mathsf{ContinuousFunctionCarrier}(source, map, t$$

Proof. In the forward direction, project the continuous-function carrier from the given continuous-map carrier. Theorem 130.4 then supplies the carrier with distance ledger $\mathsf{append}(source, target)$, and Theorem 130.13 compares the two carriers with the same source, map, target, modulus, and certificate, identifying *distance* with $\mathsf{append}(source, target)$.

Conversely, start from the displayed continuous-function carrier and the classifier $\mathsf{hsame}(distance, \mathsf{append}(sourc$ Theorem 130.4 builds the canonical-distance carrier. Its metric component contains the continuation $\mathsf{Cont}(source, target, \mathsf{append}(source, target))$ and unary membership of the canonical distance ledger. Transport the continuation by BEDC.Derived.MetricUp.MetricDistanceWitness_cont_hsame_transport, transport unary membership of the distance ledger along hsame, and repack these fields as the required $\mathsf{MetricDistanceWitness}(source, target, distance)$. Together with the original continuous-function carrier this is precisely $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$.

The ten-field fit is: traditional target normalized continuous-map distance ledger; BEDC source ContinuousFunctionCarrier, MetricDistanceWitness, and Cont; carrier ContinuousMapCarrier; classifier hsame; stability obligations distance determinacy and metric hsame transport; ledger the hidden distance history; core theorem this iff; exactness the displayed iff; standard bridge deferred; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier canonical distance exactness`

Theorem 130.15 (ContinuousMap categorical canonical distance exactness)**.** *For histories source, map, target, m*
BHist*, the continuous-map carrier is exactly the composite classifier obtained from the categorical source-target hom row, the target-side continuity-modulus row, and the canonical source-target distance ledger:*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$$
$$\iff \mathsf{CategoryHomCarrier}(source, target, map) \wedge \mathsf{ContinuousModulusWitness}(target, modulus, cert) \wedge \mathsf{hsame}(d$$

Proof. In the forward direction, apply Theorem 130.2 to the given carrier. This yields the categorical hom row and the target-side modulus row, together with the metric distance witness.

Apply Theorem 130.14 to the same carrier. Its distance component replaces the metric witness by the canonical classifier $\mathsf{hsame}(distance, \mathsf{append}(source, target))$, so the displayed three-part conjunction follows.

Conversely, unpack $\mathsf{CategoryHomCarrier}(source, target, map)$ into the unary source, target, and map histories plus the graph continuation. Unpack $\mathsf{ContinuousModulusWitness}(target, modulus, cert)$ into the target, modulus, and certificate histories plus the modulus continuation. These rows rebuild $\mathsf{ContinuousFunctionCarrier}(source, map, target, modulus, cert)$.

Now use Theorem 130.14 in the reverse direction with the rebuilt continuous-function carrier and the displayed classifier $\mathsf{hsame}(distance, \mathsf{append}(source, target))$. The result is precisely $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$.

The ten-field fit is: traditional target continuous maps as morphisms with a canonical endpoint distance ledger; BEDC source CategoryUp/ContinuousUp/MetricUp/ContinuousMapUp; carrier ContinuousMapCarrier; classifier hsame; stability supplied by the categorical hom row, the modulus witness, and canonical distance exactness; ledger source, target, map, modulus, certificate, and distance histories; core theorem the displayed equivalence; exactness replacement of the metric witness by $\mathsf{hsame}(distance, \mathsf{append}(source, target))$; standard bridge is the same morphism-layer reading; downstream consumer $\mathsf{ContinuousMap}^{\uparrow}$ as the morphism layer for compact-continuous certificates. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier categorical canonical distance exactness`

Theorem 130.16 (ContinuousMap composition category-metric package)**.** *For histories source, mid, target, mapl*
BHist*, assume the two concrete continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, distG),$$

and assume the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

Then the composite exposes a category-metric package:

1. *the canonical composite continuous-map carrier,*

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{append}(source, target));$$

2. *the composite categorical hom row,*

$$\mathsf{CategoryHomCarrier}(source, target, mapFG);$$

3. the composite target-side modulus row,

$$\mathsf{ContinuousModulusWitness}(target, modFG, certFG);$$

4. the canonical metric distance row,

$$\mathsf{MetricDistanceWitness}(source, target, \mathsf{append}(source, target));$$

5. every displayed composite carrier with the same visible fields has the canonical distance ledger,

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, displayed) \Rightarrow \mathsf{hsame}(displayed, \mathsf{append}(source,$$

Proof. Project the continuous-function halves from the two ContinuousMapCarrier hypotheses. Apply Theorem 59.7 to those halves and the three continuation ledgers, obtaining the composite $\mathsf{ContinuousFunctionCarrier}(source, mapFG, target, modFG, certFG)$.

Package the canonical source-target distance by applying Theorem 130.4 from right to left to this composite continuous-function carrier. This gives the first package row,

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{append}(source, target)).$$

Apply Theorem 130.2 to the canonical composite carrier. Its three projections are exactly the displayed CategoryHomCarrier row, the ContinuousModulusWitness row, and the canonical MetricDistanceWitness row.

For the final determinacy clause, compare any displayed composite carrier with the canonical composite carrier by Theorem 130.13. The two carriers have the same source, map, target, modulus, and certificate histories, so the distance component of the determinacy conclusion is precisely $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier composition category metric package`

Theorem 130.17 (ContinuousMap carrier hsame-field transport with depth ledger)**.** *For histories* $source, source', map, map', target, target', modulus, modulus', cert, cert', distance, distance'$: BHist*, suppose*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$$

and

$$\mathsf{hsame}(source, source') \wedge \mathsf{hsame}(map, map') \wedge \mathsf{hsame}(target, target') \wedge \mathsf{hsame}(modulus, modulus') \wedge \mathsf{hsame}(cert, cert')$$

hold. Then the transported histories again form a continuous-map carrier, and the transported distance exposes the endpoint continuation and depth ledger:

$$\begin{aligned}&\mathsf{ContinuousMapCarrier}(source', map', target', modulus', cert', distance')\\ &\wedge\ \mathsf{Cont}(source', target', distance')\\ &\wedge\ \mathsf{MetricDistanceDepth}(distance') = \mathsf{MetricDistanceDepth}(source') + \mathsf{MetricDistanceDepth}(target').\end{aligned}$$

Proof. Unpack the displayed ContinuousMapCarrier into its ContinuousFunctionCarrier half and its MetricDistanceWitness half. Apply Definition 59.14 to the five function fields $source, map, target, modulus, cert$ and their displayed hsame images. This gives the transported continuous-function half.

For the metric half, apply Definition 57.347 to $source, target, distance$ and $source', target', distance'$. The resulting unary fields and transported continuation repack as $\mathsf{MetricDistanceWitness}(source', target', distance')$

Apply Definition 57.348 to the same three hsame witnesses and the original metric witness. It supplies the displayed $\mathsf{Cont}(source', target', distance')$ and the displayed depth equation. Pairing the transported continuous-function half with the transported metric witness gives the carrier component; pairing this with the continuation and depth ledger gives the stated conjunction.

The ten-field fit is: traditional target stable uniformly continuous map under classifier transport; BEDC source ContinuousFunctionCarrier, MetricDistanceWitness, and hsame; carrier ContinuousMapCarrier; classifier hsame; stability obligation six-field transport plus transported metric depth ledger; ledger hidden distance history; core theorem this block; exactness transported carrier and distance-depth equation; standard bridge deferred; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier hsame field transport depth`

Theorem 130.18 (ContinuousMap function carrier metric graph exactness)**.** *For histories $source, map, target, mo$ BHist, if*

$$\mathsf{ContinuousFunctionCarrier}(source, map, target, modulus, cert)$$

and

$$\mathsf{MetricDistanceWitness}(source, map, dist)$$

both hold, then the carrier exposes the graph continuation and the metric distance endpoint is exactly the same history as the graph target:

$$\mathsf{Cont}(source, map, target) \wedge \mathsf{hsame}(dist, target).$$

Proof. Read back the continuous-function carrier to obtain its graph continuation $\mathsf{Cont}(source, map, target)$. The metric witness supplies the continuation $\mathsf{Cont}(source, map, dist)$ over the same source and map. Continuation determinacy identifies the two endpoints, giving $\mathsf{hsame}(dist, target)$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapFunctionCarrier metric graph exactness`

Theorem 130.19 (ContinuousMap empty map with empty distance boundaries)**.** *For histories source, target, modulus, and cert, a concrete continuous-map carrier with empty graph map and empty distance ledger is equivalent to empty source and target boundaries together with the empty-source modulus witness:*

$$\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, target, modulus, cert, \mathsf{e}) \iff \mathsf{hsame}(source, \mathsf{e}) \wedge \mathsf{hsame}(target, \mathsf{e}) \wedge \mathsf{ContinuousModu}$$

Proof. In the forward direction, empty-map exactness for the continuous-function component gives a modulus witness over the target, while empty-distance exactness for the metric witness collapses both endpoint histories to e. Transporting across the target collapse presents the modulus witness over e.

Conversely, the empty endpoint data presents the graph carrier as the empty-map exactness case, and metric empty-distance exactness builds the distance witness over the two empty endpoints. Their conjunction is exactly the concrete continuous-map carrier. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty map empty distance boundaries iff`

Theorem 130.20 (ContinuousMap prefix canonical distance closure)**.** *For histories* $p, source, map, target, modulu$ BHist*, if* p *is unary and* $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$ *holds, then the prefixed endpoints carry the same map and modulus with the prefixed certificate and canonical prefixed distance:*

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier prefix canonical distance closed`

Proof. Prefix closure for the continuous-function carrier gives the prefixed function half. The metric half is built canonically: the prefixed source and target are unary by unary append closure, their appended distance is unary by another append-closure step, and the distance continuation is the defining append equation. □

Theorem 130.21 (ContinuousMap prefixed carrier canonical distance determinacy)**.** *For histories* $p, source, map, target, modulus, cert, distance, distance' : \mathsf{BHist}$*, if* $\mathsf{UnaryHistory}(p)$*,* $\mathsf{ContinuousMapCarrier}(source,$ *and*

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), distance')$$

hold, then the displayed prefixed carrier has the canonical prefixed distance ledger:

$$\mathsf{hsame}(distance', \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

Proof. First build the canonical prefixed carrier from the original one. Apply Theorem 130.20 to the unary prefix and the original carrier.

Now compare the displayed prefixed carrier with that canonical prefixed carrier. They have the same prefixed source, map, prefixed target, modulus, and prefixed certificate, so Theorem 130.13 determines the distance component.

Projecting that distance component gives exactly the displayed orientation: $\mathsf{hsame}(distance', \mathsf{append}(\mathsf{append}(p,$ □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier prefix canonical distance deterministic`

Theorem 130.22 (ContinuousMap prefixed carrier canonical distance exactness)**.** *For histories* $p, source, map, target, modulus, cert, distance, distance' : \mathsf{BHist}$*, if* $\mathsf{UnaryHistory}(p)$ *and* $\mathsf{ContinuousMapCarrier}(sour$ *then the prefixed continuous-map carrier is equivalent to the displayed canonical prefixed distance classifier:*

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), distance') \iff \mathsf{hsame}(distance', \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

Proof. In the forward direction, apply Theorem 130.21 to the unary prefix, the original carrier, and the displayed prefixed carrier. This identifies $distance'$ with the canonical prefixed source-target ledger.

Conversely, first build the canonical prefixed carrier by applying Theorem 130.20 to $\mathsf{UnaryHistory}(p)$ and the original continuous-map carrier. Project its continuous-function half.

Now apply Theorem 130.14 in the reverse direction to that continuous-function half and the displayed classifier $\mathsf{hsame}(distance', \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target)))$. This repacks the prefixed continuous-function data with the arbitrary displayed distance ledger $distance'$.

The ten-field fit is: traditional target prefixed continuous-map distance normalization; BEDC source ContinuousMapCarrier, ContinuousFunctionCarrier, MetricDistanceWitness, and Cont; carrier ContinuousMapCarrier; classifier hsame; stability from prefix closure, distance determinacy, and canonical distance exactness; ledger the hidden prefixed distance history; core theorem this iff; exactness the displayed iff; downstream use compact-continuous map endpoint and composition normalization; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier prefix canonical distance exactness`

Theorem 130.23 (ContinuousMap prefixed canonical distance package)**.** *The ten-field fit is: traditional target continuous-map prefix-normalization package; BEDC source* ContinuousMapCarrier *plus* MetricDistanceWitness*; carrier* ContinuousMapCarrier*; classifier* hsame*; stability prefix closure, determinacy, and exactness; ledger prefix and displayed distance; core theorem this package; exactness the iff row; standard bridge deferred; status* ProofTarget*.*

For histories $p, source, map, target, modulus, cert, distance, displayed : \mathsf{BHist}$*, if* $\mathsf{UnaryHistory}(p)$ *and* $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$*, then the following three facts hold:*

1.

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

2.

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), displayed) \to \mathsf{hsame}(displayed, \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

3.

$$\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), displayed) \iff \mathsf{hsame}(displayed, \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).$$

Proof. For the canonical carrier clause, apply Theorem 130.20 to the unary prefix and the original continuous-map carrier.

For the displayed determinacy clause, fix a displayed prefixed carrier with the same source, map, target, modulus, and prefixed certificate fields. Apply Theorem 130.21 to the unary prefix, the original carrier, and this displayed prefixed carrier.

For the exact classifier clause, apply Theorem 130.22 to the same unary prefix and original carrier. Its conclusion is precisely the iff between the displayed prefixed carrier and the hsame classifier for the canonical prefixed distance ledger. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier prefixed canonical distance package`

Theorem 130.24 (ContinuousMap empty map and empty distance certificate readback)**.** *For histories source, target, modulus, and cert, if* $\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, target, modulus, cert, \mathsf{e})$*, then the endpoint collapses and the modulus certificate reads back as a unary history equivalent to the modulus:*

$$\mathsf{hsame}(source, \mathsf{e}) \wedge \mathsf{hsame}(target, \mathsf{e}) \wedge \mathsf{UnaryHistory}(cert) \wedge \mathsf{hsame}(cert, modulus).$$

Proof. Apply Theorem 130.19 to the carrier. The forward implication yields $\mathsf{hsame}(source, \mathsf{e})$, $\mathsf{hsame}(target, \mathsf{e})$, and $\mathsf{ContinuousModulusWitness}(\mathsf{e}, modulus, cert)$.

Apply the empty-source modulus-witness readback theorem from the continuous chapter to the final witness. It gives $\mathsf{UnaryHistory}(cert)$ and $\mathsf{hsame}(modulus, cert)$; symmetry of hsame presents the last conjunct in the displayed certificate-to-modulus orientation. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty map empty distance certificate readback`

Theorem 130.25 (ContinuousMap empty map and empty distance certificate exactness)**.** *For histories source, target, modulus, and cert, a concrete continuous-map carrier with empty graph map and empty distance ledger is equivalent to empty endpoint boundaries together with a readable modulus certificate:*

$$\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, target, modulus, cert, \mathsf{e}) \iff \mathsf{hsame}(source, \mathsf{e}) \wedge \mathsf{hsame}(target, \mathsf{e}) \wedge \mathsf{UnaryHistory}(cer$$

Proof. In the forward direction, apply Theorem 130.24. This is exactly the displayed endpoint collapse and certificate readback.

For the reverse direction, start from the four displayed conjuncts. Apply Theorem 59.4 with target $cert$: the unary certificate field and symmetry of $\mathsf{hsame}(cert, modulus)$ give $\mathsf{ContinuousModulusWitness}(\mathsf{e}, modul$

Together with $\mathsf{hsame}(source, \mathsf{e})$ and $\mathsf{hsame}(target, \mathsf{e})$, this is the right-hand side of Theorem 130.19. Applying that theorem in the reverse direction rebuilds $\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, target, modulu$ □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty map empty distance certificate exactness`
Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty map empty distance certificate iff`

The ten-field fit is: traditional target empty continuous-map readback, BEDC source ContinuousMapUp with ContinuousModulusWitness, carrier ContinuousMapCarrier, classifier hsame, graph ledger e, distance ledger e, certificate ledger $cert$, core theorem Theorem 130.24, exactness the displayed conjunction, and downstream consumer compact-continuous map endpoint readback.

Theorem 130.26 (ContinuousMap visible-context canonical distance exactness)**.** *For histories* $p, q, source, map, target, modulus, cert, distance : \mathsf{BHist}$*, the visible continuous-map carrier is exactly the central continuous-function carrier together with the canonical source-target distance classifier:*

$$\begin{aligned}&\mathsf{ContinuousMapCarrier}(p \cdot source, map, p \cdot target, modulus \cdot q, (p \cdot cert) \cdot q, p \cdot distance)\\ &\quad\iff \quad \mathsf{UnaryHistory}(p) \wedge \mathsf{UnaryHistory}(q) \wedge \mathsf{ContinuousFunctionCarrier}(source, map, target, modulus, cert) \wedge \mathsf{hsa}\end{aligned}$$

Proof. For the forward direction, apply Theorem 130.3 to the displayed carrier. This produces unary evidence for p and q, the central category hom row, the central modulus row, and $\mathsf{MetricDistanceWitness}(sour$

The category hom row and the modulus row repack as $\mathsf{ContinuousFunctionCarrier}(source, map, target, modulus,$ Compare the resulting central continuous-map carrier with its canonical-distance form by Theorem 130.14. This replaces the central metric witness by the classifier $\mathsf{hsame}(distance, \mathsf{append}(source, target))$.

For the reverse direction, start from the two unary context histories, the central continuous-function carrier, and the displayed canonical classifier. Theorem 130.14 builds the central continuous-map carrier, equivalently transporting the canonical metric witness for $\mathsf{append}(source, target)$ along $\mathsf{hsame}(distance, \mathsf{append}(source, target))$.

Project the central carrier into its category hom, modulus, and metric rows. Then apply Theorem 130.3 from right to left with the two unary context histories. The result is precisely the displayed visible-context ContinuousMapCarrier. □

Theorem 130.27 (ContinuousMapUp public export surface)**.** *The metric certificate bridge of Definition 130.39, together with the existing identity, composition, canonical-distance, field-transport, and associativity rows, exports the public* $\mathsf{ContinuousMap}^{\uparrow}$ *surface over* BHist*. The exported data are exactly the source row, pattern row, componentwise classifier, stability rows, canonical distance ledger, identity rows, and composition rows.*

This public surface does not claim host functions, function-space topology, standard topological-space bridges, or pointwise or uniform convergence.

Proof. The source row, pattern row, componentwise classifier, stability rows, and canonical distance ledger are the five certificate rows packaged by Definition 130.39. The componentwise classifier and its stability are transported by Definition 130.17, while the canonical distance ledger is the endpoint append ledger used by the same bridge.

The public identity rows are the empty source and target carriers of Definition 130.40. Their two-sided behavior inside composition is supplied by Definition 130.41.

The public composition rows are closed by Definition 130.47 and repackaged by Definition 130.52. The associative bracketing row is the canonical package of Definition 130.57.

These cited rows exhaust the displayed $\mathsf{ContinuousMap}^{\uparrow}$ public surface over BHist. Since none of them introduces host functions, a function-space topology, a standard topological-space bridge, or a pointwise/uniform convergence interface, the theorem exports only the stated BEDC surface. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapPublic export surface`

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$.

Constructive story: A continuous map is built as a six-history package: source, map, target, modulus, certificate, and distance, where the first five form a ContinuousFunctionCarrier and the final history is a MetricDistanceWitness between the source and target. The carrier accepts only packages that decompose into a categorical hom row, a target-side modulus witness, and a metric distance row; missing graph continuation, modulus continuation, or distance ledger data leaves the package outside the surface. Two packages are classified together by componentwise hsame on all six visible histories, with the hidden canonical-distance row identifying the displayed distance with the endpoint append that identity and composition will consume. The source is the category, continuity, and metric triple, the pattern is the six-field continuous-map carrier, and the ledger records the graph, modulus, certificate, distance, canonical distance exactness, identities, composition rows, and associative bracketing. The five name-certificate obligations follow from empty identity carriers for inhabitation, from history-equality for reflexive, symmetric, and transitive comparison, and from field transport plus composition closure for preservation of admitted carriers under the classifier. A package h lies in the signature gap of a $\mathsf{ContinuousMap}^{\uparrow}$ token p when the source-domain accepts its category-continuity-metric rows, the signature relation pairs the six-history carrier with an answer package and evidence ledger, and the token-introduction relation names that answer as p; concretely, p records the same map, modulus, certificate, target, and canonical distance ledgers. The category-metric terminal extension bridge reads the same carrier after extending the terminal modulus certificate, and the chapter registers this package under $\mathsf{ContinuousMap}^{\uparrow}$ without host functions, function-space topology, pointwise convergence, uniform convergence, or a standard topological bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper-side scope is exactly the public export surface of Definition 130.27, the metric certificate bridge of Definition 130.39, and the category-metric terminal extension bridge of Definition 130.55.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier\_category\_metric\_terminal\_extension\_bridge`

Bridge status: bridgeChecked

Not claimed: Host functions, function-space topology, sheafified continuity, exponentiability, pointwise or uniform convergence, and any standard topological-space bridge stronger than the checked BEDC schema bridge.

Upgrade path: no further upgrade – chapter at top of formal axis

Theorem 130.28 (ContinuousMap visible-context composition category-metric exactness)**.** *For histories* $p, q, source, middle, target, f, g, fg, modF, modG, modFG, certF, certG, cert, distF, distG, displayed$: BHist*, assume the two visible-context carriers*

$$\mathsf{ContinuousMapCarrier}(p \cdot source, f, p \cdot middle, modF \cdot q, (p \cdot certF) \cdot q, p \cdot distF),$$
$$\mathsf{ContinuousMapCarrier}(p \cdot middle, g, p \cdot target, modG \cdot q, (p \cdot certG) \cdot q, p \cdot distG),$$

and assume the graph, modulus, and target-certificate ledgers

$$\mathsf{Cont}(f, g, fg), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, cert).$$

Then visible-context composition exposes the full category-metric package:

1. the composite categorical hom row,

$$\mathsf{CategoryHomCarrier}(source, target, fg);$$

2. the composite target-side modulus row,

$$\mathsf{ContinuousModulusWitness}(target, modFG, cert);$$

3. the canonical source-target metric distance row,

$$\mathsf{MetricDistanceWitness}(source, target, \mathsf{append}(source, target));$$

4. the visible composite carrier has exactly the canonical distance classifier,

$$\mathsf{ContinuousMapCarrier}(p \cdot source, fg, p \cdot target, modFG \cdot q, (p \cdot cert) \cdot q, p \cdot displayed)$$
$$\iff \quad \mathsf{hsame}(displayed, \mathsf{append}(source, target)).$$

Proof. Apply Theorem 130.3 to the first visible carrier. This recovers unary evidence for p and q, the central categorical row $\mathsf{CategoryHomCarrier}(source, middle, f)$, the central modulus row $\mathsf{ContinuousModulusWitness}(middle, modF, certF)$, and the metric row $\mathsf{MetricDistanceWitness}(source, middle, distF$

Apply the same decomposition theorem to the second visible carrier. The result has the same visible contexts and exposes $\mathsf{CategoryHomCarrier}(middle, target, g)$, $\mathsf{ContinuousModulusWitness}(target, modG, certG$ and $\mathsf{MetricDistanceWitness}(middle, target, distG)$.

The two category and modulus rows repack as the two central ContinuousFunctionCarrier hypotheses. Apply Theorem 59.7 with the three displayed continuation ledgers. The composite central carrier $\mathsf{ContinuousFunctionCarrier}(source, fg, target, modFG, cert)$ follows.

Apply Theorem 59.139 to this composite central carrier. Its graph projection is exactly $\mathsf{CategoryHomCarrier}(source, target, fg)$, and its target-modulus projection is exactly $\mathsf{ContinuousModulusWitness}(tar$

Use Theorem 130.4 from right to left on the composite central carrier. Decomposing the resulting canonical ContinuousMapCarrier by Theorem 130.2 gives the canonical row $\mathsf{MetricDistanceWitness}(source, target$

It remains to classify visible displayed distances. The unary witnesses for p and q are already available, and the composite central ContinuousFunctionCarrier has been constructed. Therefore Theorem 130.26 specializes the displayed visible carrier exactly to $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$. □

Lean4 ✓ BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier visible context composition category metric exactness

The categorical hom row in Theorem 130.28 is the concrete sibling surface of chapter 61. The canonical source-target distance row is the metric sibling surface of chapter 57. The theorem consumes both through the visible-context carrier and does not create either structure.

The ten-field fit is: traditional uniformly continuous maps with visible source and target context under composition; BEDC source CategoryUp/ContinuousUp/MetricUp/ContinuousMapUp; carrier ContinuousMapCarrier; classifier hsame; stability from visible carrier decomposition, central continuous-function composition, graph and modulus readback, canonical metric packaging, and visible canonical-distance exactness; ledger visible contexts, source, middle, target, graph maps, moduli, certificates, and metric-distance histories; core theorem Theorem 130.28; exactness the displayed category hom row, target-side modulus row, canonical metric row, and visible distance classifier; standard bridge is deferred; status ProofTarget. The top-level $\mathsf{ContinuousMap}^{\uparrow}$ node reads the metric carrier through chapter 57, the pointwise-modulus surface through chapter 59, and the graph and composition surface through chapter 61. Compact-uniform consumers read this combined horizontal lattice through the existing child rows, rather than through an isolated kernel-only entry.

130.2 The certificate

Definition 130.29 (Metric ContinuousMapUp source specification)**.** *For histories source, map, target, modulus, ce* BHist*, the metric* $\mathsf{ContinuousMap}^{\uparrow}$ *source row is the conjunction*

$$\mathsf{CategoryHomCarrier}(source, target, map) \wedge \mathsf{ContinuousModulusWitness}(target, modulus, cert) \wedge \mathsf{MetricDistanceWi}$$

It names the categorical graph carrier, the target-side modulus witness, and the endpoint distance witness carried by the six-history certificate object.

Lean4 (definition) BEDC.Derived.ContinuousMapUp.ContinuousMapMetricSourceSpec
Lean4 ✓ BEDC.Derived.ContinuousMapUp.ContinuousMapMetricSourceSpec canonical carrier

Definition 130.30 (Metric ContinuousMapUp pattern specification)**.** *The metric* $\mathsf{ContinuousMap}^{\uparrow}$ *pattern is the six-field carrier formation*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance).$$

The displayed carrier is the public pattern consumed by compact-continuous and Heine–Cantor arguments: it packages the source, map, target, modulus, certificate, and distance histories in one BEDC object.

Lean4 (definition) BEDC.Derived.ContinuousMapUp.ContinuousMapMetricPatternSpec
Lean4 ✓ BEDC.Derived.ContinuousMapUp.ContinuousMapMetricPatternSpec carrier readback

Definition 130.31 (Metric ContinuousMapUp classifier specification)**.** *For two metric* $\mathsf{ContinuousMap}^{\uparrow}$ *carriers with histories* $source, map, target, modulus, cert, distance$ *and* $source', map', target', modulus', cert', dista$ *the classifier is componentwise* hsame *on the six displayed histories:*

$$\mathsf{hsame}(source, source') \wedge \mathsf{hsame}(map, map') \wedge \mathsf{hsame}(target, target') \wedge \mathsf{hsame}(modulus, modulus') \wedge \mathsf{hsame}(cert, c$$

The same classifier row records the hidden canonical-distance exactness

$$\mathsf{hsame}(distance, \mathsf{append}(source, target))$$

for each admitted carrier, and similarly for the primed carrier.

Lean4 (definition) `BEDC.Derived.ContinuousMapUp.ContinuousMapMetricClassifierSpec`

Definition 130.32 (Metric ContinuousMapUp stability certificate)**.** *The metric* ContinuousMap$^{\uparrow}$ *stability certificate consists of:*

1. *field transport of the six histories under the componentwise* hsame *classifier;*
2. *canonical-distance exactness for each admitted carrier;*
3. *two-sided identity closure by empty maps and empty distance ledgers;*
4. *composition closure by categorical graph composition, modulus composition, and canonical endpoint-distance normalization;*
5. *associativity of the composed canonical package.*

Lean4 (definition) `BEDC.Derived.ContinuousMapUp.ContinuousMapMetricStabilityCertificate`
Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapMetricStabilityCertificate field transport`

Definition 130.33 (Metric ContinuousMapUp ledger policy)**.** *The metric* ContinuousMap$^{\uparrow}$ *ledger policy records the six histories* $source, map, target, modulus, cert, distance$*, the visible source row of Definition 130.29, and the hidden canonical-distance ledger* hsame$(distance,$ append$(source, target))$*. Under composition it keeps the graph and modulus continuation ledgers visible and rewrites the displayed distance to the canonical endpoint append.*

Lean4 (definition) `BEDC.Derived.ContinuousMapUp.ContinuousMapMetricLedgerPolicy`

Theorem 130.34 (ContinuousMap CompleteMetric CompactMetric uniform route)**.** *Let a metric* ContinuousMap$^{\uparrow}$ *carrier have source row supplied by a* CompactMetric$^{\uparrow}$ *certificate and target row supplied by a* CompleteMetric$^{\uparrow}$ *certificate. Every uniform-modulus read factors through the displayed six-history ContinuousMap carrier, the* CompactMetric$^{\uparrow}$ *total-bounded finite-net and complete-limit rows, and the* CompleteMetric$^{\uparrow}$ *limit-witness rows.*

The route exports no open-cover compactness, no choice-selected subnet, and no host function equality. It is a finite certificate route over the ContinuousMap source, map, target, modulus, certificate, distance, hsame*,* Cont*,* Pkg*, and* NameCert *rows together with the compact and complete metric ledgers.*

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier compact complete uniform route`

Proof. Project the ContinuousMap side through Definition 130.29, Definition 130.30, and Definition 130.33. These rows expose exactly the six histories, the categorical graph row, the modulus row, the metric source and target rows, and the canonical endpoint-distance ledger.

Read the compact source through Definition 129.5 and Definition 129.20. The source contributes total-bounded finite-net rows and complete-limit witness rows over the same metric carrier, not open-cover compactness or a selected subnet.

Read the complete target through the complete-metric limit-witness surface, in particular Definition 128.2 and Definition 128.4. These rows provide the target-side limit witness and its transport without adding a host function equality test.

Repack the ContinuousMap, CompactMetric, and CompleteMetric rows as one uniform-modulus consumer route. The visible hsame, Cont, Pkg, and NameCert ledgers carry the route, so every uniform-modulus read remains finite and excludes open-cover compactness, choice-selected subnets, and host function equality. □

Theorem 130.35 (ContinuousMap compact-complete uniform finite route sharpening)**.** *Let a metric* $\mathsf{ContinuousMap}^{\uparrow}$ *carrier be displayed by the six histories* $source, map, target, modulus, cert, distance$: BHist. *Suppose the source metric row is read through a* $\mathsf{CompactMetric}^{\uparrow}$ *certificate and the target metric row is read through a* $\mathsf{CompleteMetric}^{\uparrow}$ *certificate. Then every uniform-modulus consumer route factors through exactly the following finite surface:*

1. *the displayed ContinuousMap histories* $source, map, target, modulus, cert, distance$*;*
2. *the compact finite-net rows and complete-limit rows exported by the* $\mathsf{CompactMetric}^{\uparrow}$ *source;*
3. *the target complete-limit witness rows exported by* $\mathsf{CompleteMetric}^{\uparrow}$*;*
4. *the* $\mathsf{MetricDistanceWitness}$ *row for the source-target metric read;*
5. *componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

The route exports no open-cover compactness, no selected subnet, no host function equality, no quotient stream equality, and no ambient completeness principle. In particular, any later compact-uniform-continuity or Real-completion consumer reading the route receives only this finite $\mathsf{NameCert}$ *consumer surface.*

Proof. First project the ContinuousMap carrier by Definition 130.29, Definition 130.30, and Definition 130.33. These definitions expose the six histories, the categorical graph row, the target modulus row, the metric distance witness, the componentwise hsame classifier, displayed Cont rows, Pkg provenance, and local $\mathsf{NameCert}$ bookkeeping.

Next apply Definition 130.34. This already forces every uniform-modulus read through the ContinuousMap carrier, the compact finite-net and complete-limit rows, and the complete-metric limit-witness rows, while refusing open-cover compactness, selected subnets, and host function equality.

Read the compact coordinate through Definition 129.5 and Definition 129.20. The compact source therefore contributes only finite-net coverage, total-bounded rows, complete-limit rows, and their displayed metric ledgers.

Read the complete coordinate through Definition 128.2 and Definition 128.4. The target contributes only named limit witnesses, threshold rows, late-distance witnesses, and their classifier-stable transport rows.

Finally repack the three readings as the finite consumer surface listed in the theorem. Since each coordinate is displayed as a BHist row with its own hsame, Cont, Pkg, and $\mathsf{NameCert}$ evidence, no quotient stream equality, ambient completeness principle, or host-level equality test can be read from the route. □

Theorem 130.36 (ContinuousMap compact-complete uniform route refinement)**.** *Let a metric* $\mathsf{ContinuousMap}^{\uparrow}$ *carrier be displayed by the histories* $source, map, target, modulus, cert, distance$: BHist*, with the source row read through a* $\mathsf{CompactMetric}^{\uparrow}$ *certificate and the target row read through a* $\mathsf{CompleteMetric}^{\uparrow}$ *certificate. Then every compact-complete uniform-modulus consumer of this carrier has the exact finite surface consisting only of:*

1. *the six* $\mathsf{ContinuousMap}^{\uparrow}$ *histories* $source, map, target, modulus, cert, distance$*;*
2. *the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net rows for the source metric;*
3. *the* $\mathsf{CompleteMetric}^{\uparrow}$ *limit-witness rows for the target metric;*
4. *the* $\mathsf{MetricDistanceWitness}(source, target, distance)$ *row;*
5. *componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

No open-cover compactness, selected subnet, quotient stream equality, or host function equality is part of the consumer surface.

Proof. Begin with Definition 130.34. It places every uniform-modulus read behind the six-history $\mathsf{ContinuousMap}^{\uparrow}$ carrier, the compact metric rows, and the complete-metric limit-witness rows.

Sharpen the carrier boundary with Definition 130.35. This identifies the visible consumer coordinates as the displayed histories, finite-net rows, target limit-witness rows, the source-target MetricDistanceWitness row, and the componentwise hsame, Cont, Pkg, and NameCert ledgers.

The compact coordinate is then read through Definition 129.5 and Definition 129.20. These theorems keep the source contribution on finite-net and complete-limit rows, so an open-cover compactness principle or selected subnet has no exported row to consume.

The target coordinate is read through Definition 128.2 and Definition 128.4. The target contribution is therefore a named limit-witness surface with stable transported rows, not quotient stream equality or a host function equality test.

Combining these projections leaves exactly the five listed families of rows. Every later compact-uniform or Real-completion consumer must enter through that finite NameCert surface, and the excluded objects remain outside the route because none of the cited certificate surfaces exports them. □

Theorem 130.37 (ContinuousMap compact-complete uniform exact consumer surface)**.** *Let a displayed* $\mathsf{ContinuousMap}^{\uparrow}$ *carrier have histories* $source, map, target, modulus, cert, distance$: BHist*. Suppose the source metric row is supplied by a* $\mathsf{CompactMetric}^{\uparrow}$ *certificate, the target metric row is supplied by a* $\mathsf{CompleteMetric}^{\uparrow}$ *certificate, and the endpoint distance row is displayed as* MetricDistanceWitness($sourc$ *A compact-complete uniform-modulus consumer of* ContinuousMapCarrier($source, map, target, modulus, cert, distan$ *is accepted exactly when its finite surface consists of the following rows:*

1. *the six displayed* $\mathsf{ContinuousMap}^{\uparrow}$ *histories* $source, map, target, modulus, cert, distance$*;*
2. *the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net and complete-limit rows supplied by Definition 129.5 and Definition 129.20;*
3. *the target* $\mathsf{CompleteMetric}^{\uparrow}$ *limit-witness rows supplied by Definition 128.2 and Definition 128.4;*
4. *the row* MetricDistanceWitness($source, target, distance$)*;*
5. *componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *provenance for the displayed rows.*

Equivalently, every accepted consumer projects to precisely these rows, and any display of precisely these rows repacks as the same finite compact-complete uniform consumer surface. No open-cover compactness, selected subnet, quotient stream equality, host function equality, or ambient completeness principle is exported.

Proof. For the forward direction, first apply Definition 130.34. It places the consumer behind the six-history $\mathsf{ContinuousMap}^{\uparrow}$ carrier, the compact source rows, and the complete target rows.

Apply Definition 130.35 and Definition 130.36 to identify the visible rows. These route theorems leave only the displayed histories, the compact finite-net contribution, the target limit-witness contribution, the metric-distance witness, and the componentwise hsame, Cont, Pkg, and NameCert provenance.

The compact rows are then read through Definition 129.5 and Definition 129.20. Thus the compact source coordinate contributes finite-net and complete-limit rows, not an open-cover compactness principle or a selected subnet.

The target rows are read through Definition 128.2 and Definition 128.4. Thus the complete target coordinate contributes named limit-witness and stable transport rows, not quotient stream equality, host function equality, or an ambient completeness principle.

For the reverse direction, start from a displayed finite surface containing exactly the five listed families of rows. The six ContinuousMap histories, the metric-distance witness, and the componentwise hsame, Cont, Pkg, and NameCert provenance rebuild the displayed carrier boundary.

The compact finite-net and complete-limit rows supply the source side, while the complete limit-witness rows supply the target side. Repacking these rows through the same three route theorems gives the compact-complete uniform-modulus consumer and no additional exported object. Hence acceptance is exactly the displayed finite surface. □

Theorem 130.38 (ContinuousMap CompactMetric MetricTriangle handoff)**.** *Let a metric* $\mathsf{ContinuousMap}^{\uparrow}$ *carrier be displayed by the six histories* $source, map, target, modulus, cert, distance : \mathsf{BHist}$*. Suppose its source row is read through a compact* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net certificate, its target row is read through a* $\mathsf{CompleteMetric}^{\uparrow}$ *limit-witness certificate, and an accepted* $\mathsf{MetricTriangleUniformEstimate}^{\uparrow}$ *carrier uses the same compact-net center, the two* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise target-estimate rows, the target* $\mathsf{Met}^{\uparrow}$ *triangle row, and the downstream* $\mathsf{UniformModulus}^{\uparrow}$ *handoff. Then the combined handoff factors through exactly the finite surface of the six* $\mathsf{ContinuousMap}^{\uparrow}$ *histories, the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net rows, the* $\mathsf{CompleteMetric}^{\uparrow}$ *target limit-witness rows, the source and target metric-triangle rows, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

The handoff exports no open-cover compactness, selected subnet, choice principle, host function equality, quotient stream equality, semantic continuity theorem, or $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Begin with Definition 130.36. It places the ContinuousMap consumer behind the six displayed histories, the compact finite-net source rows, the complete target limit-witness rows, the metric distance witness, and the visible hsame, Cont, Pkg, and NameCert ledgers.

Next read the accepted $\mathsf{MetricTriangleUniformEstimate}^{\uparrow}$ packet through Definition 1159.31. This binds the same compact-net center to the two pointwise target estimates and to the target metric triangle row before the downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer can read the estimate.

Use Definition 1159.30 to identify the consumer boundary. The boundary contains the selected finite-net center, source metric rows, pointwise target estimates, target triangle row, and support rows, so it agrees with the ContinuousMap route on the finite carrier data rather than on host-level functions or quotient streams.

Finally apply Definition 1159.34. It packages the public $\mathsf{MetricTriangleUniformEstimate}^{\uparrow}$ export as the same finite BHist, hsame, Cont, Pkg, and NameCert surface required by the ContinuousMap refinement. Since none of the cited surfaces exports open-cover compactness, selected subnets, choice, semantic continuity, $\mathsf{Real}^{\uparrow}$ completeness, host function equality, or quotient stream equality, the composed handoff cannot supply those objects to a downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer. □

Theorem 130.39 (Metric ContinuousMapUp certificate bridge)**.** *The five rows of Definition 130.29–Definition 130.33 form the paper-side* NameCert *obligations for* $\mathsf{ContinuousMap}^{\uparrow}$ *with carrier*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance).$$

The bridge identifies the source row with the CategoryUp*,* ContinuousUp*, and* MetricUp *components; exposes componentwise* hsame *on the six displayed histories; and uses the hidden canonical-distance exactness* $\mathsf{hsame}(distance, \mathsf{append}(source, target))$ *as the distance certificate consumed by identity and composition.*

Proof. First unpack the carrier through Definition 130.15. This gives the categorical hom row, the target-side modulus row, and the canonical endpoint-distance classifier. Together with Definition 130.29, these are exactly the visible source obligations.

Next use Definition 130.17 to transport the six displayed histories along the componentwise classifier. The transport step supplies the classifier and stability fields without changing the public carrier shape.

Identity closure is supplied by Definition 130.41. It shows that empty identity maps and empty distance ledgers serve as the two-sided units required by the certificate policy.

Finally apply Definition 130.57. It composes the graph, modulus, certificate, and distance rows while normalizing the distance back to the canonical endpoint append. This is the ledger behavior stated in Definition 130.33, so the five displayed rows give the advertised NameCert obligations for $\mathsf{ContinuousMap}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.continuousmap semantic name certificate`

Theorem 130.40 (ContinuousMap empty identity carriers)**.** *For histories* $source, target, map, modulus, cert, dist$ BHist*, assume*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance).$$

Then the empty-map identities at the source and target are continuous-map carriers:

1. *the source identity carrier is*

$$\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, source, \mathsf{e}, source, \mathsf{append}(source, source));$$

2. *the target identity carrier is*

$$\mathsf{ContinuousMapCarrier}(target, \mathsf{e}, target, \mathsf{e}, target, \mathsf{append}(target, target));$$

Proof. Project the continuous-function carrier from the given ContinuousMapCarrier. Its fields supply unary endpoint data and the certificate continuation $\mathsf{Cont}(target, modulus, cert)$.

For the source identity, use the unary source field and the left-unit continuation $\mathsf{Cont}(source, \mathsf{e}, source)$ to form $\mathsf{ContinuousModulusWitness}(source, \mathsf{e}, source)$. Apply Theorem 59.12, then package the canonical distance by Theorem 130.4.

For the target identity, the same construction uses the unary target field and the left-unit continuation $\mathsf{Cont}(target, \mathsf{e}, target)$. The empty-map identity theorem builds the continuous-function carrier at $target$, and canonical distance packaging gives the displayed target identity carrier. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty identities closed`

Theorem 130.41 (ContinuousMap empty identities are two-sided composition units)**.** *For histories* $source, target, map, modulus, cert, distance, displayed_L, displayed_R$: BHist*, assume*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance).$$

Then the empty-map identities are two-sided units for composition:

1. *composing the source identity on the left with the displayed carrier, using*

$$\mathsf{Cont}(\mathsf{e}, map, map), \qquad \mathsf{Cont}(\mathsf{e}, modulus, modulus), \qquad \mathsf{Cont}(target, modulus, cert),$$

closes as the canonical carrier

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, \mathsf{append}(source, target));$$

2. *composing the displayed carrier with the target identity on the right, using*

$$\mathsf{Cont}(map, \mathsf{e}, map), \qquad \mathsf{Cont}(modulus, \mathsf{e}, modulus), \qquad \mathsf{Cont}(target, modulus, cert),$$

closes as the same canonical carrier

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, \mathsf{append}(source, target));$$

3. *if the left and right unit composites are displayed with distances* $displayed_L$ *and* $displayed_R$*, respectively, then*

$$\mathsf{hsame}(displayed_L, \mathsf{append}(source, target)) \wedge \mathsf{hsame}(displayed_R, \mathsf{append}(source, target)).$$

Proof. Apply Theorem 130.40 to the displayed carrier. This supplies the source and target empty identity carriers used as the unit factors.

Now apply Theorem 130.47 to the source identity carrier and the displayed carrier, with the BEDC left-unit laws $\mathsf{Cont}(\mathsf{e}, map, map)$ and $\mathsf{Cont}(\mathsf{e}, modulus, modulus)$ and the projected certificate ledger $\mathsf{Cont}(target, modulus, cert)$. This gives the left unit composite over $\mathsf{append}(source, target)$.

Apply the same composition-closure theorem to the displayed carrier and the target identity carrier, using the right-unit laws $\mathsf{Cont}(map, \mathsf{e}, map)$ and $\mathsf{Cont}(modulus, \mathsf{e}, modulus)$ together with the same certificate ledger. This gives the right unit composite over the same canonical distance.

Finally, apply Theorem 130.50 to each unit composite presentation. Comparing any displayed left or right unit-composite distance with the corresponding canonical composite identifies it by hsame with $\mathsf{append}(source, target)$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty identities two sided composition units`

Theorem 130.42 (ContinuousMap identity carrier distance determinacy)**.** *For histories* $source, map, target, modu$ BHist*, assume*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance).$$

If the displayed source and target identity carriers are

$$\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, source, \mathsf{e}, source, displayedSource)$$

and

$$\mathsf{ContinuousMapCarrier}(target, \mathsf{e}, target, \mathsf{e}, target, displayedTarget),$$

then their hidden distance ledgers are the canonical self-distance ledgers:

$$\mathsf{hsame}(displayedSource, \mathsf{append}(source, source)) \wedge \mathsf{hsame}(displayedTarget, \mathsf{append}(target, target)).$$

Proof. Apply Theorem 130.40 to the given continuous-map carrier. Project its source-identity row to obtain the canonical carrier $\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, source, \mathsf{e}, source, \mathsf{append}(source, source))$. Project its target-identity row to obtain $\mathsf{ContinuousMapCarrier}(target, \mathsf{e}, target, \mathsf{e}, target, \mathsf{append}(target, target))$.

Compare the displayed source identity carrier with the canonical source identity carrier by Theorem 130.13. The two carriers have the same source, graph map, and modulus ledgers, so the distance component of the comparison gives $\mathsf{hsame}(displayedSource, \mathsf{append}(source, source))$.

Compare the displayed target identity carrier with the canonical target identity carrier in the same way. Projecting the distance component gives $\mathsf{hsame}(displayedTarget, \mathsf{append}(target, target))$, and pairing the two classifiers gives the displayed conjunction.

The ten-field fit is: traditional target identity maps with stable self-distance ledgers; BEDC source BHist with Cont and hsame; carrier ContinuousMapCarrier; classifier hsame; stability obligation identity-carrier distance determinacy; ledger the self-distance ledger $\mathsf{append}(source, source)$ or $\mathsf{append}(target, target)$; core theorem this identity-carrier comparison; exactness the displayed conjunction; standard bridge deferred; downstream consumer $\mathsf{Cat}^{\uparrow}$ identity-morphism normalization. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty identity distance deterministic`

Theorem 130.43 (ContinuousMap composite graph depth addition)**.** *For histories source, mid, target, mapF, ma*
assume the two continuous-function carriers

$$\mathsf{ContinuousFunctionCarrier}(source, mapF, mid, modF, certF),$$
$$\mathsf{ContinuousFunctionCarrier}(mid, mapG, target, modG, certG),$$

and the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG),$$

then the composite graph has metric depth

$$\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapFG).$$

Proof. Composition closure for continuous-function carriers builds the composite carrier from the two displayed carriers and the continuation ledgers. Its graph fields are exactly a metric distance witness with endpoints *source*, *mapFG*, and *target*.

Metric-distance depth addition for that witness gives the displayed equality. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMap comp graph depth add`

Theorem 130.44 (ContinuousMap carrier graph depth addition)**.** *For histories source, map, target, modulus, cert*
BHist*, every continuous-map carrier*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$$

exposes its graph continuation and the corresponding metric depth identity:

$$\mathsf{Cont}(source, map, target) \quad \wedge \quad \mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDeptl}$$

Proof. Project the continuous-function carrier from the displayed ContinuousMapCarrier. Its graph field is exactly the continuation $\mathsf{Cont}(source, map, target)$. Repackage the source, map, and target unary rows with this graph continuation as a metric-distance witness from *source* and *map* to *target*, then apply metric-distance depth addition. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier graph cont depth add`

Theorem 130.45 (ContinuousMap carrier distance empty iff)**.** *For histories source, map, target, modulus, cert, di*
BHist*, every continuous-map carrier satisfies*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance) \Longrightarrow (\mathsf{hsame}(distance, \mathsf{e}) \Longleftrightarrow \mathsf{hsame}(source, \mathsf{e})$$

Proof. Project the metric-distance witness from the displayed ContinuousMapCarrier. If the displayed distance is hsame to e, transport it to the empty distance ledger and apply metric empty-distance readback to identify both endpoints with e. Conversely, empty endpoint classifiers build the metric-distance witness with empty distance ledger; metric result determinacy compares this witness with the carrier's displayed distance. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier distance empty iff`

Theorem 130.46 (ContinuousMap carrier zero distance iff empty endpoints)**.** *For histories source, map, target, m* BHist*, every continuous-map carrier satisfies*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance) \Longrightarrow (\mathsf{MetricDistanceDepth}(distance) = 0 \Longleftrightarrow$$

Proof. Metric depth zero is equivalent to the distance history being hsame to e. Apply the preceding continuous-map carrier distance boundary theorem to translate that empty distance classifier exactly into empty source and target endpoints. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier distance zero iff empty endpoints`

Theorem 130.47 (ContinuousMap carrier composition closure)**.** *For histories source, mid, target, mapF, mapG, n* BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, distG),$$

and the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

Then the composite is again a continuous-map carrier with the canonical source-target distance ledger:

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{append}(source, target)).$$

Proof. Project the continuous-function halves from the two ContinuousMapCarrier hypotheses. Apply Theorem 59.7 to those halves and the three continuation ledgers. This produces the composite $\mathsf{ContinuousFunctionCarrier}(source, mapFG, target, modFG, certFG)$.

Now package the canonical distance ledger. Apply Theorem 130.4 in the reverse direction to the composite continuous-function carrier, yielding the displayed ContinuousMapCarrier with distance $\mathsf{append}(source, target)$.

The ten-field fit is: traditional target composition of uniformly continuous maps, BEDC source ContinuousMapCarrier plus Cont, carrier ContinuousMapCarrier, classifier hsame, stability from continuous-function composition and canonical metric ledger packaging, ledger the hidden canonical distance, core theorem this closure, exactness canonical-distance carrier iff, standard bridge deferred, and status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier comp closed`

Theorem 130.48 (ContinuousMap empty distance composition closure)**.** *For histories source, mid, target, mapF,* BHist*, assume the two continuous-map carriers have empty distance ledgers:*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, \mathsf{e}),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, \mathsf{e}),$$

and assume the continuation ledgers for graph composition, modulus composition, and final certificate formation. Then source, mid, and target are all hsame *to* e*, and the composite carrier also has empty distance ledger:*

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{e}).$$

Proof. Apply the empty-distance metric readback to the two input carriers. The first carrier identifies *source* and *mid* with e, while the second identifies *mid* and *target* with e. Composition closure supplies the composite continuous-function carrier. The empty endpoint comparisons repackage the metric-distance witness for the composite as the empty distance ledger. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty distance comp closed`

Theorem 130.49 (ContinuousMap empty-distance empty-graph composition certificate readback)**.** *For histories* $source, mid, target, mapF, mapG, modF, modG, modFG, certF, certG, certFG$: BHist*, assume the two continuous-map carriers have empty distance ledgers:*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, \mathsf{e}),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, \mathsf{e}),$$

and assume

$$\mathsf{Cont}(mapF, mapG, \mathsf{e}), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

Then source, mid, and target are all hsame *to* e*, and the final composition certificate is a unary history satisfying*

$$\mathsf{UnaryHistory}(certFG) \qquad \textit{and} \qquad certFG\mathsf{hsame}modFG.$$

Proof. Apply Definition 130.48 with the empty composite graph. This gives the three empty endpoint readbacks and a composite continuous-map carrier $\mathsf{ContinuousMapCarrier}(source, \mathsf{e}, target, modFG, certFG, \mathsf{e}$ The empty-map, empty-distance certificate readback theorem then identifies $certFG$ as unary and hsame to $modFG$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier empty distance empty graph comp certificate readback`

Theorem 130.50 (ContinuousMap carrier composition distance determinacy)**.** *For histories* $source, mid, target, m$ BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, distG),$$

the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG),$$

and a displayed composite carrier

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, displayed).$$

Then the displayed composite distance is the canonical source-target ledger:

$$\mathsf{hsame}(displayed, \mathsf{append}(source, target)).$$

Proof. Theorem 130.47 applied to the two input carriers and the three continuation ledgers builds the canonical composite carrier

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{append}(source, target)).$$

Compare the displayed composite carrier with this canonical carrier by Theorem 130.13, with the same source, map, target, modulus, and certificate histories on both sides. The distance component of that determinacy conclusion gives $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier comp distance deterministic`

Theorem 130.51 (ContinuousMap composite canonical distance exactness)**.** *For histories* $source, mid, target, ma$ BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, distG),$$

and the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

Then the displayed composite carrier predicate is exactly the canonical source-target distance classifier:

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, displayed) \iff \mathsf{hsame}(displayed, \mathsf{append}(source, t$$

Proof. In the forward direction, suppose the displayed composite carrier is given. Apply Theorem 130.50 to the two input carriers, the three continuation ledgers, and the displayed composite carrier. This gives $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$.

Conversely, suppose the displayed distance satisfies $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$. Theorem 130.47 applied to the two input carriers and the three continuation ledgers builds the canonical composite carrier with distance $\mathsf{append}(source, target)$. Project its continuous-function half.

Now apply Theorem 130.14 in the reverse direction to that continuous-function half and the displayed hsame row. The result is the composite $\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, disp$

The ten-field fit is: traditional target composition of uniformly continuous maps with exact hidden distance ledger; BEDC source two ContinuousMapCarrier hypotheses plus three continuation ledgers; carrier ContinuousMapCarrier; classifier hsame on the displayed distance; stability from composition closure and canonical-distance exactness; ledger the hidden source-target distance; core theorem this iff; exactness the displayed equivalence; standard bridge ordinary composition distance bookkeeping; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier comp displayed distance canonical iff`

Theorem 130.52 (ContinuousMap composition canonical certificate package)**.** *For histories* $source, mid, target, n$ BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF),$$
$$\mathsf{ContinuousMapCarrier}(mid, mapG, target, modG, certG, distG),$$

and the continuation ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

Then the composition data determine the canonical certificate package:

1. *the composite carrier closes over the canonical source-target distance ledger,*

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, \mathsf{append}(source, target));$$

2. *every displayed composite carrier with the same visible fields has that canonical distance ledger, namely if*

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG, displayed),$$

then

$$\mathsf{hsame}(displayed, \mathsf{append}(source, target));$$

3. *the composite graph obeys metric-depth accounting,*

$$\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapFG).$$

Proof. For the carrier row, apply Theorem 130.47 to the two input carriers and the three continuation ledgers. This gives the displayed ContinuousMapCarrier with distance $\mathsf{append}(source, target)$.

For distance uniqueness, suppose a displayed composite carrier with the same source, map, target, modulus, and certificate histories is given. Compare the displayed carrier with the canonical carrier just obtained by Theorem 130.13. The distance component gives $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$.

For metric-depth accounting, project the continuous-function halves from the two input ContinuousMapCarrier hypotheses. Apply Theorem 130.43 to those halves and the same three continuation ledgers, producing the stated equality for MetricDistanceDepth. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier composition canonical certificate package`

Theorem 130.53 (ContinuousMap composition certificate determinacy)**.** *For histories* $source, mid, target, mapF,$ BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF), \qquad \mathsf{ContinuousMapCarrier}(mid, mapG, target, mod$$

and the composition ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

If another displayed composite carrier has the same source, map, target, modulus, and a certificate $certFG_2$*,*

$$\mathsf{ContinuousMapCarrier}(source, mapFG, target, modFG, certFG_2, displayed),$$

then the certificate histories agree:

$$\mathsf{hsame}(certFG, certFG_2).$$

Proof. First close the canonical composite carrier from the two input carriers and the three continuation ledgers by Theorem 130.47. Compare this canonical carrier with the displayed carrier by Theorem 130.13. The certificate component of that comparison is the required $\mathsf{hsame}(certFG, certFG_2)$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier comp certificate deterministic`

Theorem 130.54 (ContinuousMap composite target, certificate, and distance determinacy)**.** *For histories* $source, mid, target, target_2, mapF, mapG, mapFG, modF, modG, modFG, certF, certG, certFG, certFG_2$ BHist*, assume the two continuous-map carriers*

$$\mathsf{ContinuousMapCarrier}(source, mapF, mid, modF, certF, distF), \qquad \mathsf{ContinuousMapCarrier}(mid, mapG, target, mod$$

and the composition ledgers

$$\mathsf{Cont}(mapF, mapG, mapFG), \qquad \mathsf{Cont}(modF, modG, modFG), \qquad \mathsf{Cont}(target, modFG, certFG).$$

If a displayed composite carrier uses the same source, composite map, and modulus but displays target $target_2$*, certificate* $certFG_2$*, and distance displayed, then the displayed rows agree with the canonical composite:*

$$\mathsf{hsame}(target, target_2) \wedge \mathsf{hsame}(certFG, certFG_2) \wedge \mathsf{hsame}(displayed, \mathsf{append}(source, target)) \\ \wedge \mathsf{Cont}(source, target, \mathsf{append}(source, target)).$$

Proof. First close the canonical composite carrier from the two input carriers and the three continuation ledgers. Its target is *target*, its certificate is *certFG*, and its distance ledger is $\mathsf{append}(source, target)$. Compare this canonical carrier with the displayed composite carrier by Definition 130.13. The comparison gives target and certificate determinacy, identifies the canonical distance with *displayed*, and exposes the canonical endpoint continuation. Symmetry of hsame orients the displayed distance as $\mathsf{hsame}(displayed, \mathsf{append}(source, target))$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier comp target cert distance deterministic`

Theorem 130.55 (ContinuousMap category-metric terminal extension bridge)**.** *For histories* $source, map, target, modulus, cert, extra, modulus', cert', distance$: BHist*, assume the category, continuity, and metric rows*

$$\mathsf{CategoryHomCarrier}(source, target, map),$$
$$\mathsf{ContinuousModulusWitness}(target, modulus, cert),$$
$$\mathsf{MetricDistanceWitness}(source, target, distance),$$

and assume the terminal modulus-extension data

$$\mathsf{ContinuousModulusWitness}(cert, extra, cert') \qquad \textit{and} \qquad \mathsf{Cont}(modulus, extra, modulus').$$

Then these three sources assemble the extended continuous-map carrier

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus', cert', distance).$$

Proof. Use the reverse direction of Theorem 130.2 on the displayed category, continuity, and metric rows. This gives the base carrier $\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance)$.

Unpack this base carrier by Definition 130.1. The continuous-function half is $\mathsf{ContinuousFunctionCarrier}(source,$ while the metric half remains the supplied $\mathsf{MetricDistanceWitness}(source, target, distance)$.

Apply Theorem 59.162 to the continuous-function half, the witness $\mathsf{ContinuousModulusWitness}(cert, extra, cert'$ and the ledger $\mathsf{Cont}(modulus, extra, modulus')$. This yields $\mathsf{ContinuousFunctionCarrier}(source, map, target, modulu$

Pair that extended continuous-function carrier with the unchanged metric witness by Definition 130.1. The result is the displayed $\mathsf{ContinuousMapCarrier}(source, map, target, modulus', cert', distance)$.

The ten-field fit is: traditional target a continuous map whose modulus certificate is extended at the terminal end; BEDC source CategoryHomCarrier, ContinuousModulusWitness, MetricDistanceWitness,

and Cont; carrier ContinuousMapCarrier; classifier hsame on the preserved visible rows; stability from the category-metric decomposition and terminal modulus-extension closure; ledger source, map, target, modulus, certificate, extra modulus, extended modulus, extended certificate, and distance histories; core theorem this bridge; exactness the displayed carrier conclusion; standard bridge deferred; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier category metric terminal extension bridge`

Theorem 130.56 (ContinuousMap prefixed categorical canonical distance exactness)**.** *For histories* $p, source, map, target, modulus, cert, distance, displayed$: BHist*, assume* UnaryHistory(p)*, the categorical and continuity rows*

$$\begin{aligned}&\mathsf{CategoryHomCarrier}(source, target, map),\\&\mathsf{ContinuousModulusWitness}(target, modulus, cert),\end{aligned}$$

and the canonical source-target distance classifier

$$\mathsf{hsame}(distance, \mathsf{append}(source, target)).$$

Then the prefixed continuous-map carrier is exactly the prefixed canonical distance classifier:

$$\begin{aligned}&\mathsf{ContinuousMapCarrier}(\mathsf{append}(p, source), map, \mathsf{append}(p, target), modulus, \mathsf{append}(p, cert), displayed)\\&\iff \mathsf{hsame}(displayed, \mathsf{append}(\mathsf{append}(p, source), \mathsf{append}(p, target))).\end{aligned}$$

Proof. First assemble the unprefixed central carrier. Apply Theorem 130.15 in the reverse direction to the categorical hom row, the target-side modulus witness, and hsame$(distance, \mathsf{append}(source, target))$. This gives ContinuousMapCarrier$(source, map, target, modulus, cert, distance)$.

With that carrier in hand, apply Theorem 130.22 to the unary prefix p and the central carrier. Its conclusion is exactly the displayed equivalence between the prefixed carrier and the canonical prefixed source-target distance classifier.

The ten-field fit is: traditional target continuous maps read as categorical arrows with visible modulus data under a unary prefix; BEDC source CategoryHomCarrier, ContinuousModulusWitness, hsame, and UnaryHistory; carrier ContinuousMapCarrier; classifier hsame on the displayed prefixed distance; stability from categorical canonical-distance exactness and prefix canonical-distance exactness; ledger prefix, source, map, target, modulus, certificate, and displayed distance histories; core theorem this iff; exactness the displayed prefixed classifier; downstream use compact-continuous and category-bridge normalization; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier prefixed categorical canonical distance exactness`

Theorem 130.57 (ContinuousMap associative composition canonical package)**.** *For histories* $source, mid_1, mid_2, target, mapF, mapG, mapH, mapFG, mapGH, mapL, mapR, modF, modG, modH, modFG, m$ BHist*, assume the three concrete continuous-map carriers*

$$\begin{aligned}&\mathsf{ContinuousMapCarrier}(source, mapF, mid_1, modF, certF, distF),\\&\mathsf{ContinuousMapCarrier}(mid_1, mapG, mid_2, modG, certG, distG),\\&\mathsf{ContinuousMapCarrier}(mid_2, mapH, target, modH, certH, distH),\end{aligned}$$

the left-bracketed continuation ledgers

$$\begin{aligned}&\mathsf{Cont}(mapF, mapG, mapFG), \quad \mathsf{Cont}(modF, modG, modFG), \quad \mathsf{Cont}(mid_2, modFG, certFG),\\&\mathsf{Cont}(mapFG, mapH, mapL), \quad \mathsf{Cont}(modFG, modH, modL), \quad \mathsf{Cont}(target, modL, certL),\end{aligned}$$

and the right-bracketed continuation ledgers

$$\begin{array}{lll} \mathsf{Cont}(mapG, mapH, mapGH), & \mathsf{Cont}(modG, modH, modGH), & \mathsf{Cont}(target, modGH, certGH), \\ \mathsf{Cont}(mapF, mapGH, mapR), & \mathsf{Cont}(modF, modGH, modR), & \mathsf{Cont}(target, modR, certR). \end{array}$$

Then the threefold composition data determine the associative canonical certificate package:

1. *the left-bracketed composite carrier closes over the canonical source-target distance ledger,*

$$\mathsf{ContinuousMapCarrier}(source, mapL, target, modL, certL, \mathsf{append}(source, target));$$

2. *the right-bracketed composite carrier closes over the same canonical source-target distance ledger,*

$$\mathsf{ContinuousMapCarrier}(source, mapR, target, modR, certR, \mathsf{append}(source, target));$$

3. *the two composite graph-map histories are classified together,*

$$\mathsf{hsame}(mapL, mapR);$$

4. *the two composite modulus histories are classified together,*

$$\mathsf{hsame}(modL, modR);$$

5. *every displayed carrier with either bracketed visible fields has the canonical distance ledger:*

$$\mathsf{ContinuousMapCarrier}(source, mapL, target, modL, certL, displayedL) \Rightarrow \mathsf{hsame}(displayedL, \mathsf{append}(source, t$$
$$\mathsf{ContinuousMapCarrier}(source, mapR, target, modR, certR, displayedR) \Rightarrow \mathsf{hsame}(displayedR, \mathsf{append}(source,$$

Proof. Build the left bracketing in two closure steps. First apply Theorem 130.47 to the $source \to mid_1$ and $mid_1 \to mid_2$ carriers, using the graph, modulus, and certificate ledgers ending at $certFG$. Apply the same theorem again to that intermediate carrier and the $mid_2 \to target$ carrier, using the ledgers ending at $certL$. This gives the left composite carrier with distance $\mathsf{append}(source, target)$.

Build the right bracketing symmetrically. Apply Theorem 130.47 to the $mid_1 \to mid_2$ and $mid_2 \to target$ carriers, using the ledgers ending at $certGH$. Then compose the $source \to mid_1$ carrier with that intermediate carrier using the ledgers ending at $certR$. This gives the right composite carrier with the same displayed distance ledger $\mathsf{append}(source, target)$.

For the graph-map row, apply continuation associativity up to history sameness, Theorem 4.56, to $\mathsf{Cont}(mapF, mapG, mapFG)$, $\mathsf{Cont}(mapFG, mapH, mapL)$, $\mathsf{Cont}(mapG, mapH, mapGH)$, and $\mathsf{Cont}(mapF, mapGH, mapR)$. This is the paper form of the checked kernel theorem `continuation_associativity_` uniqueness of the associative continuation endpoint is also recorded by `cont_assoc_unique`.

For the modulus row, use the same continuation-associativity argument on $\mathsf{Cont}(modF, modG, modFG)$, $\mathsf{Cont}(modFG, modH, modL)$, $\mathsf{Cont}(modG, modH, modGH)$, and $\mathsf{Cont}(modF, modGH, modR)$. The resulting classifier row is $\mathsf{hsame}(modL, modR)$.

Finally apply Theorem 130.50 to the left two-step composition data for any displayed left-bracketed carrier, and apply the same theorem to the right two-step composition data for any displayed right-bracketed carrier. The two applications give the two displayed distance-determinacy clauses. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier composition associative canonical package`

Theorem 130.58 (ContinuousMap associative composition certificate determinacy)**.** *Under the hypotheses of Definition 130.57, the two target-modulus certificate ledgers selected by the two bracketings determine the same certificate history:*

$$\mathsf{hsame}(certL, certR).$$

Proof. Apply Definition 130.57 to the three input carriers and the two displayed continuation spines. Its modulus row gives $\mathsf{hsame}(modL, modR)$. Combine this modulus sameness with reflexivity of the target history and the two target-modulus continuation ledgers $\mathsf{Cont}(target, modL, certL)$ and $\mathsf{Cont}(target, modR, certR)$. The continuation respect theorem for hsame then gives $\mathsf{hsame}(certL, certR)$. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier composition associative certificate deterministic`

Theorem 130.59 (ContinuousMap associative composition depth synchronization)**.** *For histories* $source, mid_1, mid_2, target, mapF, mapG, mapH, mapFG, mapGH, mapL, mapR, modF, modG, modH, modFG, m$ BHist*, assume the three concrete continuous-map carriers*

$$\begin{aligned}&\mathsf{ContinuousMapCarrier}(source, mapF, mid_1, modF, certF, distF),\\&\mathsf{ContinuousMapCarrier}(mid_1, mapG, mid_2, modG, certG, distG),\\&\mathsf{ContinuousMapCarrier}(mid_2, mapH, target, modH, certH, distH),\end{aligned}$$

the left-bracketed continuation ledgers

$$\begin{aligned}&\mathsf{Cont}(mapF, mapG, mapFG), \quad \mathsf{Cont}(modF, modG, modFG), \quad \mathsf{Cont}(mid_2, modFG, certFG),\\&\mathsf{Cont}(mapFG, mapH, mapL), \quad \mathsf{Cont}(modFG, modH, modL), \quad \mathsf{Cont}(target, modL, certL),\end{aligned}$$

and the right-bracketed continuation ledgers

$$\begin{aligned}&\mathsf{Cont}(mapG, mapH, mapGH), \quad \mathsf{Cont}(modG, modH, modGH), \quad \mathsf{Cont}(target, modGH, certGH),\\&\mathsf{Cont}(mapF, mapGH, mapR), \quad \mathsf{Cont}(modF, modGH, modR), \quad \mathsf{Cont}(target, modR, certR).\end{aligned}$$

Then both bracketings synchronize the endpoint depth with their displayed composite graph histories:

$$\begin{aligned}&\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapL),\\&\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapR).\end{aligned}$$

Proof. First build the left intermediate carrier. Apply Theorem 130.47 to the first two continuous-map carriers and the ledgers ending at $certFG$. Project its continuous-function half, and project the continuous-function half of the $mid_2 \to target$ carrier.

Apply Theorem 130.43 to those two continuous-function carriers and the left-bracketed ledgers ending at $certL$. This gives

$$\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapL).$$

Next build the right intermediate carrier. Apply Theorem 130.47 to the second and third continuous-map carriers and the ledgers ending at $certGH$. Project its continuous-function half, and project the continuous-function half of the $source \to mid_1$ carrier.

Apply Theorem 130.43 to the $source \to mid_1$ continuous-function carrier, the projected $mid_1 \to target$ continuous-function carrier, and the right-bracketed ledgers ending at $certR$. This gives

$$\mathsf{MetricDistanceDepth}(target) = \mathsf{MetricDistanceDepth}(source) + \mathsf{MetricDistanceDepth}(mapR).$$

The two displayed equalities are exactly the depth-synchronization conclusion. □

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier associative composition depth synchronizatio`

Theorem 130.60 (ContinuousMap identity sandwich coherence)**.** *For histories* $source, target, map, modulus, cert$ BHist*, assume*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance),$$

and assume the left-bracketed identity-sandwich ledger spine

$$\begin{array}{lll} \mathsf{Cont}(\mathsf{e}, map, map_{LF}), & \mathsf{Cont}(\mathsf{e}, modulus, mod_{LF}), & \mathsf{Cont}(target, mod_{LF}, cert_{LF}), \\ \mathsf{Cont}(map_{LF}, \mathsf{e}, map_L), & \mathsf{Cont}(mod_{LF}, \mathsf{e}, mod_L), & \mathsf{Cont}(target, mod_L, cert_L), \end{array}$$

and the right-bracketed identity-sandwich ledger spine

$$\begin{array}{lll} \mathsf{Cont}(map, \mathsf{e}, map_{RT}), & \mathsf{Cont}(modulus, \mathsf{e}, mod_{RT}), & \mathsf{Cont}(target, mod_{RT}, cert_{RT}), \\ \mathsf{Cont}(\mathsf{e}, map_{RT}, map_R), & \mathsf{Cont}(\mathsf{e}, mod_{RT}, mod_R), & \mathsf{Cont}(target, mod_R, cert_R). \end{array}$$

Then the two bracketed identity sandwiches are coherent with the displayed carrier:

1. *the left-bracketed sandwich closes as*

$$\mathsf{ContinuousMapCarrier}(source, map_L, target, mod_L, cert_L, \mathsf{append}(source, target));$$

2. *the right-bracketed sandwich closes as*

$$\mathsf{ContinuousMapCarrier}(source, map_R, target, mod_R, cert_R, \mathsf{append}(source, target));$$

3. *the selected graph histories are the original graph history,*

$$\mathsf{hsame}(map_L, map) \wedge \mathsf{hsame}(map_R, map);$$

4. *the selected modulus histories are the original modulus history,*

$$\mathsf{hsame}(mod_L, modulus) \wedge \mathsf{hsame}(mod_R, modulus);$$

5. *the selected certificate histories and the original certificate history are pairwise classified together,*

$$\mathsf{hsame}(cert_L, cert) \wedge \mathsf{hsame}(cert_R, cert) \wedge \mathsf{hsame}(cert_L, cert_R).$$

Lean4 ✓ `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier identity sandwich coherence`

Proof. Apply Definition 130.40 to the displayed ContinuousMapCarrier. This supplies the source and target empty identity carriers used as the outer factors of the sandwich.

For the left bracketing, first apply Definition 130.47 to the source identity carrier and the displayed carrier, using the ledgers ending at $cert_{LF}$. Apply the same closure theorem again to that intermediate carrier and the target identity carrier, using the ledgers ending at $cert_L$. This gives the left sandwich carrier over $\mathsf{append}(source, target)$.

For the right bracketing, first compose the displayed carrier with the target identity carrier, using the ledgers ending at $cert_{RT}$. Then compose the source identity carrier with that intermediate carrier, using the ledgers ending at $cert_R$. The same closure theorem gives the right sandwich carrier over the same canonical source-target distance ledger.

Apply Definition 130.57 to the source identity carrier, the displayed carrier, and the target identity carrier. Its graph and modulus rows identify the two bracketed selected histories. Apply Definition 130.58 to the same three-carrier spine to get $\mathsf{hsame}(cert_L, cert_R)$.

The remaining readback is by continuation units. The ledgers $\mathsf{Cont}(\mathsf{e}, map, map_{LF})$ and $\mathsf{Cont}(map_{LF}, \mathsf{e}, map_L)$ combine `cont_left_unit_result` and `cont_right_unit_result` to give $\mathsf{hsame}(map_L, map)$, and the right-bracketed graph ledgers give $\mathsf{hsame}(map_R, map)$ in the same way. The identical argument applied to *modulus* gives the two modulus classifiers.

Project the original certificate ledger $\mathsf{Cont}(target, modulus, cert)$ from the carrier. With target reflexivity, the modulus classifiers, and the displayed target-modulus certificate ledgers, `cont_respects_hsame` identifies $cert_L$ and $cert_R$ with $cert$. Together with the associative certificate row, these are exactly the pairwise certificate classifiers.

The ten-field fit is: traditional target identity-sandwich coherence for uniformly continuous maps, BEDC source BHist with Cont, hsame, and ContinuousMapCarrier, carrier ContinuousMapCarrier, classifier hsame, stability from unit continuation and associative composition, ledger graph/modulus/certificate histories, core theorem this coherence package, exactness the canonical source-target distance rows, standard bridge deferred, and status ProofTarget. □

↪ variant `BEDC.Derived.ContinuousMapUp.ContinuousMapCarrier identity sandwich coherence`

The sibling lattice for $\mathsf{ContinuousMap}^{\uparrow}$ is horizontal rather than kernel-isolated. It consumes the $\mathsf{Met}^{\uparrow}$ distance witness from chapter 57, the $\mathsf{Continuous}^{\uparrow}$ pointwise-modulus rows from chapter 59, and the $\mathsf{Cat}^{\uparrow}$ graph, identity, and composition rows from chapter 61. Downstream compact-uniform packets consume this $\mathsf{ContinuousMap}^{\uparrow}$ surface as the common entry point for finite metric rows, pointwise continuity certificates, and categorical composition data.

Theorem 130.61 (ContinuousMap sibling lattice exactness)**.** *An accepted* $\mathsf{ContinuousMap}^{\uparrow}$ *packet is admitted exactly through the* $\mathsf{Met}^{\uparrow}$ *distance witness, the* $\mathsf{Continuous}^{\uparrow}$ *pointwise-modulus rows, and the* $\mathsf{Cat}^{\uparrow}$ *graph, identity, and composition rows, together with the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

The admitted surface excludes host functions, function-space topology, pointwise convergence, uniform convergence, and standard bridge rows. In particular, downstream compact, complete, and uniform consumers may read only the horizontal sibling lattice determined by the metric, continuity, and category coordinates plus the displayed BEDC support rows.

Proof. Apply Definition 130.2 to split the carrier into the categorical hom row, the target-side modulus row, and the metric-distance row. These are precisely the $\mathsf{Cat}^{\uparrow}$, $\mathsf{Continuous}^{\uparrow}$, and $\mathsf{Met}^{\uparrow}$ sibling coordinates named in the theorem statement.

Apply Definition 130.39 to read the same surface through the certificate packet. The bridge exposes the visible BHist, hsame, Cont, Pkg, and NameCert bookkeeping without adding a host function or a function-space topology.

Apply Definition 130.16 to the composition rows. The package shows that identities and composites remain inside the same category-metric lattice and that the displayed distance ledger is fixed by the finite carrier data.

Finally apply Definition 130.34. Its consumer route uses the ContinuousMap surface as input while refusing pointwise convergence, uniform convergence as an ambient topology, and standard bridge rows. Hence the exact admitted surface is the stated horizontal lattice and no larger host-level structure is exported. □

Chapter 131

A Concrete Naming Certificate for $\mathsf{Eq}^{\uparrow}$

The equality-type interface $\mathsf{Eq}^{\uparrow}$ packages the constructive identity type over a carrier, with reflexivity as the sole constructor and explicit transport for kernel-licit substitution. It supplies the foundational equality layer underlying every psame classifier.

Its visible endpoint absurdity and anchor-readback rows supply the same constructor-separation discipline consumed by the $\mathsf{Bool}^{\uparrow}$ finite-data classifier of chapter 32. In particular, $\mathsf{Bool}^{\uparrow}$ may use the empty-anchor and visible-endpoint no-confusion rows of $\mathsf{Eq}^{\uparrow}$ as the equality-class boundary for branch classifiers.

131.1 Carrier definition

Theorem 131.1 (EqType e1 anchor tail readback)**.** *For BEDC histories anchor, tail, and h, if h belongs to the equality-type class anchored at* $\mathsf{E1}(anchor)$ *and* $h\mathsf{hsameE1}(tail)$*, then* $tail\mathsf{hsame}anchor$*.*

Proof. The class predicate is the transparent history-sameness class. Compose the class comparison with the reverse of the displayed comparison to obtain $\mathsf{E1}(tail)\mathsf{hsameE1}(anchor)$, then invert the e1 constructor under hsame. □

Closure status for $\mathsf{NameCert}_{\mathsf{Eq}^{\uparrow}}$**.**

Constructive story: The equality-type certificate is generated from the minimal $BHist$ anchors that witness equality classes. The carrier first reads the anchor tail, visible context, and pair rows that identify when a history is in the class of another history. The $hsame$ relation is the generating comparison, so transport is not a host equality assertion but a ledger-visible movement from one anchor to another. Continuations enter only through contexts whose visible core is already determined by the anchor rows. The chapter then derives determinacy, absurdity for incompatible anchors, semantic certification, anchor transport, and transitivity from those visible class-carrier conventions.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Eq}^{\uparrow}}$, seed)

Scope closed: This chapter binds the EqType carrier sections, anchor readback and determinacy theorems, identity semantic NameCert, anchor transport, and transitivity.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Eq}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim host definitional equality, quotient equality of all histories, or equality principles beyond the displayed $hsame$ class carrier.

Upgrade path: Reaching obligationClosure requires a formal EqType carrier whose anchor readback, transport, and transitivity theorems are checked in Lean.

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier e1 anchor tail readback`

Theorem 131.2 (EqType e0 anchor tail readback)**.** *For BEDC histories anchor, tail, and h, if h belongs to the equality-type class anchored at* E0(*anchor*) *and h*hsameE0(*tail*)*, then tail*hsame*anchor.*

Proof. The class predicate is the transparent history-sameness class. Compose the class comparison with the reverse of the displayed comparison to obtain E0(*tail*)hsameE0(*anchor*), then invert the e0 constructor under hsame. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier e0 anchor tail readback`

Theorem 131.3 (EqType e0 anchor pair determinism)**.** *For BEDC histories anchor, left, and right, if both left and right belong to the equality-type class anchored at* E0(*anchor*)*, then left*hsame*right.*

Proof. Both carrier witnesses are concrete comparisons with the same anchor E0(*anchor*). Compose the first comparison with the reverse of the second comparison to obtain *left*hsame*right.* □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier e0 anchor pair deterministic`

Theorem 131.4 (EqType e0 anchor e1 tail absurdity)**.** *For BEDC histories anchor, tail, and h, if h belongs to the equality-type class anchored at* E0(*anchor*) *and h*hsameE1(*tail*)*, then contradiction follows.*

Proof. The carrier comparison identifies *h* with E0(*anchor*). Composing it with the reverse of the displayed comparison gives E1(*tail*)hsameE0(*anchor*), which is impossible by constructor separation for history sameness. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier e0 anchor e1 tail absurd`

Theorem 131.5 (EqType e1 anchor e0 tail absurdity)**.** *For BEDC histories anchor, tail, and h, if h belongs to the equality-type class anchored at* E1(*anchor*) *and h*hsameE0(*tail*)*, then contradiction follows.*

Proof. The carrier comparison identifies *h* with E1(*anchor*). Composing it with the reverse of the displayed comparison gives E0(*tail*)hsameE1(*anchor*), which is impossible by constructor separation for history sameness. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier e1 anchor e0 tail absurd`

Theorem 131.6 (EqType empty anchor visible absurdity)**.** *For BEDC histories tail and h, if h belongs to the equality-type class anchored at* e*, then h cannot also classify to either visible endpoint* E0(*tail*) *or* E1(*tail*)*.*

Proof. The class predicate unfolds to *h*hsamee. Compose its reverse with the displayed visible comparison. The zero-headed branch gives ehsameE0(*tail*), and the one-headed branch gives ehsameE1(*tail*). Constructor separation for histories rules out both comparisons. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier empty anchor visible absurd`

Theorem 131.7 (EqType visible-context anchor readback)**.** *For BEDC histories anchor, h, and core, if h belongs to the equality-type class anchored at anchor and the display of h inside a common left and right append context agrees with the corresponding display of core, then core*hsame*anchor.*

Proof. Reassociate the two displays into a common-context form and cancel the common prefix and suffix, obtaining *h*hsame*core*. Symmetry composes this readback with the carrier comparison *h*hsame*anchor*, so *core*hsame*anchor*. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier visible context anchor readback`

Theorem 131.8 (EqType visible-context e0 anchor e1 tail absurdity)**.** *For BEDC histories p, r, anchor, h, and tail, if h belongs to the equality-type class anchored at* $\mathsf{E0}(anchor)$*, then the display of h inside a common visible context cannot agree with the corresponding display of* $\mathsf{E1}(tail)$*:*

$$\mathsf{EqtypeClassCarrier}(\mathsf{E0}(anchor), h) \Longrightarrow \mathsf{hsame}((p \cdot h) \cdot r, (p \cdot \mathsf{E1}(tail)) \cdot r) \Longrightarrow \mathsf{False}.$$

Proof. Visible-context anchor readback identifies the displayed core $\mathsf{E1}(tail)$ with the zero-headed anchor $\mathsf{E0}(anchor)$. BEDC history constructor separation rules out this $\mathsf{E1}/\mathsf{E0}$ comparison. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier visible context e0 anchor e1 tail absurd`

Theorem 131.9 (EqType visible-context empty anchor visible core absurdity)**.** *For BEDC histories p, r, h, core, and tail, if h belongs to the equality-type class anchored at* e *and the common visible context displays h as core, then core cannot classify to either visible endpoint* $\mathsf{E0}(tail)$ *or* $\mathsf{E1}(tail)$*.*

Proof. Visible-context anchor readback identifies *core* with the empty anchor. The empty-anchor visible absurdity theorem then rules out both visible endpoint alternatives for *core* by BEDC history constructor separation. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier visible context empty anchor visible core absurd`

Theorem 131.10 (EqType visible-context core determinism)**.** *For BEDC histories p, r, anchor, $left$, $right$, $coreLeft$, and $coreRight$, if both $left$ and $right$ belong to the equality-type class anchored at anchor, and the common visible context displays $left$ as $coreLeft$ and $right$ as $coreRight$, then $coreLeft\,\mathsf{hsame}\,coreRight$.*

Proof. Apply visible-context anchor readback to both displays. This identifies each displayed core with the shared anchor. Composing the left readback with the reverse of the right readback gives the core comparison. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier visible context cores deterministic`

Theorem 131.11 (EqType visible-context pair determinacy)**.** *For BEDC histories p, r, anchor, $left$, $right$, $leftCore$, and $rightCore$, suppose $left$ and $right$ both belong to the equality-type class anchored at anchor. If the display of $left$ inside the common context p, r agrees with the corresponding display of $leftCore$, and the display of $right$ inside the same common context agrees with the display of $rightCore$, then $leftCore\,\mathsf{hsame}\,rightCore$.*

Proof. Apply visible-context anchor readback to the left comparison to obtain $leftCore\,\mathsf{hsame}\,anchor$. Apply the same readback to the right comparison to obtain $rightCore\,\mathsf{hsame}\,anchor$. The first comparison and the reverse of the second compose by transitivity of hsame, giving $leftCore\,\mathsf{hsame}\,rightCore$. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier visible context pair deterministic`

131.2 The certificate

Theorem 131.12 (EqType identity semantic name certificate)**.** *The identity classifier on histories forms a semantic name certificate when source, pattern, and ledger are all the self-identity predicate:*

$$\mathsf{SemanticNameCert}(\lambda h.\ h\mathsf{hsame}h, \lambda h.\ h\mathsf{hsame}h, \lambda h.\ h\mathsf{hsame}h, \mathsf{hsame}).$$

Proof. The empty history supplies inhabitation. Reflexivity, symmetry, transitivity, and carrier transport are exactly the corresponding closure laws of hsame. The pattern and ledger maps are the identity maps on the self-identity predicate. □

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeIdentity semanticNameCert`

Theorem 131.13 (EqType class carrier anchor transport)**.** *For BEDC histories anchor, anchor′, and h, if h belongs to the equality-type class anchored at anchor and anchor*hsame*anchor′, then h belongs to the equality-type class anchored at anchor′:*

$$\mathsf{EqtypeClassCarrier}(anchor, h) \Longrightarrow anchor\mathsf{hsame}anchor' \Longrightarrow \mathsf{EqtypeClassCarrier}(anchor', h).$$

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier anchor hsame transport`

Proof. By the carrier definition in section 131.1, membership in the class anchored at *anchor* is the comparison $h\mathsf{hsame}anchor$. Compose this comparison with the displayed anchor comparison $anchor\mathsf{hsame}anchor'$ by transitivity of hsame, obtaining $h\mathsf{hsame}anchor'$. This is exactly the carrier witness for the equality-type class anchored at $anchor'$. □

Theorem 131.14 (EqType class carrier transitivity)**.** *For BEDC histories anchor, h, and h′, equality-type class membership is transitive along class anchors:*

$$\mathsf{EqtypeClassCarrier}(anchor, h) \Longrightarrow \mathsf{EqtypeClassCarrier}(h, h') \Longrightarrow \mathsf{EqtypeClassCarrier}(anchor, h').$$

Lean4 ✓ `BEDC.Derived.EqtypeUp.EqtypeClassCarrier transitive`

Proof. By the carrier definition in section 131.1, the first hypothesis is the comparison $h\mathsf{hsame}anchor$. Apply Definition 131.13 to the second hypothesis, viewed as membership of h' in the class anchored at h, and to this anchor comparison $h\mathsf{hsame}anchor$. The result is exactly membership of h' in the class anchored at *anchor*. □

Chapter 132

A Concrete Naming Certificate for $\mathsf{Func}^{\uparrow}$

The function-object interface $\mathsf{Func}^{\uparrow}$ packages the carrier of functions $A \to B$ between two naming certificates, together with the pointwise hsame-respecting structure. It supplies the substrate for $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$ (chapter 48) and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ (chapter 130) as restrictions of the general function object.

132.1 Carrier definition

Theorem 132.1 (Function object linear singleton continuous-map components are empty)**.** *For histories source, map, target, modulus, cert, distance* : BHist*, suppose* ContinuousMapCarrier(*source, map, target, m holds and the source, map, and modulus histories lie in the linear-map singleton carrier. Then*

$$\mathsf{hsame}(target, \mathsf{e}) \wedge \mathsf{hsame}(cert, \mathsf{e}) \wedge \mathsf{hsame}(distance, \mathsf{e}).$$

Proof. The singleton carrier identifies *source*, *map*, and *modulus* with e. The continuous-map graph continuation compares with the right-unit continuation at e, forcing *target*hsamee. The certificate continuation then compares against the same empty right unit, forcing *cert*hsamee. Finally, the metric-distance continuation from *source* to *target* compares against the empty right unit after both endpoints have been identified with e, so *distance*hsamee. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map components empty`

Theorem 132.2 (Function object linear singleton continuous-map graphs are empty)**.** *For histories source, map, target, modulus, cert, distance* : BHist*, suppose* ContinuousMapCarrier(*source, map, target, modul holds and the source, map, and modulus histories lie in the linear-map singleton carrier. Then the displayed graph, certificate, and distance continuations can be read over the empty components:*

$$\mathsf{Cont}(source, map, \mathsf{e}) \wedge \mathsf{Cont}(\mathsf{e}, modulus, cert) \wedge \mathsf{Cont}(source, \mathsf{e}, distance).$$

Proof. The component-empty theorem identifies *target*, *cert*, and *distance* with e. Transport the continuous-map graph continuation across *target*hsamee. Transport the certificate continuation across *target*hsamee on the source side, and transport the metric-distance continuation across *target*hsamee on the right endpoint. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map empty graphs`

Theorem 132.3 (Function object linear singleton continuous-map empty components iff)**.** *For histories* $source, map, target, modulus, cert, distance : \mathsf{BHist}$*, if the source, map, and modulus histories lie in the linear-map singleton carrier, then*

$$\mathsf{ContinuousMapCarrier}(source, map, target, modulus, cert, distance) \iff \mathsf{hsame}(target, \mathsf{e}) \wedge \mathsf{hsame}(cert, \mathsf{e}) \wedge \mathsf{hsame}(d$$

Proof. The forward direction is the component-empty theorem for linear singleton continuous maps. Conversely, the three singleton carrier assumptions identify *source*, *map*, and *modulus* with e, while the displayed component equalities identify *target*, *cert*, and *distance* with e. The continuous-function carrier and metric-distance witness are then assembled from unary emptiness and the empty right-unit continuation rows. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map empty components iff`

Theorem 132.4 (Function object linear singleton continuous-map target graph empty iff)**.** *For histories* $source, map, target, modulus, cert, distance : \mathsf{BHist}$*, suppose* $\mathsf{ContinuousMapCarrier}(source, map, target, m$ *holds and the source and map histories lie in the linear-map singleton carrier. Then the empty graph continuation is equivalent to the target endpoint being empty:*

$$\mathsf{Cont}(source, map, \mathsf{e}) \iff \mathsf{hsame}(target, \mathsf{e}).$$

Proof. The continuous-map carrier contains the graph continuation $\mathsf{Cont}(source, map, target)$. In the forward direction, the singleton carrier identifies *source* and *map* with e, so this graph continuation compares with the right-unit continuation at e and forces $target\mathsf{hsame}\mathsf{e}$. Conversely, if $target\mathsf{hsame}\mathsf{e}$, transport the graph continuation result along this history comparison to obtain $\mathsf{Cont}(source, map, \mathsf{e})$. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map target graph empty iff`

Theorem 132.5 (Function object linear singleton continuous-map cert graph empty iff)**.** *For histories* $source, map, target, modulus, cert, distance : \mathsf{BHist}$*, suppose* $\mathsf{ContinuousMapCarrier}(source, map, target, modul$ *holds and the target and modulus histories lie in the linear-map singleton carrier. Then the empty certificate graph is equivalent to the certificate being empty:*

$$\mathsf{Cont}(target, modulus, \mathsf{e}) \iff \mathsf{hsame}(cert, \mathsf{e}).$$

Proof. The continuous-map carrier contains the certificate continuation $\mathsf{Cont}(target, modulus, cert)$. The forward direction compares it with the displayed empty certificate graph by continuation determinism. Conversely, if $cert\mathsf{hsame}\mathsf{e}$, transport the result of the certificate continuation to obtain $\mathsf{Cont}(target, modulus, \mathsf{e})$. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map cert graph empty iff`

Theorem 132.6 (Function object linear singleton continuous-map distance graph empty iff)**.** *For histories* $source, map, target, modulus, cert, distance : \mathsf{BHist}$*, suppose* $\mathsf{ContinuousMapCarrier}(source, map, target, m$ *holds. Then the empty distance graph is equivalent to the distance endpoint being empty:*

$$\mathsf{Cont}(source, target, \mathsf{e}) \iff \mathsf{hsame}(distance, \mathsf{e}).$$

Proof. The continuous-map carrier contains the distance continuation $\mathsf{Cont}(source, target, distance)$. The forward direction compares this witness with the displayed empty distance graph by continuation determinism. Conversely, if $distance\mathsf{hsame}\mathsf{e}$, transport the continuation result to obtain $\mathsf{Cont}(source, target, \mathsf{e})$. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map distance graph empty iff`

Lemma 132.7 (Function object linear singleton continuous-map distance graph empty)**.** *For histories* $source, map, target, modulus, cert, distance$: BHist*, suppose* ContinuousMapCarrier$(source, map, target, modul$ *holds and the source, map, and modulus histories lie in the linear-map singleton carrier. Then*

$$\mathsf{Cont}(source, target, \mathsf{e}).$$

Proof. The component-empty theorem identifies the distance witness with e. The continuous-map carrier contains the metric-distance continuation $\mathsf{Cont}(source, target, distance)$, and result transport along $distance$hsamee gives the displayed empty distance graph. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncObjLinearSingleton continuous map distance graph empty`

132.2 The certificate

Theorem 132.8 (Function-object pointwise hom carrier semantic certificate)**.** *For a unary prefix* p *and a categorical hom carrier* CategoryHomCarrier(a, b, f)*, the pointwise function-object carrier*

$$\mathsf{CategoryHomCarrier}(a, b, t) \wedge \mathsf{CategoryHomCarrier}(\mathsf{append}(p, a), \mathsf{append}(p, b), t)$$

has a semantic naming certificate with source, pattern, and ledger predicates all equal to this carrier and classifier hsame*.*

Proof. The witness is the original hom history f. Prefix preservation for the unary-continuation category supplies the prefixed hom carrier at the same history. The classifier laws are reflexivity, symmetry, and transitivity of hsame. Transport along a classifier proof keeps the endpoints fixed and moves both the base and prefixed hom-carrier conjuncts across the displayed history comparison. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncobjPointwiseHomCarrier semanticNameCert`

Theorem 132.9 (Function-object pointwise hom carrier composition readback)**.** *For a unary prefix* p*, categorical hom carriers* CategoryHomCarrier(a, b, f) *and* CategoryHomCarrier(b, c, g)*, and a continuation* Cont(f, g, fg)*, the composite history* fg *carries both the base composite hom carrier and the pointwise prefixed composite hom carrier:*

$$\mathsf{CategoryHomCarrier}(a, c, fg) \wedge \mathsf{CategoryHomCarrier}(\mathsf{append}(p, a), \mathsf{append}(p, c), fg).$$

Moreover, every displayed history carrying both of these composite carrier fields is hsame *to* fg*.*

Proof. The base composite is supplied by the categorical composition readback theorem. Prefix preservation transports that base composite through the unary prefix p, giving the pointwise prefixed carrier at the same history fg. If a displayed history carries both fields, the base field alone is enough for the categorical readback uniqueness proof, which identifies the displayed history with fg. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncobjPointwiseHomCarrier comp public readback`

Theorem 132.10 (Function-object pointwise hom carrier composite transport)**.** *For a unary prefix p, categorical hom carriers* $\mathsf{CategoryHomCarrier}(a, b, f)$ *and* $\mathsf{CategoryHomCarrier}(b, c, g)$*, a continuation* $\mathsf{Cont}(f, g, fg)$*, and a history comparison* $fg\mathsf{hsame}fg'$*, the transported composite history* fg' *carries both the base composite hom carrier and the pointwise prefixed composite hom carrier:*

$$\mathsf{CategoryHomCarrier}(a, c, fg') \wedge \mathsf{CategoryHomCarrier}(\mathsf{append}(p, a), \mathsf{append}(p, c), fg').$$

Proof. First read back the base and prefixed composite carriers at fg from the pointwise composition theorem. Then transport each carrier along $fg\mathsf{hsame}fg'$, keeping the source and target endpoints fixed by reflexive history sameness. □

Lean4 ✓ `BEDC.Derived.FuncobjUp.FuncobjPointwiseHomCarrier comp hsame transport`

Closure status for $\mathsf{NameCert}_{\mathsf{Func}\uparrow}$**.**

Constructive story: The function-object certificate is generated from $BHist$ rows that name source histories, target histories, hom carriers, pointwise prefixes, and composite histories. The carrier convention does not begin with a host function space; it reads a graph or hom row from the visible ledger and then uses $hsame$ to transport that row across representative changes. Continuation data appear as $\mathsf{Cont}(f, g, fg)$, the explicit composition witness for two hom rows. The chapter first eliminates empty linear-singleton graph components, then builds the pointwise hom carrier and its semantic NameCert, composition readback, and composite transport from those visible rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Func}\uparrow}, \mathsf{seed})$

Scope closed: This chapter binds the function-object carrier sections, empty graph component theorems, pointwise hom semantic NameCert, composition readback, and composite transport.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Func}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim an ambient exponential object, total host function equality, or composition outside the recorded Cont witness.

Upgrade path: Reaching obligationClosure requires a formal hom-carrier packet and checked preservation of pointwise composition under $hsame$.

Chapter 133

A Concrete Naming Certificate for $\mathsf{RiemannianMetric}^{\uparrow}$

The Riemannian-metric interface $\mathsf{RiemannianMetric}^{\uparrow}$ packages a smooth field of positive-definite inner products on the tangent fibres of a manifold carrier. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{InnerProduct}^{\uparrow}}$ (chapter 86), and supplies the metric substrate for length, geodesic, and curvature certificates.

133.1 Carrier definition

Theorem 133.1 (RiemannianMetricUp source fibre carrier row)**.** *A* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *certificate carries the following source-fibre rows. Its base carrier is a* $\mathsf{Manifold}^{\uparrow}$ *point carrier over* BHist*. For each carried point history* x*, it displays a tangent fibre row* T_x *over* x*. For each displayed fibre* T_x*, it displays an* $\mathsf{InnerProduct}^{\uparrow}$ *row*

$$g_x : T_x \times T_x \to \mathsf{BHist}$$

on that fibre. The visible ledger records only the manifold point provenance, the tangent-witness provenance over the point, and the fibre inner-product provenance; it contains no length, geodesic, curvature, or bridge row.

Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricSingleton source fibre carrier row`
Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricSingletonFibreSurface carrier rows`

Proof. Read the certificate through the ten-field $\mathsf{NameCert}$ template. The only outer carrier named by the template is the $\mathsf{Manifold}^{\uparrow}$ carrier, so every base point is a BHist point accepted by that source.

For a displayed point x, the fibre entry is a dependent row over the same BHist witness. The row has no independent endpoint: its source is the carried $\mathsf{Manifold}^{\uparrow}$ point and its classifier is inherited through the point row.

On each such fibre, the metric entry is exactly an $\mathsf{InnerProduct}^{\uparrow}$ row. The ledger projection of the ten-field template therefore has three visible provenance classes: the $\mathsf{Manifold}^{\uparrow}$ point row, the tangent row over that point, and the $\mathsf{InnerProduct}^{\uparrow}$ row on the displayed fibre. □

Theorem 133.2 (RiemannianMetricUp classifier stability obligation)**.** *For a* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *certificate, classifier stability has the following obligation shape. If point histories* x *and* y *are related by* hsame *and by the* $\mathsf{Manifold}^{\uparrow}$ *point classifier, then every tangent row over* x *transports to*

a tangent row over y. If tangent witnesses u, v over x transport to tangent witnesses u', v' over y, then the $\mathsf{InnerProduct}^{\uparrow}$ *classifier transports the fibrewise metric endpoint*

$$g_x(u, v)$$

to

$$g_y(u', v').$$

Proof. Start with the ten-field NameCert classifier field. Its base comparison is the hsame comparison on BHist histories together with the $\mathsf{Manifold}^{\uparrow}$ point classifier, so the transported endpoint remains inside the same carried point surface.

The tangent row is dependent on that transported point. Applying the NameCert stability field moves the displayed tangent witness from the source point to the target point without adding any classifier beyond hsame and the $\mathsf{Manifold}^{\uparrow}$ point classifier.

It remains to compare metric endpoints. The metric row on each fibre is an $\mathsf{InnerProduct}^{\uparrow}$ row, so its own classifier transports the endpoint through the transported tangent witnesses and yields the displayed target endpoint. □

Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricSingletonFibreSurface classifier stability`

Theorem 133.3 (RiemannianMetricUp fibrewise positivity and chart compatibility obligation)**.** *A* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *certificate carries the following fibrewise metric obligations. For every displayed point x and nonzero tangent witness $u : T_x$, the fibre row has a positive-definite entry*

$$g_x(u, u) > 0.$$

For every displayed fibre, symmetry and bilinearity are inherited from the $\mathsf{InnerProduct}^{\uparrow}$ *row on that fibre. For every overlap in the* $\mathsf{Manifold}^{\uparrow}$ *atlas, chart-change transport carries tangent witnesses through the atlas classifier and preserves the displayed fibre metric endpoint under the* $\mathsf{InnerProduct}^{\uparrow}$ *classifier. These obligations do not assert length, geodesic, curvature, or a standard bridge.*

Proof. Unpack the ten-field NameCert template at a displayed BHist point. The point is supplied only by $\mathsf{Manifold}^{\uparrow}$, and the tangent witness is supplied only as a fibre row over that point.

The metric row on the fibre is an $\mathsf{InnerProduct}^{\uparrow}$ row. Its positive, symmetric, and bilinear entries give the positive-definite, symmetry, and bilinearity obligations after restricting all arguments to the displayed tangent fibre.

For a chart overlap, use the $\mathsf{Manifold}^{\uparrow}$ atlas classifier to transport the point and tangent witnesses across the overlap. Then apply the $\mathsf{InnerProduct}^{\uparrow}$ classifier on the target fibre to identify the metric endpoint after transport.

The template has no row whose endpoint is a length functional, geodesic equation, curvature tensor, or standard bridge. Hence those interfaces are outside the stated obligation scope. □

Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricSingletonFibreSurface fibrewise compatibility scope`

Theorem 133.4 (RiemannianMetricUp public source-fibre NameCert surface)**.** *The public exported* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *source-fibre surface is exactly the conjunction of the source-fibre carrier row of Definition 133.1, the classifier stability obligation of Definition 133.2, and the fibrewise positivity and chart-compatibility obligation of Definition 133.3. Downstream length, geodesic, and curvature consumers may cite this theorem as the single* $\mathsf{RiemannianMetric}^{\uparrow}$ *surface, but the surface does not assert those downstream interfaces or a standard bridge.*

Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricPublicSourceFibre name certificate`

Proof. Project the public $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ surface onto its source-fibre carrier component. This gives exactly the manifold point row, the tangent row over each displayed point, and the $\mathsf{InnerProduct}^{\uparrow}$ metric row of Definition 133.1.

Project the same surface onto its classifier component. The ten-field roadmap template exposes precisely the point transport, tangent-row transport, and fibrewise metric endpoint transport recorded in Definition 133.2.

Finally project the fibrewise metric obligation component. The resulting positive-definite, symmetric, bilinear, and chart-compatible fibre rows are exactly those of Definition 133.3. Repacking these three projections under the roadmap ten-field template gives a single exported source-fibre surface, and the absence of length, geodesic, curvature, and bridge rows is preserved by the same repacking. □

Theorem 133.5 (RiemannianMetricUp source-fibre standard bridge)**.** *The public source-fibre surface of Definition 133.4 gives a conservative paper-level bridge from* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *to the ordinary fibrewise metric presentation. Forward readback exposes exactly the* $\mathsf{Manifold}^{\uparrow}$ *point row, the tangent-fibre row, and the* $\mathsf{InnerProduct}^{\uparrow}$ *metric row of Definition 133.1. Reverse admission accepts only such displayed rows. Classifier preservation is exactly Definition 133.2, and fibre positivity together with chart compatibility is exactly Definition 133.3. The bridge exports no length, geodesic, curvature, or host metric object.*

Proof. Start from the public export theorem Definition 133.4. Its carrier projection is precisely the source-fibre carrier row of Definition 133.1, so forward readback has only the manifold point row, the tangent-fibre row over that point, and the displayed $\mathsf{InnerProduct}^{\uparrow}$ metric row.

For reverse admission, use the same public export theorem in the opposite direction of packaging. A displayed ordinary fibrewise metric row is admitted only when it has the three rows named by Definition 133.1; no additional row is available in the exported surface.

The transport component is supplied by Definition 133.2, while the positive-definite and chart-compatible fibre obligations are supplied by Definition 133.3. Composing these two obligations with the public export theorem gives the conservative bridge, and the same boundary excludes length, geodesic, curvature, and host metric objects. □

Lean4 ✓ `BEDC.Derived.RiemannianMetricUp.RiemannianMetricPublicSourceFibre standard bridge`

133.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$**.**

Constructive story: A Riemannian metric is admitted only after a $\mathsf{Manifold}^{\uparrow}$ point row has been displayed, a tangent-fibre row has been placed over that same history, and an $\mathsf{InnerProduct}^{\uparrow}$ row has been attached fibrewise; histories lacking any one of those three rows stay outside the carrier. Two displayed metric packets classify together when the point histories are matched by the manifold classifier and hsame, the tangent rows transport across that point match, and the inner-product endpoint on transported tangent witnesses is classified fibre by fibre. The source therefore covers exactly manifold points with tangent fibres and inner-product rows, the pattern records positive-definiteness, symmetry, bilinearity, and chart-overlap compatibility on those fibres, and the ledger keeps visible only the point provenance, tangent-witness provenance, and fibre inner-product provenance. Nonemptiness comes from the displayed source-fibre row, while reflexivity, symmetry, transitivity, and carrier closure are inherited componentwise from hsame, $\mathsf{Manifold}^{\uparrow}$, and $\mathsf{InnerProduct}^{\uparrow}$, so the five naming-certificate obligations never ask for a host metric space. A history h lies in the signature gap of a $\mathsf{RiemannianMetric}^{\uparrow}$ token p when the source accepts the manifold point and fibre packet for h, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; unfolded, this says that p records precisely the same carried point, tangent fibre, and positive compatible inner-product row. The paper bridge

reads the package as an ordinary smooth field of positive-definite inner products on tangent fibres and reads it back by the same three provenance rows. The chapter registers this fibrewise construction under the name RiemannianMetric$^{\uparrow}$; length, geodesics, curvature, and a host metric object are not part of the primitive data.

Theory closure: TheoryGate(NameCert$_{\mathsf{RiemannianMetric}\uparrow}$, maturePackageClosed)

Scope closed: The public paper-side surface is Definition 133.4, and the conservative paper-level standard bridge is Definition 133.5, built from the carrier row of Definition 133.1, the classifier-stability row of Definition 133.2, and the positivity and chart-compatibility row of Definition 133.3.

Formal verification: FormalStatus(NameCert$_{\mathsf{RiemannianMetric}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.RiemannianMetricUp.RiemannianMetricSingleton\_source\_fibre\_carrier\_row`

Bridge status: paperBridge

Not claimed: This chapter does not close an exactness theorem, length/geodesic/curvature interface, Lean-side bridgeChecked verification, or a host metric object.

Upgrade path: Remaining strengthening is Lean-side bridgeChecked verification and downstream length, geodesic, and curvature consumers, not a further paper-side closure grade.

Chapter 134

A Concrete Naming Certificate for $\mathsf{Connection}^{\uparrow}$

The connection interface $\mathsf{Connection}^{\uparrow}$ packages a covariant derivative on a fibre bundle, with linearity in the section argument and the Leibniz rule against scalar functions. It depends on $\mathsf{NameCert}_{\mathsf{Bundle}^{\uparrow}}$ (chapter 97) and $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96), and supplies the parallel-transport and curvature substrate.

134.1 Carrier definition

Definition 134.1 (Connection carrier packet)**.** *A* $\mathsf{Connection}^{\uparrow}$ *carrier packet is a displayed* BHist *tuple*

$$\mathcal{C} = (\mathcal{B}, \mathcal{M}, b, f, s, t, \nabla, \eta_{\mathcal{B}}, \eta_{\mathcal{M}}, \rho)$$

where $\mathcal{B}$ *is the* $\mathsf{Bundle}^{\uparrow}$ *source certificate,* $\mathcal{M}$ *is the* $\mathsf{Manifold}^{\uparrow}$ *source certificate,* $b : \mathsf{BHist}$ *is a base-point row,* $f : \mathsf{BHist}$ *is the fibre row over* b*,* $s : \mathsf{BHist}$ *is a section row with endpoint in* f*,* $t : \mathsf{BHist}$ *is a tangent-direction row at* b*, and* $\nabla : \mathsf{BHist}$ *is the covariant-derivative endpoint row. The witnesses* $\eta_{\mathcal{B}}$ *and* $\eta_{\mathcal{M}}$ *retain the two dependency* $\mathsf{NameCert}$ *rows, while* ρ *records that the visible source rows are compared only by the inherited* hsame *and classifier data supplied by* $\mathsf{Bundle}^{\uparrow}$ *and* $\mathsf{Manifold}^{\uparrow}$*.*

The packet carries no ambient manifold object beyond those rows. Its public surface is the base point, fibre, section, tangent direction, derivative endpoint, dependency witnesses, and finite Cont *ledger connecting the derivative endpoint back to the displayed source rows.*

Lean4 (definition) `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket`
Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionTasteGate single carrier alignment`

Definition 134.2 (Connection classifier and derivative row)**.** *Two connection packets* $\mathcal{C}$ *and* $\mathcal{C}'$ *are classified by* $\mathsf{ConnCls}$ *when their base-point rows are related by the* $\mathsf{Manifold}^{\uparrow}$ *point classifier, their fibre rows are related by the* $\mathsf{Bundle}^{\uparrow}$ *fibre classifier, their section rows are related by the* $\mathsf{Bundle}^{\uparrow}$ *section classifier, their tangent-direction rows are related by the* $\mathsf{Manifold}^{\uparrow}$ *tangent classifier, and their derivative endpoint rows are related by* hsame*. The* Pkg *provenance rows of the two dependency certificates remain part of the comparison, so a classifier witness also records the source packets from which the displayed derivative rows were read.*

Thus the derivative row is a carried BHist *endpoint, not a host-level function value. It is accepted precisely when the source base, fibre, section, and tangent rows are accepted by the inherited certificates and the endpoint comparison is witnessed by* hsame *inside the same finite history ledger.*

Lean4 (definition) `BEDC.Derived.ConnectionUp.ConnectionClassifierDerivativeRow`

Theorem 134.3 (Connection section-linearity obligation)**.** *For the carrier of Definition 134.1, the derivative row is stable under the section-addition and scalar-action rows supplied by the* $\mathsf{Bundle}^{\uparrow}$ *and* $\mathsf{Manifold}^{\uparrow}$ *dependency sources. If* s_1*,* s_2*, and* a *are certified section and scalar rows over the same base and tangent packet, then the derivative endpoints for* $s_1 + s_2$ *and* $a \cdot s_1$ *are classified by the same* ConnCls *rows obtained by applying the corresponding carried addition and scalar-action ledgers to the derivative endpoints of* s_1 *and* s_2*.*

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket section linearity obligation`

Proof. Read the two section rows, their sum row, and the scalar-action row through the $\mathsf{Bundle}^{\uparrow}$ certificate. The $\mathsf{Manifold}^{\uparrow}$ source keeps the base point and tangent-direction rows fixed under the displayed classifier.

Apply endpoint transport for hsame along the finite Cont ledgers representing section addition and scalar action. The derivative endpoint row is then compared componentwise with the transported endpoint rows, while the Pkg provenance remains the original pair of dependency certificates.

Repack the transported base, fibre, section, tangent, and derivative comparisons into ConnCls. No external vector-space equality is used, because all linearity data is read from the dependency rows carried by the packet. □

Theorem 134.4 (Connection parallel-transport obligation)**.** *Let a displayed path spine be a finite* BHist *chain of base-point rows whose adjacent tangent-direction and derivative endpoint rows are compatible by* ConnCls*. Then the chain determines a parallel-transport packet whose initial and terminal section endpoints remain in the carried fibre classifier of the* $\mathsf{Bundle}^{\uparrow}$ *source.*

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket parallel transport obligation`

Proof. Induct on the displayed path spine. For the empty spine, the transport packet is the identity Cont row at the initial fibre, and the fibre classifier holds by reflexivity of the inherited $\mathsf{Bundle}^{\uparrow}$ classifier.

For a nonempty spine, use the head derivative row to append one certified transport step. The compatibility premise supplies the hsame endpoint comparison needed to move from the current fibre row to the next carried fibre row.

Apply the induction hypothesis to the remaining spine and compose the two finite ledgers by Cont associativity. The terminal endpoint is therefore classified with the carried terminal fibre row by the same $\mathsf{Bundle}^{\uparrow}$ classifier used at every visible step. □

Theorem 134.5 (Connection curvature-boundary obligation)**.** *Given two displayed tangent-direction rows for a connection packet, the commutator of the corresponding derivative rows is a visible* BHist *boundary row. This boundary row is consumable by* $\mathsf{Curvature}^{\uparrow}$ *as the source row for the curvature packet, with base, fibre, section, tangent-pair, derivative-endpoint, and* Pkg *provenance data inherited from Definition 134.1.*

Proof. Build the two derivative composites by appending the first tangent direction and then the second, and by appending them in the reverse order. Each composite is a finite Cont ledger over the same base, fibre, and section rows.

The commutator boundary is the displayed comparison between these two endpoint ledgers. Its source rows are exactly the two tangent-direction rows and the two derivative endpoint rows already accepted by ConnCls.

Package that comparison as a BHist boundary row. Since the packet exposes the dependency certificates and provenance rows, $\mathsf{Curvature}^{\uparrow}$ can read the boundary without adding a new carrier object or quotienting the derivative endpoints. □

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket curvature boundary obligation`

Theorem 134.6 (Connection stability-ledger exactness obligation)**.** *The displayed connection surface has exactly the classifier reflexivity, symmetry, and transitivity rows inherited from* hsame*,* $\mathsf{Bundle}^{\uparrow}$*, and* $\mathsf{Manifold}^{\uparrow}$*; the carrier transport rows generated by those classifiers; the ledger readback rows for base, fibre, section, tangent, derivative, and* Pkg *provenance; and the exactness rows for section-linearity, parallel transport, and curvature-boundary formation. No additional coordinate chart, host connection operator, or standard bridge row is part of the obligation surface.*

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket stability ledger exactness obligation`

Proof. Classifier stability is componentwise. Reflexivity, symmetry, and transitivity for derivative endpoints come from hsame, while the base, fibre, section, and tangent components are supplied by the two dependency certificates.

Carrier transport follows by applying those componentwise classifier rows to the tuple of Definition 134.1. Ledger readback is by projection from the tuple: each accepted connection row exposes exactly its base, fibre, section, tangent, derivative endpoint, dependency certificate, and provenance fields.

Exactness is the reverse reading. The section-linearity, parallel-transport, and curvature-boundary obligations use only the projected rows and finite Cont ledgers already listed above, so any accepted certificate step is one of the displayed connection rows and every displayed row is used by one of those certificate steps. □

134.2 The certificate

Theorem 134.7 (ConnectionUp public certificate consumer surface)**.** *A public consumer of* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *may read exactly the carrier packet of Definition 134.1, the* ConnCls *classifier of Definition 134.2, the section-linearity row, the parallel-transport row, the curvature-boundary row, the stability-ledger exactness row, and the displayed* $\mathsf{Bundle}^{\uparrow}$*,* $\mathsf{Manifold}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *dependencies carried by those rows. It does not receive a coordinate chart, a host connection operator, a curvature theory beyond the displayed boundary row, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket public certificate consumer surface`

Proof. Project the consumer request to the carrier and classifier rows. The carrier packet supplies exactly the $\mathsf{Bundle}^{\uparrow}$ and $\mathsf{Manifold}^{\uparrow}$ dependency rows, base, fibre, section, tangent, derivative endpoint, provenance, and finite readback data, while ConnCls supplies the public classifier.

Apply Definition 134.3, Definition 134.4, and Definition 134.5. These are precisely the derivative, transport, and curvature rows a consumer may follow from the carrier packet.

Finally apply Definition 134.6. Its exactness statement excludes any additional public ledger row, so the listed rows repack as the whole consumer surface for $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$. □

Theorem 134.8 (ConnectionUp standard bridge boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet determines a bridge-facing boundary consisting exactly of the section-linearity row, the parallel-transport row, the curvature-boundary row, and the stability-ledger exactness row displayed in this chapter. Any standard connection interpretation may read those rows together with their* BHist*,*

Cont, Pkg, *and* hsame *provenance, but it may not import a coordinate connection, smooth atlas, or host bundle operation.*

Lean4 ✓ `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket standard bridge boundary`

Proof. Start from the public consumer surface of Definition 134.7. It allows a consumer to project only the displayed carrier, classifier, dependency, and certificate rows of $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$.

Now select the four rows that face a standard interpretation. The section-linearity row is Definition 134.3, the parallel-transport row is Definition 134.4, the curvature-boundary row is Definition 134.5, and the stability row is Definition 134.6.

These four rows form a finite row family. Their proofs already project all permitted BHist endpoints, Cont ledgers, Pkg provenance, and hsame comparisons from the public packet, so a bridge can read exactly that provenance without adding another row sort.

The exclusion clause follows from the same consumer-surface and ledger exactness statements. Since no coordinate connection, smooth atlas, or host bundle operation is among the projected public rows, none is part of the bridge-facing boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$.

Constructive story: A connection packet is generated by taking the already certified Bundle$^\uparrow$ and Manifold$^\uparrow$ rows, then displaying a base point, a fibre over that point, a section endpoint in the fibre, a tangent-direction row, and a covariant-derivative endpoint tied back to them by finite Cont provenance. A packet is accepted only when all of those source rows are visible through the two dependency certificates; two packets classify together when their base, fibre, section, tangent, dependency-provenance, and derivative endpoint rows are compared componentwise by the inherited classifiers and hsame. The source covers exactly these displayed derivative packets, the pattern records section-linearity, finite parallel-transport chains, and the commutator boundary consumable by Curvature$^\uparrow$, while the ledger keeps the base, fibre, section, tangent, derivative, package provenance, and finite continuation rows aligned. The five certificate obligations follow componentwise: a displayed packet inhabits the carrier, reflexivity, symmetry, and transitivity are supplied by hsame, Bundle$^\uparrow$, and Manifold$^\uparrow$, and classifier transport moves each accepted field without producing an ambient connection operator. A history h lies in the signature gap of a Connection$^\uparrow$ token p when the source accepts such a packet for h, the signature relation pairs it with an answer derivative packet and evidence ledger, and token introduction identifies that answer as p; concretely, h presents the same base, fibre, section, tangent, derivative, and provenance rows that p encodes. The displayed obligations also say how section linearity, parallel transport, and curvature-boundary formation read from this finite ledger, but no coordinate semantics or checked standard bridge is exported. The chapter registers this displayed derivative-packet construction under the name Connection$^\uparrow$; no Leibniz theorem, host covariant derivative, or independent chart-level connection primitive is added here.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$, maturePackageClosed)

Scope closed: The mature scope is the displayed public Connection$^\uparrow$ packet over Bundle$^\uparrow$, Manifold$^\uparrow$, BHist, hsame, Cont, Pkg, and NameCert, together with the four bridge-facing obligation rows and the downstream Curvature$^\uparrow$/ChernWeil$^\uparrow$ consumer boundary already cited.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.ConnectionUp.ConnectionCarrierPacket\_stability\_ledger\_exactness\_obligation`

Bridge status: none

Not claimed: This chapter does not close Leibniz, coordinate-chart semantics, or curvature compatibility.

Upgrade path: Only Lean-side bridgeChecked verification remains on the separate verification axis.

Chapter 135

A Concrete Naming Certificate for $\mathsf{Curvature}^{\uparrow}$

The curvature interface $\mathsf{Curvature}^{\uparrow}$ packages the antisymmetric bracket of a connection, certifying the Bianchi identities and the tensorial behaviour under section change. It depends on $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ (chapter 134) and supplies the local invariants on which Riemannian and gauge-field certificates rest.

135.1 Carrier definition

Definition 135.1 (Curvature bracket carrier)**.** *A* $\mathsf{Curvature}^{\uparrow}$ *carrier packet is a displayed* BHist *tuple*

$$\mathcal{R} = (\mathcal{C}, b, f, s, u, v, d_{uv}, d_{vu}, \kappa, \beta, \rho)$$

where $\mathcal{C}$ *is a source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet,* $b : \mathsf{BHist}$ *is the base row,* $f : \mathsf{BHist}$ *is the fibre row over* b*,* $s : \mathsf{BHist}$ *is the section row,* $u, v : \mathsf{BHist}$ *are the two tangent-direction rows,* $d_{uv}, d_{vu} : \mathsf{BHist}$ *are the two iterated derivative endpoint rows,* $\kappa : \mathsf{BHist}$ *is the displayed commutator boundary supplied by Definition 134.5,* β *is the finite* Cont *ledger reading that boundary from the two derivative orders, and* ρ *records the* Pkg *provenance of the connection packet.*

The carrier is accepted only when the base, fibre, section, tangent, derivative endpoint, commutator-boundary, ledger, and provenance rows all project from the same connection certificate. Thus curvature is a bracket package over $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$*, not an ambient tensor object added beside the BEDC history rows.*

Lean4 (definition) `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier`

Theorem 135.2 (Curvature boundary source obligation)**.** *A* $\mathsf{Curvature}^{\uparrow}$ *source row is read from a* $\mathsf{Connection}^{\uparrow}$ *carrier packet, two tangent-direction* BHist *rows, the two ordered derivative-composite* Cont *ledgers, and the commutator-boundary* hsame *row exposed by Definition 134.5. The resulting source packet carries no coordinate chart and no host curvature operator; it is exactly the displayed boundary row together with its connection, tangent, derivative, ledger, and* Pkg *provenance projections.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier boundary source obligation`

Proof. Project the source connection packet through Definition 134.5. This gives the base, fibre, section, tangent-pair, derivative-endpoint, commutator-boundary, and provenance rows already accepted by the connection certificate.

Read the two derivative orderings as the ordered Cont ledgers carried by the same connection packet. Their displayed endpoint comparison is the commutator-boundary hsame row.

Repack these projected rows as the $\mathsf{Curvature}^{\uparrow}$ source packet. Since every component is obtained by projection from the connection boundary obligation, the curvature carrier adds no independent coordinate datum and no further quotient of the history ledger. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBoundarySource connection projection`

Theorem 135.3 (Curvature connection classifier stability)**.** *Transport of the source connection packet by* ConnCls*, together with* $\mathsf{Manifold}^{\uparrow}$ *transport of the tangent pair, transports the* $\mathsf{Curvature}^{\uparrow}$ *boundary source row componentwise by* hsame*. In particular, classified replacements of the connection packet and of the two tangent-direction rows preserve the two derivative-composite ledgers and the commutator boundary endpoint row read by* $\mathsf{Curvature}^{\uparrow}$*.*

Proof. Start with the ConnCls comparison between the two connection packets. It transports the base, fibre, section, derivative endpoint, and provenance components by the classifier rows already exposed by $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$.

Use the $\mathsf{Manifold}^{\uparrow}$ classifier on the two tangent-direction rows. Componentwise transport sends the ordered tangent pair to the classified ordered tangent pair, so both derivative composites retain the same source and target projections after the connection transport.

Apply endpoint transport to the two Cont ledgers and then to the displayed commutator boundary. The result is an hsame comparison of the transported boundary rows, which is exactly the classifier stability required of the $\mathsf{Curvature}^{\uparrow}$ source packet. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier connection classifier stability`

Theorem 135.4 (Curvature carrier boundary row)**.** *Every accepted* $\mathsf{Curvature}^{\uparrow}$ *endpoint is exactly a displayed* BHist *commutator-boundary row inherited from Definition 134.5. Conversely, every curvature carrier packet of Definition 135.1 whose two derivative endpoints are accepted by the source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *determines an accepted curvature endpoint with the same base, fibre, section, tangent-direction,* Cont*, and* Pkg *provenance rows.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier carrier boundary row`

Proof. Project an accepted curvature endpoint to its carrier packet. By the carrier definition, the endpoint component is the row κ, and κ is declared only as the commutator boundary read from the two derivative orders of the source connection packet.

Apply Definition 134.5 to the displayed tangent rows u and v of that packet. The theorem supplies a BHist boundary whose source data are precisely the base, fibre, section, tangent-pair, derivative-endpoint, and Pkg rows already present in the curvature source row.

For the converse, start with such a carrier packet and the two accepted derivative endpoints. The connection boundary theorem produces κ; repack κ together with the unchanged Pkg and Cont ledger as the curvature endpoint. No coordinate curvature object is introduced, because the endpoint is only the displayed boundary row. □

Theorem 135.5 (Curvature classifier transport row)**.** *Let $\mathcal{R}$ and $\mathcal{R}'$ be curvature carrier packets over connection packets $\mathcal{C}$ and $\mathcal{C}'$. If the inherited* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *classifier transports the base, fibre, section, tangent-direction, and derivative-endpoint rows of $\mathcal{C}$ to those of $\mathcal{C}'$, if the two commutator boundaries are related by* hsame*, and if both rows carry the same* Pkg *provenance through a finite* Cont *reassociation ledger, then the* $\mathsf{Curvature}^{\uparrow}$ *classifier transports the curvature endpoint of $\mathcal{R}$ to the curvature endpoint of $\mathcal{R}'$.*

Proof. Unpack the two curvature carrier packets. The connection classifier supplies the comparisons for the base, fibre, section, tangent-direction, and derivative-endpoint components, while the common provenance row supplies the package comparison.

Reassociate the finite Cont ledger so that the two derivative orders are read with the same source grouping. This reassociation does not change any endpoint; it only exposes the two commutator-boundary rows as comparable BHist entries in the same provenance context.

Use the assumed hsame comparison between the two boundary rows. Repack the transported connection classifier rows, the boundary hsame witness, and the provenance ledger as the curvature classifier witness. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier classifier transport row`

Theorem 135.6 (Curvature Bianchi ledger row)**.** *For any cyclic triple of tangent-direction rows* u, v, w : BHist *over the same curvature carrier packet, the three commutator boundaries for* (u, v)*,* (v, w)*, and* (w, u) *carry a visible* SigRel *ledger witnessing the Bianchi boundary. This ledger is a finite* Cont *consequence of the three inherited connection boundary rows and their shared* Pkg *provenance, and it does not assert coordinate equality, exterior-calculus equality, or a host-level curvature identity.*

Proof. Read u, v, and w through the same source connection packet and the same finite Cont spine. For each cyclic ordered pair, apply Definition 134.5 to obtain the displayed commutator boundary row with the common base, fibre, section, and provenance projections.

Collect the three boundary rows into the signature ledger whose entries are the cyclic boundary readings. The SigRel witness records that the three readings belong to one finite certificate surface, while the Cont ledger records the append order of the boundary rows.

The Bianchi row is this ledger. It is visible because every entry is a carried BHist or SigRel row, and it is conservative because no equality outside those displayed rows is used. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier bianchi ledger row`

Theorem 135.7 (Curvature tensorial section-change row)**.** *Replacing the section row or fibre representative of a curvature carrier packet through the inherited* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *classifier transports the curvature endpoint through the same* BHist *boundary row and* Pkg *ledger. The derivative endpoint rows, the commutator boundary, and the cyclic* SigRel *ledger are carried along by the corresponding* hsame *and* Cont *witnesses, so the transported carrier packet presents the same* $\mathsf{Curvature}^{\uparrow}$ *classifier class.*

Proof. Begin with the source connection classifier witness for the section or fibre replacement. It identifies the displayed base, fibre, section, tangent, and derivative endpoint rows by the inherited component classifiers and exposes the needed hsame rows.

Transport the two derivative endpoint rows along those component comparisons. Applying the connection curvature-boundary theorem to the transported derivative orders gives the same boundary construction in the transported provenance context.

Finally carry the cyclic SigRel ledger through the same Cont and hsame witnesses. Repacking these rows yields the transported curvature carrier packet, and the endpoint remains in the same classifier class because the boundary and package ledgers have not changed their source certificate. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier tensorial section change row`

Theorem 135.8 (Curvature public obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Curvature}^\uparrow}$ *obligation surface over* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *consists exactly of the carrier packet of Definition 135.1, the boundary row of Definition 135.4, the classifier transport row of Definition 135.5, the Bianchi ledger row of Definition 135.6, and the tensorial section-change row of Definition 135.7. A downstream certificate such as* $\mathsf{ChernWeil}^\uparrow$ *may consume these rows as* BHist*,* Cont*,* hsame*,* Pkg*, and* SigRel *data, but it may not assume any additional coordinate curvature form or standard bridge from* $\mathsf{Curvature}^\uparrow$ *alone.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier public obligation surface`

Proof. Assemble the carrier by projecting the source connection packet, the tangent rows, the derivative endpoint rows, the commutator boundary, the package provenance, and the finite ledger from Definition 135.1.

The boundary theorem identifies the accepted endpoint; the classifier theorem transports it under inherited connection classification; the Bianchi theorem records the cyclic signature ledger; and the section-change theorem carries the endpoint through replacement of the section or fibre representative.

Conversely, every row exposed by the public surface appears in one of those five clauses. Thus the obligation surface is exact: it provides a concrete certificate surface for downstream geometry while leaving coordinate curvature forms, de Rham representatives, and standard bridges to their own certificate chapters. □

Theorem 135.9 (Curvature connection-boundary source projection)**.** *Every* BHist *curvature-boundary row accepted from the* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *source of Definition 134.5 projects to the visible rows required by the* $\mathsf{Curvature}^\uparrow$ *source surface: the base row supplied by* $\mathsf{Manifold}^\uparrow$*, the fibre row supplied by* $\mathsf{Bundle}^\uparrow$*, the section row, the ordered tangent-pair rows, the two derivative-endpoint rows, and the* Pkg *provenance rows of the* $\mathsf{Bundle}^\uparrow$ *and* $\mathsf{Manifold}^\uparrow$ *dependency certificates. The projection is a finite* Cont *readback from the accepted boundary row; it does not inspect host-level equality of base points, fibres, sections, tangent directions, or derivative endpoints.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureCarrierPacket connection boundary source projection`

Proof. Read the boundary row through the $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ packet. Its construction in Definition 134.5 already lists the base, fibre, section, tangent-pair, derivative-endpoint, and dependency rows used to build the commutator ledger.

Project those entries one at a time along the finite Cont readback. The base component is the $\mathsf{Manifold}^\uparrow$ point row, the fibre and section components are the $\mathsf{Bundle}^\uparrow$ rows, and the derivative endpoints are the two BHist endpoint rows compared by the boundary.

The Pkg entries are retained rather than recomputed. Thus the $\mathsf{Curvature}^\uparrow$ source receives exactly the connection boundary surface, with all comparison data still mediated by hsame and the dependency classifiers. □

Theorem 135.10 (Curvature antisymmetric boundary classifier)**.** *For a* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *boundary row whose ordered tangent pair is* (t_1, t_2)*, swapping the displayed tangent rows to* (t_2, t_1) *reverses the commutator boundary classifier by the inherited* hsame *endpoint comparisons and the* SigRel *orientation row. The reversed row has the same base, fibre, section, derivative-endpoint carrier rows, and* Pkg *provenance rows, but its classifier is the opposite boundary relation in* SigRel*, not a judgmental or host equality between the two commutator histories.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier antisymmetric boundary classifier`

Proof. Start with the two finite Cont composites that define the accepted boundary: first t_1 then t_2, and first t_2 then t_1. Swapping the tangent rows interchanges these two composites while leaving their base, fibre, section, and provenance rows unchanged.

Use symmetry of hsame on the derivative endpoint comparison to reverse the displayed endpoint relation. The reversal is recorded as a SigRel orientation row attached to the boundary classifier.

Repack the same source rows with the opposite SigRel classifier. Since no host equality of histories is asserted, the antisymmetry belongs to the BEDC classifier data exposed by $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ and consumed by $\mathsf{Curvature}^\uparrow$. □

Theorem 135.11 (Curvature tensorial section transport)**.** *Let a* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *curvature-boundary row be accepted over a section row and fibre row carried by the* $\mathsf{Bundle}^\uparrow$ *source. If the section classifier and fibre classifier are transported inside the same* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *dependency by finite* Cont *ledgers, then the transported section and fibre rows preserve the accepted* BHist *curvature boundary row. The transported boundary has the same* $\mathsf{Manifold}^\uparrow$ *base row, tangent-pair rows, derivative-endpoint comparison up to* hsame*, and* Pkg *provenance rows, so* $\mathsf{Curvature}^\uparrow$ *reads it as the same tensorial source boundary.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier tensorial section transport`

Proof. Apply the $\mathsf{Bundle}^\uparrow$ fibre and section classifiers supplied inside the $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ dependency. These classifiers transport the fibre and section rows by finite Cont ledgers while keeping the $\mathsf{Manifold}^\uparrow$ base row and tangent-pair rows fixed.

Transport the two derivative endpoint rows along those ledgers and compare the transported endpoints by hsame. The commutator boundary row is therefore carried to a boundary row with the same ordered tangent pair and the same source provenance.

The Pkg rows of the dependency certificates are copied through the transport. Hence the $\mathsf{Curvature}^\uparrow$ source surface sees tensorial section and fibre transport as classifier-preserving readback, not as a change of the underlying boundary object. □

135.2 The certificate

Theorem 135.12 (Curvature manifold-base dependency row)**.** *For every* $\mathsf{Curvature}^\uparrow$ *carrier packet* $\mathcal{R}$ *of Definition 135.1, the displayed base row* b *and tangent rows* u, v *are exactly the* $\mathsf{Manifold}^\uparrow$ BHist *dependency rows read from the source* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *packet. Any accepted transport of these rows is mediated by the inherited* hsame *endpoint comparisons and finite* Cont *ledgers, and no further base or tangent carrier is available to the curvature certificate.*

Proof. Unpack $\mathcal{R} = (\mathcal{C}, b, f, s, u, v, d_{uv}, d_{vu}, \kappa, \beta, \rho)$ as a curvature bracket carrier. The components b, u, v occur there only as source rows of the connection certificate $\mathcal{C}$.

Project the $\mathsf{Manifold}^\uparrow$ dependency rows through the source $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ packet. The same projection supplies the endpoint hsame comparisons and the finite Cont ledgers used when those rows are transported.

Conversely, every base or tangent row exposed by the curvature surface must be one of b, u, v in the carrier tuple. Repacking the projected rows therefore gives the exact $\mathsf{Manifold}^\uparrow$ consumption row for $\mathsf{Curvature}^\uparrow$. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier manifold base dependency row`

Theorem 135.13 (Curvature bundle-fibre dependency row)**.** *For every* $\mathsf{Curvature}^{\uparrow}$ *carrier packet over a fixed base packet, the fibre row* f *and section row* s *are exactly the* $\mathsf{Bundle}^{\uparrow}$ *dependency rows supplied by the same source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet. Their accepted transports are the inherited bundle classifier transports over the already fixed* $\mathsf{Manifold}^{\uparrow}$ *base row, recorded as* hsame *comparisons and finite* Cont *ledger entries inside the curvature packet.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier bundle fibre dependency row`

Proof. Keep the base row b fixed through the previous dependency row. In the carrier tuple of Definition 135.1, the rows f and s are read from the same connection certificate $\mathcal{C}$ over that base.

Project the $\mathsf{Bundle}^{\uparrow}$ fibre and section dependencies from $\mathcal{C}$. The connection certificate carries their classifier transport ledgers, so curvature receives the transported fibre and section rows by readback rather than by constructing a new bundle object.

For the reverse containment, inspect the curvature packet. The only fibre and section entries visible to downstream certificates are f and s, together with their inherited hsame and Cont data, so the bundle dependency surface is exact. □

Theorem 135.14 (Curvature connection-derivative dependency row)**.** *For every* $\mathsf{Curvature}^{\uparrow}$ *carrier packet, the derivative endpoint rows* d_{uv} *and* d_{vu} *and the commutator boundary row* κ *are projected from* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *by Definition 134.5. The curvature packet may repackage these rows with its boundary ledger* β*, but it does not add an independent derivative operator, endpoint equality, or commutator carrier outside that connection boundary obligation.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier connection derivative dependency row`

Proof. Apply Definition 134.5 to the source connection packet $\mathcal{C}$ and the ordered tangent rows u, v. It supplies the two ordered derivative endpoint rows and the displayed commutator boundary in BHist form.

Read d_{uv}, d_{vu}, and κ from that boundary surface through the finite ledger β. The ledger records the two derivative orders and the endpoint comparison used by the curvature packet.

Repack these three rows as curvature data. Since each row is obtained by projection from the connection boundary theorem, any downstream use of the derivative surface factors through $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$. □

Theorem 135.15 (Curvature ChernWeil export dependency row)**.** *The complete* $\mathsf{ChernWeil}^{\uparrow}$ *export surface of a* $\mathsf{Curvature}^{\uparrow}$ *packet consists of the* BHist *curvature boundary row* κ*, the cyclic ledger recorded by the Bianchi* SigRel *rows, the classifier rows exposed by the curvature transport obligations, and the* Pkg *provenance* ρ *already listed in Definition 135.1. No additional coordinate form, host tensor equality, or exterior-calculus representative is exported from* $\mathsf{Curvature}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier chernweil export dependency surface`

Proof. Project the boundary row κ and package provenance ρ from the curvature carrier. The same carrier exposes the finite Cont ledger β that downstream certificates use to read the boundary from the ordered derivative endpoints.

Add the cyclic Bianchi ledger and classifier rows from the existing curvature obligation rows. These rows are already presented as SigRel, hsame, Cont, and Pkg data, so they can be consumed by $\mathsf{ChernWeil}^{\uparrow}$ without changing the carrier.

Conversely, inspect the public curvature obligation surface. Every row named for downstream consumption is one of the boundary, cyclic ledger, classifier, or provenance rows just listed, and no theorem in the packet grants a coordinate curvature form or host tensor equality. □

Theorem 135.16 (Curvature source row coverage)**.** *Every accepted* $\mathsf{Curvature}^{\uparrow}$ *carrier packet projects exactly the source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet, the* $\mathsf{Manifold}^{\uparrow}$ *base row, the* $\mathsf{Bundle}^{\uparrow}$ *fibre and section rows, the ordered tangent-pair rows, the two derivative endpoint rows, the commutator-boundary row, the finite* Cont *ledger reading that boundary, and the* Pkg *provenance row. Conversely, any such rows over one accepted source connection packet repack as the source surface of the carrier in Definition 135.1.*

Proof. Project an accepted carrier through the tuple of Definition 135.1. Its fields name the source connection packet, the base, fibre, section, tangent-pair, derivative endpoint, boundary, ledger, and provenance rows without asking for a coordinate chart or host tensor.

Apply Definition 134.5 to the projected tangent pair. This identifies the commutator boundary as the displayed BHist row read from the two derivative orders, with the same source connection and Pkg provenance.

For the converse, start with exactly those rows over the same source packet. The carrier definition gives the constructor pattern, and the boundary obligation supplies the compatibility condition for the boundary and ledger entries, so the listed rows repack as the $\mathsf{Curvature}^{\uparrow}$ source surface and nothing else is needed. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier source row coverage`

Theorem 135.17 (Curvature boundary row determinacy)**.** *Fix a source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet, an ordered tangent pair, the two derivative* Cont *ledgers, and the* Pkg *provenance row. Two accepted* $\mathsf{Curvature}^{\uparrow}$ *boundary rows classify together precisely by the carried* hsame *boundary comparison and its* SigRel *orientation row. This determinacy uses no host curvature tensor, no coordinate representative, and no quotient of the* BHist *ledger.*

Proof. With the source packet, tangent pair, derivative ledgers, and provenance fixed, Definition 134.5 leaves only the displayed commutator boundary row to compare. The carrier of Definition 135.1 records that row as κ and records its finite readback as the Cont ledger.

If the two accepted rows carry an hsame boundary comparison with the same SigRel orientation, the curvature classifier repacks that comparison over the fixed source fields. The fixed rows guarantee that no further geometric datum can distinguish the two boundary packets.

Conversely, any classification of the two accepted boundary rows must project to the boundary component of the carrier. Since all other source fields are fixed, that projection is exactly the carried hsame comparison together with the SigRel boundary row, not an equality of host curvature tensors and not a quotient of histories. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier boundary row determinacy`
↪ variant `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier boundary determinacy`

Theorem 135.18 (Curvature ChernWeil visible input exhaustion)**.** *The only* $\mathsf{Curvature}^{\uparrow}$ *rows exported to* $\mathsf{ChernWeil}^{\uparrow}$ *are the curvature boundary row, the cyclic Bianchi ledger, the tensorial transport row, the source connection provenance, and the finite* Cont *and* Pkg *ledgers. De Rham representatives, characteristic-class rows, invariant-polynomial exactness rows, and standard bridge data remain obligations of* $\mathsf{ChernWeil}^{\uparrow}$ *or* $\mathsf{DeRham}^{\uparrow}$*, not exports of* $\mathsf{Curvature}^{\uparrow}$*.*

Proof. Project the public curvature carrier by Definition 135.1 and the scope theorem Definition 135.45. The visible source entries are the boundary row, the connection provenance, and the finite ledger rows that carry the bracket packet.

Next apply Definition 135.42 and Definition 135.43. These add only the cyclic SigRel ledger and the tensorial transport row, both still carried as BHist, Cont, hsame, and Pkg data.

The exhaustion clause is the reverse projection. Every row named by the export appears in one of the listed carrier or obligation projections, while de Rham representatives and characteristic-class rows do not appear in those projections. They therefore belong to the downstream certificates that consume the curvature packet. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope visible input exhaustion`

Definition 135.19 (Curvature Chern-Weil source envelope)**.** *The* $\mathsf{Curvature}^{\uparrow}$ *export to* $\mathsf{ChernWeil}^{\uparrow}$ *is the finite source envelope*

$$\mathsf{CurvatureChernWeilSourceEnvelope}(\kappa, \delta, \rho, \lambda, \chi)$$

where $\kappa : \mathsf{BHist}$ *is the curvature commutator-boundary row,* $\delta : \mathsf{BHist}$ *is the displayed de Rham target row supplied by the consumer,* $\rho : \mathsf{BHist}$ *is the shared* Pkg *provenance row,* $\lambda : \mathsf{BHist}$ *is the connection ledger row, and* $\chi : \mathsf{BHist}$ *is the classifier row read by the Chern-Weil packet.*

The envelope is admitted only when $\mathsf{UnaryHistory}(\kappa)$*,* $\mathsf{UnaryHistory}(\delta)$*,* $\mathsf{UnaryHistory}(\rho)$*,* $\mathsf{UnaryHistory}(\lambda)$*, and* $\mathsf{UnaryHistory}(\chi)$ *hold, when finite* Cont *ledgers read* ρ *from* κ *and* δ *and read* χ *from* ρ *and* λ*, and when the carried* hsame *readback identifies* χ *with the finite appended history obtained by first pairing the curvature boundary with the de Rham row and then appending the connection ledger. The* Pkg *provenance binds all five rows to the same accepted curvature source and consumer-facing de Rham display.*

Lean4 (definition) `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope`

Theorem 135.20 (Curvature Chern-Weil source envelope coverage)**.** *Every accepted* $\mathsf{Curvature}^{\uparrow}$ *carrier of Definition 135.1, together with a displayed de Rham consumer row* $\delta : \mathsf{BHist}$ *whose provenance is tied to the same finite* Pkg *ledger, repacks as a* $\mathsf{CurvatureChernWeilSourceEnvelope}(\kappa, \delta, \rho, \lambda, \chi)$*. The row* κ *is the exported commutator boundary,* ρ *is the shared provenance row,* λ *is the chosen connection ledger row, and* χ *is the classifier row obtained by the finite* Cont *readback from those rows.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope coverage`

Proof. Project the accepted curvature carrier through Definition 135.1. This gives the boundary row κ, the source connection packet, the derivative ledgers, and the Pkg provenance row already tied to the same finite history surface.

Apply Definition 135.24. Its forward direction lists every exported curvature witness and its reverse direction repacks exactly those rows as the visible curvature ledger.

Add the displayed consumer row δ with the assumed provenance tie. The finite Cont rows first bind κ and δ into ρ and then bind ρ and the connection ledger λ into χ, while the carried hsame readback supplies the displayed appended history required by Definition 135.19. □

Theorem 135.21 (Curvature Chern-Weil source envelope readback)**.** *An admitted* CurvatureChernWeilSourceEnvelo *projects exactly the five rows consumed by* $\mathsf{ChernWeil}^{\uparrow}$*: the curvature boundary row* κ*, the de Rham target row* δ*, the shared provenance row* ρ*, the connection ledger row* λ*, and the classifier row* χ*. These projections are the same row positions as the existing Chern-Weil source envelope consumes, with* κ *occupying the curvature input and* δ *occupying the de Rham input.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope derham transport readback`
Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope readback`

Proof. Unpack the envelope definition. The tuple has five displayed BHist coordinates, and each coordinate is constrained by UnaryHistory inside the same finite source packet.

Read the two finite Cont rows. The first identifies ρ as the provenance row produced from the curvature and de Rham coordinates; the second identifies χ as the classifier endpoint produced from that provenance row and the connection ledger.

Finally use the hsame readback clause. It states that the classifier row is precisely the appended history over κ, δ, and λ, so projection returns no hidden coordinate besides the five displayed rows. □

Theorem 135.22 (Curvature Chern-Weil source envelope exactness)**.** *The envelope of Definition 135.19 exports no coordinate curvature form, no de Rham cohomology class, no characteristic-class equality, and no standard bridge. Its public content is exactly the curvature boundary row, the displayed de Rham target row, the shared* Pkg *provenance row, the connection ledger row, the classifier row, and the finite* Cont *and* hsame *witnesses tying those rows together.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope exactness`
Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope semantic name certificate`

Proof. Use Definition 135.25 to identify the curvature side exported to the invariant-polynomial consumer. That theorem supplies the source connection certificate, boundary row, transported endpoint ledger, visible classifier rows, and provenance row, while excluding de Rham classes, characteristic-class equalities, and standard bridges from $\mathsf{Curvature}^{\uparrow}$ itself.

The source envelope adds only the displayed row δ and the two finite readback ledgers required to match the Chern-Weil input shape. By Definition 135.24, every curvature contribution is already one of the listed BHist, Cont, hsame, or Pkg rows.

Therefore any attempted coordinate curvature form, cohomology class, characteristic-class equality, or standard bridge would have to be a sixth public coordinate. No such coordinate appears in Definition 135.19, so the export is exact. □

Theorem 135.23 (Curvature tensorial endpoint transport)**.** *Bundle, manifold, and section classifier transport of the section, fibre, base, and tangent rows preserves the curvature endpoint row. After transporting the two derivative orderings by the source* $\mathsf{Connection}^{\uparrow}$ *section-linearity and stability-ledger exactness obligations, the transported commutator boundary is* hsame *to the boundary row of the transported* $\mathsf{Curvature}^{\uparrow}$ *packet.*

Proof. Transport the base and tangent rows by the $\mathsf{Manifold}^{\uparrow}$ classifiers and the fibre and section rows by the inherited bundle and section classifiers. The source connection certificate keeps these transports tied to the same carrier packet and provenance row.

Apply the section-linearity and stability-ledger exactness obligations of $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ to the first derivative ordering. Repeat the same construction for the reversed derivative ordering, so the two transported endpoints remain the endpoints of certified Cont ledgers.

Compare the two transported endpoint ledgers through the commutator-boundary row. The boundary comparison is componentwise hsame, hence the curvature endpoint row is preserved by the transported $\mathsf{Curvature}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier tensorial endpoint transport`

Theorem 135.24 (Curvature visible ledger coverage)**.** *Every exported* $\mathsf{Curvature}^{\uparrow}$ *witness is one of the source connection certificate rows, the base, fibre, section, tangent-pair, two derivative-composite ledger rows, the commutator boundary row, the classifier transport rows, or the* Pkg *provenance rows. Conversely, exactly these rows repack as the visible* $\mathsf{Curvature}^{\uparrow}$ *ledger.*

Proof. For the forward reading, project an accepted curvature witness through the carrier tuple of Definition 135.1. The projections are precisely the source connection certificate, geometric rows, tangent pair, derivative composites, boundary row, classifier transports, and provenance rows.

For the reverse reading, begin with those listed rows over a common source connection packet. The boundary source obligation repacks the connection, tangent, derivative, boundary, and provenance rows, while the classifier stability and endpoint transport obligations repack the transport rows.

Thus the public ledger is exact. Each exported witness is a listed row, and each listed row has a constructor role in the visible $\mathsf{Curvature}^{\uparrow}$ certificate surface. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier visible ledger coverage`

Theorem 135.25 (Curvature ChernWeil consumer boundary)**.** *Any accepted* $\mathsf{Curvature}^{\uparrow}$ *row exports exactly the invariant-polynomial input packet consumed by* $\mathsf{ChernWeil}^{\uparrow}$*: the source connection certificate, the curvature boundary row, the transported endpoint ledger, the visible Bianchi and classifier rows when present, and the* Pkg *provenance row. This export does not assert a de Rham class, a characteristic-class equality, a standard bridge, or a Lean verification target for* $\mathsf{ChernWeil}^{\uparrow}$*.*

Proof. Project the accepted curvature row to the fields listed in Definition 135.1 and to the public certificate rows in this section. These projections provide the boundary row and transport ledgers that an invariant-polynomial consumer can read.

Package those projections as the input side of $\mathsf{NameCert}_{\mathsf{ChernWeil}^{\uparrow}}$. The packet contains only the curvature boundary, the connection provenance, and the visible ledger rows needed to form polynomial expressions over the accepted curvature data.

The exclusions follow from ledger coverage. Since no de Rham row, characteristic-class comparison, standard bridge, or Lean target is part of the exported $\mathsf{Curvature}^{\uparrow}$ ledger, none is available to $\mathsf{ChernWeil}^{\uparrow}$ without an independent certificate. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope consumer boundary`

Definition 135.26 (Curvature-to-ChernWeil input envelope)**.** *The* $\mathsf{Curvature}^{\uparrow}$ *export to* $\mathsf{ChernWeil}^{\uparrow}$ *is admitted as a five-row source envelope*

$$(\mathsf{curvature}, \mathsf{derham}, \mathsf{provenance}, \mathsf{connectionLedger}, \mathsf{classRow})$$

when $\mathsf{curvature}$ *is the carried curvature boundary row of Definition 135.25,* derham *is the de Rham target row consumed by* $\mathsf{ChernWeil}^{\uparrow}$*,* $\mathsf{provenance}$ *is obtained by* $\mathsf{Cont}(\mathsf{curvature}, \mathsf{derham}, \mathsf{provenance})$*, and* $\mathsf{classRow}$ *is obtained by* $\mathsf{Cont}(\mathsf{provenance}, \mathsf{connectionLedger}, \mathsf{classRow})$*. The row* $\mathsf{connectionLedger}$ *records the chosen-connection face already carried by the curvature provenance packet, so the envelope contains only displayed* BHist *and* Cont *data.*

Lean4 (definition) `BEDC.Derived.CurvatureUp.CurvatureChernWeilConsumerRow`

Theorem 135.27 (Curvature ChernWeil source-envelope projection)**.** *Every envelope of Definition 135.26 projects to unary rows for* $\mathsf{curvature}$*,* derham*,* $\mathsf{provenance}$*,* $\mathsf{connectionLedger}$*, and* $\mathsf{classRow}$*; to the continuation rows* $\mathsf{Cont}(\mathsf{curvature}, \mathsf{derham}, \mathsf{provenance})$ *and* $\mathsf{Cont}(\mathsf{provenance}, \mathsf{connectionLedger}, \mathsf{class}$ *and to the readback row*

$$\mathsf{hsame}(\mathsf{classRow}, \mathsf{append}(\mathsf{append}(\mathsf{curvature}, \mathsf{derham}), \mathsf{connectionLedger})).$$

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope source envelope projection`

Proof. Unpack the five-row envelope. Its admission clauses give the unary curvature row, unary de Rham row, unary connection-ledger row, and the two displayed Cont rows.

Apply closure of unary history under the first Cont row to obtain the provenance unary row. Apply the same closure principle to the second Cont row to obtain the class-row unary projection.

Finally compose the readbacks carried by the two Cont rows. The first readback identifies provenance with append(curvature, derham); the second appends connectionLedger and identifies the endpoint with classRow. This is exactly the displayed hsame row. □

Theorem 135.28 (Curvature ChernWeil consumer exactness)**.** *The* $\mathsf{Curvature}^{\uparrow}$ *export to* $\mathsf{ChernWeil}^{\uparrow}$ *consists exactly of the source envelope rows of Definition 135.26 together with the existing connection provenance exposed by Definition 135.24. It exports no de Rham class, characteristic-class equality, or standard bridge beyond those rows.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope consumer exactness`

Proof. First project the accepted curvature packet by Definition 135.24 and Definition 135.25. These give the curvature boundary row, transported endpoint ledger, visible classifier and Bianchi rows, and the connection provenance available to a $\mathsf{ChernWeil}^{\uparrow}$ consumer.

Next form the five-row envelope of Definition 135.26. By Definition 135.27, every public row of that envelope is one of the unary row projections, one of the two continuation rows, or the displayed hsame readback of the class row.

Combining the two projections gives exactness. The only rows exported from $\mathsf{Curvature}^{\uparrow}$ are the existing connection provenance and the source-envelope rows just listed; a de Rham class, characteristic-class equality, or standard bridge would require an additional certificate not present in the curvature ledger. □

Definition 135.29 (Curvature Chern-Weil consumer row)**.** *A curvature Chern-Weil consumer row is a concrete* BHist *packet*

$$\mathsf{CurvatureChernWeilConsumerRow}(\kappa, d, p, \gamma, \lambda)$$

whose coordinates are the exported curvature boundary row κ, the displayed de Rham row d, the shared provenance row p, the connection ledger row γ, and the characteristic-class endpoint row λ. The packet is accepted exactly when these five rows form the source envelope consumed by Definition 272.1: κ, d, and γ are unary source rows, p is the shared Cont *provenance over the curvature and de Rham inputs, and λ is the final* Cont *endpoint with its carried* hsame *readback against the appended curvature, de Rham, and connection ledger.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureTasteGate single carrier alignment`

Theorem 135.30 (Curvature Chern-Weil consumer stability)**.** *Let* $\mathsf{CurvatureChernWeilConsumerRow}(\kappa, d, p, \gamma, \lambda)$ *be accepted. If an exported curvature boundary κ' is related to κ by the* hsame *transport supplied by* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$*, and the invariant-polynomial row, provenance row p, de Rham row d, and connection ledger row γ are kept in the same carrier classifier, then the Chern-Weil endpoint transported through that classifier is again the endpoint row λ of an accepted consumer packet.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope consumer stability`

Proof. Project the accepted consumer packet to its curvature source. By Definition 135.45, the boundary row, classifier rows, finite ledgers, and provenance row are all public rows of the same $\mathsf{Curvature}^{\uparrow}$ certificate.

Transport the boundary along the displayed hsame comparison while keeping the invariant-polynomial, de Rham, provenance, and connection ledger rows fixed in the carrier classifier. The projected rows therefore still occupy the same source-envelope positions.

Apply Definition 272.10. Its classifier stability clause transports the invariant-polynomial endpoint across the curvature boundary comparison, so the final class row is read as the same λ through the carrier classifier. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope curvature transport`

Theorem 135.31 (Curvature Chern-Weil consumer envelope projection)**.** *Every accepted packet of Definition 135.29 projects to the exact rows of the Chern-Weil source envelope: the unary curvature row κ, the unary de Rham row d, the unary connection ledger row γ, the shared* Cont *provenance row p, the final* Cont *class row λ, and the readback* hsame *of λ against the appended curvature, de Rham, and connection ledger.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope consumer envelope projection`

Proof. Unpack the consumer packet. Its five coordinates are concrete BHist rows, and acceptance says that they occupy the curvature, de Rham, provenance, connection ledger, and endpoint positions of the source envelope of Definition 272.1.

Project the unary row obligations for κ, d, and γ, then project the two finite Cont ledgers. The first ledger supplies the shared provenance row p from the curvature and de Rham inputs, and the second supplies the endpoint row λ from that provenance row and the connection ledger.

Apply Definition 272.14 to identify the consumer-facing curvature and de Rham rows as the Chern-Weil input surface. The checked source-envelope projection cited in the Chern-Weil chapter then reads back the same rows and the displayed hsame comparison of λ with the appended curvature, de Rham, and connection ledger. □

Theorem 135.32 (Curvature Chern-Weil source-envelope row)**.** *Let a* $\mathsf{Curvature}^{\uparrow}$ *row be accepted from the* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet in Definition 135.1. Its export to the* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope supplies exactly the five source-envelope rows consumed by the Chern-Weil projection theorem: the curvature boundary row, the de Rham target row slot, the shared* Cont *provenance row, the selected-connection ledger face, and the characteristic-class endpoint row slot. The visible curvature-side fields are projected only as* BHist *rows,* hsame *endpoint comparisons, and finite* Cont *ledgers, with the* Pkg *provenance retained from the source connection packet.*

Proof. Project the accepted row through Definition 135.1. This gives the source $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ packet, tangent-pair rows, derivative endpoints, the commutator boundary, the finite boundary ledger, and the Pkg provenance.

Apply Definition 134.5 to identify the exported curvature boundary as a BHist row. Apply Definition 135.43 and Definition 135.44 to keep the endpoint comparisons and finite readback inside the same curvature packet.

The remaining Chern-Weil rows are interface slots rather than curvature-side conclusions. The de Rham target row slot and characteristic-class endpoint row slot are left for $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ and $\mathsf{ChernWeil}^{\uparrow}$, while the selected-connection ledger face and shared provenance are copied from the projected source connection packet. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope source envelope row`

Theorem 135.33 (Curvature Chern-Weil provenance ledger)**.** *The provenance exported by* $\mathsf{Curvature}^{\uparrow}$ *for a* $\mathsf{ChernWeil}^{\uparrow}$ *consumer is exactly the source connection packet, the curvature boundary row, the Bianchi ledger, the tensorial transport row, and the* Pkg *provenance certified by Definition 135.45. No additional coordinate connection form, analytic curvature form, or uncarried equivalence relation is part of this ledger.*

Proof. Start with the carrier tuple in Definition 135.1. Its first projection is the source connection packet, and Definition 134.5 supplies the boundary row read from the two derivative orders.

Project the cyclic row by Definition 135.42. Project the section and tangent transport row by Definition 135.43. These two ledgers are finite Cont consequences of the same boundary data and the same source packet.

Finally apply Definition 135.45. That theorem collects the carrier, boundary, Bianchi, tensorial transport, exactness, and provenance rows as the public $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ surface, so the listed rows are precisely the provenance visible to the Chern-Weil consumer. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope provenance ledger transport`

Theorem 135.34 (Curvature Chern-Weil visible class boundary)**.** *The* $\mathsf{Curvature}^{\uparrow}$ *export licenses only the visible input side of the* $\mathsf{ChernWeil}^{\uparrow}$ *characteristic-class boundary. It supplies the accepted curvature boundary, its* hsame *transport, its finite* Cont *ledgers, and its* Pkg *provenance, but it does not license a de Rham class, an analytic characteristic class, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope visible class boundary`

Proof. Read the visible input from Definition 135.1. The boundary, derivative endpoints, transport comparisons, and provenance are all displayed as BEDC rows, and Definition 135.44 states that every public curvature row is generated from this listed surface.

Apply Definition 135.45 to repack those rows as the $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ export. This gives exactly the input face that $\mathsf{ChernWeil}^{\uparrow}$ may project before introducing any de Rham dependency.

The negative clauses follow from the same projection. No de Rham carrier, analytic characteristic-class equality, or standard bridge occurs among the projected rows, so those objects require their own certificate and cannot be read from $\mathsf{Curvature}^{\uparrow}$ alone. □

Definition 135.35 (Curvature Chern-Weil handoff packet)**.** *A Curvature-to-Chern-Weil handoff packet is a displayed* BHist *tuple*

$$\mathcal{H} = (\mathcal{R}, \mathcal{W}, \kappa, \beta, \tau, \lambda, \rho)$$

where $\mathcal{R}$ *is an accepted* $\mathsf{Curvature}^{\uparrow}$ *carrier row,* $\mathcal{W}$ *is the* $\mathsf{ChernWeil}^{\uparrow}$ *source-envelope row fed by* $\mathcal{R}$*,* $\kappa : \mathsf{BHist}$ *is the curvature boundary row,* β *is the cyclic Bianchi ledger,* τ *is the tensorial transport row for section and tangent replacement,* λ *is the finite* Cont *projection from the curvature rows into the Chern-Weil envelope, and* ρ *is the shared* Pkg *provenance row. The packet is accepted exactly when these fields project from the carrier of Definition 135.1, the public export of Definition 135.45, and the source-envelope interface of Definition 272.1.*

Theorem 135.36 (Curvature handoff Bianchi transport)**.** *For any handoff packet of Definition 135.35, classifier-preserving replacement of the* $\mathsf{Curvature}^{\uparrow}$ *section row and tangent-direction rows transports both the Bianchi ledger* β *and the closed-endpoint input consumed by* $\mathsf{ChernWeil}^{\uparrow}$*. The transported handoff has the same* Pkg *provenance and reaches the Chern-Weil source envelope by the transported* hsame *comparisons and the same finite* Cont *projection.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilHandoffPacket bianchi transport`

Proof. Project the handoff packet to its curvature carrier row. The Bianchi component is the cyclic ledger supplied by Definition 135.42, and the section and tangent replacements are governed by the tensorial row of Definition 135.43.

Transport the curvature boundary, Bianchi ledger, and endpoint rows through the inherited hsame comparisons. The tensorial transport keeps the base, fibre, connection source, and Pkg provenance fixed, so the transported packet still has the same dependency surface.

Apply the Chern-Weil closed-form endpoint obligation to the transported curvature input. Since the projection λ is a finite Cont row from the handoff packet into the Chern-Weil source envelope, the closed-endpoint input is transported with the envelope rather than recomputed as an external form. □

Theorem 135.37 (Curvature handoff provenance exactness)**.** *Every field of a Curvature-to-Chern-Weil handoff packet is either a public* Curvature$^{\uparrow}$ *row or a* ChernWeil$^{\uparrow}$ *envelope row reached by the displayed* Cont *projection. The handoff exports no de Rham class, no characteristic-class equality, no coordinate curvature form, and no standard bridge.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilHandoffPacket provenance exactness`

Proof. Project the handoff fields from Definition 135.35. The curvature carrier, boundary row, Bianchi ledger, tensorial transport row, and provenance row are exactly the public rows covered by Definition 135.45.

Use the ledger exactness obligation of Definition 135.44 to rule out unlisted curvature data. The only consumer-facing row beyond those projections is the finite Cont projection into the Chern-Weil source envelope.

The Chern-Weil side is therefore an envelope readback, not an added bridge theorem. De Rham classes, characteristic-class equalities, coordinate curvature forms, and standard bridges are absent because no field of the handoff packet has such a source or constructor role. □

Theorem 135.38 (Curvature handoff consumer coverage)**.** *Every* ChernWeil$^{\uparrow}$ *source envelope whose curvature component is supplied by an accepted* Curvature$^{\uparrow}$ *row admits a handoff packet of Definition 135.35. Conversely, each accepted handoff exports exactly the invariant-polynomial input rows that* ChernWeil$^{\uparrow}$ *may consume from* Curvature$^{\uparrow}$*: the boundary row, Bianchi ledger, tensorial transport row, finite projection, and shared* Pkg *provenance.*

Proof. For coverage, begin with a Chern-Weil source envelope whose curvature component is supplied by an accepted curvature row. Apply Definition 135.25 to project the boundary row, transported endpoint ledger, visible Bianchi and classifier rows, and provenance row.

Repack those rows with the source envelope as the tuple of Definition 135.35. The source-envelope definition supplies the finite Cont projection into ChernWeil$^{\uparrow}$, while the curvature carrier supplies the accepted boundary, Bianchi, transport, and provenance fields.

For the converse, project an accepted handoff packet. Its consumer-facing fields are precisely the curvature rows listed in the tuple and the finite projection into the envelope; by provenance exactness, there is no additional de Rham endpoint, characteristic-class equality, coordinate form, or bridge row available for consumption. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilHandoffPacket consumer coverage`

Theorem 135.39 (Curvature connection-carrier scope)**.** *Every* $\mathsf{Curvature}^{\uparrow}$ *carrier packet of Definition 135.1 has a visible* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet as its dependency source. The base row, fibre row, section row, tangent-pair rows, iterated derivative rows, commutator boundary row, ledger row, and provenance row are obtained by projection from that packet together with the boundary row of Definition 134.5.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier connection carrier scope`

Proof. Project the connection certificate $\mathcal{C}$ from the displayed tuple. Its base, fibre, section, tangent, derivative, dependency, and provenance rows are already named by the connection certificate surface.

Apply Definition 134.5 to the two tangent-direction rows. This gives the commutator boundary as a BHist row whose source data is the same base, fibre, section, tangent-pair, derivative-endpoint, and Pkg provenance data.

Read the ledger β from that boundary row and repack the projected rows into the curvature tuple. Since every row used in the repacking is either a projection from $\mathcal{C}$ or the displayed commutator boundary, the carrier scope contains no additional geometric object. □

Theorem 135.40 (Curvature bracket classifier obligation)**.** *For packets of Definition 135.1, the curvature classifier is stable under* hsame *on the commutator-boundary row and under the connection classifier transport inherited from* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$*. If two source connection packets classify the same base, fibre, section, tangent-direction, and derivative-endpoint rows, then their curvature packets classify the same bracket precisely when the transported boundary rows are related by* hsame *inside the carried* Cont *ledger.*

Proof. Project the two curvature packets to their source connection packets. The inherited connection classifier supplies the base, fibre, section, tangent-direction, derivative-endpoint, and provenance comparisons.

Transport the commutator boundary along those projected comparisons. Since the boundary row is the row provided by Definition 134.5, the two derivative orders remain attached to the same connection package after transport.

Repack the transported rows as a curvature classifier witness. The only additional comparison is hsame on the displayed boundary row, so classifier stability is obtained without introducing a host-level curvature tensor or quotienting the history ledger. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier classifier obligation`

Theorem 135.41 (Curvature antisymmetric bracket obligation)**.** *For a curvature packet* $\mathcal{R}$*, exchanging the tangent-direction rows* u *and* v *exchanges the iterated derivative endpoint rows* d_{uv} *and* d_{vu} *and reverses the displayed commutator boundary. The two curvature packets are classified through the same* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet and the* hsame *transport of the reversed boundary row.*

Proof. Project the shared connection certificate and the two tangent rows from $\mathcal{R}$. The connection classifier keeps the base, fibre, section, and provenance rows fixed, so the exchanged tuple has the same visible dependency source.

Apply Definition 134.5 first to (u, v) and then to (v, u). The two constructions expose the same iterated derivative rows in opposite order and therefore display opposite commutator boundaries.

Transport the reversed boundary endpoint along hsame and retain the inherited classifier witness for the connection component. Repacking these transported rows gives the required curvature-packet comparison. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier antisymmetric bracket obligation`

Theorem 135.42 (Curvature Bianchi ledger obligation)**.** *Given three tangent-direction rows u, v, w :* BHist *over the same base row of a curvature packet, the first Bianchi row is the cyclic* BHist *ledger comparing the three displayed commutator boundaries for (u, v, w), (v, w, u), and (w, u, v). The certificate obligation is exactly that this cyclic row is a finite* Cont *consequence of the three connection-boundary rows and their shared* Pkg *provenance.*

Proof. Read the three tangent rows through the same source $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ packet. For each ordered pair, apply Definition 134.5 to obtain the displayed commutator boundary row with the same base, fibre, section, and provenance projections.

Form the cyclic ledger by appending the three boundary rows in the displayed order (u, v, w), (v, w, u), and (w, u, v). Each append is a Cont step between rows already carried by the curvature packet, and each endpoint comparison is an hsame comparison of boundary rows.

The Bianchi witness is this finite cyclic ledger. It asserts no coordinate identity beyond the listed rows; it records that the cyclic commutator comparison is present as a BEDC history package generated from the connection boundary surface. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier bianchi ledger obligation`

Theorem 135.43 (Curvature tensorial transport obligation)**.** *The curvature bracket packet is tensorial with respect to certified replacement of its section row and tangent-direction rows. Replacing s, u, or v by rows classified with them by the source connection packet transports the derivative endpoints, the commutator boundary κ, and the Bianchi ledger by* Cont *and* hsame*, while preserving the same base, fibre, and* Pkg *provenance rows.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier tensorial transport obligation`

Proof. Begin with the source connection classifier witnesses for the section row and the two tangent-direction rows. They keep the base and fibre rows fixed up to the inherited dependency classifiers and expose the derivative endpoint transport rows.

Use those endpoint transports to rebuild the two derivative orders d_{uv} and d_{vu}. The commutator boundary is then transported by the same boundary construction used in Definition 134.5.

For the Bianchi row, repeat the argument for each cyclic placement of the transported tangent rows. The three transported boundary rows append to the transported cyclic ledger, and the unchanged provenance row identifies the result as the same curvature package read through classified source rows. □

Theorem 135.44 (Curvature ledger exactness obligation)**.** *The* $\mathsf{Curvature}^{\uparrow}$ *obligation surface consists exactly of the source* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *packet, the base, fibre, section, two tangent-direction rows, two derivative endpoint rows, the connection commutator-boundary row, the antisymmetric bracket transport row, the cyclic Bianchi ledger row, the classifier transport rows generated by* hsame *and the connection classifier, and the* Pkg *provenance row. No coordinate chart, host tensor object, covariant exterior derivative, characteristic-class row, or external bracket operation is part of the certificate surface.*

Proof. Every accepted curvature row projects from the tuple in Definition 135.1. Projection gives the source certificate, the geometric rows, the derivative endpoints, the commutator boundary, the ledger row, and the provenance row.

Conversely, each listed row is consumed by one of the certificate obligations. The classifier obligation uses the source comparisons and boundary hsame row; antisymmetry uses the exchanged

tangent pair and reversed boundary row; the Bianchi obligation uses the three cyclic boundary rows; tensorial transport uses the section and tangent replacement rows.

Therefore the ledger is exact: all public certificate moves are generated by the displayed BHist, Cont, hsame, and Pkg rows, and every displayed row has a named role in one of those moves. Nothing remains to be read from an uncarried host tensor. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier ledger exactness obligation`

Theorem 135.45 (Curvature NameCert scope obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{Curvature}^\uparrow}$ *surface exported to* $\mathsf{ChernWeil}^\uparrow$ *is the curvature bracket carrier, its connection-carrier scope, its classifier stability, its antisymmetric bracket row, its first Bianchi cyclic ledger, its tensorial transport row, and its ledger exactness row over* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$*. Any downstream packet consuming* $\mathsf{NameCert}_{\mathsf{Curvature}^\uparrow}$ *may project the bracket boundary* κ*, the cyclic ledger, and the provenance rows, but it may not assume a stronger analytic curvature form or a standard bridge.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier semantic name certificate`

Proof. Collect the carrier of Definition 135.1 together with the five obligation rows proved above. These rows provide the public carrier, scope, classifier, stability, ledger, and exactness fields required of a BEDC naming certificate.

The downstream projection to $\mathsf{ChernWeil}^\uparrow$ is by ordinary tuple projection. It receives the boundary row, the cyclic ledger, the source connection certificate, and the provenance fields, all still expressed as finite BHist and Cont data.

The final clause is exactness again: because the exported surface contains only those rows, no downstream consumer may read a coordinate curvature form, a de Rham class, or a standard bridge from $\mathsf{NameCert}_{\mathsf{Curvature}^\uparrow}$ alone. Such data must be supplied by its own certificate. □

Theorem 135.46 (Curvature exactness predicate surface)**.** *For* $\mathsf{Curvature}^\uparrow$*, exactness is precisely coverage, soundness, and completeness for the displayed bracket carrier, boundary classifier, Bianchi ledger, tensorial transport row, and* $\mathsf{ChernWeil}^\uparrow$ *consumer projection. The surface is read only over* BHist*,* Cont*,* hsame*,* Pkg*,* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{Bundle}^\uparrow}$*, and* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$*: coverage says every displayed row has one of these roles; soundness says every accepted curvature move is generated by the displayed rows; completeness says every downstream curvature projection factors through them.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier exactness predicate surface`

Proof. Project the carrier row from Definition 135.1. It supplies the base, fibre, section, tangent-direction, derivative endpoint, commutator-boundary, provenance, and source-certificate rows, with the $\mathsf{Bundle}^\uparrow$ and $\mathsf{Manifold}^\uparrow$ dependencies inherited through $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$.

Next project the classifier, antisymmetry, Bianchi, tensorial transport, ledger exactness, and consumer-boundary obligations. These theorems account for every public use of the bracket carrier: boundary comparison, exchange of tangent directions, cyclic ledger formation, certified replacement of section and tangent rows, and projection to $\mathsf{ChernWeil}^\uparrow$.

Coverage follows because each displayed row is named in one of those obligations. Soundness follows because each accepted move is built by finite Cont transport, hsame comparison, tuple projection, and the recorded Pkg provenance. Completeness follows because the downstream consumer receives exactly the boundary, cyclic ledger, source certificate, dependency certificate, and provenance rows already carried by the same tuple. □

Theorem 135.47 (Curvature standard bridge boundary)**.** *Any standard reading of* $\mathsf{Curvature}^{\uparrow}$ *may expose only the displayed connection-boundary row, antisymmetric classifier row, Bianchi ledger row, tensorial transport row, and exactness surface. It may not expose a coordinate curvature tensor, a de Rham representative, a characteristic class, host equality, or a* bridgeChecked *claim from* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *alone.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier standard bridge boundary`

Proof. Apply the exactness surface of Definition 135.46. A standard reader can project only rows that are covered by the carrier and generated by the named certificate obligations.

The permitted rows are therefore the connection-boundary row, the antisymmetric classifier row, the Bianchi ledger row, the tensorial transport row, and the exactness predicate itself. These are precisely the rows already exported by the NameCert scope theorem.

Apply Definition 135.45 for the negative boundary. Since the public certificate contains no coordinate curvature tensor, de Rham representative, characteristic class, host equality row, or standard-bridge witness, none of those objects can be recovered from the $\mathsf{Curvature}^{\uparrow}$ certificate without an additional certificate carrying that data. □

Theorem 135.48 (Curvature ten-field status record)**.** *The roadmap ten-field template for* $\mathsf{Curvature}^{\uparrow}$ *is populated as follows:*

1. *the traditional target is the curvature bracket of a connection;*
2. *the BEDC source is* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *together with the* $\mathsf{Bundle}^{\uparrow}$ *and* $\mathsf{Manifold}^{\uparrow}$ *dependency rows;*
3. *the carrier is Definition 135.1;*
4. *the classifier entry is the boundary classifier row of this section;*
5. *the stability entry is the antisymmetry, Bianchi, and tensorial row collection;*
6. *the ledger entry is visible ledger exactness;*
7. *the core theorem list is the named obligation row collection in this section;*
8. *the exactness entry is Definition 135.46;*
9. *the standard bridge entry is Definition 135.47;*
10. *the status entry keeps closure and verification as independent axes.*

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureUp StdBridge`

Proof. Read the template fields from the carrier and obligation rows already established in this section. The traditional target is the bracket interpretation of the connection boundary, while the BEDC source and dependency rows are projected from $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ and its $\mathsf{Bundle}^{\uparrow}$ and $\mathsf{Manifold}^{\uparrow}$ certificates.

The carrier, classifier, antisymmetry, Bianchi, tensorial transport, ledger exactness, and core obligation entries are exactly the displayed rows named by the section labels. The exactness and standard-bridge entries are supplied by Definition 135.46 and Definition 135.47.

The status field records no extra mathematical object. It reports the theory closure and verification state on separate axes, so a paper-side certificate surface does not by itself assert a Lean theorem, host equality, or standard bridge. □

Theorem 135.49 (Curvature NameCert finite basis)**.** *The public* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *basis is exactly the finite row family consisting of the carrier tuple of Definition 135.1, the connection-carrier scope row of Definition 135.39, the bracket classifier obligation of Definition 135.40, the antisymmetric bracket obligation of Definition 135.41, the Bianchi ledger obligation of Definition 135.42, the tensorial transport obligation of Definition 135.43, the ledger exactness obligation of Definition 135.44, and the scope obligation of Definition 135.45. Every public curvature certificate row is a projection from this family, and every row in the family is consumed by at least one public* $\mathsf{Curvature}^{\uparrow}$ *certificate field.*

Proof. Project first from the carrier tuple in Definition 135.1. This gives the source connection certificate, base row, fibre row, section row, two tangent-direction rows, derivative endpoints, commutator boundary, cyclic ledger, classifier transports, and provenance row.

The named obligation rows then identify how those projections are used. The connection-carrier scope row fixes the inherited source surface; the bracket classifier and antisymmetric bracket rows control boundary comparison; the Bianchi and tensorial transport rows control cyclic and replacement ledgers; and ledger exactness states that no additional public row is available.

Conversely, each listed row has a named role in the public certificate fields. Therefore the displayed family is a finite basis for $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ rather than a sample of a larger analytic curvature interface. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier finite basis`

Theorem 135.50 (Curvature consumer row coverage)**.** *Every downstream consumer of the finite basis in Definition 135.49 receives only* BHist*,* Cont*,* hsame*,* Pkg*, and* SigRel *rows. Moreover, each row visible to such a consumer has a source in one of the basis theorems: carrier and boundary rows come from the carrier tuple and connection-carrier scope row, classifier rows from the bracket classifier obligation, reversal rows from the antisymmetric bracket obligation, cyclic rows from the Bianchi ledger obligation, replacement rows from the tensorial transport obligation, provenance rows from ledger exactness, and export permission from the scope obligation.*

Proof. Case split over the finite basis named in Definition 135.49.

1. The carrier tuple and connection-carrier scope cases expose BHist rows together with inherited Pkg provenance from $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$.
2. The bracket classifier, antisymmetric bracket, Bianchi ledger, and tensorial transport cases expose only Cont, hsame, and SigRel comparison rows between already carried histories.
3. The ledger exactness and scope cases expose no new row sort. They identify which carried BHist, Cont, hsame, Pkg, and SigRel rows may be projected by a downstream certificate.

These cases cover the whole basis. Hence a consumer cannot obtain a coordinate curvature form, host tensor operation, de Rham class, or standard bridge by projecting $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ alone. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureBracketCarrier consumer row coverage`

Theorem 135.51 (Curvature Chern-Weil export determinacy)**.** *Let* $\mathcal{R}$ *and* $\mathcal{R}'$ *be two public* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *packets whose rows agree on the finite basis of Definition 135.49. Then their projections to the* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope determine the same curvature boundary* κ*, Bianchi ledger, tensorial transport row, and provenance packet. Consequently the curvature component of the* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope is determined by the finite* $\mathsf{Curvature}^{\uparrow}$ *basis and not by any uncarried connection form or host-level curvature object.*

Proof. Apply Definition 135.49 to both packets. Agreement on the basis identifies the carrier projections, the boundary row, the cyclic ledger, the tensorial transport row, and the Pkg provenance row.

Next use Definition 135.25. That theorem packages exactly those curvature projections as the input side consumed by $\mathsf{ChernWeil}^{\uparrow}$, while excluding any de Rham row, characteristic-class equality, standard bridge, or Lean verification target.

Finally project the source envelope of Definition 272.1. Its curvature component is the public $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ packet carrying the boundary and provenance exported by the scope rule, so the equal basis rows force the same curvature source component in both envelopes. □

Lean4 ✓ `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope export determinacy`

Closure status for $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$.

Constructive story: A curvature row starts from a carried $\mathsf{Connection}^{\uparrow}$ packet and selects two displayed tangent-direction derivative routes whose commutator boundary is recorded as a BHist bracket endpoint. Histories are accepted only when that bracket carrier can project back to its connection source, the two derivative rows, the antisymmetric bracket row, and the finite provenance rows; two accepted rows classify together when connection classifiers and hsame transport all bracket, boundary, and source projections. The source covers these connection-boundary packets and the Chern–Weil envelope rows derived from them, the pattern records antisymmetry, Bianchi ledger transport, tensorial section transport, and consumer coverage, and the ledger keeps connection provenance, bracket endpoints, finite continuation routes, and Chern–Weil handoff rows visible. The carrier is inhabited by the displayed boundary source, and the classifier obligations are the inherited reflexive, symmetric, and transitive transports of hsame together with connection-carrier stability, so carrier closure is just repackaging the same transported bracket row. A history h lies in the signature gap of a $\mathsf{Curvature}^{\uparrow}$ token p when the source accepts a displayed curvature bracket for h, the signature relation pairs it with an answer bracket and evidence ledger, and token introduction names that answer as p; unfolded, the connection source, tangent-pair boundary, bracket endpoint, and Chern–Weil envelope projections match the rows encoded by p. The consumer rows let downstream Chern–Weil and ledger exactness arguments read the curvature packet, but no coordinate curvature tensor, de Rham representative, characteristic class, or standard bridge is part of this surface. The chapter registers this boundary-bracket construction under the name $\mathsf{Curvature}^{\uparrow}$; curvature is a finite connection-ledger row here, not a host tensor field assumed from outside.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The BHist curvature bracket carrier, ConnectionUp boundary projection, Chern-Weil source-envelope certificate, and standard bridge boundary are closed over the finite NameCert basis rows displayed in this chapter.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.CurvatureUp.CurvatureChernWeilSourceEnvelope\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: No coordinate curvature tensor, de Rham representative, or characteristic class is closed here.

Upgrade path: No further upgrade – chapter at top of formal axis.

The $\mathsf{DiffForm}^{\uparrow}$ hub routes antisymmetric multilinear carrier rows through chapter 96 and chapter 87, and its exterior-derivative boundary is the sibling input consumed by chapter 137.

Chapter 136

A Concrete Naming Certificate for $\mathsf{DiffForm}^{\uparrow}$

The differential-form interface $\mathsf{DiffForm}^{\uparrow}$ packages the carrier of antisymmetric multilinear maps on the tangent bundle of a manifold, together with the wedge product. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87), and is the substrate for the de Rham complex.

136.1 Carrier definition

Definition 136.1 (Differential-form BHist form carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T *whose tensor rows are read over the tangent-bundle histories of* M*. A differential-form BHist row is a tuple of histories*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda) : \mathsf{BHist}^6$$

accepted by the predicate $\mathsf{DiffFormBHistCarrier}_{M,T}$ *exactly when the following BEDC rows are all present:*

1. $\mathsf{UnaryHistory}(d)$ *records the form degree.*
2. $\mathcal{P} : \mathsf{ProbeBundle}$ *is the visible finite spine of tangent probe names, and each bundled probe row is carried by the tangent-source surface exposed by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*.*
3. τ *is a* $\mathsf{TensorProduct}^{\uparrow}$ *multilinear row over the bundled tangent probes, with continuation ledgers* Cont *recording the ordered tensor concatenations used by the row.*
4. σ *is the scalar endpoint produced from that tensor row, classified by the scalar classifier retained by the manifold and tensor sources.*
5. α *is the visible permutation ledger: for every displayed adjacent swap of bundled probe rows, the transported scalar endpoint is classified with the signed endpoint demanded by antisymmetry.*
6. λ *records the source names* M *and* T*, the degree row, the probe bundle, the tensor row, the scalar endpoint row, and the antisymmetry rows as the only accepted provenance for the form row.*

Definition 136.2 (Differential-form BHist form classifier)**.** *For carried form rows*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and

$$\omega' = (d', \mathcal{P}', \tau', \sigma', \alpha', \lambda'),$$

the classifier $\omega \sim_{\mathsf{DiffForm}^\uparrow} \omega'$ *holds when the degree rows are* hsame*, the scalar endpoints agree pointwise under the retained scalar classifier for every matched multilinear probe row, and the antisymmetry and tensor-source ledgers match as visible BHist rows:*

$$\mathsf{hsame}(d, d')$$

and for every matched bundled multilinear row, $\sigma \sim_R \sigma'$

$$\textit{and } \mathsf{hsame}(\alpha, \alpha') \wedge \mathsf{hsame}(\tau, \tau') \wedge \mathsf{hsame}(\lambda, \lambda').$$

Here $\sim_R$ *is the scalar classifier already present in the upstream scalar surface; the differential-form classifier introduces no classifier outside* hsame *and the displayed source classifiers.*

Lean4 (definition) `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier`

136.2 The certificate

Definition 136.3 (Differential-form BHist NameCert core rows)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *source* T *as in Definition 136.1. The* $\mathsf{DiffForm}^\uparrow$ *BHist NameCert core-row package consists of the following ten displayed template fields:*

1. *the carrier row* $\mathsf{DiffFormBHistCarrier}_{M,T}$*;*
2. *the classifier row* $\sim_{\mathsf{DiffForm}^\uparrow}$ *of Definition 136.2;*
3. *the componentwise* hsame *transport row for carried forms;*
4. *the degree history row* d*;*
5. *the tangent-probe* ProbeBundle *row* $\mathcal{P}$*;*
6. *the* $\mathsf{TensorProduct}^\uparrow$ *multilinear row* τ*;*
7. *the tensor-continuation ledger* Cont *attached to* τ*;*
8. *the scalar endpoint classifier row retained from the upstream manifold and tensor sources;*
9. *the antisymmetry permutation ledger* α*;*
10. *the standard-bridge slot, fixed to absent data.*

These fields are read as template data for the certificate only. The package does not introduce an exterior-derivative row, a closedness predicate, a nondegeneracy predicate, or a standard bridge.

Theorem 136.4 (Differential-form BHist carrier obligation)**.** *The carrier row in Definition 136.3 is exhausted by the six coordinates*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

of Definition 136.1. In particular, accepting a $\mathsf{DiffForm}^\uparrow$ *carrier row adds no seventh coordinate and no hidden source outside the displayed degree, probe-bundle, tensor, scalar-endpoint, antisymmetry, and source-ledger histories.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistCarrier coordinate ledger`

Proof. Invert the acceptance predicate $\mathsf{DiffFormBHistCarrier}_{M,T}$ displayed in Definition 136.1. A carried row is presented as the six-tuple $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, and each acceptance clause projects one of those six histories or one relation among histories already named by the tuple.

The degree clause projects d, the bundled tangent-probe clause projects $\mathcal{P}$, the multilinear tensor clause projects τ, the scalar endpoint clause projects σ, the permutation ledger clause projects α, and the source-provenance clause projects λ. No clause has a constructor that allocates another coordinate.

It remains to check that the core-row package of Definition 136.3 does not enlarge this carrier. Its transport, classifier, continuation, endpoint-classifier, and bridge slots refer back to the six displayed carrier histories and to upstream certificate sources. Thus carrier acceptance is exactly the six coordinate surface of Definition 136.1. □

Theorem 136.5 (Differential-form BHist classifier obligation)**.** *The classifier row in Definition 136.3 uses only degree* hsame*, matched tensor and scalar comparisons, and visible ledger* hsame*. It introduces no classifier other than* hsame *on displayed BHist rows and the scalar classifier already retained by the manifold and tensor sources.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier obligation`

Proof. Project the classifier definition from Definition 136.2. The first clause is exactly $\mathsf{hsame}(d, d')$, so degree comparison is a visible BHist comparison and not a new differential-form relation.

For the tensor and scalar part, the statement quantifies only over matched bundled multilinear rows. The tensor match is the visible comparison of the displayed tensor histories, while the endpoint comparison is the retained scalar classifier $\sim_R$ supplied by the upstream scalar surface. The classifier therefore reuses source comparisons already present in M and T.

The remaining clauses are $\mathsf{hsame}(\alpha, \alpha')$, $\mathsf{hsame}(\tau, \tau')$, and $\mathsf{hsame}(\lambda, \lambda')$. These are visible ledger comparisons on the antisymmetry, tensor, and source-provenance histories. Hence every accepted classifier step is one of the claimed degree, matched tensor/scalar, or ledger comparisons. □

Theorem 136.6 (Differential-form BHist ledger exactness obligation)**.** *Every ledger row accepted by the core-row package of Definition 136.3 is visible BHist provenance from BHist,* hsame*,* Cont*,* ProbeBundle*,* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$*. No accepted ledger row may cite a hidden differential-form primitive or a standard bridge.*

Proof. First inspect the carrier ledger. By Definition 136.1, λ records only the source names M and T, the degree row, the probe bundle, the tensor row, the scalar endpoint row, and the antisymmetry rows. These are all BHist provenance entries or rows exported by the two named upstream certificates.

Next inspect the tensor and probe ledgers. The probe data are a finite ProbeBundle spine whose tangent rows are supplied by $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$. The tensor data are supplied by $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$, and their ordered concatenations are recorded by Cont. Thus the only tensor-continuation provenance admitted by the core package is visible continuation data over the displayed probe rows.

Finally inspect the classifier and bridge slots. Classifier ledgers are hsame comparisons on degree, tensor, antisymmetry, and source histories, together with the scalar endpoint classifier retained from the upstream sources. The standard-bridge slot in Definition 136.3 is fixed to absent data, so there is no additional bridge ledger to accept. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistLedger exactness obligation`

Theorem 136.7 (Differential-form classifier reflexivity obligation)**.** *Every row carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *satisfies its own* $\mathsf{DiffForm}^{\uparrow}$ *classifier:*

$$\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega.$$

Equivalently, the BHist row accepted by the displayed carrier gives a reflexive NameCert classifier row for the $\mathsf{DiffForm}^{\uparrow}$ *certificate over the fixed* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *sources.*

Proof. Unpack the classifier in Definition 136.2. The degree, tensor, antisymmetry, and source-ledger clauses are all reflexive hsame comparisons between the corresponding visible BHist rows.

For each matched multilinear probe row in the displayed ProbeBundle, the scalar endpoint is compared with itself by reflexivity of the scalar-source classifier retained by the upstream $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ data. These componentwise reflexivity clauses are exactly the clauses required by the $\mathsf{DiffForm}^{\uparrow}$ classifier. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier reflexivity obligation`

Theorem 136.8 (Differential-form classifier symmetry obligation)**.** *For rows carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, the classifier of Definition 136.2 is symmetric: if* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \eta$*, then* $\eta \sim_{\mathsf{DiffForm}^{\uparrow}} \omega$*.*

Proof. Unpack the given classifier row through Definition 136.2. The degree comparison and the tensor, antisymmetry, and source-ledger comparisons are visible hsame relations on BHist rows, so symmetry of hsame reverses each of those clauses.

The matched scalar endpoints are compared by the scalar-source classifier retained from the $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ sources. Reversing that retained classifier comparison at each bundled ProbeBundle row gives the scalar clause for $\eta \sim_{\mathsf{DiffForm}^{\uparrow}} \omega$, and the reversed hsame ledger clauses supply the remaining classifier fields. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier symmetry obligation`

Theorem 136.9 (Differential-form classifier transitivity obligation)**.** *For rows carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, the classifier of Definition 136.2 is transitive: if* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \eta$ *and* $\eta \sim_{\mathsf{DiffForm}^{\uparrow}} \theta$*, then* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \theta$*.*

Proof. Unpack the two classifier rows using Definition 136.2. Transitivity of hsame composes the degree comparisons, and the same transitive hsame composition applies to the tensor, antisymmetry, and source-ledger BHist rows.

For each matched multilinear row in the common ProbeBundle surface, compose the scalar endpoint comparisons through the scalar-source classifier retained by $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$. The composed scalar clauses and the composed hsame clauses give precisely the classifier fields required for $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \theta$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier transitivity obligation`

Theorem 136.10 (Differential-form carrier hsame transport)**.** *Let* ω *be a row accepted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, and let* ω' *be obtained by replacing its six displayed histories with* hsame*-equal histories while keeping the same* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *sources. Then* ω' *is also accepted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*.*

Proof. Unpack the carrier row of Definition 136.1. The degree condition is transported by hsame for UnaryHistory.

The probe bundle is a closed ProbeBundle spine, so its bundled tangent rows are transported pointwise through the displayed manifold source classifier. The tensor row is then transported

through the $\mathsf{TensorProduct}^{\uparrow}$ classifier, retaining the same Cont ledgers after source, probe, and endpoint histories are replaced by hsame-equal rows.

It remains to transport the scalar and antisymmetry rows. The scalar endpoint uses the retained scalar classifier, and its pointwise transport follows from classifier stability in the source surface. Each antisymmetry row is a visible permutation ledger over the same probe bundle; transporting the two scalar endpoints of the swap row gives the required signed comparison. Repacking these transported fields gives the carried row for ω'. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistCarrier hsame transport`

Theorem 136.11 (Differential-form classifier stability)**.** *For rows carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, the classifier of Definition 136.2 is stable under carrier transport: if* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \eta$ *and both rows are transported to* ω' *and* η' *by componentwise* hsame *comparisons, then* $\omega' \sim_{\mathsf{DiffForm}^{\uparrow}} \eta'$*.*

Proof. The degree comparison is the transitive composite of the transport comparison for ω, the original degree comparison, and the symmetric transport comparison for η.

For each bundled multilinear probe row, use the tensor-source classifier to identify the matched tensor rows after transport. The scalar endpoints are then compared by the scalar classifier stability already retained in the upstream scalar surface.

The antisymmetry and source-ledger clauses are pure hsame clauses on visible BHist rows. Composing their original comparisons with the two transport comparisons gives the required ledger matches for the transported rows. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistClassifier hsame component stability`

Theorem 136.12 (Differential-form probe-slot arity transport)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and

$$\omega' = (d', \mathcal{P}', \tau', \sigma', \alpha', \lambda')$$

be rows carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$*. Suppose* $\mathsf{hsame}(d, d')$ *and the displayed* $\mathsf{ProbeBundle}$ *spines of* $\mathcal{P}$ *and* $\mathcal{P}'$ *are matched componentwise through the tangent-source classifier supplied by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*. Then the visible arity of the probe slots in* $\mathcal{P}$ *is the same as the visible arity of the probe slots in* $\mathcal{P}'$*. Moreover, every transported multilinear tensor row remains classified by the* $\mathsf{TensorProduct}^{\uparrow}$ *source over those transported tangent probes.*

Proof. Unpack the carrier rows in Definition 136.1. The degree entries are unary history rows, so $\mathsf{hsame}(d, d')$ transports the displayed degree without creating or deleting a probe slot.

The probe component is a closed $\mathsf{ProbeBundle}$ spine. Induct on this spine. The empty spine has arity zero on both sides. In the cons case, the head tangent probe is transported through the classifier retained by $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and the induction hypothesis preserves the arity of the tail. Therefore the visible slot count is preserved at each spine constructor.

It remains to place the transported multilinear row back in the tensor source. The tensor component of a carried differential-form row is accepted only as a $\mathsf{TensorProduct}^{\uparrow}$ row over the bundled tangent probes. Since the probe classifier transport is componentwise and the tensor row retains its displayed Cont provenance, tensor-source classifier transport reclassifies τ' as a multilinear row over the transported probe bundle. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeAligned hsame arity transport`

Theorem 136.13 (Differential-form adjacent-swap involution ledger)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

be carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$*. If a displayed row of the antisymmetry ledger* α *records an adjacent swap of two neighboring probe slots and classifies the resulting scalar endpoint with the signed endpoint required by antisymmetry, then* α *also determines the reverse adjacent swap row. Applying the displayed adjacent swap and then its reverse returns endpoints classified with the original scalar endpoint under the retained scalar classifier, and the provenance for both swap rows remains recorded in* λ*.*

Proof. Read the chosen adjacent-swap row from the visible antisymmetry ledger of Definition 136.1. Its endpoints are scalar rows classified by the scalar classifier retained from the manifold and tensor sources, and its provenance is one of the rows listed in λ.

The reverse row uses the same two neighboring probe slots in the opposite order. The scalar comparison for the reverse row is obtained by symmetry of the retained scalar classifier, while the comparison between the double-swap endpoint and the original endpoint is the transitive composite of the forward and reverse scalar comparisons.

No hidden row is introduced in this construction. Both the displayed swap row and the reverse swap row are retained as BHist provenance in λ, so the two applications return to endpoints classified with the original scalar endpoint inside the same carried differential-form row. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormAdjacentSwapInvolutionLedger reverse closure`

Theorem 136.14 (Differential-form wedge degree additivity ledger)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and

$$\eta = (e, \mathcal{Q}, \upsilon, \rho, \beta, \mu)$$

be carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$*. If an admitted wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ *is carried with output degree row* $d \star e$*, then its visible degree ledger contains the unary continuation row* $\mathsf{Cont}(d, e, d \star e)$*. If the two input form rows are transported by componentwise classifier comparisons with degree rows* d' *and* e' *satisfying* $\mathsf{hsame}(d, d')$ *and* $\mathsf{hsame}(e, e')$*, the wedge degree row is transported to a row* $d' \star e'$ *classified with the same unary continuation/append degree construction.*

Proof. Start with the admitted wedge row and apply Definition 136.15. The wedge carrier contains the visible tensor concatenation row joining the tensor component of ω to the tensor component of η, and the carrier provenance records the degree row of the wedge output.

The input degree rows are unary histories. Closure of unary histories under continuation supplies the displayed degree ledger $\mathsf{Cont}(d, e, d \star e)$ for the output degree row. This ledger is part of the same BHist provenance that carries the wedge row, so it is visible to downstream exterior-derivative consumers.

Now transport the two input form rows. The degree comparisons $\mathsf{hsame}(d, d')$ and $\mathsf{hsame}(e, e')$ transport the two unary inputs, and the componentwise classifier comparisons transport the probe, tensor, scalar, and antisymmetry rows. Applying unary-history closure under the transported continuation yields $d' \star e'$ with its corresponding Cont row.

Repackage the transported probe bundle, tensor concatenation, scalar endpoint, antisymmetry ledger, and degree ledger as the wedge carrier row. The resulting wedge row has degree additivity classified by the same differential-form carrier and classifier surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDegreeLedger degree additivity transport`

Theorem 136.15 (Differential-form wedge ledger coverage)**.** *A wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ *is admitted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *only when its ledger visibly contains a* $\mathsf{TensorProduct}^{\uparrow}$ *concatenation row joining the tensor row of* ω *to the tensor row of* η*. When that concatenation ledger is present, carrier and classifier stability of the wedge row follow by transporting the two input form rows through the tensor classifier and then through the retained scalar classifier.*

Proof. Read the wedge candidate through the carrier definition. The only provenance accepted for a form row is its displayed ledger, and the tensor component of a wedge must therefore be the visible tensor concatenation recorded there. If no such $\mathsf{TensorProduct}^{\uparrow}$ continuation row appears, the candidate has no accepted carrier witness.

Assume the concatenation row is present. Transport the left and right form rows by Definition 136.10. The $\mathsf{TensorProduct}^{\uparrow}$ source classifies the concatenated tensor endpoint after the two input tensor rows have been transported, and the scalar endpoint is classified by applying the retained scalar classifier to the transported multilinear endpoints.

The antisymmetry ledger of the wedge is the concatenation of the two input antisymmetry ledgers together with the displayed cross-permutation rows. Each row is a visible BHist row, so hsame transport preserves it. These fields reassemble into the carried wedge row and into the classifier comparison for the transported wedge endpoints. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeLedger coverage`

Definition 136.16 (Differential-form wedge probe concatenation ledger)**.** *For carried form rows*

$$\omega = (d_\omega, \mathcal{P}_\omega, \tau_\omega, \sigma_\omega, \alpha_\omega, \lambda_\omega)$$

and

$$\eta = (d_\eta, \mathcal{P}_\eta, \tau_\eta, \sigma_\eta, \alpha_\eta, \lambda_\eta),$$

the wedge probe concatenation ledger is the visible BHist package whose output probe bundle is

$$\mathcal{P}_{\omega\wedge\eta} = \mathsf{bundleAppend}(\mathcal{P}_\omega, \mathcal{P}_\eta).$$

It records the left input ledger λ_ω*, the right input ledger* λ_η*, the two input* $\mathsf{ProbeBundle}$ *spines, the displayed output* $\mathsf{ProbeBundle}$ *spine, and the same tensor-concatenation provenance row used by the wedge ledger coverage of Definition 136.15.*

Theorem 136.17 (Differential-form wedge probe concatenation coverage)**.** *Every wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ *admitted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *carries the wedge probe concatenation ledger of Definition 136.16. Its output probe bundle has length equal to the sum of the two input probe-bundle lengths, and a probe row is in the output bundle exactly when it is in the left input spine or in the right input spine.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeProbeConcatenationLedger coverage`

Proof. Apply Definition 136.15. The tensor concatenation row in that ledger is read over the same two probe spines that occur in the two carried input form rows, so the output probe surface is forced to be $\mathsf{bundleAppend}(\mathcal{P}_\omega, \mathcal{P}_\eta)$.

Now induct on the left $\mathsf{ProbeBundle}$ spine. The empty case exposes the right input spine as the whole output, giving the length and membership claims directly from the right bundle.

In the cons case, the head probe remains the head of the output spine and the induction hypothesis applies to the tail. Reassembling the head case with the tail comparison gives length additivity for bundleAppend and the membership iff splitting membership into the left spine or the right spine.

The BHist row of Definition 136.16 stores exactly these input ledgers, the output bundle, and the tensor provenance row. Therefore every admitted wedge row carries the displayed probe concatenation surface. □

Theorem 136.18 (Differential-form wedge probe concatenation classifier stability)**.** *Let (ω, η) and (ω', η') be two pairs of carried* $\mathsf{DiffForm}^{\uparrow}$ *rows with $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$ and $\eta \sim_{\mathsf{DiffForm}^{\uparrow}} \eta'$. If their wedge rows are admitted, then the wedge probe concatenation ledgers of Definition 136.16 are related by* hsame*, and the transported wedge outputs remain classified under $\sim_{\mathsf{DiffForm}^{\uparrow}}$.*

Proof. Use Definition 136.11 to transport the two input form classifiers componentwise. The probe-slot part of that transport is controlled by Definition 136.12, so the left input probe bundles match and the right input probe bundles match with the same visible arities.

Apply Definition 136.15 to the two admitted wedge rows. Their tensor concatenation rows transport through the $\mathsf{TensorProduct}^{\uparrow}$ classifier, and the scalar endpoint rows transport through the retained scalar classifier.

Finally transport the $\mathsf{bundleAppend}(\mathcal{P}_\omega, \mathcal{P}_\eta)$ row componentwise along the two input probe-bundle comparisons. The length and membership clauses are preserved by Definition 136.17, and the left ledger, right ledger, output probe bundle, and tensor provenance rows repack as the required hsame comparison between the two probe concatenation ledgers. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeProbeConcatenation classifier stability`

Definition 136.19 (Differential-form wedge associator ledger)**.** *For carried form rows ω, η, and θ in* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, the visible wedge associator ledger is the BHist package recording four rows: the* $\mathsf{TensorProduct}^{\uparrow}$ *concatenation spine for $(\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta) \wedge_{\mathsf{DiffForm}^{\uparrow}} \theta$, the* $\mathsf{TensorProduct}^{\uparrow}$ *concatenation spine for $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} (\eta \wedge_{\mathsf{DiffForm}^{\uparrow}} \theta)$, the* Cont *associativity comparison between those tensor spines, and the common scalar endpoint classifier obtained by transporting through the retained scalar classifier. It also records the permutation-ledger comparison required to identify the two antisymmetry ledgers after the tensor associativity comparison has been applied.*

Theorem 136.20 (Differential-form wedge associator closure)**.** *Let ω, η, and θ be carried* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *rows. If the two binary wedge ledgers needed for $(\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta) \wedge_{\mathsf{DiffForm}^{\uparrow}} \theta$ and the two binary wedge ledgers needed for $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} (\eta \wedge_{\mathsf{DiffForm}^{\uparrow}} \theta)$ are visible, then the associator ledger of Definition 136.19 carries both parenthesized wedge rows and classifies them as equal under $\sim_{\mathsf{DiffForm}^{\uparrow}}$.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDegreeLedger associator closure`

Proof. Apply Definition 136.15 to $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ and then to the wedge with θ. This constructs the left-parenthesized carrier row and its scalar endpoint classifier from the two visible binary ledgers.

Apply the same theorem to $\eta \wedge_{\mathsf{DiffForm}^{\uparrow}} \theta$ and then to the wedge with ω. This constructs the right-parenthesized carrier row and its scalar endpoint classifier from the other two visible binary ledgers.

The two tensor endpoints are compared by the Cont associativity row in the visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation ledger. Transport the scalar endpoint classifier across that comparison and the retained scalar classifier from Definition 136.2.

It remains to identify the antisymmetry ledgers. The associator ledger carries the required permutation comparison, and each permutation row is a visible BHist row. Composing those rows by hsame transitivity gives the $\mathsf{DiffForm}^{\uparrow}$ classifier equality between the two parenthesized wedge rows. □

Theorem 136.21 (Differential-form exterior-algebra obligation surface)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *exterior-algebra surface available to* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *consists of carrier transport, classifier stability, binary wedge ledger coverage, wedge probe concatenation coverage, the wedge associator ledger, and the wedge degree ledger. This surface does not assert* $d^2 = 0$*, closedness, nondegeneracy, or contact nonintegrability.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormUp StdBridge`

Proof. Carrier transport and classifier stability are supplied by Definition 136.10 and Definition 136.11. Binary wedge admission and transport are exactly Definition 136.15, while the visible output probe spine is the probe concatenation ledger of Definition 136.16 with coverage and classifier stability from Definition 136.17 and Definition 136.18.

Associativity of the exposed exterior product is not an unrecorded algebraic law. It is the visible associator ledger of Definition 136.19, closed under the carrier and classifier by Definition 136.20. Degree bookkeeping is the visible unary-history ledger of Definition 136.22.

Combining these rows with the NameCert surface of Definition 136.165 and the downstream scope of Definition 136.61 gives exactly the surface available to de Rham, symplectic, and contact consumers. The operator identity $d^2 = 0$ and the geometric conditions named in the statement are not rows of this $\mathsf{DiffForm}^{\uparrow}$ surface, so they remain obligations of the downstream certificates that use it. □

Definition 136.22 (Differential-form wedge degree ledger)**.** *For carried form rows*

$$\omega = (d_\omega, \mathcal{P}_\omega, \tau_\omega, \sigma_\omega, \alpha_\omega, \lambda_\omega)$$

and

$$\eta = (d_\eta, \mathcal{P}_\eta, \tau_\eta, \sigma_\eta, \alpha_\eta, \lambda_\eta),$$

a wedge degree ledger is the visible BHist row $\delta_{\omega,\eta}$ *accepted by* $\mathsf{DiffFormWedgeDegreeLedger}_{M,T}$ *exactly when it displays the two input degree rows, an output degree row* $d_{\omega\wedge\eta}$*, and a continuation row*

$$\mathsf{Cont}(d_\omega, d_\eta, d_{\omega\wedge\eta})$$

whose unary-history endpoint records the concatenation/addition of the two input degrees. The only accepted provenance for $\delta_{\omega,\eta}$ *is the pair of input form ledgers* $\lambda_\omega, \lambda_\eta$*, the two* UnaryHistory *witnesses for* d_ω *and* d_η*, the displayed* Cont *row, the output* UnaryHistory *witness, and the tensor concatenation row used by the wedge ledger of Definition 136.15.*

Theorem 136.23 (Differential-form wedge degree classifier stability)**.** *Let* (ω, η) *and* (ω', η') *be two pairs of carried* $\mathsf{DiffForm}^{\uparrow}$ *rows with* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$ *and* $\eta \sim_{\mathsf{DiffForm}^{\uparrow}} \eta'$*. If* $\delta_{\omega,\eta}$ *and* $\delta_{\omega',\eta'}$ *are the wedge degree ledgers of Definition 136.22, and if the corresponding wedge rows are admitted by the wedge ledger coverage of Definition 136.15, then*

$$\mathsf{hsame}(\delta_{\omega,\eta}, \delta_{\omega',\eta'})$$

and the wedge rows remain classified under $\sim_{\mathsf{DiffForm}^{\uparrow}}$*.*

Proof. The classifier comparison on the two input form pairs includes hsame comparisons on their degree rows by Definition 136.2. Transporting UnaryHistory along these comparisons gives the same unary degree witnesses for the two transported inputs.

The displayed continuation row of Definition 136.22 is a BHist row. Continuation associativity and unit stability identify the output degree row obtained from the transported input degrees with the output degree row in the second wedge degree ledger, so the two degree ledgers are related by hsame.

For the remaining wedge fields, apply Definition 136.15. The tensor concatenation row transports through the $\mathsf{TensorProduct}^{\uparrow}$ classifier, and the scalar endpoint transports through the retained scalar classifier. Together with the degree ledger comparison above and the visible antisymmetry ledger transport, these rows repack as the required $\mathsf{DiffForm}^{\uparrow}$ classifier comparison for the wedge rows. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDegreeLedger classifier stability`

Theorem 136.24 (Differential-form de Rham input boundary)**.** *Any* $\mathsf{DeRham}^{\uparrow}$ *exterior-derivative row sourced from* $\mathsf{DiffForm}^{\uparrow}$ *may depend on the* $\mathsf{DiffForm}^{\uparrow}$ *source only through the carried* ProbeBundle*, the unary degree row, the multilinear* $\mathsf{TensorProduct}^{\uparrow}$ *tensor row, the scalar endpoint classifier, the antisymmetry ledger, wedge ledger coverage, and the wedge probe concatenation ledger of Definition 136.16 together with the wedge degree ledger of Definition 136.22. It cannot import* $d^2 = 0$*, closedness, nondegeneracy, or contact nonintegrability from the* $\mathsf{DiffForm}^{\uparrow}$ *certificate.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDerhamInputBoundary source scope`

Proof. Inspect the carrier of Definition 136.1. The rows visible to an exterior-derivative construction are the probe bundle, unary degree row, tensor row, scalar endpoint, antisymmetry ledger, and source ledger, all carried as BHist data.

The wedge interfaces exported by $\mathsf{DiffForm}^{\uparrow}$ are exactly the tensor coverage of Definition 136.15, the probe concatenation surface of Definition 136.16, and the degree ledger of Definition 136.22. Their stability is supplied by Definition 136.18 and Definition 136.23 together with the carrier and classifier stability theorems above.

The identities $d^2 = 0$, closedness, nondegeneracy, and contact nonintegrability require operator or geometric rows not listed in the $\mathsf{DiffForm}^{\uparrow}$ carrier. Therefore a downstream $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, or $\mathsf{Contact}^{\uparrow}$ certificate must state those rows in its own surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeInputRow derham input boundary`

136.3 DiffForm degree-probe support

Definition 136.25 (Differential-form degree-probe support row)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T *as in Definition 136.1. A differential-form degree-probe support row is the ten-field template whose traditional target is the finite degree surface of differential forms, and whose BEDC source data are BHist,* UnaryHistory*,* ProbeBundle*,* Cont*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*

The carrier field is the six-coordinate row $\mathsf{DiffFormBHistCarrier}_{M,T}$ *with displayed coordinates* $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$ *from Definition 136.1. The classifier field is* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *from Definition 136.2. The stability obligations are degree and probe transport, wedge concatenation, and carrier transport. The ledger fields are the unary degree witness* d*, the visible probe spine* $\mathcal{P}$*, the tensor row* τ*, the scalar endpoint* σ*, the antisymmetry ledger* α*, and the source ledger* λ*.*

The core theorem list consists of Definition 136.26, Definition 136.27, and Definition 136.28. The support row is accepted if and only if the displayed carrier row supplies exactly the unary degree witness and the visible ProbeBundle *spine consumed by the tensor, scalar, antisymmetry, and source-ledger rows above. There is no standard bridge field in this support row, and its verification status is a paper proof target.*

Theorem 136.26 (Differential-form degree-probe carrier admissibility)**.** *Every row carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *supplies the degree-probe support row of Definition 136.25. In particular, the degree coordinate is the visible* UnaryHistory *row* d*, the arity surface is the visible* ProbeBundle *spine* $\mathcal{P}$*, and the tensor, scalar-endpoint, antisymmetry, and source-ledger rows consume no hidden probe slot outside* $\mathcal{P}$*.*

Proof. Invert the carrier acceptance predicate displayed in Definition 136.1. A carried row is exactly the six-tuple $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, and the first two acceptance clauses name d as a UnaryHistory row and $\mathcal{P}$ as the finite ProbeBundle spine.

The remaining carrier clauses do not allocate another arity source. The tensor row τ is read over the bundled tangent probes in $\mathcal{P}$, the scalar endpoint σ is produced from that tensor row, and the antisymmetry ledger α ranges over displayed adjacent swaps of the same bundled probe rows.

Finally inspect the source ledger λ. Its accepted provenance is the source pair M, T together with the degree row, the probe bundle, the tensor row, the scalar endpoint row, and the antisymmetry rows. Repacking these visible fields gives precisely the ten-field support row, with no additional probe or degree coordinate to certify. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeSupport carrier admissibility`

Theorem 136.27 (Differential-form degree-probe transport)**.** *Let* ω *and* ω' *be rows carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *with* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$*. If* ω *supplies the degree-probe support row of Definition 136.25, then* ω' *supplies the transported degree-probe support row with the same visible probe-slot arity.*

Proof. Project the classifier comparison through Definition 136.2. Its degree clause gives hsame between the two unary degree histories, and its tensor, antisymmetry, and source-ledger clauses give visible hsame comparisons on the rows that record how the probe spine is consumed.

Apply Definition 136.12 to the two carried rows. The componentwise tangent-source transport of the two ProbeBundle spines preserves the visible number of probe slots, and the transported multilinear tensor row remains a $\mathsf{TensorProduct}^{\uparrow}$ row over those transported tangent probes.

It remains to move the support classifier itself. Use Definition 136.11 on the carried rows after the componentwise transport. The degree, tensor, scalar-endpoint, antisymmetry, and source-ledger comparisons repack into the same ten-field support row for ω', and the previous paragraph supplies the preserved probe arity. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeSupport transport`

Theorem 136.28 (Differential-form degree-probe wedge compatibility)**.** *Let* ω *and* η *be carried* $\mathsf{DiffForm}^{\uparrow}$ *rows supplying degree-probe support rows. If the wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ *is admitted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, then its support row is obtained by concatenating the two visible probe spines and by using the continuation row of Definition 136.22 to produce the output unary degree. Thus the wedge consumes exactly the arity displayed by the two input support rows.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeSupport wedge compatibility`

Proof. First apply Definition 136.17. The admitted wedge row carries the visible output bundle $\mathsf{bundleAppend}(\mathcal{P}_\omega, \mathcal{P}_\eta)$, its length is the sum of the two input bundle lengths, and membership in the output bundle is exactly membership in the left or right input spine.

Next use Definition 136.22. Its row displays the two input unary degree histories, the output unary degree history, and the continuation row

$$\mathsf{Cont}(d_\omega, d_\eta, d_{\omega\wedge\eta})$$

whose endpoint records the degree of the admitted wedge.

Finally repack the admitted wedge carrier row. The tensor concatenation row is read over the concatenated probe bundle, the scalar endpoint is produced from that tensor row, and the antisymmetry and source ledgers cite only the two input ledgers, the output probe bundle, and the displayed degree continuation. Therefore the wedge support row consumes exactly the visible arity supplied by the two input support rows and no hidden exterior-input slot. □

136.4 DiffForm degree-probe alignment

Definition 136.29 (Differential-form degree-probe alignment row)**.** *For a unary degree history d and a visible probe bundle $\mathcal{P}$, the row* $\mathsf{DegreeProbeAligned}(d, \mathcal{P})$ *is the closed structural relation generated by the following constructors:*

1. $\mathsf{DegreeProbeAligned}(\mathsf{e}, \mathsf{ProbeBundle.Bnil})$.
2. *If* $\mathsf{DegreeProbeAligned}(d, \mathcal{P})$ *holds, and if p is a tangent-probe row admitted by the manifold source, then* $\mathsf{DegreeProbeAligned}(\mathsf{E1}(d), \mathsf{ProbeBundle.Bcons}(p, \mathcal{P}))$.

Thus the unary degree row and the ProbeBundle *spine expose the same visible length. The relation is part of the displayed differential-form row: it does not import a host tangent-space dimension and does not allocate a second arity counter outside $BHist$.*

Lean4 (definition) `BEDC.Derived.DiffFormUp.DegreeProbeAligned`

Theorem 136.30 (Differential-form carrier refines to degree-probe alignment)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

be carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$*. Suppose that the tensor row τ is read over exactly the displayed bundled tangent probes in $\mathcal{P}$, with one unary degree constructor in d for each visible probe slot and with no tensor input outside the bundle. Then ω supplies* $\mathsf{DegreeProbeAligned}(d, \mathcal{P})$.

Proof. First unpack the carrier through Definition 136.1. The carrier exposes $\mathsf{UnaryHistory}(d)$, the finite ProbeBundle spine $\mathcal{P}$, and the tensor row τ over that same bundle.

Induct simultaneously on the visible probe spine and on the unary degree row selected by the tensor-input reading. In the empty bundle case, the carrier clauses and the exact-reading hypothesis leave no tensor input slot. The unary row is therefore the empty degree row, and the empty constructor of Definition 136.29 applies.

In the cons case, the carrier exposes a head tangent probe and a tail ProbeBundle. The exact-reading hypothesis strips one E1 constructor from the degree row for that head probe and leaves the tail tensor row over the tail bundle. The induction hypothesis gives alignment for the tail, and the Bcons constructor of Definition 136.29 rebuilds alignment for the whole row.

Finally apply Definition 136.26. It says that the carried row supplies the displayed degree row and the visible probe spine as the support surface consumed by the tensor, scalar, antisymmetry,

and source ledgers. Hence no hidden probe slot or hidden degree constructor remains outside the aligned row. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeAligned empty iff`

Theorem 136.31 (Differential-form degree-probe alignment transport)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and

$$\omega' = (d', \mathcal{P}', \tau', \sigma', \alpha', \lambda')$$

be rows carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$ *with* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$*. If* $\mathsf{DegreeProbeAligned}(d, \mathcal{P})$ *holds, then* $\mathsf{DegreeProbeAligned}(d', \mathcal{P}')$ *holds.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeAligned hsame transport`

Proof. Project the classifier comparison through Definition 136.2. The degree clause gives $\mathsf{hsame}(d, d')$, while the probe and tensor clauses match the displayed ProbeBundle spines componentwise through the manifold and tensor sources.

Apply Definition 136.27. The support row carried by ω transports to the support row carried by ω', with the same visible probe-slot arity.

Now apply Definition 136.12. Since the probe slot count is preserved and the unary degree row is transported by hsame, each constructor step in Definition 136.29 has a matching transported constructor step. Rebuilding the transported spine gives $\mathsf{DegreeProbeAligned}(d', \mathcal{P}')$. □

Theorem 136.32 (Differential-form wedge preserves degree-probe alignment)**.** *Let* ω *and* η *be carried* $\mathsf{DiffForm}^{\uparrow}$ *rows with* $\mathsf{DegreeProbeAligned}(d_\omega, \mathcal{P}_\omega)$ *and* $\mathsf{DegreeProbeAligned}(d_\eta, \mathcal{P}_\eta)$*. If the wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$ *is admitted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *with output degree* $d_{\omega\wedge\eta}$ *and output probe bundle* $\mathcal{P}_{\omega\wedge\eta}$*, then* $\mathsf{DegreeProbeAligned}(d_{\omega\wedge\eta}, \mathcal{P}_{\omega\wedge\eta})$ *holds.*

Proof. Expose the admitted wedge probe surface with Definition 136.28. The output bundle is the visible append

$$\mathcal{P}_{\omega\wedge\eta} = \mathsf{bundleAppend}(\mathcal{P}_\omega, \mathcal{P}_\eta),$$

and the tensor row consumes exactly that appended spine.

Induct on the left probe bundle $\mathcal{P}_\omega$. In the empty case, the left alignment row identifies d_ω with the empty unary degree, and the append surface reduces to the right input probe bundle. The Cont left-unit row in Definition 136.22 identifies the output degree with d_η, so the right input alignment supplies the output alignment.

In the cons case, the left alignment row strips one head probe from $\mathcal{P}_\omega$ and one E1 constructor from d_ω. The induction hypothesis aligns the wedge of the left tail with η. Reapplying the Bcons constructor in Definition 136.29 aligns the restored head probe with the restored unary constructor.

It remains to justify that the degree endpoint is the wedge endpoint rather than an auxiliary row. Use the continuation row

$$\mathsf{Cont}(d_\omega, d_\eta, d_{\omega\wedge\eta})$$

from Definition 136.22. Continuation associativity and the unit rows already cited by that ledger identify the inductive endpoint with the admitted wedge degree. Repacking with the visible appended bundle gives $\mathsf{DegreeProbeAligned}(d_{\omega\wedge\eta}, \mathcal{P}_{\omega\wedge\eta})$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDegreeProbeAligned bundleAppend cont`

136.5 DiffForm root-unblock obligations

Definition 136.33 (Differential-form root-unblock source surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *source* T *whose tensor rows are read over the tangent-bundle histories of* M*. The* $\mathsf{DiffForm}^\uparrow$ *root-unblock source surface is the following ten-field BEDC surface:*

1. *the ambient* BHist *history carrier for the displayed differential-form rows;*
2. *the visible* hsame *transport relation on all degree, tensor, scalar-endpoint, antisymmetry, and source-ledger histories;*
3. *the* Cont *ledger for ordered tensor concatenation and degree continuation rows;*
4. *the* ProbeBundle *spine of tangent-probe names;*
5. *the upstream* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *source for tangent probes and scalar endpoints;*
6. *the upstream* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *source for multilinear tensor rows;*
7. *the six-coordinate carrier* $\mathsf{DiffFormBHistCarrier}_{M,T}(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$ *of Definition 136.1;*
8. *the classifier* $\sim_{\mathsf{DiffForm}^\uparrow}$ *of Definition 136.2;*
9. *the wedge rows consisting only of tensor concatenation, probe-bundle append, wedge-degree bookkeeping, and the displayed antisymmetry ledger;*
10. *the exterior-input rows consumed by* $\mathsf{DeRham}^\uparrow$*,* $\mathsf{Contact}^\uparrow$*, and* $\mathsf{Symplectic}^\uparrow$*, restricted to degree, wedge, antisymmetry, scalar endpoint, and source-ledger projections.*

The surface contains no row for $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, or a standard bridge.*

Theorem 136.34 (Differential-form root-unblock carrier and classifier scope)**.** *Every carrier and classifier row readable from the Definition 136.33 is determined by the displayed BEDC source surface. The carrier is the six-coordinate row*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda),$$

and the classifier uses only degree hsame*, matched tensor and scalar comparisons, and visible* hsame *comparison of the tensor, antisymmetry, and source ledgers.*

Proof. Project the carrier through Definition 136.1. Its acceptance predicate lists only the degree row d, the probe bundle $\mathcal{P}$, the tensor row τ, the scalar endpoint σ, the antisymmetry ledger α, and the source ledger λ.

Next project the classifier through Definition 136.2. Degree comparison is hsame, matched tensor and scalar endpoints use the displayed tensor row and the retained scalar classifier from M and T, and the ledger comparisons are $\mathsf{hsame}(\alpha, \alpha')$, $\mathsf{hsame}(\tau, \tau')$, and $\mathsf{hsame}(\lambda, \lambda')$.

Finally use the carrier and classifier obligations Definition 136.4 and Definition 136.5. They exhaust the same six-coordinate carrier and the same displayed classifier clauses, so no carrier or classifier datum can be read outside the ten-field root-unblock surface. □

Theorem 136.35 (Differential-form root-unblock wedge continuation closure)**.** *The wedge input closure readable from the Definition 136.33 is exactly probe-bundle concatenation plus* Cont *ledger closure. An admitted wedge of carried rows may read the output probe spine from the append ledger and the tensor concatenation from* Cont*, together with the displayed degree and antisymmetry rows; it may not read an exterior-derivative law or a downstream geometric law from wedge admission.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootUnblock wedge cont closure`

Proof. Start with a wedge row admitted by Definition 136.15. The admitted row requires a visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation of the two tensor components, and the continuation data for that concatenation are exactly Cont ledger entries over the displayed input rows.

The probe part is then determined by Definition 136.16 and Definition 136.17. These rows identify the output probe bundle as the append of the two input $\mathsf{ProbeBundle}$ spines, with no additional probe source.

The remaining wedge-visible data are the unary degree bookkeeping of Definition 136.22 and the antisymmetry and associator ledgers bounded by Definition 136.20. Hence wedge closure is precisely the displayed probe append together with the Cont tensor ledger and the already-carried degree and antisymmetry rows. □

Theorem 136.36 (Differential-form root-unblock de Rham input consumption)**.** *Every* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, *or* $\mathsf{Symplectic}^{\uparrow}$ *consumer of the Definition 136.33 may read only the degree row, wedge rows, antisymmetry ledger, scalar endpoint row, and source-ledger rows exposed there. In particular, de Rham exterior input may consume the degree-shift and wedge-input surfaces, while contact and symplectic consumers must supply their nonintegrability, closedness, and nondegeneracy laws in their own certificate surfaces.*

Proof. First read the de Rham boundary from Definition 136.24. It permits an exterior-derivative row to depend on the probe bundle, degree row, tensor row, scalar endpoint, and source ledger, and on the wedge probe and degree ledgers. It explicitly gives no $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability row.

Next combine the exterior-input rows Definition 136.57, Definition 136.58, and Definition 136.56. They allow only one-step degree continuation, carried input and output rows, wedge-input transport, scalar endpoint transport, and the restricted source ledger.

Finally apply the downstream boundary rows Definition 136.61 and Definition 136.74. These rows identify $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, and $\mathsf{Symplectic}^{\uparrow}$ as consumers of the displayed DiffForm carrier, wedge, scalar, antisymmetry, and source data only. The operator and geometric laws therefore remain obligations of those downstream chapters, not projections from the DiffForm root-unblock surface. □

Definition 136.37 (DiffForm root obligation source)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *root obligation source is the visible tuple consisting of the BHist carrier rows of Definition 136.1, the classifier rows of Definition 136.2, the source certificates* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*, the wedge ledger rows of Definition 136.15, the antisymmetry chain ledgers of Definition 136.77, and the exterior-derivative input rows named by Definition 136.66. It exposes only those rows as the root surface for downstream consumers.*

Theorem 136.38 (DiffForm root source transport obligation)**.** *For the root obligation source of Definition 136.37, replacing every displayed carrier and classifier history by an* hsame*-equal history preserves the accepted* $\mathsf{DiffForm}^{\uparrow}$ *source surface. In particular, the carrier and classifier parts of the tuple transport without changing the retained* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *or* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *sources.*

Proof. Start with the carrier component of the root tuple. Apply Definition 136.10 to each displayed carried row; the retained manifold and tensor-product certificates are part of the same row, so no separate source replacement is introduced.

Next transport the classifier component. Use Definition 136.11 on the transported endpoints of each classifier row. The degree, tensor, scalar, antisymmetry, and source-ledger clauses are exactly the clauses exposed in Definition 136.2.

Repack the transported carrier rows and transported classifier rows with the unchanged source certificates. This is precisely the accepted source surface specified by Definition 136.37. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootSource transport obligation`

Theorem 136.39 (DiffForm root wedge and antisymmetry obligation)**.** *The root obligation source of Definition 136.37 closes the visible wedge and antisymmetry obligations: every admitted wedge row carries the required tensor concatenation ledger, its probe concatenation classifier is stable, its associator row remains in the carried surface, and its antisymmetry chain is classified by the displayed chain ledger.*

Proof. First read the binary wedge row through Definition 136.15. This supplies the visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation row and transports the two input form rows through the retained carrier and classifier surfaces.

The probe part of the wedge is then controlled by Definition 136.18. It identifies the output probe bundle after transporting the two input bundles and keeps the wedge output classified under $\sim_{\mathsf{DiffForm}^{\uparrow}}$.

For three carried rows, apply Definition 136.20. The two parenthesized wedge surfaces are carried by the same visible associator ledger, so the root tuple contains the needed associativity comparison.

Finally use Definition 136.77. The antisymmetry chain rows are part of the root source, and their classifier stability supplies the visible chain obligation for every transported wedge surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootWedgeAntisymmetry obligation`

Theorem 136.40 (DiffForm root exterior-derivative boundary obligation)**.** *The exterior-derivative component of the root obligation source records only the admitted input and output rows for the exported derivative boundary. It does not assert closedness, nilpotence, or a de Rham quotient; it binds the candidate derivative row to the visible input/output ledger and to the wedge boundary row consumed by downstream wedge formulas.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootExteriorDerivative boundary obligation`

Proof. Begin with Definition 136.66. It states that the exported derivative surface is exactly the displayed input/output ledger row, so the root tuple records no additional derivative law.

Transport the candidate derivative classifier by Definition 136.67. This keeps the candidate row attached to the same carrier and classifier surface under hsame replacement of the displayed histories.

The wedge-side boundary is then read from Definition 136.80. That theorem supplies the only boundary row consumed by wedge formulas, and the root surface merely keeps that row available beside the input/output ledger. □

Theorem 136.41 (DiffForm root NameCert surface)**.** *The root obligation source of Definition 136.37 presents a single* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *surface: source transport, wedge and antisymmetry transport, and exterior-derivative boundary exposure assemble into the displayed* $\mathsf{DiffForm}^{\uparrow}$ *obligation surface.*

Proof. Use Definition 136.38 to bind the carrier and classifier rows to the retained $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ sources. This gives the source part of the root certificate.

Use Definition 136.39 for the wedge ledger, probe concatenation, associator, and antisymmetry chain fields. These are exactly the visible algebraic rows required by the differential-form certificate surface.

Use Definition 136.40 for the exported derivative boundary. The derivative row is retained only as an input/output and wedge-boundary surface.

Finally apply Definition 136.165. Its certificate surface contains the same source, wedge, antisymmetry, and exterior-derivative rows, so the three root obligations repack as the displayed $\mathsf{NameCert}_{\mathsf{DiffForm}^\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootNameCert surface`

Definition 136.42 (Differential-form obligation inventory)**.** *The paper-side obligation inventory for* $\mathsf{DiffForm}^\uparrow$ *is the following ten-field roadmap:*

1. *the traditional target is the certificate surface for antisymmetric multilinear forms on tangent probes;*
2. *the BEDC sources are* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$*;*
3. *the carrier is* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *from Definition 136.1;*
4. *the classifier is* $\sim_{\mathsf{DiffForm}^\uparrow}$ *from Definition 136.2;*
5. *carrier stability is the* hsame *transport row of Definition 136.10;*
6. *classifier stability is Definition 136.11;*
7. *the ledger rows are exactly the degree, probe, tensor, scalar, antisymmetry, and source-provenance rows;*
8. *the core theorem list consists of carrier exhaustion, classifier reuse, ledger exactness, transport stability, wedge coverage, and the exterior-input boundary theorems already displayed in this chapter;*
9. *exactness is row exhaustion: every admitted downstream use must factor through one of the displayed rows;*
10. *no standard bridge is supplied here, so the inventory is the displayed paper-side obligation surface and not a bridge certificate.*

Theorem 136.43 (Differential-form carrier support obligation)**.** *The carrier support promised by the* $\mathsf{DiffForm}^\uparrow$ *obligation inventory is exactly the six-coordinate surface*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

of Definition 136.1. It is therefore exhausted by the degree row, probe-bundle row, tensor row, scalar endpoint row, antisymmetry ledger, and source-provenance ledger, as projected by Definition 136.4.

Proof. Unfold Definition 136.42. Its carrier field points to $\mathsf{DiffFormBHistCarrier}_{M,T}$ and introduces no second carrier predicate.

Apply Definition 136.1. A carried row is displayed as the tuple $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, with one acceptance clause for each of its six coordinates.

Now apply Definition 136.4. That theorem states that carrier acceptance adds no seventh coordinate and no hidden source outside the displayed histories. The support field of the inventory is therefore exactly the six-coordinate carrier surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistCarrier support obligation`
Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormCarrier support obligation`

Theorem 136.44 (Differential-form classifier transport obligation)**.** *The classifier obligation recorded by Definition 136.42 consists of reflexivity, symmetry, transitivity, carrier transport, and classifier stability for the displayed* $\mathsf{DiffForm}^{\uparrow}$ *rows. These obligations are projections of Definition 136.2, Definition 136.5, Definition 136.10, and Definition 136.11.*

Proof. For reflexivity, read each classifier component in Definition 136.2 against itself. The degree, tensor, antisymmetry, and source-ledger clauses are reflexive hsame rows, and the scalar endpoint clause uses the retained source classifier on the same endpoint row.

For symmetry and transitivity, compose the same displayed clauses componentwise. The hsame clauses supply the ledger-side comparisons, while the scalar endpoint comparison stays inside the upstream scalar classifier named in the definition.

It remains to identify the transport obligations. Carrier transport is exactly Definition 136.10. Once transported rows are accepted, classifier stability is exactly Definition 136.11. Thus the inventory records no classifier law beyond the existing displayed classifier and transport theorems. □

Theorem 136.45 (Differential-form exterior input boundary obligation)**.** *Downstream* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *consumers of* $\mathsf{DiffForm}^{\uparrow}$ *may use only the listed* $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, *wedge-ledger, and exterior-input rows. In particular, their access is bounded by Definition 136.24 and Definition 136.61.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorInputBoundary obligation`

Proof. First unfold the source and carrier entries of Definition 136.42. They name only $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, the carried $BHist$ rows, $\mathsf{ProbeBundle}$, hsame, and the Cont ledgers attached to tensor concatenation.

Next apply Definition 136.24. It permits exterior-derivative consumers to read the probe bundle, degree row, tensor row, scalar endpoint classifier, antisymmetry ledger, wedge coverage, wedge probe concatenation ledger, and wedge degree ledger, and it excludes $d^2 = 0$, closedness, nondegeneracy, and contact nonintegrability from the $\mathsf{DiffForm}^{\uparrow}$ source.

Finally apply Definition 136.61. The downstream scope theorem adds the exterior-derivative candidate ledger and confirms that the three named consumer chapters must state any operator or geometric laws inside their own surfaces. The obligation boundary is therefore exactly the listed rows and no broader import surface. □

Definition 136.46 (Differential-form zero-degree scalar boundary)**.** *Fix* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *sources* M, T *as in Definition 136.1. A differential-form zero-degree scalar boundary row is a carried* $\mathsf{DiffForm}^{\uparrow}$ *row*

$$\omega_0 = (d_0, \mathcal{P}_0, \tau_0, \sigma, \alpha_0, \lambda_0)$$

accepted by $\mathsf{DiffFormBHistCarrier}_{M,T}$ *with the following visible coordinates:*

1. d_0 *is the empty unary-zero history, so* $\mathsf{hsame}(d_0, \mathsf{e})$ *and* $\mathsf{UnaryHistory}(d_0)$.
2. $\mathcal{P}_0$ *is the empty probe spine* $\mathsf{ProbeBundle.Bnil}$.
3. τ_0 *is the empty tensor-unit surface of the* $\mathsf{TensorProduct}^{\uparrow}$ *source over* $\mathcal{P}_0$.
4. α_0 *is the empty antisymmetry ledger, with no adjacent-swap row and no cross-permutation row.*

5. *σ is the retained scalar classifier endpoint row supplied by the upstream manifold and tensor sources.*

6. *λ_0 records exactly $M, T, d_0, \mathcal{P}_0, \tau_0, \sigma$, and α_0 as the source ledger for this boundary row.*

Thus the row is a scalar-valued 0-form surface inside the displayed $\mathsf{DiffForm}^{\uparrow}$ carrier, not a host-level exception outside the carrier and classifier of Definition 136.1 and Definition 136.2.

Theorem 136.47 (Differential-form zero-degree empty-probe exhaustion)**.** *Let ω_0 be a differential-form zero-degree scalar boundary row of Definition 136.46. For every probe row p, the membership claim $\mathsf{InBundle}(p, \mathcal{P}_0)$ is impossible. Equivalently, every downstream use of ω_0 sees an empty probe spine, with no hidden tangent input slot.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree empty probe exhaustion`

Proof. Unpack the boundary row through Definition 136.46. Its probe coordinate is the closed constructor ProbeBundle.Bnil.

Invert an assumed $\mathsf{InBundle}(p, \mathcal{P}_0)$ claim. The ProbeBundle membership constructors can only expose a head probe from a nonempty spine or recurse into a nonempty tail. The constructor ProbeBundle.Bnil has neither, so no membership constructor can produce the assumed claim.

The same empty-spine inversion is compatible with the carrier and classifier rows of Definition 136.1 and Definition 136.2. The scalar endpoint remains present as σ, but no probe row can be read from the boundary. □

Theorem 136.48 (Differential-form zero-degree scalar classifier readback)**.** *Let*

$$\omega_0 = (d_0, \mathcal{P}_0, \tau_0, \sigma, \alpha_0, \lambda_0)$$

and

$$\omega_0' = (d_0', \mathcal{P}_0', \tau_0', \sigma', \alpha_0', \lambda_0')$$

be two differential-form zero-degree scalar boundary rows over the same M, T sources. Then $\omega_0 \sim_{\mathsf{DiffForm}^{\uparrow}} \omega_0'$ is exactly the retained scalar endpoint classifier comparison $\sigma \sim_R \sigma'$, together with the visible source-ledger comparisons

$$\mathsf{hsame}(d_0, d_0'), \quad \mathsf{hsame}(\tau_0, \tau_0'), \quad \mathsf{hsame}(\alpha_0, \alpha_0'), \quad \mathsf{hsame}(\lambda_0, \lambda_0').$$

No probe-indexed classifier clause remains after empty ProbeBundle.Bnil *inversion.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree scalar classifier readback`

Proof. Read the two boundary rows through Definition 136.46. Both probe spines are ProbeBundle.Bnil, both degree rows are the empty unary-zero history, both tensor rows are empty tensor-unit surfaces, and both antisymmetry ledgers are empty.

Now unfold the differential-form classifier of Definition 136.2. The degree, tensor, antisymmetry, and source-ledger clauses are exactly the displayed hsame comparisons on the boundary rows. The scalar endpoint clause is the retained source classifier comparison $\sigma \sim_R \sigma'$.

It remains to rule out any further probe-indexed clause. By Definition 136.47, no InBundle claim exists for either boundary spine. Hence every matched multilinear probe row in the classifier is exhausted by the empty tensor-unit endpoint, and the public readback surface is precisely the scalar endpoint classifier plus the visible hsame ledger comparisons. □

Theorem 136.49 (Differential-form zero-degree wedge Cont unit boundary)**.** *Let ω_0 be a differential-form zero-degree scalar boundary row and let*

$$\eta = (d_\eta, \mathcal{P}_\eta, \tau_\eta, \rho, \beta, \mu)$$

be any carried $\mathsf{DiffForm}^\uparrow$ *row over the same M, T sources. Whenever the wedge rows $\omega_0 \wedge_{\mathsf{DiffForm}^\uparrow} \eta$ and $\eta \wedge_{\mathsf{DiffForm}^\uparrow} \omega_0$ are admitted by Definition 136.15, their probe and degree surfaces are the nonempty side's surfaces:*

$$\mathsf{bundleAppend}(\mathsf{ProbeBundle.Bnil}, \mathcal{P}_\eta) \quad \textit{and} \quad \mathsf{bundleAppend}(\mathcal{P}_\eta, \mathsf{ProbeBundle.Bnil})$$

are classified with $\mathcal{P}_\eta$, and the degree ledgers of Definition 136.22 reduce through the Cont *left and right unit rows to d_η. The tensor-unit component of ω_0 therefore contributes no additional probe slot and no additional degree history to either wedge boundary.*

Proof. First expose the wedge probe ledger. Apply Definition 136.16 and Definition 136.15. The output probe spine of the left wedge is $\mathsf{bundleAppend}(\mathsf{ProbeBundle.Bnil}, \mathcal{P}_\eta)$, and the output probe spine of the right wedge is $\mathsf{bundleAppend}(\mathcal{P}_\eta, \mathsf{ProbeBundle.Bnil})$.

For the left wedge, invert the empty left spine. The bundleAppend empty-left law identifies the output spine with $\mathcal{P}_\eta$, and Definition 136.47 rules out an additional probe contributed by ω_0.

For the right wedge, induct on $\mathcal{P}_\eta$. The empty case is the same ProbeBundle.Bnil endpoint. In the cons case, the head probe is preserved and the induction hypothesis identifies the appended tail with the original tail, so the empty-right law identifies the output spine with $\mathcal{P}_\eta$.

It remains to read the degree surface. By Definition 136.22, both admitted wedges carry visible continuation rows for their output degrees. Since the boundary degree of ω_0 is e, the left wedge uses the Cont left-unit row $\mathsf{Cont}(\mathsf{e}, d_\eta, d_\eta)$, and the right wedge uses the Cont right-unit row $\mathsf{Cont}(d_\eta, \mathsf{e}, d_\eta)$. Thus the wedge output degree is classified with d_η on both sides.

Finally, the tensor component of ω_0 is the empty tensor-unit surface from Definition 136.46. The tensor concatenation ledger named by Definition 136.15 therefore records only the unit-row concatenation with τ_η, while the scalar endpoint comparison remains in the retained source classifier described by Definition 136.2. Repacking these probe, degree, tensor, and endpoint rows gives the claimed unit boundary for both wedge orders. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree wedge cont unit boundary`

Definition 136.50 (Differential-form zero-degree consumer-neutrality surface)**.** *Fix* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *sources M, T as in Definition 136.1. The differential-form zero-degree consumer-neutrality surface is the zero-degree scalar boundary row of Definition 136.46, read together with the shared rows visible to every downstream consumer:*

1. *the carried BHist row, its* hsame *ledger, and the displayed* Cont *unit rows on the empty degree history;*
2. *the empty probe spine* ProbeBundle.Bnil *and its absence of probe membership rows;*
3. *the* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *source ledgers supplying the manifold and tensor endpoints;*
4. *the retained scalar endpoint classifier row;*
5. *the empty antisymmetry ledger and the source ledger rows recorded by the boundary coordinate λ_0.*

This surface is a shared root-face package only. It contains the data needed to reuse the scalar 0-form boundary, but it does not add a consumer-specific law row.

Lean4 (definition) `BEDC.Derived.DiffFormUp.DiffFormZeroDegreeConsumerNeutralitySurface`

Theorem 136.51 (Differential-form zero-degree shared consumer face)**.** *The zero-degree consumer-neutrality surface of Definition 136.50 lies wholly in the shared root face consumed by* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$.

Proof. Unpack the surface through Definition 136.50. Its probe coordinate is ProbeBundle.Bnil, so Definition 136.47 removes every probe-indexed membership row from the exported data.

The remaining classifier information is exactly the retained scalar endpoint and the visible source-ledger comparisons by Definition 136.48. These rows are carried $BHist$, classifier, scalar endpoint, empty antisymmetry, wedge-unit, and source-ledger rows.

Apply Definition 136.117. The shared root face is precisely the face that may be consumed by the three downstream chapters without assigning a row to a consumer-specific law. Hence the whole zero-degree surface lies in that shared face. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree shared consumer face`

Theorem 136.52 (Differential-form zero-degree consumer law separation)**.** *The zero-degree consumer-neutrality surface exports no* $d^2 = 0$ *row, no closedness row, no nondegeneracy row, and no contact nonintegrability row.*

Proof. By Definition 136.51, the surface lies inside the shared root face. Apply Definition 136.118: nilpotence is owned by $\mathsf{DeRham}^{\uparrow}$, closedness and nondegeneracy by $\mathsf{Symplectic}^{\uparrow}$, and contact nonintegrability by $\mathsf{Contact}^{\uparrow}$.

It remains to check that the wedge contribution does not smuggle in one of those laws. The wedge row available at zero degree is only the Cont unit boundary of Definition 136.49. That theorem identifies the empty probe and empty degree contribution of the scalar endpoint; it supplies no exterior-derivative square, no symplectic closedness or nondegeneracy clause, and no contact nonintegrability clause.

Therefore every law row named in the statement remains outside the exported zero-degree surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree consumer law separation`

Theorem 136.53 (Differential-form zero-degree deps-ready consumer seal)**.** *The definition Definition 136.50, the shared consumer-face theorem Definition 136.51, and the consumer law separation theorem Definition 136.52 form the citable zero-degree shared package for the* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *consumers.*

Proof. The definition names the exact rows carried by the scalar 0-form boundary. The shared consumer-face theorem places those rows in the common root face seen by the three downstream chapters.

The consumer law separation theorem records the complementary exclusion: nilpotence, closedness, nondegeneracy, and contact nonintegrability are not part of the zero-degree root package. Thus downstream consumers may cite this package for the shared zero-degree boundary while keeping their own laws separate. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormZeroDegree deps ready consumer seal`

Definition 136.54 (Differential-form exterior-derivative candidate ledger)**.** *For a carried* $\mathsf{DiffForm}^{\uparrow}$ *row* ω *and a displayed candidate output* $\partial\omega$*, the visible package* $\mathsf{DiffFormExteriorDerivativeLedger}_{M,T}(\omega, \partial\omega)$ *is the BHist ledger whose accepted rows are exactly the input carrier row for* ω*, the output carrier row for* $\partial\omega$*, the unary degree continuation row from* d_ω *to the displayed successor degree* $d_{\partial\omega}$*, the transported probe-bundle endpoint row, the transported tensor endpoint row, and the transported scalar endpoint row. Its provenance is restricted to* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*

Lean4 (definition) `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeCandidateLedger`

Theorem 136.55 (Differential-form exterior-derivative degree-raise ledger)**.** *Any row accepted by* $\mathsf{DiffFormExteriorDerivativeLedger}_{M,T}(\omega, \partial\omega)$ *exposes the input degree row* d_ω*, the output degree row* $d_{\partial\omega}$*, and the unary continuation row*

$$\mathsf{Cont}(d_\omega, d_{\partial\omega})$$

connecting the input degree to the displayed successor degree. This is only a degree-raising ledger for the candidate exterior-derivative row; it does not assert $d^2 = 0$*.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger degree raise`

Proof. Unfold Definition 136.54. The accepted package contains the input $\mathsf{DiffForm}^{\uparrow}$ carrier row for ω and the output $\mathsf{DiffForm}^{\uparrow}$ carrier row for $\partial\omega$, so projecting those two rows exposes d_ω and $d_{\partial\omega}$ through Definition 136.1.

The same definition requires the displayed unary continuation row from d_ω to $d_{\partial\omega}$. Repack that row with the two projected carrier degree rows as the visible unary-history provenance of the candidate exterior-derivative ledger.

No nilpotence row is present in the accepted package. The construction records only the successor-degree continuation, so an assertion of $d^2 = 0$ must be supplied by a downstream $\mathsf{DeRham}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivative degree raise ledger`

Theorem 136.56 (Differential-form exterior-derivative wedge-input stability)**.** *Let* $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$*, and suppose* $\mathsf{DiffFormExteriorDerivativeLedger}_{M,T}(\omega, \partial\omega)$ *accepts a candidate exterior-derivative ledger from* ω *to* $\partial\omega$*. Componentwise transport along the* $\mathsf{DiffForm}^{\uparrow}$ *classifier carries this data to a candidate ledger* $\mathsf{DiffFormExteriorDerivativeLedger}_{M,T}(\omega', \partial\omega')$ *whose output row is classified with* $\partial\omega$ *through the transported probe-bundle, tensor, scalar endpoint, antisymmetry, wedge, and degree rows.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivative wedge input stability`

Proof. Start with the classifier comparison $\omega \sim_{\mathsf{DiffForm}^{\uparrow}} \omega'$. By Definition 136.11, the carrier components of ω transport to the carrier components of ω' while preserving the visible probe-bundle, tensor, scalar endpoint, antisymmetry, and source-ledger comparisons.

Apply Definition 136.23 to the wedge and degree bookkeeping exposed at the boundary. The unary degree row used by the candidate ledger moves to the corresponding degree row for ω', and the successor continuation remains a visible Cont row.

For the scalar endpoint, use Definition 136.64. Together with the transported probe-bundle and tensor endpoint rows, this repacks the accepted rows of Definition 136.54 as a candidate ledger from ω' to an output row $\partial\omega'$ classified with $\partial\omega$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger classifier transport`
Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger hsame transport degree raise`

Definition 136.57 (Differential-form exterior-derivative input row)**.** *An accepted* $\mathsf{DiffForm}^{\uparrow}$ *input row for a downstream exterior-derivative candidate is the visible BEDC package*

$$(\omega, \eta, d, d^{+}, \kappa, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

where ω *is the source carried form row,* η *is the target carried form row,* d *is the source unary degree row,* d^{+} *is the target unary degree row, and* κ *is the one-step continuation row*

$$\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^{+}).$$

The remaining entries are the carried ProbeBundle *row* $\mathcal{P}$*, multilinear* $\mathsf{TensorProduct}^{\uparrow}$ *tensor row* τ*, retained scalar endpoint row* σ*, antisymmetry ledger* α*, and source ledger* λ *exposed by Definition 136.24. This input row is only admissible data for an exterior-derivative candidate; it carries no claim that* $d^2 = 0$*.*

Lean4 (definition) `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeInputRow`

Theorem 136.58 (Differential-form exterior-derivative degree-shift boundary)**.** *Every accepted input row of Definition 136.57 exposes exactly the source degree* d*, the target degree* d^{+}*, and the one-step continuation ledger* $\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^{+})$ *as its degree-raising boundary. The boundary may also cite the wedge degree ledger of Definition 136.22 when the same source participates in a wedge row, but it asserts no exterior-derivative identity.*

Proof. Unpack the accepted input row. Its displayed degree entries are d, d^{+}, and the continuation row κ, so the degree-raising boundary is already visible as BHist data.

The source form row is one of the carried rows bounded by Definition 136.24. Thus a downstream consumer can read its unary degree row, probe bundle, tensor row, scalar endpoint, antisymmetry ledger, and source ledger without importing any operator law.

When the same form is used in a wedge row, the compatible degree bookkeeping is the ledger of Definition 136.22. That ledger supplies only degree provenance for the wedge, so repacking it with the one-step row still leaves $d^2 = 0$ outside the $\mathsf{DiffForm}^{\uparrow}$ boundary. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeInputRow degree shift boundary`

Theorem 136.59 (Differential-form exterior-derivative scalar-transport boundary)**.** *Let* R *and* R' *be accepted input rows of Definition 136.57. If their source form rows are related componentwise by* hsame *on probe bundles, tensor rows, antisymmetry ledgers, and source ledgers, and if the retained scalar classifier relates their scalar endpoint rows, then the accepted scalar endpoint part of* R *transports to the accepted scalar endpoint part of* R'*.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivative scalar transport boundary`

Proof. First transport the source carried form. The componentwise hsame hypotheses are exactly the carrier entries used by Definition 136.10, so the transported source form row remains accepted by the $\mathsf{DiffForm}^{\uparrow}$ carrier.

Next preserve the classifier row. By Definition 136.11, the scalar endpoint clause in the form classifier is stable under the same componentwise transport.

Finally apply the scalar endpoint boundary itself. The scalar part of an accepted input row is the retained scalar classifier entry bounded by Definition 136.64. Therefore the scalar endpoint accepted for R transports to the corresponding accepted scalar endpoint for R' without adding a new exterior-derivative law. □

Theorem 136.60 (Differential-form exterior-derivative two-step continuation ledger)**.** *Let $R_{\omega\eta}$ and $R_{\eta\theta}$ be accepted exterior-derivative input rows of Definition 136.57. Suppose $R_{\omega\eta}$ has source row ω, target row η, source degree d_ω, and target degree d_η, while $R_{\eta\theta}$ has source row η, target row θ, source degree d_η, and target degree d_θ. Then the shared middle row exposes the two-step degree continuation row*

$$\mathsf{Cont}(d_\omega, \mathsf{E1}(\mathsf{E1}(\mathsf{e})), d_\theta).$$

This composite is only a degree-continuation ledger from ω through η to θ; it does not assert that the second exterior derivative vanishes.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger degree continuation composite`

Proof. Apply Definition 136.58 to $R_{\omega\eta}$. Its degree boundary supplies

$$\mathsf{Cont}(d_\omega, \mathsf{E1}(\mathsf{e}), d_\eta).$$

Apply the same boundary theorem to $R_{\eta\theta}$. Since the target row of the first accepted input is the source row of the second, the middle degree row is the same displayed d_η, and the second boundary supplies

$$\mathsf{Cont}(d_\eta, \mathsf{E1}(\mathsf{e}), d_\theta).$$

By Definition 21.31, the two continuation ledgers compose through the shared middle degree. It remains only to compute the exposed tail. The constructor clause in the generated continuation relation of Definition 21.7 gives

$$\mathsf{Cont}(\mathsf{E1}(\mathsf{e}), \mathsf{E1}(\mathsf{e}), \mathsf{E1}(\mathsf{E1}(\mathsf{e}))).$$

Substituting this tail in the composite-tail equivalence yields the displayed row

$$\mathsf{Cont}(d_\omega, \mathsf{E1}(\mathsf{E1}(\mathsf{e})), d_\theta).$$

All rows used in the construction are the two accepted input rows and the kernel continuation composition rule. The conclusion records only that two successor-degree continuations are composable as BHist data, so it leaves any $d^2 = 0$ assertion to the downstream $\mathsf{DeRham}^\uparrow$ surface. □

Theorem 136.61 (Differential-form exterior-derivative downstream scope)**.** *Downstream exterior-derivative chapters may use a* $\mathsf{DiffForm}^\uparrow$ *row only through its degree row, its carried* ProbeBundle *of tangent probes, its multilinear* $\mathsf{TensorProduct}^\uparrow$ *tensor row, its scalar endpoint classifier, its anti-symmetry ledger, wedge ledger coverage, the wedge associator ledger, the wedge degree ledger, and the exterior-derivative candidate ledger of Definition 136.54. In particular, the DiffForm surface supplies the carrier, classifier, exterior-algebra substrate, degree-raise candidate row, and endpoint transport substrate for* $\mathsf{DeRham}^\uparrow$, $\mathsf{Symplectic}^\uparrow$, *and* $\mathsf{Contact}^\uparrow$, *but it does not by itself assert $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivative downstream scope`

Proof. Inspect the exported fields of Definition 136.165. Each accessible component is one of the displayed carrier, classifier, stability, wedge, or ledger rows.

The exterior derivative needs the degree row and the multilinear scalar endpoint surface in order to state degree raising and scalar endpoint transport. Those rows are available from the carrier and classifier; the wedge degree ledger supplies the visible input-degree bookkeeping allowed at the de Rham boundary. The candidate ledger of Definition 136.54 supplies the positive output-carrier

and successor-degree row allowed at that boundary. Stability is supplied by the two transport theorems, Definition 136.23, and Definition 136.56.

The identities $d^2 = 0$, closedness, nondegeneracy, and contact nonintegrability require additional operator or geometric rows. They are not fields of the $\mathsf{DiffForm}^{\uparrow}$ surface, so downstream chapters must state and certify them in their own $\mathsf{NameCert}$ surfaces. □

Theorem 136.62 (Differential-form source scope)**.** *Every row accepted by* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *depends only on* $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$. *No accepted row may import a carrier component, classifier clause, or endpoint comparison from outside those six displayed sources.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistCarrier source scope`

Proof. Project the accepted row through Definition 136.1. Its six components are exactly the degree history, probe bundle, tensor row, scalar endpoint, antisymmetry ledger, and source ledger. The only structural rows mentioned there are $BHist$, $\mathsf{ProbeBundle}$, the $\mathsf{TensorProduct}^{\uparrow}$ continuation ledgers Cont, and the two upstream $\mathsf{NameCert}$ sources.

Now read the classifier clauses in Definition 136.2. Degree, tensor, antisymmetry, and source-ledger comparisons are hsame comparisons on visible histories, while scalar endpoint comparison is the retained scalar classifier supplied by the manifold and tensor sources. Thus every accepted classifier step remains inside the stated source scope. □

Theorem 136.63 (Differential-form wedge degree ledger)**.** *For a carried wedge row* $\omega \wedge_{\mathsf{DiffForm}^{\uparrow}} \eta$, *the visible BHist provenance exposes the degree row of* ω, *the degree row of* η, *the* $\mathsf{TensorProduct}^{\uparrow}$ *concatenation ledger supplied by Definition 136.15, and the resulting unary degree row of the wedge. This ledger states provenance for the wedge degree and does not assert any exterior-derivative identity.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDegreeLedger visible source rows`

Proof. Unpack the wedge row by Definition 136.15. Admission of the wedge requires a visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation row joining the tensor component of the left carried form to the tensor component of the right carried form.

Read the two input degree rows from Definition 136.1. They are the first carrier components of ω and η, and the wedge row records them in its source ledger together with the tensor concatenation row.

Repack those displayed histories as the wedge degree ledger. The output degree row is a unary history visible in the carried wedge row, so downstream chapters may cite the two input degree rows, the concatenation provenance, and the output degree row without adding any law about d. □

Theorem 136.64 (Differential-form scalar endpoint transport)**.** *Let* ω *and* ω' *be* $\mathsf{DiffForm}^{\uparrow}$ *rows with componentwise* hsame *comparisons on their probe bundles, tensor rows, antisymmetry ledgers, and source ledgers. If the scalar endpoint of* ω *is accepted by the retained scalar classifier from the upstream manifold and tensor sources, then the scalar endpoint comparison transports to* ω' *through the* $\mathsf{DiffForm}^{\uparrow}$ *classifier.*

Proof. First transport the carrier row. The componentwise comparisons on the probe bundle, tensor row, antisymmetry ledger, and source ledger are exactly the visible histories required by Definition 136.10, so the transported row is again accepted by $\mathsf{DiffFormBHistCarrier}_{M,T}$.

Next apply classifier stability. By Definition 136.11, the scalar endpoint clause of Definition 136.2 is preserved under the same componentwise transport.

Finally, the scalar comparison used in that clause is not a new $\mathsf{DiffForm}^{\uparrow}$ primitive. It is the retained scalar classifier from the manifold and tensor sources, so endpoint comparison moves along the transported probe, tensor, antisymmetry, and source ledgers already present in the carried row. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBHistCarrier scalar endpoint transport`

Definition 136.65 (Differential-form exterior-derivative candidate row)**.** *Fix carried rows ω and η of* $\mathsf{DiffFormBHistCarrier}_{M,T}$*. A differential-form exterior-derivative candidate row $D(\omega, \eta)$ is an accepted visible BHist package consisting exactly of the following data:*

1. *the input carrier row ω and the output carrier row η;*
2. *the unary input degree row d_ω, the unary output degree row d_η, and the displayed one-step degree-raise ledger* $\mathsf{Cont}(d_\omega, \mathsf{one}, d_\eta)$*;*
3. *the transported tangent-probe bundle ledger from ω to η;*
4. *the transported* $\mathsf{TensorProduct}^{\uparrow}$ *multilinear row ledger from the input tensor row to the output tensor row;*
5. *the transported scalar endpoint ledger classified by the retained scalar classifier of the manifold and tensor sources;*
6. *a source ledger naming only $BHist$,* hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *as admissible sources for the displayed input-output package.*

This row is only the input-output surface for an exterior derivative supplied by a downstream certificate. It does not assert $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, or any second-derivative identity.

Theorem 136.66 (Differential-form exterior-derivative input-output ledger exactness)**.** *Every accepted $D(\omega, \eta)$ exposes exactly the input form row, the output form row, the degree-raise* Cont *ledger, the probe transport ledger, the* $\mathsf{TensorProduct}^{\uparrow}$ *transport ledger, the scalar endpoint transport ledger, and the source ledger listed in Definition 136.65. No closedness, nondegeneracy, contact condition, or second-derivative identity can be projected from such a row.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeInputRow ledger exactness`
Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger input output exactness`

Proof. Unfold Definition 136.65. The first two displayed fields are carried $\mathsf{DiffFormBHistCarrier}_{M,T}$ rows, and their carrier status is the same visible status transported by Definition 136.10.

The output classifier is read only through Definition 136.11. The scalar endpoint entry is one of the displayed transport ledgers, so its admissible comparison is exactly the scalar endpoint transport of Definition 136.64.

The remaining provenance is the source ledger. By Definition 136.62, that ledger is restricted to $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$. These are the only fields displayed by the candidate row, so exhausting the list gives the claimed input-output ledger surface and leaves the excluded geometric and operator identities unavailable. □

Theorem 136.67 (Differential-form exterior-derivative candidate classifier transport)**.** *Let $D(\omega, \eta)$ be an accepted exterior-derivative candidate row. Suppose ω' is related to ω by $\sim_{\mathsf{DiffForm}^{\uparrow}}$, and suppose every displayed degree, probe, tensor, scalar, and source ledger of $D(\omega, \eta)$ is transported componentwise by* hsame *and by the retained source classifiers named in the candidate source ledger. Then the transported output row η' is related to η by $\sim_{\mathsf{DiffForm}^{\uparrow}}$, and the transported package $D(\omega', \eta')$ is again an accepted exterior-derivative candidate row.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger candidate classifier transport`

Proof. Transport the input and output carrier rows through Definition 136.10. The hypothesis gives the componentwise hsame comparisons for the displayed degree, probe, tensor, scalar, and source ledgers, and the source ledger permits only the retained manifold and tensor classifiers for non-hsame endpoint comparisons.

The scalar endpoint clause is transported by Definition 136.64. The output form classifier then follows from Definition 136.11, applied to the transported degree, tensor, antisymmetry, scalar endpoint, and source ledger fields of η and η'.

It remains to rebuild the candidate row. Repack the transported input carrier, transported output carrier, transported one-step degree-raise Cont ledger, transported probe ledger, transported tensor ledger, transported scalar endpoint ledger, and the same restricted source ledger. This is exactly the field list of Definition 136.65, so $D(\omega', \eta')$ is accepted. □

Definition 136.68 (Differential-form exterior-derivative visible input package)**.** *Let*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

be a source row carried by $\mathsf{DiffFormBHistCarrier}_{M,T}$*, and let*

$$D\omega = (d^+, \mathcal{P}^+, \tau^+, \sigma^+, \alpha^+, \lambda^+)$$

be a carried output candidate. The package $\mathsf{DiffFormExteriorInput}_{M,T}(\omega, D\omega)$ *is accepted exactly when its visible provenance consists of the two displayed* $\mathsf{DiffForm}^{\uparrow}$ *carrier rows, the unary degree rows* $\mathsf{UnaryHistory}(d)$ *and* $\mathsf{UnaryHistory}(d^+)$*, the degree-raising continuation row*

$$\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^+),$$

the transported ProbeBundle *rows connecting $\mathcal{P}$ with $\mathcal{P}^+$, the retained* $\mathsf{TensorProduct}^{\uparrow}$ *tensor row for the multilinear output candidate, the retained scalar classifier comparison between the source and output scalar endpoints, and the operator-owned source ledger recording that these rows are the only inputs supplied to the exterior-derivative construction. The package asserts no row for $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability.*

Lean4 (definition) `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeVisibleInputPackage`

Theorem 136.69 (Differential-form exterior-derivative degree successor ledger)**.** *Every package accepted by* $\mathsf{DiffFormExteriorInput}_{M,T}(\omega, D\omega)$ *exposes the source degree row* $\mathsf{UnaryHistory}(d)$*, the output degree row* $\mathsf{UnaryHistory}(d^+)$*, and the visible successor continuation row*

$$\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^+).$$

These are the only degree rows made available to a downstream exterior-derivative consumer by the package.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger degree successor nonempty`

Proof. Unpack the accepted package of Definition 136.68. Its degree fields are listed as the two unary-history rows and the displayed $\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^+)$ row.

The source and output are carried rows of Definition 136.1, so their degree components are visible BHist carrier entries rather than hidden operator data. Applying the source-scope boundary of Definition 136.62 shows that no other degree provenance may be imported through this package. □

Theorem 136.70 (Differential-form exterior-derivative input classifier stability)**.** *Let* $\mathsf{DiffFormExteriorInput}_{M,T}(\omega,$ *be accepted. If the source and output carrier rows are transported componentwise by* hsame *to* ω' *and* $D\omega'$*, then* $\mathsf{DiffFormExteriorInput}_{M,T}(\omega', D\omega')$ *is accepted. Under the same transport, the retained scalar endpoint comparison between the source and output scalar endpoints remains the scalar comparison carried by the transported package.*

Proof. First transport the two carrier rows. By Definition 136.10, the transported source ω' and transported output $D\omega'$ remain accepted $\mathsf{DiffForm}^{\uparrow}$ carrier rows.

Next transport the classifier data. Apply Definition 136.11 to the componentwise hsame comparisons of the two carrier rows. The degree rows, probe bundles, tensor rows, antisymmetry ledgers, and operator-owned source ledger remain the same visible rows up to hsame, and the successor continuation row $\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^+)$ transports to the corresponding continuation row for the transported degree endpoints.

Finally, apply Definition 136.64. The retained scalar endpoint comparison in the accepted package is preserved by the same componentwise transport, so the transported rows reassemble as $\mathsf{DiffFormExteriorInput}_{M,T}(\omega', D\omega')$ with its scalar comparison still visible. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeInputRow classifier transport`

Definition 136.71 (Differential-form downstream obligation inventory)**.** *The downstream obligation inventory for* $\mathsf{DiffForm}^{\uparrow}$ *is the ten-field boundary used when* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$ *consume the differential-form surface:*

1. *traditional target:* $\mathsf{DiffForm}^{\uparrow}$ *as the boundary source for* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$*;*
2. *BEDC source: BHist,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*;*
3. *carrier:* $\mathsf{DiffFormBHistCarrier}_{M,T}$*;*
4. *classifier:* $\sim_{\mathsf{DiffForm}^{\uparrow}}$*;*
5. *stability obligations: carrier* hsame *transport, form classifier stability, scalar endpoint transport, and exterior-input classifier stability;*
6. *ledger: only degree, probe, tensor, scalar, antisymmetry, and source rows may be projected;*
7. *core theorem: the carrier, exterior-input, and consumer-boundary rows displayed in this file;*
8. *exactness: row exhaustion of the displayed carrier and exterior-input packages;*
9. *standard bridge: absent data;*
10. *status:* $\mathsf{ProofTarget}$*.*

This inventory is a boundary statement. It supplies the rows that later chapters may consume, and it does not assert $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, or any standard bridge.*

Theorem 136.72 (Differential-form downstream carrier-source obligation)**.** *Every downstream consumer of a* $\mathsf{DiffForm}^{\uparrow}$ *carrier row may project only the six carrier coordinates*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and the source scope

$$BHist,\ \mathsf{hsame},\ \mathsf{Cont},\ \mathsf{ProbeBundle},\ \mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}},\ \mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}.$$

No $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, or* $\mathsf{Contact}^{\uparrow}$ *consumer obtains an additional carrier coordinate, hidden classifier, operator row, or geometric law from the* $\mathsf{DiffForm}^{\uparrow}$ *carrier alone.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDownstreamCarrierSource obligation`

Proof. Project the carrier row by Definition 136.1. A carried form is exactly the six-tuple $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, so the degree, probe-bundle, tensor, scalar endpoint, antisymmetry, and source-ledger entries are the full carrier surface.

Next apply Definition 136.62. The source ledger for any accepted carrier row is restricted to $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

Combining the carrier projection with the source-scope projection exhausts what a downstream consumer can read. Operator identities and geometric laws are not carrier coordinates and are not named by the source ledger, so they cannot be projected from the carrier alone. □

Theorem 136.73 (Differential-form downstream exterior-input obligation)**.** *An accepted exterior-derivative input package exposes only the source carried row, the output carried row, the one-step degree continuation ledger, the probe transport ledger, the* $\mathsf{TensorProduct}^{\uparrow}$ *tensor transport ledger, the retained scalar endpoint transport, and the restricted source ledger. It exposes no* d^2 *row, closedness row, nondegeneracy row, contact nonintegrability row, or second-derivative law.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger downstream input obligation`

Proof. Unpack Definition 136.68. The package lists the source and output carried rows, the unary degree histories, the displayed one-step continuation $\mathsf{Cont}(d, \mathsf{E1}(\mathsf{e}), d^{+})$, the probe transport rows, the tensor row, the scalar endpoint comparison, and the operator-owned source ledger.

Transport stability is exactly the row supplied by Definition 136.70. It keeps the package accepted under componentwise hsame transport and preserves the retained scalar endpoint comparison as the scalar comparison of the transported package.

The displayed list contains no row for d^2, closedness, nondegeneracy, contact nonintegrability, or a second application of the exterior derivative. By exhausting the visible package fields, those laws remain outside the $\mathsf{DiffForm}^{\uparrow}$ exterior-input obligation. □

Theorem 136.74 (Differential-form downstream consumer boundary)**.** *The chapters* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$ *consume only the displayed* $\mathsf{DiffForm}^{\uparrow}$ *carrier, source, and exterior-input rows of Definition 136.71. Each such chapter must supply its own operator law or geometric law:* $d^2 = 0$ *for de Rham structure, closedness and nondegeneracy for symplectic structure, and contact nonintegrability for contact structure.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDownstreamConsumer boundary`

Proof. First use Definition 136.72. It bounds every carrier projection by the six displayed carrier coordinates and the six named BEDC sources.

Next use Definition 136.73. It permits an exterior-derivative consumer to read the source and output carried rows, one-step degree bookkeeping, probe and tensor transport, scalar endpoint transport, and the restricted source ledger, but not d^2, closedness, nondegeneracy, or contact nonintegrability.

Finally apply Definition 136.61. That theorem identifies $\mathsf{DiffForm}^{\uparrow}$ as the carrier, classifier, exterior-algebra substrate, degree-raise candidate row, and endpoint-transport substrate for $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$. Composing it with the two obligation rows above leaves exactly the displayed DiffForm rows available to downstream consumers, so their operator and geometric laws must be supplied in their own certificate surfaces. □

Definition 136.75 (Differential-form antisymmetry chain ledger)**.** *For carried rows*

$$\omega = (d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and

$$\omega' = (d, \mathcal{P}', \tau', \sigma', \alpha', \lambda')$$

in $\mathsf{DiffFormBHistCarrier}_{M,T}$*, a differential-form antisymmetry chain ledger is a visible BHist row* $\mathsf{AntiChain}_{\omega,\omega'}$ *accepted by* $\mathsf{DiffFormAntisymmetryChainLedger}_{M,T}$ *exactly when it displays a finite spine of adjacent-swap rows*

$$\mathcal{P} = \mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_n = \mathcal{P}'$$

over the carried ProbeBundle*, with one scalar endpoint row and one signed scalar comparison row recorded for each adjacent step* $\mathcal{P}_i \rightsquigarrow \mathcal{P}_{i+1}$*. Its accepted source rows are only BHist,* hsame*,* Cont*, the displayed* ProbeBundle *rows,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*; the ledger does not contain any permutation oracle outside those rows.*

Theorem 136.76 (Differential-form antisymmetry chain coverage)**.** *Every admitted finite permutation comparison between two carried* $\mathsf{DiffForm}^{\uparrow}$ *rows over the same degree row is accepted only through a differential-form antisymmetry chain ledger of Definition 136.75. In particular, each comparison row in the ledger is a visible adjacent-swap row, each adjacent swap has the reverse row supplied by Definition 136.13, and the composite comparison uses no source beyond BHist,* hsame*,* Cont*,* ProbeBundle*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*

Proof. Read the admitted permutation comparison inside the carrier row of Definition 136.1. The only place where antisymmetry data may enter a carried $\mathsf{DiffForm}^{\uparrow}$ row is the displayed ledger α together with the provenance ledger λ, so a permutation comparison without visible rows has no carrier witness.

Induct on the displayed finite adjacent-swap spine. The empty spine compares the probe bundle with itself, and the endpoint comparison is the retained scalar classifier clause already present in Definition 136.2.

For the cons step, the head row is one adjacent swap of neighboring carried probe slots. Apply Definition 136.13 to obtain the reverse row and the scalar comparison returning the double swap to the original endpoint. The induction hypothesis supplies coverage for the tail of the chain, and hsame transitivity composes the visible BHist rows.

All rows used in the construction are the rows listed in Definition 136.75. Therefore the finite permutation comparison is exhausted by the adjacent-swap ledger, with no hidden permutation rule or external classifier. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormAntisymmetryChainLedger coverage`

Theorem 136.77 (Differential-form antisymmetry chain classifier stability)**.** *Let ω and η be carried* $\mathsf{DiffForm}^{\uparrow}$ *rows whose permutation comparison is witnessed by a differential-form antisymmetry chain ledger. If ω and η are transported componentwise by* hsame *comparisons on their degree rows, probe bundles, tensor rows, scalar endpoint rows, antisymmetry ledgers, and source ledgers, then the transported rows carry the transported antisymmetry chain ledger and remain compared by* $\sim_{\mathsf{DiffForm}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormAntisymmetryChainLedger classifier stability`

Proof. First transport the two carrier rows by Definition 136.10. Componentwise hsame comparisons carry the probe bundles, tensor rows, scalar endpoints, antisymmetry ledgers, and source ledgers to the transported rows while retaining the same manifold and tensor source certificates.

Next transport the finite chain ledger. Each row of Definition 136.75 is a visible BHist row, and each adjacent swap in the chain is a row over the transported ProbeBundle. Transport the scalar endpoint comparison for each step through Definition 136.64.

Apply Definition 136.76 to the transported chain. The theorem identifies the transported finite permutation comparison as exactly the composite of adjacent swaps in the visible ledger, and it retains the reverse rows supplied by Definition 136.13.

Finally apply Definition 136.11. The degree, tensor, antisymmetry, and source-ledger clauses are hsame clauses, while the scalar endpoint clause has already been transported through the retained scalar classifier. These clauses reassemble into the required $\sim_{\mathsf{DiffForm}^{\uparrow}}$ comparison for the transported rows. □

Theorem 136.78 (Differential-form derived antisymmetry normal form)**.** *Every finite permutation comparison admitted for carried* $\mathsf{DiffForm}^{\uparrow}$ *rows over the same degree row factors through the differential-form antisymmetry chain ledger of Definition 136.75. Each step of the factorization is a visible adjacent swap, reverse rows are supplied by Definition 136.13, and any transported comparison remains a* $\mathsf{DiffForm}^{\uparrow}$ *classifier comparison by Definition 136.77.*

Proof. Begin with the carried rows in Definition 136.1. Their permutation data are not an external oracle: the carrier exposes only the antisymmetry ledger and the source ledger, so any admitted comparison must be read as a displayed finite spine of probe-bundle rows.

Apply Definition 136.75 to identify this spine as adjacent swaps over the carried ProbeBundle rows. For each step, Definition 136.13 supplies the reverse row and the scalar endpoint comparison needed to return along the same visible data.

Finally transport the comparison componentwise. The stability theorem Definition 136.77 carries the degree, probe, tensor, scalar endpoint, antisymmetry, and source rows to the transported carrier rows, so the derived comparison remains internal to $\sim_{\mathsf{DiffForm}^{\uparrow}}$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDerivedAntisymmetry normal form`

Theorem 136.79 (Differential-form de Rham boundary consumption)**.** *A downstream* $\mathsf{DeRham}^{\uparrow}$ *exterior-derivative row can consume* $\mathsf{DiffForm}^{\uparrow}$ *only through the carried form rows, their classifier rows, wedge ledger coverage, the wedge degree ledger, exterior-derivative candidate and input rows, scalar endpoint transport, and the antisymmetry normal form of Definition 136.78. It cannot read $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability from* $\mathsf{DiffForm}^{\uparrow}$.

Proof. The carrier and classifier entries are exactly the displayed $\mathsf{DiffFormBHistCarrier}_{M,T}$ and $\sim_{\mathsf{DiffForm}^\uparrow}$ rows. Wedge admission is bounded by Definition 136.15, and its degree bookkeeping is the ledger of Definition 136.22.

The exterior-derivative interface is bounded by Definition 136.24 and Definition 136.61. These theorems list the visible candidate rows, input rows, probe/tensor/scalar transport rows, and source ledgers available to a consumer.

It remains to control permutation comparisons inside the same boundary. Apply Definition 136.78: every admitted comparison is decomposed into the chain ledger, adjacent-swap reverse rows, and classifier-stable transported rows.

None of these cited rows contains an operator-square identity, a closedness predicate, a nondegeneracy predicate, or a contact nonintegrability predicate. Those obligations therefore must be stated by the consuming $\mathsf{DeRham}^\uparrow$, $\mathsf{Symplectic}^\uparrow$, or $\mathsf{Contact}^\uparrow$ surface rather than read from $\mathsf{DiffForm}^\uparrow$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormAntisymmetryBoundary derham consumption separation`
Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger classifier transport nonempty boundary`

Theorem 136.80 (Differential-form wedge derivative input boundary)**.** *When the same carried form appears both in a wedge row and in an exterior-derivative input package, the shared visible data are exactly the unary degree row, the wedge degree continuation ledger, the one-step derivative continuation ledger, the probe, tensor, and scalar transport rows, and the source ledger. No Leibniz rule and no nilpotence row are supplied by this shared boundary.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDerivativeInput boundary`

Proof. Read the wedge side first. The available multiplicative data are the tensor coverage theorem Definition 136.15 and the unary degree continuation ledger of Definition 136.22; both are rows over the same carried degree, probe, tensor, scalar endpoint, and source entries.

Read the exterior-derivative side through Definition 136.24 and Definition 136.61. These rows expose the derivative candidate, the one-step degree continuation, and the transport clauses for the probe bundle, tensor row, scalar endpoint, and source ledger.

The intersection of the two readings is therefore the visible carrier data they both name. Antisymmetry comparisons inside that intersection are governed by Definition 136.78, so even transported permutation data stay ledger-based.

A Leibniz rule would relate a derivative of a wedge to a sum of two derivative terms, and nilpotence would relate two derivative steps. Neither row is among the wedge coverage, wedge degree, exterior-derivative input, transport, or source-ledger rows listed above, so the shared boundary supplies neither one. □

Definition 136.81 (Differential-form admissible root row)**.** *For fixed sources* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$*, an admissible* $\mathsf{DiffForm}^\uparrow$ *root row is exactly the visible BEDC tuple*

$$(BHist, \mathsf{hsame}, \mathsf{Cont}, \mathsf{ProbeBundle}, \mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}, \mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}, \mathsf{Carr}, \mathsf{Class}, \mathsf{Wedge}, \mathsf{Der})$$

where Carr *is the carrier row of Definition 136.1,* Class *is the classifier row of Definition 136.2,* Wedge *is the visible family consisting of Definition 136.15, Definition 136.16, Definition 136.19, and Definition 136.22, and* Der *is the exterior-derivative input family consisting of Definition 136.65 and Definition 136.66. No further carrier, classifier, closedness, nilpotence, nondegeneracy, contact nonintegrability, or bridge row is part of the root row.*

Theorem 136.82 (Differential-form root-row carrier scope)**.** *Every admissible root row of Definition 136.81 exposes only the carried form rows of Definition 136.1, the classifier rows of Definition 136.2, and the source boundary of Definition 136.62 on its carrier side.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootRow carrier scope`

Proof. Unpack the root row. Its carrier coordinate is named as Carr and is definitionally the row of Definition 136.1; its classifier coordinate is Class and is definitionally the row of Definition 136.2.

Project the carried row through Definition 136.62. The only structural sources available to the carrier and classifier are $BHist$, hsame, Cont, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

The definition of the root row contains no second carrier slot and no additional classifier slot. Hence every carrier-side read factors through the two displayed definitions and the cited source boundary. □

Theorem 136.83 (Differential-form root-row wedge scope)**.** *Every wedge use admitted by Definition 136.81 is limited to Definition 136.15, Definition 136.16, Definition 136.19, and Definition 136.22.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootRow wedge scope`

Proof. Inspect the Wedge coordinate of the root row. It is declared as the four displayed wedge rows and no operator law beyond those rows.

The coverage theorem supplies the admitted tensor concatenation surface. The probe-concatenation ledger records the probe spine, the associator ledger records parenthesized tensor transport, and the degree ledger records the visible unary degree bookkeeping.

Since the root row has no other wedge coordinate, any downstream wedge read must choose one of these four rows. A Leibniz rule, closedness row, or nilpotence row is therefore not present in the $\mathsf{DiffForm}^{\uparrow}$ root surface. □

Theorem 136.84 (Differential-form root-row derivative scope)**.** *Every exterior-derivative input admitted by Definition 136.81 is one of the candidate rows of Definition 136.65 together with the exactness rows of Definition 136.66.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootRow derivative scope`

Proof. Read the Der coordinate. It lists the candidate row definition and the input-output ledger exactness theorem as the complete exterior-derivative input family.

The candidate row supplies only the source carried row, target carried row, degree entries, one-step continuation row, probe bundle, tensor row, scalar endpoint, antisymmetry ledger, and source ledger. The exactness theorem then states that accepted input-output use is exhausted by those visible rows.

No additional derivative law is declared in the root row. Thus a second derivative identity, closedness assertion, or bridge comparison must come from a consumer certificate rather than from $\mathsf{DiffForm}^{\uparrow}$. □

Theorem 136.85 (Differential-form root-row downstream boundary)**.** *The chapters* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$ *may consume the* $\mathsf{DiffForm}^{\uparrow}$ *surface only through the admissible root row of Definition 136.81. They must supply closedness, nondegeneracy, and contact nonintegrability in their own certificates.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootRow downstream boundary`

Proof. Combine the three scope projections above. The carrier projection gives only the carrier, classifier, and source rows; the wedge projection gives only the four wedge ledgers; the derivative projection gives only the candidate rows and input-output exactness rows.

A $\mathsf{DeRham}^{\uparrow}$ consumer may therefore read the displayed exterior-derivative input family, but it receives no $d^2 = 0$ or closedness row. A $\mathsf{Symplectic}^{\uparrow}$ consumer may read carried forms and wedge ledgers, but it receives no nondegeneracy row.

A $\mathsf{Contact}^{\uparrow}$ consumer may read the same carrier, wedge, and derivative surface, but it receives no contact nonintegrability row. These three geometric obligations are not coordinates of the admissible root row, so each must be certified on the consuming surface itself. □

Definition 136.86 (Differential-form root source obligation package)**.** *The root source obligation package for* $\mathsf{DiffForm}^{\uparrow}$ *is the following per-object template, read over the certificate section section 136.2.*

1. *The traditional target is the differential-form surface of antisymmetric multilinear tangent probes equipped with wedge.*
2. *The BEDC source language is* BHist*, with comparison rows supplied by* hsame*.*
3. *Continuation rows are exactly the visible* Cont *rows attached to tensor concatenation, wedge degree bookkeeping, and the exported exterior-derivative input boundary.*
4. *Probe data are finite* $\mathsf{ProbeBundle}$ *rows over the tangent source surface.*
5. *The upstream certificate sources are* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*
6. *The carrier choice is* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *of Definition 136.1.*
7. *The classifier choice is* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *of Definition 136.2.*
8. *Stability obligations are the carrier transport, classifier stability, wedge probe transport, wedge associator transport, wedge degree stability, antisymmetry transport, and exterior-derivative input transport rows already displayed in the chapter.*
9. *The source ledger is the visible ledger over* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*
10. *The core theorem list consists of carrier obligation, classifier obligation, ledger exactness, classifier reflexivity, wedge ledger coverage, wedge probe concatenation coverage, wedge associator closure, wedge degree stability, and the exported input-boundary statements.*
11. *The exactness predicate is ledger exhaustion: every accepted root row is one of the displayed carrier, classifier, continuation, probe, upstream certificate, wedge, antisymmetry, or input-boundary rows.*
12. *The standard bridge slot is absent, and the current status is a paper-side root obligation surface rather than a standard-object bridge.*

No closedness predicate, nondegeneracy predicate, contact predicate, or $d^2 = 0$ *row belongs to this root source package.*

Theorem 136.87 (Differential-form root carrier source obligation)**.** *Every admitted root* $\mathsf{DiffForm}^{\uparrow}$ *row factors through the six displayed carrier coordinates*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

of Definition 136.1 and through the upstream $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *certificate rows. The root carrier has no host tangent-space carrier and no external alternating-map carrier outside those displayed BEDC sources.*

Proof. Unpack the carrier definition. A row accepted by $\mathsf{DiffFormBHistCarrier}_{M,T}$ is presented by the six histories $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, and the acceptance clauses name only degree, probe, tensor, scalar endpoint, antisymmetry, and source-ledger data.

The probe coordinate is read through the tangent-source rows retained by $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$. The tensor and continuation coordinates are read through $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$, while the scalar endpoint classifier is the scalar classifier retained by the same upstream sources.

Finally inspect the source ledger λ. It records the names M and T and the five visible carrier components already listed. Since no acceptance clause constructs another carrier, a host tangent-space object or an external alternating-map object has no entry point into the root row. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootCarrierSource obligation`

Theorem 136.88 (Differential-form root wedge operation obligation)**.** *The wedge operation obligation for root* $\mathsf{DiffForm}^\uparrow$ *rows is exactly the visible concatenation, degree-additivity, associator, and classifier-stability ledger supplied by Definition 136.15, Definition 136.16, Definition 136.17, Definition 136.18, Definition 136.19, Definition 136.20, Definition 136.22, and Definition 136.23.*

Proof. Read wedge admission first. The coverage theorem Definition 136.15 bounds the operation by the two input carrier rows, the concatenated tensor row, the output scalar endpoint, the inherited antisymmetry data, and the displayed source ledger.

Next read the probe and degree ledgers. The probe spine is the visible concatenation ledger of Definition 136.16, with coverage and classifier transport supplied by Definition 136.17 and Definition 136.18. The degree row is the unary-history ledger of Definition 136.22, and its classifier transport is Definition 136.23.

It remains to account for parenthesizing. The associator data are exactly the visible ledger of Definition 136.19, and closure under the carried classifier is supplied by Definition 136.20. These cited rows exhaust the operation obligation, so no additional wedge source is being assumed. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootWedgeOperation obligation`

Theorem 136.89 (Differential-form root source ledger obligation)**.** *All accepted source ledger entries for the root* $\mathsf{DiffForm}^\uparrow$ *package are exhausted by* $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *rows. No standard bridge, closedness predicate, nondegeneracy predicate, contact predicate, or* $d^2 = 0$ *row is part of the root obligation.*

Proof. Begin with the root package of Definition 136.86. Its source language, comparison rows, continuation rows, probe rows, and upstream certificate rows are explicitly listed as $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$.

The carrier and classifier definitions do not widen that list. Definition 136.1 exposes only the six carried coordinates and their upstream sources, while Definition 136.2 uses only hsame and the retained scalar classifier. The core ledger exactness statement Definition 136.6 gives the same exhaustion for the core certificate rows.

The remaining root operation rows are wedge rows. By Definition 136.88, these are the visible concatenation, degree, associator, and classifier-stability ledgers already named above. None of those ledgers contains a standard bridge, a closedness predicate, a nondegeneracy predicate, a contact predicate, or a two-step exterior-derivative identity. □

Definition 136.90 (Differential-form root obligation package)**.** *The root obligation package for* $\mathsf{DiffForm}^{\uparrow}$ *is the displayed* $BHist$ *package over* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *whose public rows are the following four surfaces.*

1. *The visible source surface is the carrier and classifier surface of Definition 136.1 and Definition 136.3, with no source outside the six displayed inputs.*
2. *The antisymmetry ledger is the finite adjacent-swap chain surface of Definition 136.75, transported through the* $\mathsf{DiffForm}^{\uparrow}$ *classifier.*
3. *The wedge-probe ledger is the wedge degree, tensor-continuation, and probe-concatenation surface carried by admitted wedge rows.*
4. *The downstream consumption row is the boundary through which* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$ *may consume* $\mathsf{DiffForm}^{\uparrow}$ *data.*

The package exports no standard bridge and no geometric identity beyond these listed rows.

Theorem 136.91 (Differential-form visible source surface obligation)**.** *The root obligation package of Definition 136.90 exposes no source beyond* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*. Its carrier, classifier, and core ledger rows are exactly the rows of Definition 136.1, Definition 136.3, Definition 136.6, and Definition 136.62.*

Proof. Read the carrier first. By Definition 136.1, a carried form row consists of the degree history, probe bundle, tensor row, scalar endpoint row, antisymmetry ledger, and source ledger. Each entry is a visible row over the displayed $BHist$, $\mathsf{ProbeBundle}$, Cont, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, or $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ surface.

The classifier and core rows introduce no further source. The core rows of Definition 136.3 are exhausted by the displayed carrier, classifier, transport, wedge, antisymmetry, and source provenance clauses, and Definition 136.6 states that every accepted ledger row is visible BHist provenance.

Finally apply Definition 136.62. It identifies the source boundary of every accepted row with the same six inputs named in the root package. Hence the root package exposes the displayed kernel and upstream NameCert rows, and nothing else. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootObligationPackage visible source surface`

Theorem 136.92 (Differential-form root antisymmetry ledger obligation)**.** *In the root obligation package of Definition 136.90, antisymmetry enters only through the finite* $\mathsf{ProbeBundle}$ *permutation chain ledger of Definition 136.75. Every admitted antisymmetry comparison is covered by Definition 136.76 and transports through the* $\mathsf{DiffForm}^{\uparrow}$ *classifier by Definition 136.77.*

Proof. Locate the antisymmetry data inside the carried form row. The carrier has a single antisymmetry ledger slot, and Definition 136.75 identifies its public content as a finite spine of adjacent-swap rows over the carried $\mathsf{ProbeBundle}$.

Apply Definition 136.76. The theorem exhausts an admitted finite permutation comparison by the displayed adjacent swaps and their scalar endpoint rows. No permutation oracle or hidden classifier clause is available outside that ledger.

It remains to check transport. By Definition 136.77, componentwise hsame transport of the carried rows transports the finite chain ledger and reassembles the transported endpoints as a $\mathsf{DiffForm}^{\uparrow}$ classifier comparison. Thus the root package treats antisymmetry only as visible ledger data. □

Theorem 136.93 (Differential-form root wedge-probe obligation)**.** *Every wedge row exposed by the root obligation package of Definition 136.90 exposes precisely the degree additivity ledger, probe concatenation ledger, tensor-continuation provenance, and classifier stability rows supplied by Definition 136.14, Definition 136.15, Definition 136.17, and Definition 136.18.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootWedgeProbe obligation`

Proof. Begin with an admitted wedge row. The coverage theorem Definition 136.15 requires a visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation row joining the tensor component of the left form to the tensor component of the right form. This is the tensor continuation provenance available at the root boundary.

Next read the degree and probe rows. The degree additivity statement of Definition 136.14 records the unary degree continuation for the wedge output. The probe coverage theorem Definition 136.17 records the output probe bundle as the append of the two input probe spines, with the visible length and membership clauses.

Finally transport the row. The classifier stability theorem Definition 136.18 transports the concatenated probe ledger together with the tensor and scalar endpoint comparisons. These are exactly the wedge rows listed in the root package, so no further multiplicative source is exposed. □

Theorem 136.94 (Differential-form root downstream consumption obligation)**.** *The downstream consumers* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *receive from the root obligation package of Definition 136.90 only the carried* $\mathsf{DiffForm}^{\uparrow}$ *rows, classifier rows, wedge rows, antisymmetry rows, and exterior-input boundary rows described by Definition 136.61, Definition 136.79, Definition 136.80, and Definition 136.165. The identities* $d^2 = 0$*, closedness, nondegeneracy, and contact nonintegrability remain obligations of the consuming chapters.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDownstreamConsumption obligation`

Proof. Inspect the exported surface first. Definition 136.165 lists the carrier, classifier, transport, wedge, antisymmetry, exterior-input, and downstream scope rows that the $\mathsf{DiffForm}^{\uparrow}$ surface exports. This is the entire public obligation surface of the root package.

Now apply the downstream boundary statements. Definition 136.61 bounds exterior-derivative consumers to the degree row, probe bundle, tensor row, scalar endpoint row, antisymmetry ledger, wedge ledgers, and exterior-derivative candidate ledger. Definition 136.79 gives the same boundary for $\mathsf{DeRham}^{\uparrow}$ consumption, including the normal-form antisymmetry row.

The shared wedge and derivative input boundary is controlled by Definition 136.80. It permits only the visible unary degree row, degree-continuation ledgers, probe, tensor, scalar, and source rows common to the wedge and exterior-input readings.

None of the cited rows contains nilpotence, closedness, nondegeneracy, or contact nonintegrability. Therefore those four facts are not imported from $\mathsf{DiffForm}^{\uparrow}$; they must be supplied by the $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ chapters that use the root package. □

Theorem 136.95 (Differential-form root source obligation)**.** *The root* $\mathsf{DiffForm}^{\uparrow}$ *chapter reads every displayed differential-form row only from* $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*, as witnessed by the carrier of Definition 136.1. In particular, the root surface has no source row outside the six displayed entries*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda).$$

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootSource obligation`

Proof. Read the root chapter through the carrier definition. The row $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$ displays the degree history, the probe bundle, the tensor row, the scalar endpoint, the antisymmetry ledger, and the source ledger.

Each coordinate is sourced by one of the named BEDC rows. The degree, endpoint, antisymmetry, and provenance entries are $BHist$ rows; comparison and transport use hsame; tensor concatenation uses Cont; probe exposure uses ProbeBundle; and the only upstream certificates are $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$.

No clause of Definition 136.1 allocates another source. Therefore the root chapter may be scanned as exactly this displayed source surface. □

Theorem 136.96 (Differential-form root carrier and classifier obligation)**.** *The carrier and classifier obligations visible at the* $\mathsf{DiffForm}^\uparrow$ *root are exactly the carrier of Definition 136.1, the classifier of Definition 136.2, carrier transport of Definition 136.10, and classifier stability of Definition 136.11. No further root classifier or carrier transport principle is exposed.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootCarrierClassifier obligation`

Proof. The carrier obligation is the accepted BHist row of Definition 136.1. Its six displayed coordinates give the complete carrier data used by all later wedge and boundary rows.

The classifier obligation is the comparison of Definition 136.2. It compares degrees by hsame, matched tensor and ledger rows by visible BHist comparisons, and scalar endpoints by the retained scalar classifier from the upstream sources.

The two stability obligations are precisely the transport theorem Definition 136.10 and the classifier theorem Definition 136.11. Those results repack the same displayed rows after componentwise hsame transport, so the root obligation set contains no additional carrier or classifier field. □

Theorem 136.97 (Differential-form root wedge ledger obligation)**.** *The wedge surface visible at the* $\mathsf{DiffForm}^\uparrow$ *root is exhausted by wedge ledger coverage in Definition 136.15, the probe-concatenation ledger of Definition 136.16, the wedge-degree ledger of Definition 136.22, and the associator ledger of Definition 136.19. All four ledgers are rows over the displayed BEDC carrier and classifier surface.*

Proof. Start with an admitted wedge row. By Definition 136.15, admission requires a visible $\mathsf{TensorProduct}^\uparrow$ concatenation row joining the tensor components of the two carried inputs.

The output probe data are then bounded by Definition 136.16; its coverage theorem identifies the output bundle as the displayed append of the two input probe spines. The degree data are bounded by Definition 136.22, which records only the two input degree rows, the concatenation provenance, and the output unary degree row.

Associativity is not a hidden algebraic law at the root. It is the displayed ledger of Definition 136.19, with closure stated by Definition 136.20. These four rows exhaust the wedge surface because each refers back to the same carried form rows and their visible hsame, Cont, probe, tensor, scalar, and antisymmetry ledgers. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootWedgeLedger obligation`

Theorem 136.98 (Differential-form root exterior boundary obligation)**.** *Exterior-derivative consumers of* $\mathsf{DiffForm}^\uparrow$ *may use only the candidate ledger of Definition 136.54, the input row of Definition 136.57, and the boundary theorems already displayed for degree shift, scalar transport, wedge-input stability, and downstream scope. The identities* $d^2 = 0$*, closedness, nondegeneracy, and contact nonintegrability are outside this* $\mathsf{DiffForm}^\uparrow$ *root surface.*

Proof. First read the candidate ledger. It exposes an input carrier row, an output carrier row, the successor-degree continuation, and transported probe, tensor, and scalar endpoint rows. Its degree-raise theorem records only this degree-raising candidate data.

Next read the accepted input row. The row of Definition 136.57 supplies the source and target carried forms, the source and target degree rows, the one-step continuation, and the carrier ledgers exposed by the de Rham input boundary.

Finally apply the boundary theorems already present in the chapter: Definition 136.56, Definition 136.58, Definition 136.59, and Definition 136.61. These theorems permit downstream consumers to cite the displayed candidate and input ledgers, while leaving nilpotence, closedness, nondegeneracy, and contact nonintegrability to the downstream certificate surfaces. □

136.6 DiffForm root export threshold

Definition 136.99 (Differential-form root export threshold source)**.** *Fix the* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and the* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T *used in Definition 136.1. The root export threshold source for* $\mathsf{DiffForm}^{\uparrow}$ *is the displayed row package consisting exactly of* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*, the carrier and classifier rows of Definition 136.1 and Definition 136.2, the wedge-ledger rows cited by Definition 136.97, the exterior-derivative input boundary cited by Definition 136.98, and the downstream-consumer boundary of Definition 136.74.*

This threshold source is an export boundary. It names the rows that a consumer may read from the $\mathsf{DiffForm}^{\uparrow}$ *root surface, and it names no nilpotence, closedness, nondegeneracy, contact nonintegrability, or standard bridge row.*

Theorem 136.100 (Differential-form carrier and classifier export threshold)**.** *At the threshold of Definition 136.99, the exported carrier is exactly the six-coordinate row*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

of Definition 136.1. The exported classifier is only the comparison of degree rows by hsame*, matched tensor and scalar endpoint comparisons through the displayed source rows, and visible ledger comparisons by* hsame *as stated in Definition 136.2. No additional carrier coordinate, classifier, operator row, or geometric law is exported at the root threshold.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerExport exactness`

Proof. Read the source boundary through Definition 136.95. That theorem restricts every root row to the displayed $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ sources, with no source row outside the six carrier entries.

Project the carrier with Definition 136.1. The row is the tuple $(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$, and each coordinate is respectively the degree history, probe bundle, tensor row, scalar endpoint, antisymmetry ledger, or source ledger. Therefore the export carrier has no seventh coordinate.

Project the classifier with Definition 136.2. Its degree clause is hsame, its tensor and scalar clauses compare matched displayed rows using the retained source classifiers, and its remaining clauses are visible ledger hsame comparisons. These are precisely the classifier rows permitted by the threshold source. □

Theorem 136.101 (Differential-form wedge export threshold)**.** *At the threshold of Definition 136.99, the exported wedge surface is exactly the visible tensor concatenation row, the probe-append ledger,*

the degree-bookkeeping ledger, and the antisymmetry ledgers over the carried input rows. The root threshold exports no exterior law beyond these wedge rows.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootExport wedge threshold`

Proof. Start from the wedge boundary of Definition 136.97. It says that an admitted wedge row is exhausted by wedge ledger coverage, probe concatenation, degree bookkeeping, and associator ledger rows over the displayed carrier and classifier surface.

The tensor component is the visible $\mathsf{TensorProduct}^{\uparrow}$ concatenation row joining the tensor entries of the two carried forms. The probe component is the displayed append of the two finite $\mathsf{ProbeBundle}$ spines, and the degree component is the ledger recording the two input degrees and the output degree row.

The antisymmetry contribution is not a hidden exterior identity. It is the visible permutation and associator ledger attached to the carrier rows and transported through hsame. Since each wedge row cited by the root wedge obligation refers back to those displayed histories, the threshold exports exactly the stated wedge surface. □

Theorem 136.102 (Differential-form downstream law separation)**.** *The root threshold of Definition 136.99 separates the usable* $\mathsf{DiffForm}^{\uparrow}$ *surface from downstream exterior laws:* $\mathsf{DeRham}^{\uparrow}$ *must supply nilpotence,* $\mathsf{Symplectic}^{\uparrow}$ *must supply closedness and nondegeneracy, and* $\mathsf{Contact}^{\uparrow}$ *must supply contact nonintegrability in their own certificate surfaces. None of those laws is exported by the* $\mathsf{DiffForm}^{\uparrow}$ *root threshold.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootExport downstream law separation`

Proof. First apply Definition 136.98. It permits exterior-derivative consumers to use only the displayed candidate ledger, input row, degree shift, scalar transport, wedge-input stability, and downstream scope rows.

Next apply Definition 136.74. That theorem identifies the rows consumed by $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$, and states that $d^2 = 0$, closedness, nondegeneracy, and contact nonintegrability must be supplied by the corresponding downstream chapters.

Combining the two boundary statements gives the separation. The root threshold can export carried forms, classifier data, wedge ledgers, and exterior-input rows, but it cannot certify an operator identity or geometric law that is not one of those displayed rows. □

Theorem 136.103 (Differential-form NameCert root threshold)**.** *The paper-side* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *root threshold is assembled by the rows of Definition 136.99: the six-coordinate carrier, the displayed classifier, the wedge ledger surface, the exterior-derivative input boundary, and the downstream-consumer separation. This assembly exports the usable* $\mathsf{DiffForm}^{\uparrow}$ *root surface and leaves downstream operator and geometric laws off the root table.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootExport namecert threshold`

Proof. Use Definition 136.95 for the source rows and Definition 136.100 for the carrier and classifier rows. These two statements bind the export surface to the six displayed carrier coordinates and the classifier clauses already available from the upstream manifold and tensor sources.

Use Definition 136.101 for the wedge surface. It contributes exactly tensor concatenation, probe append, degree bookkeeping, and antisymmetry ledger data over the carried forms.

Finally use Definition 136.102. That statement imports the exterior-input boundary of Definition 136.98 and the consumer boundary of Definition 136.74. The assembled package is therefore

a root threshold for $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ and not a certificate for $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability. □

Definition 136.104 (Differential-form downstream boundary package)**.** *The root downstream boundary package for* $\mathsf{DiffForm}^{\uparrow}$ *is the visible certificate surface*

$$\mathsf{DiffFormDownstreamBoundary}_{M,T}.$$

It consists exactly of the carried-form rows of Definition 136.1, the classifier rows of Definition 136.2, the exterior-input rows of Definition 136.68, the wedge rows supplied by Definition 136.22, Definition 136.15, Definition 136.17, Definition 136.18, and Definition 136.23, the finite antisymmetry rows of Definition 136.75, and the downstream scope rows of Definition 136.61, Definition 136.24, and Definition 136.80. The package has no field for $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, or a standard bridge.*

Theorem 136.105 (Differential-form exterior input root closure)**.** *Every row of* $\mathsf{DiffFormExteriorInput}_{M,T}(\omega, D\omega)$ *that a downstream* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, or* $\mathsf{Contact}^{\uparrow}$ *chapter may read is already a row of* $\mathsf{DiffFormDownstreamBoundary}_{M,T}$*. In particular, the source carrier, output carrier, successor-degree continuation, transported* $\mathsf{ProbeBundle}$ *rows, transported* $\mathsf{TensorProduct}^{\uparrow}$ *tensor row, retained scalar endpoint comparison, and restricted source ledger are all root-visible rows, and no second exterior-derivative or closedness row is introduced by passing through the package.*

Proof. Unpack the exterior-input package of Definition 136.68. Its source and output are carried form rows of Definition 136.1; its comparison clauses are exactly the hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{TensorProduct}^{\uparrow}$, scalar endpoint, and source-ledger rows listed there and in Definition 136.2.

Repack those rows into Definition 136.104. The boundary package keeps the exterior-input row as a visible component, and it retains the classifier-stability interface through the same componentwise histories.

Finally apply the downstream scope theorem Definition 136.61. That theorem allows downstream exterior-derivative chapters to consume the carrier, classifier, degree-raise candidate, endpoint transport, and exterior-algebra substrate, but it does not add a second derivative, closedness, nondegeneracy, or contact nonintegrability row. Thus exterior input closes at the root boundary package without importing any downstream law. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorInput root transport closure`

Theorem 136.106 (Differential-form wedge derivative boundary compatibility)**.** *When a carried row participates both in an admitted wedge row and in an accepted exterior-input row, their common downstream boundary is exactly the intersection recorded by Definition 136.80 inside* $\mathsf{DiffFormDownstreamBoundary}_{M,T}$*. The common rows are the carried form row, its unary degree row, the wedge degree continuation ledger, the one-step exterior-derivative continuation ledger, the transported probe, tensor, scalar endpoint, antisymmetry, and source rows, and their* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *classifier comparisons.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDownstreamBoundary exterior wedge common rows`

Proof. Read the wedge side first. Wedge admission is bounded by Definition 136.15; the probe output is bounded by Definition 136.17; the degree bookkeeping is the visible ledger of Definition 136.22. Classifier transport for these rows is supplied by Definition 136.18 and Definition 136.23.

Read the exterior-input side next. By Definition 136.68, an accepted input exposes the source and output carried rows, the successor-degree continuation, transported probe and tensor rows, scalar endpoint comparison, and the operator-owned source ledger.

Now apply Definition 136.80. It states that the shared visible data are precisely the rows named by both readings, with no Leibniz rule and no nilpotence row. The antisymmetry portion is controlled by Definition 136.75 and remains classifier-stable through the displayed $\mathsf{DiffForm}^{\uparrow}$ comparison rows.

These rows are all components of Definition 136.104. Therefore the wedge and exterior-input interfaces are compatible at the downstream boundary without importing any closedness, nondegeneracy, contact nonintegrability, or operator-square assertion. □

Theorem 136.107 (Differential-form downstream boundary exhaustion)**.** *The package* DiffFormDownstreamBound *exhausts the* $\mathsf{DiffForm}^{\uparrow}$ *root rows visible to* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$. *Any downstream consumption of* $\mathsf{DiffForm}^{\uparrow}$ *must factor through the carrier and classifier rows, exterior-input rows, wedge rows, antisymmetry-chain rows, and the three downstream scope rows listed in Definition 136.104; no downstream consumer can project a closedness, nondegeneracy, contact nonintegrability, nilpotence, or bridge row from* $\mathsf{DiffForm}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormDownstreamBoundary exhaustion`

Proof. Start with an arbitrary downstream read of a $\mathsf{DiffForm}^{\uparrow}$ row. The carrier and classifier projections are exhausted by Definition 136.1, Definition 136.2, Definition 136.10, and Definition 136.11. These rows mention only $BHist$, hsame, Cont, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

For derivative input, apply Definition 136.105. It repacks every accepted exterior-input row into the boundary package and leaves all operator and geometric laws outside the root surface.

For wedge interaction, apply Definition 136.106. It identifies the wedge-degree, probe-concatenation, antisymmetry, and exterior-input rows that can be shared at the downstream boundary, and it excludes the Leibniz and nilpotence rows.

Finally use the downstream scope rows Definition 136.61, Definition 136.24, and Definition 136.80. They name $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ as the downstream consumers and restrict their access to the same visible carrier, classifier, wedge, antisymmetry, exterior-input, transport, and source ledgers. Since Definition 136.104 contains exactly those rows, every downstream read factors through it and no hidden row remains to be consumed. □

136.7 Boundary exhaustion for DiffFormUp

Definition 136.108 (Differential-form boundary exhaustion source)**.** *The boundary exhaustion source for* $\mathsf{DiffForm}^{\uparrow}$ *is the complete paper-side obligation surface displayed by the chapter. It consists of the following ten fields:*

1. *the traditional target surface of differential forms;*
2. *the BEDC sources* $BHist$, hsame, Cont, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*;*
3. *the carrier and classifier rows of Definition 136.33, Definition 136.37, and Definition 136.96;*
4. *the wedge ledger rows visible through Definition 136.39;*
5. *the exterior-derivative candidate row of Definition 136.65;*
6. *the input-output exactness row of Definition 136.66;*

7. *the downstream boundary rows for* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$*;*
8. *the exactness scope asserting that every displayed row is read as one of the named carrier, classifier, wedge, antisymmetry, exterior-input, transport, source-ledger, or downstream rows;*
9. *the absent standard bridge slot;*
10. *the status row saying that this is a paper-side obligation surface, not a standard-object bridge and not a Lean-checked theorem package.*

The source contains no row for $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, a de Rham quotient, or a standard bridge.*

Theorem 136.109 (Differential-form boundary carrier coverage)**.** *The carrier and classifier rows of Definition 136.108 are exactly the root source rows already displayed in Definition 136.33, Definition 136.37, and Definition 136.96. No additional carrier over tangent spaces, alternating maps, quotient forms, or external classifier is part of the* $\mathsf{DiffForm}^{\uparrow}$ *boundary exhaustion source.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBoundaryExhaustion carrier coverage`

Proof. Read the source surface first. The ten-field root-unblock surface lists the ambient $BHist$ carrier, the hsame comparisons, the Cont rows, the ProbeBundle spine, the two upstream NameCert sources, the displayed six-coordinate carrier, and the displayed $\mathsf{DiffForm}^{\uparrow}$ classifier.

Next read the root obligation source. It selects the same carried rows from Definition 136.1 and the same classifier rows from Definition 136.2, with the retained $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ sources.

Finally apply Definition 136.96. That theorem repackages the displayed carrier and classifier obligations without adding a host tangent-space carrier, an alternating-map carrier, or a quotient classifier. Therefore the carrier and classifier entries of Definition 136.108 are exactly the displayed root source entries. □

Theorem 136.110 (Differential-form wedge and derivative routing)**.** *The wedge, antisymmetry, degree, and exterior-derivative candidate rows of Definition 136.108 are exactly the rows supplied by Definition 136.39, Definition 136.40, Definition 136.65, and Definition 136.66. The boundary source routes those rows as visible ledger data and does not add a Leibniz rule, a nilpotence row, or a closedness row.*

Proof. Start with the wedge and antisymmetry side. The root wedge theorem supplies the admitted tensor concatenation ledger, the probe concatenation classifier stability row, the associator row, and the finite antisymmetry chain ledger. These are the only multiplicative and permutation rows named by the boundary source.

Now read the exterior-derivative side. The root exterior-derivative boundary obligation keeps only the candidate derivative row, the displayed input-output ledger, and the wedge-side boundary row consumed by downstream wedge formulas.

Unfold the candidate row. Its fields are the input carried form, the output carried form, the one-step degree-raise Cont ledger, the transported probe, tensor, scalar endpoint, and source ledgers, all over the same BEDC sources named in the boundary source.

Finally apply the input-output exactness theorem. It says that the candidate row exposes exactly those fields and no closedness, nondegeneracy, contact condition, or second-derivative identity. Hence the wedge, antisymmetry, degree, and derivative entries of the boundary source are precisely the cited ledger rows. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBoundaryExhaustion wedge derivative routing`

Theorem 136.111 (Differential-form downstream export exhaustion)**.** *The downstream chapters* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *may consume* $\mathsf{DiffForm}^{\uparrow}$ *only through the rows named by Definition 136.108: carrier rows, classifier rows, wedge rows, antisymmetry rows, the exterior-derivative candidate and input-output rows, transport rows, source-ledger rows, and the displayed downstream boundary rows. They receive no* $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, quotient, or standard-bridge row from* $\mathsf{DiffForm}^{\uparrow}$*.*

Proof. Project the common input first. By Definition 136.109, every downstream read begins with the same carried $\mathsf{DiffForm}^{\uparrow}$ rows and the same $\sim_{\mathsf{DiffForm}^{\uparrow}}$ classifier rows already displayed at the root boundary.

Project the operation rows next. By Definition 136.110, the only available wedge, antisymmetry, degree, and exterior-derivative entries are the visible ledger rows named by the root obligation and input-output exactness statements.

Now use the downstream boundary package. Its scope rows name $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ as consumers of the same carrier, classifier, wedge, antisymmetry, exterior-input, transport, and source-ledger surface, and they exclude nilpotence and geometric laws from the exported DiffForm boundary.

Repack these projections as Definition 136.108. Every downstream row is one of the displayed source fields, and none of the cited projections contains a row for $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, a quotient, or a standard bridge. Thus the displayed rows exhaust the paper-side $\mathsf{DiffForm}^{\uparrow}$ obligation surface available downstream. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormBoundaryExhaustion downstream export`

136.8 DiffForm root consumer threshold certificate

Definition 136.112 (Differential-form root consumer threshold certificate)**.** *Fix the* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and the* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T *used by Definition 136.1. The differential-form root consumer threshold certificate is the following ten-field surface:*

1. *the ambient* $BHist$ *history carrier for all displayed form rows;*
2. *the* hsame *transport relation on degree, tensor, scalar endpoint, antisymmetry, and source-ledger histories;*
3. *the* Cont *continuation ledger for ordered tensor concatenation and degree bookkeeping;*
4. *the* $\mathsf{ProbeBundle}$ *spine of tangent-probe names;*
5. *the upstream* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source for tangent probes and scalar endpoint data;*
6. *the upstream* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source for multilinear tensor rows;*
7. *the six-coordinate carrier* $\mathsf{DiffFormBHistCarrier}_{M,T}(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$ *of Definition 136.1;*
8. *the displayed classifier* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *of Definition 136.2;*
9. *the wedge and exterior-input rows consisting of tensor concatenation, probe-bundle append, degree bookkeeping, antisymmetry ledgers, scalar endpoint transport, and source-ledger projections;*
10. *the downstream consumer slots for* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, *and* $\mathsf{Symplectic}^{\uparrow}$*.*

The certificate explicitly excludes $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, and any standard bridge.

Theorem 136.113 (Differential-form root consumer carrier readback)**.** *Every consumer admitted by the Definition 136.112 reads exactly the six-coordinate carrier*

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda)$$

and the displayed classifier $\sim_{\mathsf{DiffForm}^\uparrow}$ from Definition 136.2. No downstream consumer slot may read an additional carrier coordinate, replacement classifier, operator law, or standard bridge from the $\mathsf{DiffForm}^\uparrow$ *root.*

Proof. First apply Definition 136.34. It reads the root surface through Definition 136.1 and Definition 136.2, so the only carrier available to a consumer is the displayed six-tuple and the only classifier available is the displayed $\mathsf{DiffForm}^\uparrow$ classifier.

Next apply Definition 136.100. The export threshold states the same carrier and classifier boundary at the public root table, with no seventh carrier coordinate and no replacement classifier.

Finally use Definition 136.165. The exported NameCert surface lists carrier, classifier, transport, wedge, exterior-input, and downstream scope rows, and it names no standard bridge or downstream operator law. Therefore every threshold consumer reads exactly the stated carrier and classifier surface. □

Theorem 136.114 (Differential-form root consumer wedge input readback)**.** *Every accepted wedge or exterior-input consumer row admitted by the Definition 136.112 reads only probe append,* Cont *tensor and degree ledgers, antisymmetry ledgers, scalar endpoint transport, and source ledgers from the displayed* $\mathsf{DiffForm}^\uparrow$ *root surface.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerWedgeInput readback`

Proof. Start with the wedge side. Apply Definition 136.35. It identifies wedge closure with probe-bundle concatenation, visible tensor concatenation through Cont, degree bookkeeping, and the displayed antisymmetry ledger.

Next read the exterior-input boundary through Definition 136.36 and Definition 136.24. These rows allow exterior-input consumers to inspect carried input and output rows, degree shift, wedge-input stability, scalar endpoint transport, and the restricted source ledger.

The export side contributes no broader input. By Definition 136.165 and Definition 136.101, the NameCert root exports the wedge ledger and exterior-input rows only through those displayed histories. Hence accepted wedge and exterior-input consumers read exactly the stated probe, continuation, antisymmetry, scalar, and source surfaces. □

Theorem 136.115 (Differential-form root consumer downstream law separation)**.** *The downstream slots of the Definition 136.112 are input slots only.* $\mathsf{DeRham}^\uparrow$, $\mathsf{Contact}^\uparrow$, *and* $\mathsf{Symplectic}^\uparrow$ *must supply their operator and geometric laws in their own certificate surfaces; the* $\mathsf{DiffForm}^\uparrow$ *root certificate does not project $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, or any standard bridge.*

Proof. Apply Definition 136.36 to identify the consumer boundary at the root-unblock surface. It permits downstream chapters to consume degree, wedge, antisymmetry, scalar endpoint, and source-ledger rows, while leaving their laws outside the DiffForm root.

Then apply Definition 136.165 together with the boundary rows Definition 136.61, Definition 136.74, and Definition 136.102. These rows give the same separation at the NameCert and export surfaces.

Thus the consumer threshold is citable by $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, and $\mathsf{Symplectic}^{\uparrow}$ as a root input certificate, but each downstream chapter must close its own nilpotence, closedness, nondegeneracy, nonintegrability, or bridge obligations within its own surface. □

Definition 136.116 (Differential-form root consumer face classifier)**.** *Fix the root export threshold source of Definition 136.99. Its consumer face classifier partitions the exported rows into three consumer faces and one shared root face.*

1. *The* $\mathsf{DeRham}^{\uparrow}$ *face contains the exterior-derivative candidate and input rows, the one-step degree-shift row, the wedge-input stability row, and the downstream exterior-derivative scope row.*
2. *The* $\mathsf{Symplectic}^{\uparrow}$ *face contains the carried form rows, wedge ledgers, antisymmetry ledgers, scalar endpoint rows, and Manifold/TensorProduct source ledgers needed to state a symplectic input surface. It excludes closedness and nondegeneracy.*
3. *The* $\mathsf{Contact}^{\uparrow}$ *face contains the same carried-form, wedge-ledger, and derivative-input surface needed to state contact data. It excludes contact nonintegrability.*
4. *The shared root face consists only of the six-coordinate* $BHist$ *carrier, the displayed* $\mathsf{DiffForm}^{\uparrow}$ *classifier, wedge ledger rows, scalar endpoint rows, and the* $\mathsf{Manifold}^{\uparrow}/\mathsf{TensorProduct}^{\uparrow}$ *source ledgers.*

Rows not named in these four clauses are not exported from the $\mathsf{DiffForm}^{\uparrow}$ *root threshold.*

Theorem 136.117 (Differential-form root consumer face coverage)**.** *Every row exported by Definition 136.99 to* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, or* $\mathsf{Contact}^{\uparrow}$ *belongs to exactly one of the three consumer faces of Definition 136.116, or to the explicitly shared root face. No exported row lies outside those four faces.*

Proof. Project the exported root table with Definition 136.103. It lists the complete threshold surface as the six-coordinate carrier, the displayed classifier, wedge ledgers, the exterior-derivative input boundary, and the downstream consumer separation.

Next apply Definition 136.74. The de Rham consumer receives the exterior-input and degree-shift surface, while the symplectic and contact consumers receive the carried form, wedge, antisymmetry, scalar endpoint, and source-ledger surface needed to state their own data.

Finally apply Definition 136.111. The exhaustion statement says every downstream row is one of the displayed carrier, classifier, wedge, antisymmetry, exterior-input, transport, source-ledger, or downstream rows. Matching these rows against the four clauses of Definition 136.116 gives coverage, and the last sentence of that definition excludes any fifth face. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFace coverage`

Theorem 136.118 (Differential-form root consumer face disjointness)**.** *The consumer-specific laws separated by the Definition 136.116 are disjoint: nilpotence remains* $\mathsf{DeRham}^{\uparrow}$*-specific, closedness and nondegeneracy remain* $\mathsf{Symplectic}^{\uparrow}$*-specific, and contact nonintegrability remains* $\mathsf{Contact}^{\uparrow}$*-specific. Only carried* $BHist$ *rows, classifier rows, wedge ledgers, scalar endpoint rows, and source ledgers may be shared across consumer faces.*

Proof. Start from Definition 136.102. It states that the $\mathsf{DiffForm}^{\uparrow}$ root threshold exports no $d^2 = 0$, closedness, nondegeneracy, or contact nonintegrability row. Those rows therefore cannot belong to the shared root face.

Now use Definition 136.74. That boundary assigns $d^2 = 0$ to the de Rham certificate surface, closedness and nondegeneracy to the symplectic certificate surface, and contact nonintegrability to the contact certificate surface. Hence the laws themselves are pairwise consumer-specific.

The rows allowed to cross consumer faces are exactly the displayed carrier, classifier, wedge, scalar endpoint, and source-ledger rows named in the shared root face of Definition 136.116. Since the law rows are absent from the root export threshold, no consumer-specific law is shared by the classifier. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFace disjointness`

Theorem 136.119 (Differential-form root cross-consumer threshold package)**.** *The definition Definition 136.116, the coverage theorem Definition 136.117, and the disjointness theorem Definition 136.118 form the cross-consumer root threshold package for the* $\mathsf{DiffForm}^{\uparrow}$ *surface consumed by* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFace cross consumer threshold package`

Proof. The classifier supplies the four faces: de Rham, symplectic, contact, and the shared root face.

Coverage then shows that every exported downstream row is assigned to one of those faces. Disjointness shows that the downstream laws remain outside the shared root face and are owned by the corresponding consumer chapters.

Together these two properties make the root export threshold citable as a single cross-consumer package: downstream chapters can reuse the shared root rows without reading nilpotence, closedness, nondegeneracy, or contact nonintegrability back into the $\mathsf{DiffForm}^{\uparrow}$ root. □

Definition 136.120 (Differential-form root consumer face exhaustion source)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *root consumer face exhaustion source is the following ten-field package.*

1. *The traditional target is the finite-degree differential-form surface consumed by* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$.
2. *The BEDC source is* $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.
3. *The carrier is* $\mathsf{DiffFormBHistCarrier}$ *on the displayed manifold, tensor, degree, probe, scalar endpoint, and route histories.*
4. *The classifier is* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *transported by the root classifier rows.*
5. *The stability rows are carrier transport, classifier transport, wedge routing, and exterior-input routing.*
6. *The ledger rows are exactly the degree, probe, tensor, manifold, and* Cont *route ledgers named by the root* $BHist$ *surface.*
7. *The core theorem list is Definition 136.117, Definition 136.118, Definition 136.121, Definition 136.122, and Definition 136.123.*
8. *Exactness means consumer-row exhaustion: every downstream row exported from the root threshold is shared root data or belongs to exactly one of the* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *faces, and no other row is exported.*

9. *The standard bridge field is absent.*
10. *The status is the paper-side obligation surface for the three downstream geometry consumers.*

Theorem 136.121 (Differential-form root consumer face exhaustion)**.** *Every row exported by the root threshold of Definition 136.120 is either shared root data or belongs to exactly one of the* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *consumer faces.*

Proof. Start with the finite face classifier of Definition 136.116. Its four clauses name the de Rham face, the symplectic face, the contact face, and the shared root face.

Apply Definition 136.117. It assigns every row exported to the downstream consumers to one of those four faces and excludes any fifth face.

Finally apply Definition 136.111. The downstream export is exhausted by carrier rows, classifier rows, wedge rows, antisymmetry rows, exterior-derivative input-output rows, transport rows, source-ledger rows, and the displayed downstream boundary rows. Matching those finite rows against the classifier clauses gives the stated shared-or-unique consumer assignment. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFaceExhaustionSource exhaustion`

Theorem 136.122 (Differential-form root consumer boundary exactness)**.** *The exhaustion source of Definition 136.120 admits no* $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, quotient, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFaceExhaustionSource boundary exactness`

Proof. First apply Definition 136.118. It keeps nilpotence, closedness, nondegeneracy, and contact nonintegrability outside the shared root face and assigns those laws only to their downstream consumer surfaces.

Next use Definition 136.102. The root threshold exports carried forms, classifier data, wedge ledgers, and exterior-input rows, but no downstream exterior or geometric law.

It remains to exclude quotient and standard-bridge rows. Apply Definition 136.131; the visible ledger witnesses are exactly the degree, probe, tensor, manifold, wedge, exterior-input, and Cont route histories. Since that exactness statement contains neither quotienting nor a standard bridge, the exhaustion source contains neither row. □

Theorem 136.123 (Differential-form root downstream consumer unblock package)**.** *The definition Definition 136.120, the exhaustion theorem Definition 136.121, and the boundary exactness theorem Definition 136.122 form the citable* $\mathsf{DiffForm}^{\uparrow}$ *root package consumed by* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$.

Proof. The definition supplies the ten named fields of the root consumer surface: traditional target, BEDC source, carrier, classifier, stability rows, ledgers, core theorems, exactness predicate, absent standard bridge, and obligation status.

The exhaustion theorem supplies the positive consumer boundary. Every exported row is shared root data or belongs to the de Rham, symplectic, or contact face.

The boundary exactness theorem supplies the negative boundary. The package exports no nilpotence, closedness, nondegeneracy, contact nonintegrability, quotient, or standard-bridge row. Therefore the three downstream chapters may cite this block as the complete root $BHist$ consumer boundary. □

Definition 136.124 (Differential-form manifold-tensor source envelope)**.** *The differential-form manifold-tensor source envelope is the visible BEDC package*

$$\mathsf{DiffFormSourceEnvelope}_{M,T}.$$

Its rows are exactly the BHist carrier rows of Definition 136.1, the classifier rows of Definition 136.2, the hsame *transport rows used by the classifier, the* Cont *rows used by degree and wedge continuation, the displayed* ProbeBundle *spines, the tangent-probe rows certified by* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$*, and the multilinear tensor rows certified by* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$*. It also contains the wedge probe concatenation ledger of Definition 136.16, the degree-probe alignment rows of Definition 136.29, and the exterior-derivative input rows of Definition 136.57. The envelope has no field for nilpotence, closedness, nondegeneracy, contact nonintegrability, or a standard bridge.*

Theorem 136.125 (Differential-form manifold-tensor source scope)**.** *Every carrier witness and every classifier witness read from* $\mathsf{DiffFormSourceEnvelope}_{M,T}$ *is obtained only from the displayed BHist,* hsame*,* Cont*,* ProbeBundle*,* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *rows of Definition 136.124. No downstream* $\mathsf{DeRham}^\uparrow$*,* $\mathsf{Symplectic}^\uparrow$*, or* $\mathsf{Contact}^\uparrow$ *law is a source for the* $\mathsf{DiffForm}^\uparrow$ *carrier or classifier.*

Proof. Unpack the envelope definition. Its carrier part is exactly the six-coordinate *BHist* row of Definition 136.1; its classifier part is exactly the componentwise comparison of Definition 136.2. Those two rows expose the unary degree history, the visible probe bundle, the tensor row, the scalar endpoint, the antisymmetry ledger, and the source ledger.

Project the manifold and tensor inputs. Tangent probes are read through the displayed ProbeBundle spine and the $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ source. Multilinear tensor rows are read through the same probe spine and the $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ source. The remaining classifier comparisons are hsame and retained Cont rows over the same BHist provenance.

Finally compare this list with the downstream consumer face classifier of Definition 136.116. That classifier places nilpotence, closedness, nondegeneracy, and contact nonintegrability outside the shared root face. Hence carrier and classifier witnesses are sourced only from the envelope rows named above. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormManifoldTensorSource scope`

Theorem 136.126 (Differential-form wedge continuation input closure)**.** *Let* ω *and* η *be carried rows in* $\mathsf{DiffFormSourceEnvelope}_{M,T}$*. If their admitted wedge row is obtained through the visible continuation and probe append data, then the wedge input and output rows remain inside* $\mathsf{DiffFormSourceEnvelope}_{M,T}$*. The retained rows are the wedge probe concatenation ledger, the coverage row for its output probe bundle, and the degree-probe alignment row for the wedge output.*

Proof. Start with the two carried input rows. By Definition 136.124, each input row already carries its *BHist* carrier witness, classifier witness, probe bundle, Manifold source row, TensorProduct source row, and degree-probe alignment row.

Apply Definition 136.16. The wedge input is recorded by the two input ledgers, the two input probe spines, the output probe spine, and the tensor-concatenation provenance row. These are all rows named in the source envelope.

Next apply Definition 136.17. It identifies the output probe bundle as the visible append of the two input bundles and shows that every output probe comes from one of the two input spines. Thus the manifold and tensor source readings remain the same displayed source readings.

Finally apply Definition 136.32. The output degree row and output probe bundle are aligned by the wedge continuation row. Repack the two input rows, the output append row, the tensor provenance, and the aligned degree-probe row into Definition 136.124. The wedge continuation therefore stays inside the source envelope. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeContinuation input closure`

Theorem 136.127 (Differential-form exterior-derivative consumer coverage)**.** *Every witness in* $\mathsf{DiffFormSourceEnvelope}_{M,T}$ *that satisfies the exterior-derivative input boundary supplies the downstream exterior-derivative consumer face for* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$*. The supplied face is exactly the carrier, classifier, degree-shift, wedge-input, endpoint-transport, source-ledger, and downstream boundary surface already listed for those consumers, with no downstream law imported into* $\mathsf{DiffForm}^{\uparrow}$*.*

Proof. Begin with an envelope witness satisfying the exterior-derivative input boundary. The input boundary row is the visible package of Definition 136.57, and its downstream visible form is the package of Definition 136.68.

Use Definition 136.105. It repacks the source carrier, output carrier, successor-degree continuation, transported probe and tensor rows, scalar endpoint comparison, and restricted source ledger into $\mathsf{DiffFormDownstreamBoundary}_{M,T}$.

Now combine the downstream boundary rows. The exterior-derivative scope row Definition 136.61 names the carrier, classifier, degree-raise candidate, endpoint transport, and exterior-algebra substrate consumed downstream. The consumer boundary theorem Definition 136.74 identifies $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ as the downstream consumers of that surface.

Finally apply Definition 136.111. It says the downstream export is exhausted by the carrier, classifier, wedge, antisymmetry, exterior-input, transport, source-ledger, and downstream rows. The consumer face classifier of Definition 136.116 assigns those rows to the de Rham, symplectic, contact, or shared root faces. Thus every exterior-input envelope witness supplies the advertised downstream consumer face and still leaves nilpotence, closedness, nondegeneracy, and contact nonintegrability to the consuming chapters. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormSourceEnvelope exterior derivative consumer coverage`
↪ variant `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivative consumer coverage`

Definition 136.128 (Differential-form root BHist NameCert surface)**.** *The root BHist NameCert surface for* $\mathsf{DiffForm}^{\uparrow}$ *is the ten-field obligation surface*

$$\mathsf{DiffFormRootBHistNameCert}_{M,T}.$$

Its fields are:

1. *traditional target: finite-degree differential forms;*
2. *BEDC source: BHist,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*;*
3. *carrier:* $\mathsf{DiffFormBHistCarrier}_{M,T}$*;*
4. *classifier:* $\sim_{\mathsf{DiffForm}^{\uparrow}}$*;*
5. *stability rows: carrier transport, degree-probe alignment transport, wedge degree routing, and exterior-derivative input routing;*
6. *ledger: degree histories, probe bundles, tensor rows, manifold rows, and* Cont *route histories;*

7. *core theorem list: Definition 136.129, Definition 136.130, Definition 136.131, and Definition 136.132;*
8. *exactness boundary: the exhaustion rows of Definition 136.108;*
9. *standard bridge: absent;*
10. *status:* (obligation, unformalized).

The surface contains no row for $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, a de Rham quotient, or a standard-object bridge.

Theorem 136.129 (Differential-form root BHist carrier obligation)**.** *Every admissible root row of Definition 136.81 supplies the carrier* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, the degree-probe alignment row, the manifold source row* $\mathsf{NameCert}_{\mathsf{Manifold}\uparrow}$*, and the tensor source row* $\mathsf{NameCert}_{\mathsf{TensorProduct}\uparrow}$ *displayed by Definition 136.128.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBHistCarrier obligation`

Proof. Unpack Definition 136.81. Its carrier coordinate is the carried form row of Definition 136.1, and its source coordinates are exactly the displayed manifold and tensor NameCert rows.

Apply Definition 136.109. The boundary exhaustion theorem identifies the visible carrier and classifier rows with the root source rows and excludes tangent-space, alternating-map, quotient, or external classifier carriers.

It remains to bind the degree and probe entries. Apply Definition 136.30; the carried row supplies the unary degree history and the ProbeBundle spine over the same tensor input reading. Repack these projections as the carrier field of Definition 136.128. □

Theorem 136.130 (Differential-form root BHist classifier stability obligation)**.** *Classifier transport along* $\sim_{\mathsf{DiffForm}\uparrow}$ *preserves the carrier, degree-probe alignment, wedge routing, and exterior-derivative input rows of Definition 136.128.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBHistClassifier stability obligation`

Proof. First transport the carried row. Apply Definition 136.10 to the displayed histories; the transported endpoint remains a carried $\mathsf{DiffFormBHistCarrier}_{M,T}$ row over the same BEDC source surface.

Next transport the degree-probe alignment. Apply Definition 136.31; the hsame degree comparison and transported ProbeBundle spine rebuild the aligned row at the target endpoint.

Finally read the operation boundary. Apply Definition 136.106. The common wedge and exterior-input rows are exactly the carried form, unary degree, probe, tensor, scalar endpoint, antisymmetry, source, and classifier rows already transported. Hence classifier stability preserves all operation routing named by the root surface. □

Theorem 136.131 (Differential-form root BHist ledger exactness obligation)**.** *The visible ledger witnesses of Definition 136.128 are exactly degree histories, probe bundles, tensor source rows, manifold source rows, wedge rows, exterior-derivative input rows, and* Cont *route histories. No closedness, nondegeneracy, nilpotence, contact nonintegrability, quotient, or standard bridge row is a ledger witness of the root surface.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBHistNameCert semantic name certificate`

Proof. Begin with the carrier side. Apply Definition 136.109; it restricts the carrier and classifier ledger entries to the displayed root rows over $BHist$, hsame, Cont, ProbeBundle, and the two source NameCert rows.

Now read the operation side. Apply Definition 136.110; the wedge, antisymmetry, degree, and exterior-derivative entries are exactly the visible ledger rows named by the root obligation and input-output exactness statements.

Finally apply Definition 136.111. Downstream export is exhausted by the same carrier, classifier, wedge, antisymmetry, exterior-input, transport, and source-ledger rows. Since none of the cited exhaustion theorems contains a row for closedness, nondegeneracy, nilpotence, contact nonintegrability, quotienting, or a standard bridge, the displayed ledger is exact. □

Theorem 136.132 (Differential-form root BHist downstream boundary)**.** *The chapters* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *consume* $\mathsf{DiffForm}^{\uparrow}$ *only through the root surface of Definition 136.128. Their downstream reads factor through the carried row, classifier row, degree-probe alignment, wedge routing, exterior-input routing, source NameCert rows, and* Cont *route histories named there.*

Proof. Start from an arbitrary downstream read. Apply Definition 136.107; every read by $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, or $\mathsf{Contact}^{\uparrow}$ factors through the carrier and classifier rows, exterior-input rows, wedge rows, antisymmetry rows, and downstream scope rows listed in the boundary package.

For exterior input, apply Definition 136.105. It repacks every accepted input row into the root-visible carrier, output carrier, successor-degree continuation, transported probe bundle, transported tensor row, scalar endpoint comparison, and source ledger.

Finally apply Definition 136.85. The admissible root row supplies no $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, or bridge row, so those obligations cannot be projected from $\mathsf{DiffForm}^{\uparrow}$. The only remaining reads are precisely the fields of Definition 136.128. □

136.9 DiffForm root degree-classifier package

Definition 136.133 (DiffForm root degree-classifier package)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T*. The root degree-classifier package for* $\mathsf{DiffForm}^{\uparrow}$ *is the citable surface*

$$\mathsf{DiffFormRootDegreeClassifier}_{M,T}.$$

Its BEDC source is the tuple consisting of $BHist$, hsame, Cont, UnaryHistory, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

Its carrier is the pair of the concrete carried row $\mathsf{DiffFormBHistCarrier}_{M,T}$ *and the alignment witness* $\mathsf{DegreeProbeAligned}(d, \mathcal{P})$ *for the displayed unary degree row* d *and visible probe bundle* $\mathcal{P}$*. Its classifier is equality of the transported unary degree row and equality of the transported visible probe arity under* $\sim_{\mathsf{DiffForm}^{\uparrow}}$*; the remaining transported carrier rows are read only through that same* $BHist$ *classifier surface.*

Its ledger consists exactly of the displayed degree history d*, the probe bundle* $\mathcal{P}$*, the tensor row* τ*, the scalar endpoint* σ*, the antisymmetry row* α*, the source ledger* λ*, and the continuation route that records the degree endpoint used by wedge and exterior-input routing. The package contains no row for nilpotence, closedness, nondegeneracy, contact nonintegrability, quotienting, or a standard bridge.*

Theorem 136.134 (DiffForm root degree-classifier coverage)**.** *Every root* $BHist$ *surface row of Definition 136.128 supplies the package* $\mathsf{DiffFormRootDegreeClassifier}_{M,T}$*. In particular, the carrier*

part is the concrete $\mathsf{DiffFormBHistCarrier}_{M,T}$ *row, the arity part is the visible* ProbeBundle *spine aligned with its unary degree row, and the ledger part is exhausted by the displayed degree, probe, tensor, scalar endpoint, antisymmetry, source, and continuation rows.*

Proof. First read the carrier field of the root $BHist$ surface. Apply Definition 136.129. It supplies the concrete carrier row together with the manifold and tensor source rows named by the package.

Next bind the degree and arity interface. Apply Definition 136.30; the carried row exposes the unary degree history and the visible probe bundle as an aligned pair, with no second arity counter outside the displayed bundle.

Finally read the ledger. Apply Definition 136.131. Its exactness statement lists precisely the degree histories, probe bundles, tensor source rows, manifold source rows, wedge rows, exterior-input rows, and Cont route histories available at the root surface. Repacking those rows gives the announced degree-classifier package. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDegreeClassifier coverage`

Theorem 136.135 (DiffForm root degree-classifier transport)**.** *Transport along* $\sim_{\mathsf{DiffForm}^\uparrow}$ *preserves* $\mathsf{DiffFormRootDegreeClassifier}_{M,T}$*. If a carried row with degree* d *and probe bundle* $\mathcal{P}$ *supplies the package, then every* $\sim_{\mathsf{DiffForm}^\uparrow}$*-equivalent carried row supplies the transported package with the transported unary degree row and the same visible probe arity.*

Proof. Begin with classifier stability for the root surface. Apply Definition 136.130. The transported endpoint remains in the concrete carrier surface and keeps the root classifier rows available.

Now transport the aligned pair. Apply Definition 136.31. The degree comparison carried by hsame and the transported probe bundle rebuild DegreeProbeAligned at the target endpoint.

It remains to identify the arity read. Apply Definition 136.12. The visible number of probe slots is preserved by the transported bundle, so the classifier interface is exactly equality of transported degree rows together with equality of transported visible probe arity under $\sim_{\mathsf{DiffForm}^\uparrow}$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDegreeClassifier transport`

Theorem 136.136 (DiffForm root degree-classifier downstream consumption)**.** *The downstream chapters* $\mathsf{DeRham}^\uparrow$*,* $\mathsf{Symplectic}^\uparrow$*, and* $\mathsf{Contact}^\uparrow$ *consume the* $\mathsf{DiffForm}^\uparrow$ *degree and arity data only through* $\mathsf{DiffFormRootDegreeClassifier}_{M,T}$*. Their reads of degree rows and probe-slot arity factor through the root* $BHist$ *surface, the aligned degree-probe pair, and the root consumer face classifier; they do not read nilpotence, closedness, nondegeneracy, contact nonintegrability, quotienting, or a standard bridge from this package.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDegreeClassifier downstream consumption`

Proof. Start from a downstream read by one of the three consumer chapters. Apply Definition 136.132. It factors every such read through the root carrier row, classifier row, degree-probe alignment, wedge routing, exterior-input routing, source NameCert rows, and Cont route histories.

Next apply Definition 136.117. The consumer face classifier assigns every exported row to the de Rham, symplectic, contact, or shared root face, with no row outside those faces.

The shared degree and arity interface is therefore exactly the package surface: transported unary degree equality and transported visible probe-arity equality under $\sim_{\mathsf{DiffForm}^\uparrow}$. The consumer-specific laws remain in their own faces, so this package carries no nilpotence, closedness, nondegeneracy, contact nonintegrability, quotienting, or standard bridge claim. □

Definition 136.137 (Differential-form root degree-probe consumer face)**.** *The root degree-probe consumer face of* $\mathsf{DiffForm}^{\uparrow}$ *is the subface of Definition 136.128 whose rows are exactly:*

1. *the unary degree history of a carried* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *row;*
2. *the visible* $\mathsf{ProbeBundle}$ *spine carried by the same row;*
3. *the degree-probe alignment transport row of Definition 136.31;*
4. *the wedge degree routing row exposed by the wedge ledger;*
5. *the exterior-derivative successor-degree input routing row of Definition 136.105;*
6. *the displayed* $BHist$*,* hsame*,* Cont*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source rows.*

The face contains no row for nilpotence, closedness, nondegeneracy, contact nonintegrability, a de Rham quotient, or a standard bridge. It is a consumer face for downstream reads of degree and probe data only; all consumer-specific laws remain outside $\mathsf{DiffForm}^{\uparrow}$*.*

Theorem 136.138 (Differential-form root degree-probe face coverage)**.** *Every* $\mathsf{DiffForm}^{\uparrow}$ *row read by* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, or* $\mathsf{Contact}^{\uparrow}$ *for degree bookkeeping, visible probe bookkeeping, degree-probe alignment, wedge degree routing, or exterior-derivative successor-degree input routing belongs to Definition 136.137 or to the shared root rows named by Definition 136.116.*

Proof. First read the root carrier surface. Apply Definition 136.129. It identifies the carried degree history, the visible $\mathsf{ProbeBundle}$ spine, and the ManifoldUp and TensorProductUp source rows as fields of the root $BHist$ NameCert surface.

Next isolate the degree-probe row. Apply Definition 136.30. The carried form row refines to the unary degree history and the matching probe bundle over the same tensor input reading, so the downstream degree/probe read is one of the rows named in Definition 136.137.

For operation routing, use Definition 136.105 and Definition 136.132. These theorems place the successor-degree exterior input, wedge degree routing, carried row, classifier row, source rows, and Cont histories on the root-visible surface.

Finally apply Definition 136.117. Every downstream exported row is in a consumer face or in the shared root face. Intersecting that coverage with the rows listed in Definition 136.137 gives the stated coverage for degree and probe reads, with no residual row outside the two named faces. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDegreeProbeFace coverage`

Theorem 136.139 (Differential-form root degree-probe face stability)**.** *Classifier transport along* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *preserves the root degree-probe consumer face. In particular, transported downstream reads of degree history,* $\mathsf{ProbeBundle}$ *spine, degree-probe alignment, wedge degree routing, exterior-derivative successor-degree input routing, and the displayed source rows remain inside Definition 136.137.*

Proof. Transport the root surface first. Apply Definition 136.130; carrier transport preserves the degree history, probe bundle, wedge routing, exterior-input routing, and displayed source rows of Definition 136.128.

Now transport the aligned subrow. Apply Definition 136.31. The classifier comparison carries the hsame degree comparison and the transported $\mathsf{ProbeBundle}$ spine to the target endpoint, rebuilding the aligned degree/probe row there.

It remains to keep consumer laws out of the transported face. Apply Definition 136.118. Nilpotence, closedness, nondegeneracy, and contact nonintegrability are consumer-specific law rows, and the root degree-probe face contains no quotient or standard bridge row. Thus classifier transport preserves the face without enlarging it. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootDegreeProbeFace stability`

Theorem 136.140 (Differential-form root degree-probe downstream factorization)**.** *Every read by* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, or* $\mathsf{Contact}^{\uparrow}$ *that uses* $\mathsf{DiffForm}^{\uparrow}$ *degree or probe data factors first through Definition 136.137, and only after that through the law rows owned by the downstream chapter.*

Proof. Start with an arbitrary downstream read of $\mathsf{DiffForm}^{\uparrow}$ degree or probe data. Apply Definition 136.132; downstream access to $\mathsf{DiffForm}^{\uparrow}$ factors through the carried row, classifier row, degree-probe alignment, wedge routing, exterior-input routing, source NameCert rows, and Cont route histories.

Refine the degree/probe component with Definition 136.30 and transport it with Definition 136.31. The consumer therefore reads the unary degree history and the $\mathsf{ProbeBundle}$ spine through the face defined in Definition 136.137, not through a separate downstream carrier.

For exterior-derivative input, apply Definition 136.105. The successor-degree input row is repacked from the same carried row, transported probe bundle, tensor row, scalar endpoint comparison, and source ledger. For wedge routing, use the wedge degree routing already listed by the root $BHist$ downstream boundary.

Finally apply Definition 136.117 and Definition 136.118. Coverage places all downstream reads in the named consumer or shared root faces, while disjointness keeps nilpotence, closedness, nondegeneracy, contact nonintegrability, quotient data, and bridge data outside this face. Hence $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ first factor through the degree-probe consumer face and then state their own laws on their own surfaces. □

136.10 DiffForm root consumer-readable package

Definition 136.141 (DiffForm root consumer-readable package)**.** *The root consumer-readable package for* $\mathsf{DiffForm}^{\uparrow}$ *is the ten-field interface*

$$\mathsf{DiffFormRootConsumerPackage}_{M,T}.$$

Its fields are:

1. *traditional target: finite-degree differential forms as consumed by downstream exterior-calculus chapters;*
2. *BEDC source:* $BHist$*,* hsame*,* Cont*,* $\mathsf{ProbeBundle}$*,* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*;*
3. *carrier: the six-coordinate surface consisting of the carried form row, degree history, probe bundle, tensor source row, manifold source row, and* Cont *route history;*
4. *classifier: the displayed relation* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *on the carried root surface;*
5. *stability: carrier transport, classifier stability, degree-probe alignment transport, wedge routing, and exterior-input routing;*
6. *ledger: exactly the histories and source rows named in the carrier, together with the wedge and exterior-input boundary rows;*
7. *core theorem list: Definition 136.129, Definition 136.130, Definition 136.131, and Definition 136.132;*
8. *exactness boundary: no consumer receives a row outside the boundary exhausted by Definition 136.128;*

9. *absent bridge: no standard bridge or quotient bridge is exported;*

10. *status:* (obligation, unformalized).

The package is only a reader-facing projection of Definition 136.128; it introduces no additional exterior law.

Theorem 136.142 (DiffForm root consumer carrier projection)**.** *Every consumer read of Definition 136.141 projects only the six-coordinate carrier consisting of the carried form row, degree history, probe bundle, tensor source row, manifold source row, and* Cont *route history, together with the displayed classifier* $\sim_{\mathsf{DiffForm}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerPackage carrier projection`

Proof. Unpack the package definition. Its carrier and classifier fields are copied from Definition 136.128, so a consumer read has no independent carrier coordinate to inspect.

Apply Definition 136.129. The root obligation supplies exactly the carried form row, the aligned degree and probe entries, and the two source NameCert rows named by the package.

It remains to exclude hidden classifier data. Apply Definition 136.130; classifier transport preserves the displayed root rows and does not create a tangent, quotient, standard-object, or external classifier coordinate. Hence the consumer projection is exactly the six-coordinate carrier plus $\sim_{\mathsf{DiffForm}^{\uparrow}}$. □

Theorem 136.143 (DiffForm root consumer operation routing)**.** *Every wedge read and every exterior-input read through Definition 136.141 routes only through the root wedge boundary row and the root exterior-input boundary row already listed by Definition 136.128.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerPackage operation routing`

Proof. Begin with a wedge read. The package ledger names the wedge row only as part of the root surface, so the read is routed through the wedge boundary component already exposed by Definition 136.128.

For an exterior-input read, use the same ledger field. The exterior input is the root input row carried by the displayed $BHist$, hsame, Cont, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ source data.

Apply Definition 136.131. Its ledger exactness statement says that the visible operation witnesses are only degree histories, probe bundles, tensor and manifold source rows, wedge rows, exterior-derivative input rows, and Cont route histories. Therefore the consumer package has no separate operation-routing surface. □

Theorem 136.144 (DiffForm root consumer NameCert boundary)**.** *The downstream chapters* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$ *may cite Definition 136.141 as the root* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *boundary. This citation supplies the carrier, classifier, stability, ledger, wedge-routing, exterior-input, and source NameCert rows named there, but supplies no* $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, quotient, or standard bridge row.*

Proof. Start from a downstream citation by $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, or $\mathsf{Contact}^{\uparrow}$. Apply Definition 136.132; every such read factors through the carried row, classifier row, degree-probe alignment, wedge routing, exterior-input routing, source NameCert rows, and Cont route histories of the root surface.

Now replace the root surface by the consumer package. The definition of Definition 136.141 lists exactly those fields and names the same core theorem list, so the downstream citation is a readable package citation rather than a new source of structure.

Finally apply Definition 136.131. Since the root ledger has no row for $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, quotienting, or a standard bridge, none of those obligations can be received from the package. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerPackage namecert boundary`

136.11 DiffForm root consumer entry

Definition 136.145 (DiffForm root consumer entry source)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *root consumer entry source is the tuple*

$$\mathsf{DiffFormRootConsumerEntry}_{M,T}.$$

Its entries are the BHist carrier and classifier rows of Definition 136.128, the root consumer carrier readback of Definition 136.113, the wedge input readback of Definition 136.114, the exterior-derivative input row covered by Definition 136.127, and the downstream consumer boundary packaged by Definition 136.119. The entry source contains no row for $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, or a standard bridge.*

Theorem 136.146 (DiffForm root consumer entry carrier)**.** *Every carrier or classifier read admitted by Definition 136.145 factors through the root BHist surface of Definition 136.128. The only carrier projected to a downstream consumer is* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, and the only classifier projected to a downstream consumer is the displayed* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *classifier.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerEntry carrier`

Proof. Start with the entry tuple. Its carrier and classifier coordinates are defined to be the root *BHist* rows of Definition 136.128.

Apply Definition 136.129. It projects the carried form row, degree-probe alignment row, manifold source row, and tensor source row from the displayed root surface.

Now apply Definition 136.113. That readback theorem states that every threshold consumer reads exactly the six-coordinate carrier and displayed classifier, with no additional carrier coordinate, replacement classifier, operator law, or standard bridge. The carrier entry therefore factors through precisely the advertised root surface. □

Theorem 136.147 (DiffForm root consumer entry wedge)**.** *Every wedge input read admitted by Definition 136.145 is covered by the root consumer threshold certificate. Its visible data are probe append,* Cont *tensor and degree ledgers, antisymmetry ledgers, scalar endpoint transport, and source-ledger projections from the* $\mathsf{DiffForm}^{\uparrow}$ *root.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerEntry wedge`

Proof. Read the wedge coordinate of the entry source. By definition it is the wedge input readback of Definition 136.114.

Next use the cross-consumer threshold package Definition 136.119. The package assigns exported downstream rows to de Rham, symplectic, contact, or shared root faces while keeping downstream laws outside the shared root face.

Combining these two rows gives exactly the visible wedge surface: probe append, Cont tensor and degree ledgers, antisymmetry ledgers, scalar endpoint transport, and source-ledger projections. No wedge input read can project a de Rham, symplectic, or contact law from the root entry. □

Theorem 136.148 (DiffForm root consumer entry derivative)**.** *Every exterior-derivative input read admitted by Definition 136.145 routes through the manifold-tensor source envelope of Definition 136.124. The route supplies carrier, classifier, degree-shift, wedge-input, endpoint-transport, source-ledger, and downstream boundary data, but it does not assert $d^2 = 0$.*

Proof. Begin with the exterior-derivative entry. It is the input row covered by Definition 136.127.

Use Definition 136.125 to identify the source envelope. Carrier and classifier witnesses in that envelope come only from the displayed $BHist$, hsame, Cont, ProbeBundle, $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ rows.

Now apply Definition 136.127. The coverage theorem routes the accepted exterior-derivative input through the carrier, classifier, degree-shift, wedge-input, endpoint-transport, source-ledger, and downstream boundary surface. Its statement leaves nilpotence to the downstream chapter, so the entry source supplies input data without claiming $d^2 = 0$. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerEntry derivative boundary`

Theorem 136.149 (DiffForm root consumer entry threshold)**.** *The carrier, wedge, and exterior-derivative projections of Definition 136.145 form the root entry threshold for* $\mathsf{DeRham}^\uparrow$, $\mathsf{Symplectic}^\uparrow$, *and* $\mathsf{Contact}^\uparrow$. *Downstream consumers may cite this entry threshold for their shared* $\mathsf{DiffForm}^\uparrow$ *input surface, while their nilpotence, closedness, nondegeneracy, contact nonintegrability, and bridge obligations remain outside the root entry.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerEntry threshold`

Proof. First use Definition 136.146. It supplies the shared carrier and classifier surface from the root $BHist$ NameCert rows.

Next use Definition 136.147. It supplies the shared wedge input surface through the root consumer threshold certificate.

Then use Definition 136.148. It supplies the exterior-derivative input route through the manifold-tensor source envelope, without importing $d^2 = 0$ into $\mathsf{DiffForm}^\uparrow$.

Finally apply Definition 136.119. The package places the de Rham, symplectic, and contact laws in their consumer faces and keeps the shared carrier, classifier, wedge, scalar endpoint, and source-ledger rows in the root face. The three projections therefore assemble as the advertised root entry threshold. □

Definition 136.150 (Differential-form root boundary consumer package)**.** *The differential-form root boundary consumer package is the tuple*

$$\mathsf{DiffFormRootBoundaryConsumer}_{M,T}.$$

It has ten fields.

1. *The source field is the pair* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *already exposed by the root $BHist$ surface.*
2. *The carrier field is* $\mathsf{DiffFormBHistCarrier}_{M,T}$.
3. *The classifier field is the displayed* $\sim_{\mathsf{DiffForm}^\uparrow}$ *classifier.*

4. *The carrier-transport stability field is the* hsame *transport row of Definition 136.10.*
5. *The classifier-stability field is the transported classifier row of Definition 136.11.*
6. *The wedge-transport field is the wedge and derivative boundary compatibility row of Definition 136.106.*
7. *The exterior-input transport field is the root closure row of Definition 136.105.*
8. *The ledger field consists of* $\mathsf{DiffFormDownstreamBoundary}_{M,T}$ *from Definition 136.104 together with the entry rows of Definition 136.145.*
9. *The exactness field says that these fields exhaust the shared rows consumed by* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *and* $\mathsf{Contact}^{\uparrow}$.
10. *The bridge-status field contains no standard bridge row and records the package as a proof target.*

Theorem 136.151 (Differential-form root boundary consumer carrier scope)**.** *Every carrier or classifier read admitted by* $\mathsf{DiffFormRootBoundaryConsumer}_{M,T}$ *factors through the root* $BHist$ *surface of Definition 136.128, the entry carrier theorem Definition 136.146, and the carrier coverage theorem Definition 136.109. In particular, the package exposes no carrier beyond* $\mathsf{DiffFormBHistCarrier}_{M,T}$ *and no classifier beyond* $\sim_{\mathsf{DiffForm}^{\uparrow}}$.

Proof. Read the carrier and classifier fields of $\mathsf{DiffFormRootBoundaryConsumer}_{M,T}$. By definition, they are the carrier and classifier fields of Definition 136.128.

Apply Definition 136.146. It states that the root consumer entry projects exactly the root $BHist$ carrier and the displayed $\mathsf{DiffForm}^{\uparrow}$ classifier, with no replacement carrier and no downstream law.

Apply Definition 136.109. The coverage theorem identifies the carrier and classifier rows visible to downstream consumers with the displayed source rows. Therefore every carrier or classifier read of the package factors through the named root surface and through the two carrier-scope theorems. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBoundaryConsumer carrier scope`

Theorem 136.152 (Differential-form root boundary consumer classifier scope)**.** *Componentwise* hsame *transport preserves* $\mathsf{DiffFormRootBoundaryConsumer}_{M,T}$. *The carrier field is preserved by Definition 136.10, the classifier field by Definition 136.11, the exterior-input field by Definition 136.105, and the shared wedge and derivative boundary field by Definition 136.106.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBoundaryConsumer classifier scope`

Proof. Start with componentwise hsame data on the displayed source histories. For the carrier field, apply Definition 136.10. It transports the carried form row without changing the root source.

For the classifier field, apply Definition 136.11. It gives stability of $\sim_{\mathsf{DiffForm}^{\uparrow}}$ under the same componentwise histories and keeps the classifier inside the root surface.

For the exterior-input field, use Definition 136.105. That theorem repacks the accepted exterior-input rows into the downstream boundary package after the same transported carrier and classifier rows have been fixed.

For the wedge and derivative boundary field, apply Definition 136.106. It identifies the common transported rows used by wedge admission and exterior-input admission. The ledger and exactness fields are defined from these transported rows, so the whole package is preserved. □

Theorem 136.153 (Differential-form root boundary consumer exactness)**.** *Every* $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, *or* $\mathsf{Contact}^{\uparrow}$ *read of the* $\mathsf{DiffForm}^{\uparrow}$ *shared root factors through* $\mathsf{DiffFormRootBoundaryConsumer}_{M,T}$. *No such read can project* $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, nilpotence, or a bridge row from this package.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootBoundaryConsumer exactness`

Proof. First route carrier and classifier reads through Definition 136.151. This accounts for the shared carried-form row, the displayed $\mathsf{DiffForm}^{\uparrow}$ classifier, and the source certificates visible from $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

Next route exterior-input reads through Definition 136.105. The theorem places source carrier, output carrier, successor-degree continuation, transported probe rows, tensor rows, scalar endpoint comparison, and source ledger inside $\mathsf{DiffFormDownstreamBoundary}_{M,T}$.

Now route wedge and mixed wedge-derivative reads through Definition 136.106. The common rows are exactly the carried form, unary degree row, wedge degree ledger, one-step exterior continuation ledger, transported probe, tensor, scalar endpoint, antisymmetry, source rows, and their classifier comparisons.

Finally apply Definition 136.107 together with Definition 136.149. These theorems name $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$ as the downstream consumers of the shared boundary and root-entry rows. Since the package contains exactly those ledgers and its bridge-status field contains no standard bridge, every downstream read factors through the package and none can project nilpotence, closedness, nondegeneracy, contact nonintegrability, or bridge structure from $\mathsf{DiffForm}^{\uparrow}$. □

136.12 DiffForm root consumer factorization

Definition 136.154 (DiffForm root consumer factorization surface)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *root consumer factorization surface is the tuple*

$$\mathsf{DiffFormRootConsumerFactor}_{M,T}.$$

Its coordinates are the entry source of Definition 136.145, the carrier row of Definition 136.146, the wedge row of Definition 136.147, the exterior-derivative row of Definition 136.148, and the threshold row of Definition 136.149. The surface is a consumer-facing route table, not a downstream law table: it contains no row for $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, quotienting, or a standard bridge.*

Theorem 136.155 (DiffForm root carrier factorization)**.** *Every downstream carrier or classifier read from* $\mathsf{DiffForm}^{\uparrow}$ *factors through Definition 136.154. The only carrier route is the root* $BHist$ *carrier* $\mathsf{DiffFormBHistCarrier}_{M,T}$*, and the only classifier route is the displayed* $\sim_{\mathsf{DiffForm}^{\uparrow}}$ *classifier bound by the root* $BHist$ *surface.*

Proof. Start with an arbitrary carrier or classifier read by $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, or $\mathsf{Contact}^{\uparrow}$. Apply Definition 136.132. It places every downstream read through the carried row, classifier row, degree-probe alignment, wedge routing, exterior-input routing, source NameCert rows, and Cont histories named by the root $BHist$ surface.

Now apply Definition 136.146. This entry row identifies the consumer carrier coordinate with $\mathsf{DiffFormBHistCarrier}_{M,T}$ and the consumer classifier coordinate with the displayed $\sim_{\mathsf{DiffForm}^{\uparrow}}$ classifier, with no replacement carrier or classifier.

Finally read these two coordinates inside Definition 136.154. Since the factorization surface contains the entry source and the carrier entry row, the downstream carrier and classifier read factors through exactly that surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFactorization carrier route closure`

Theorem 136.156 (DiffForm wedge and derivative factorization)**.** *Every downstream wedge read or exterior-derivative input read from* $\mathsf{DiffForm}^{\uparrow}$ *factors through Definition 136.154. Wedge reads use the wedge-entry row, and exterior-derivative reads use the exterior-derivative entry row; neither route projects a downstream law from the* $\mathsf{DiffForm}^{\uparrow}$ *root.*

Proof. First consider a downstream wedge read. Apply Definition 136.147. It routes accepted wedge input through probe append, Cont tensor and degree ledgers, antisymmetry ledgers, scalar endpoint transport, and source-ledger projections from the $\mathsf{DiffForm}^{\uparrow}$ root.

Next consider an exterior-derivative input read. Apply Definition 136.148. It routes the input through the manifold-tensor source envelope, supplying carrier, classifier, degree-shift, wedge-input, endpoint-transport, source-ledger, and downstream boundary data while leaving $d^2 = 0$ outside the root.

Finally apply Definition 136.119. The package assigns the de Rham, symplectic, and contact laws to their consumer faces and keeps the shared carrier, classifier, wedge, scalar endpoint, and source-ledger rows in the root face. Since Definition 136.154 contains both entry rows and the threshold row, every wedge or exterior-input read factors through the shared surface. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerFactorization wedge derivative`

Theorem 136.157 (DiffForm threshold consumer factorization)**.** *The three consumer faces* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Symplectic}^{\uparrow}$*, and* $\mathsf{Contact}^{\uparrow}$ *may cite only Definition 136.154 for their shared* $\mathsf{DiffForm}^{\uparrow}$ *input. Nilpotence, closedness, nondegeneracy, and contact nonintegrability must be supplied in the corresponding downstream chapters and are not projected by the* $\mathsf{DiffForm}^{\uparrow}$ *root.*

Proof. Begin with the shared input side. Apply Definition 136.149. It assembles the carrier, wedge, and exterior-derivative projections as the root entry threshold for $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Symplectic}^{\uparrow}$, and $\mathsf{Contact}^{\uparrow}$.

Now apply Definition 136.119. It separates the shared root rows from the de Rham, symplectic, and contact law rows, so consumer chapters receive only the common input surface from $\mathsf{DiffForm}^{\uparrow}$.

Finally apply Definition 136.132. The root $BHist$ boundary excludes $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, and bridge rows from the $\mathsf{DiffForm}^{\uparrow}$ projection. Thus the three consumer faces may cite the shared factorization surface for input, and their own chapters must supply the corresponding downstream laws. □

136.13 DiffForm root consumer export packet

Definition 136.158 (DiffForm root consumer export packet)**.** *The* $\mathsf{DiffForm}^{\uparrow}$ *root consumer export packet is the paper-side union*

$$\mathsf{DiffFormRootConsumerExport}_{M,T}.$$

Its positive surface consists exactly of the root-unblock source surface of Definition 136.33, the carrier and classifier scope theorem Definition 136.34, the wedge and Cont *closure theorem Definition 136.35, the exterior-input consumption theorem Definition 136.36, the consumer face classifier*

of Definition 136.116, the face exhaustion theorem Definition 136.121, and the consumer-readable package of Definition 136.141 with its boundary theorem Definition 136.144. The packet contains no row outside these cited root-unblock, face-classifier, face-exhaustion, and readable-package surfaces.

Theorem 136.159 (DiffForm root consumer export coverage)**.** *Every* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Contact}^{\uparrow}$*, or* $\mathsf{Symplectic}^{\uparrow}$ *consumer row admitted at the* $\mathsf{DiffForm}^{\uparrow}$ *root factors through Definition 136.158.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerExport coverage`

Proof. Start with a consumer row admitted at the $\mathsf{DiffForm}^{\uparrow}$ root. By the source surface in Definition 136.33, such a row may read only the displayed $BHist$, hsame, Cont, probe-bundle, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, carrier, classifier, wedge, and exterior-input coordinates.

Apply Definition 136.36. It restricts $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, and $\mathsf{Symplectic}^{\uparrow}$ consumers to the degree, wedge, antisymmetry, scalar endpoint, and source-ledger rows exposed by the root-unblock surface.

Now apply Definition 136.121. Every row exported by the root threshold is shared root data or belongs to exactly one of the de Rham, symplectic, and contact faces.

Finally use Definition 136.144. The downstream citation surface is the consumer-readable package named in Definition 136.158, so the admitted consumer row factors through that packet and has no independent root route. □

Theorem 136.160 (DiffForm root consumer export exactness)**.** *The packet Definition 136.158 exposes exactly the six-coordinate carrier, displayed classifier, wedge-continuation rows, antisymmetry ledger, scalar endpoint row, source ledger, and exterior-input rows named by the cited root-unblock and consumer-face surfaces.*

Proof. Project the carrier and classifier coordinates with Definition 136.34. The carrier is the six-coordinate row

$$(d, \mathcal{P}, \tau, \sigma, \alpha, \lambda),$$

and the classifier reads only the displayed degree, tensor, scalar endpoint, antisymmetry, tensor-ledger, and source-ledger comparisons.

Next project the operation rows with Definition 136.35. Wedge admission reads only probe append, the Cont tensor ledger, degree bookkeeping, and the displayed antisymmetry ledger.

The exterior side is supplied by Definition 136.36. It restricts exterior consumers to degree, wedge, antisymmetry, scalar endpoint, and source-ledger projections.

Finally use Definition 136.121 and Definition 136.144. Face exhaustion says there is no exported row beyond the shared root and three consumer faces, and the readable boundary repacks the same carrier, classifier, stability, ledger, wedge-routing, exterior-input, and source NameCert rows. Hence the packet is exactly the stated export surface. □

Theorem 136.161 (DiffForm root consumer export no extra laws)**.** *The packet Definition 136.158 contains no* $d^2 = 0$*, closedness, nondegeneracy, contact nonintegrability, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumerExport no extra laws`

Proof. First inspect the defining source surface Definition 136.33. It explicitly contains no row for $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, or a standard bridge.

Apply Definition 136.36. The theorem keeps de Rham nilpotence, symplectic closedness and nondegeneracy, and contact nonintegrability in the downstream certificate surfaces.

Then apply Definition 136.121 together with Definition 136.122. Exhaustion assigns every exported row to the shared root or a unique consumer face, while boundary exactness excludes the downstream law rows and any standard bridge.

The readable package boundary Definition 136.144 names the same negative boundary. Therefore the export packet carries the root-unblocking surface and no extra exterior or geometric law. □

136.14 DiffForm consumer boundary obligations

Theorem 136.162 (DiffForm consumer source scope)**.** *Every* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Contact}^{\uparrow}$*, or* $\mathsf{Symplectic}^{\uparrow}$ *consumer row exported from* $\mathsf{DiffForm}^{\uparrow}$ *is a projection of the root-unblock source surface of Definition 136.33. Hence such a row may read only* $BHist$*,* hsame*,* Cont*,* ProbeBundle*, the* $\mathsf{Manifold}^{\uparrow}$ *and* $\mathsf{TensorProduct}^{\uparrow}$ NameCert *sources, the six-coordinate carrier, and the* $\mathsf{DiffForm}^{\uparrow}$ *classifier.*

Proof. Start from the displayed root-unblock source surface. Its entries list the only histories and certificates made available to downstream consumers, so a consumer row must be obtained by forgetting part of that displayed surface.

Apply Definition 136.34 to restrict the visible carrier and classifier data to the six-coordinate carrier and the $\mathsf{DiffForm}^{\uparrow}$ classifier.

Finally apply Definition 136.131. It identifies the exposed source ledger with the stated $BHist$, hsame, Cont, ProbeBundle, $\mathsf{Manifold}^{\uparrow}$, and $\mathsf{TensorProduct}^{\uparrow}$ sources, leaving no additional source row for a downstream consumer to read. □

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormRootConsumer source projection scope`

Theorem 136.163 (DiffForm wedge degree ledger consumption)**.** *Any* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Contact}^{\uparrow}$*, or* $\mathsf{Symplectic}^{\uparrow}$ *consumer using a* $\mathsf{DiffForm}^{\uparrow}$ *wedge may consume the wedge degree ledger only through its* UnaryHistory *endpoints and the displayed* $\mathsf{Cont}(d_\omega, d_\eta, d_{\mathrm{out}})$ *row. This consumption rule is stable under* hsame *transport of the two input degree histories and the output degree history.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormWedgeDegreeLedger consumer boundary`

Proof. Read the ledger in Definition 136.22. The displayed data consist of the two input unary histories, the output unary history, and the single continuation row joining them.

Classifier stability is then exactly Definition 136.23: transporting the input form rows by hsame transports the degree histories and preserves the wedge classifier row.

The root-unblock wedge closure of Definition 136.35 identifies the same continuation row as the wedge-visible Cont entry. Therefore a downstream consumer can use the wedge degree ledger only through those unary endpoints and that displayed continuation row, and the rule is invariant under hsame transport. □

Theorem 136.164 (DiffForm exterior consumer boundary)**.** *The chapters* $\mathsf{DeRham}^{\uparrow}$*,* $\mathsf{Contact}^{\uparrow}$*, and* $\mathsf{Symplectic}^{\uparrow}$ *must supply nilpotence, closedness, nondegeneracy, and contact nonintegrability in their own certificate surfaces. The* $\mathsf{DiffForm}^{\uparrow}$ *export supplies only carrier/classifier rows, wedge rows, degree rows, source rows, and the ledger data made visible by the preceding consumer-source and wedge-degree obligations.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorConsumer boundary`

Proof. First apply Definition 136.162. This bounds every downstream consumer source to the displayed root-unblock carrier, classifier, history, continuation, probe, and NameCert rows.

Next apply Definition 136.163. It bounds all wedge-degree use to unary-history endpoints and the visible continuation row, with no extra operator law.

Finally combine these two bounds with Definition 136.36 and Definition 136.24. Those rows already separate exterior-derivative input consumption from $d^2 = 0$, closedness, nondegeneracy, and contact nonintegrability. The listed geometric laws therefore remain obligations of the $\mathsf{DeRham}^{\uparrow}$, $\mathsf{Contact}^{\uparrow}$, and $\mathsf{Symplectic}^{\uparrow}$ certificate surfaces rather than exports of $\mathsf{DiffForm}^{\uparrow}$. □

Theorem 136.165 (Differential-form NameCert obligation surface)**.** *The paper-side* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *obligation surface consists exactly of the carrier of Definition 136.1, the classifier of Definition 136.2, carrier transport, classifier stability, wedge ledger coverage, the wedge associator ledger, the wedge probe concatenation ledger, wedge probe concatenation classifier stability, the wedge degree ledger, wedge degree classifier stability, the exterior-derivative candidate ledger, its degree-raise and wedge-input stability rows, the antisymmetry permutation ledger, the de Rham input boundary of Definition 136.24, and the downstream scope row of Definition 136.61. It asserts no standard bridge beyond these BEDC rows and no identity* $d^2 = 0$*, closedness, nondegeneracy, or contact nonintegrability.*

Lean4 ✓ `BEDC.Derived.DiffFormUp.DiffFormExteriorDerivativeLedger semantic name certificate`

Proof. The carrier and classifier fields are the two displayed definitions. Carrier transport is Definition 136.10, and classifier stability is Definition 136.11.

The multiplicative operation exposed by the surface is the wedge row, whose admission and stability are exactly the visible tensor-concatenation statement of Definition 136.15. Its output probe spine is the visible concatenation ledger of Definition 136.16, with coverage and transport supplied by Definition 136.17 and Definition 136.18. Its associativity obligation is the visible ledger of Definition 136.19 and the closure statement of Definition 136.20. Its degree bookkeeping is the visible unary-history ledger of Definition 136.22, and classifier stability for that ledger is Definition 136.23. Antisymmetry is not hidden in the wedge operation: it is the explicit permutation ledger retained in every carrier row.

The exterior-derivative candidate interface is the visible package of Definition 136.54. Its degree bookkeeping is Definition 136.55, and its transport along the wedge-input classifier is Definition 136.56.

The remaining exported row is the downstream scope for exterior derivative consumers, bounded by Definition 136.24. Since all fields are stated with $BHist$, hsame, Cont, $\mathsf{ProbeBundle}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, this is a BEDC obligation surface and not a claim of equivalence with a standard differential-form object. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$**.**

Constructive story: A differential form is generated as a six-coordinate BHist row over fixed $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{TensorProduct}^{\uparrow}$ sources: a unary degree, a finite tangent-probe ProbeBundle, a multilinear tensor row, a scalar endpoint, an antisymmetry permutation ledger, and a source-provenance ledger. The carrier accepts exactly those rows whose probes are carried by the manifold source, whose tensor and scalar endpoints are certified by the tensor and scalar sources, and whose antisymmetry and provenance are displayed; any hidden alternating-map object, quotient, closedness predicate, or operator identity is excluded. Two carried forms are classified by degree hsame, matched tensor and scalar comparisons through retained source classifiers, and visible hsame on the antisymmetry, tensor, and provenance ledgers. The source is the manifold-plus-tensor certificate surface, the pattern records degree/probe/tensor/scalar/antisymmetry shape together with wedge and exterior-input routing, and the ledger keeps wedge concatenation, degree bookkeeping, permutation rows, and exterior-derivative candidate inputs visible. The five name-certificate obligations are supplied by a displayed carried form for inhabitation, by componentwise reflexivity, symmetry, and transitivity of hsame and the retained scalar classifier,

and by carrier and classifier transport for closure under recognized representatives. A row h lies in the signature gap of a DiffForm$^{\uparrow}$ token p when the source-domain accepts its six-coordinate form data, the signature relation pairs it with an answer form and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records the same degree, probe, tensor, scalar, antisymmetry, wedge, and exterior-input rows. The chapter registers this displayed form surface under DiffForm$^{\uparrow}$; downstream de Rham, symplectic, and contact consumers may read only these BEDC ledgers, with no $d^2 = 0$, closedness, nondegeneracy, contact nonintegrability, or standard bridge introduced here.

Theory closure: TheoryGate(NameCert$_{\mathsf{DiffForm}\uparrow}$, maturePackageClosed)

Scope closed: Definition 136.165 is the paper-side scope for the displayed BHist, hsame, Cont, ProbeBundle, ManifoldUp, TensorProductUp, wedge-ledger, exterior-derivative input, and downstream boundary rows.

Chapter 137

A Concrete Naming Certificate for $\mathsf{DeRham}^{\uparrow}$

The de Rham interface $\mathsf{DeRham}^{\uparrow}$ packages the exterior-derivative chain complex on differential forms, certifying $d^2 = 0$ and hsame-stability. It depends on $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ (chapter 136) and $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ (chapter 99), and supplies the de Rham cohomology of a manifold.

137.1 Carrier definition

137.2 The certificate

Definition 137.1 (De Rham chain-complex boundary row)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *cochain differential* $d_{\mathrm{dR}} : \mathsf{BHist} \to \mathsf{BHist}$*. A row* $b : \mathsf{BHist}$ *is accepted by the* $\mathsf{DeRham}^{\uparrow}$ *chain-complex boundary predicate when it is in the image of the same cochain differential:*

$$\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(b) :\Longleftrightarrow \exists a : \mathsf{BHist},\ \mathsf{hsame}(b, d_{\mathrm{dR}}(a)).$$

The witness a *is the cochain preimage row. The predicate adds no quotient row and no host-level differential-form operation beyond the displayed cochain differential.*

Lean4 (definition) `BEDC.Derived.DeRhamUp.DeRhamBoundary`

Definition 137.2 (De Rham double exterior-derivative packet)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *source* T *as in Definition 136.1. Fix a* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *cochain differential* $d_{\mathrm{dR}} : \mathsf{BHist} \to \mathsf{BHist}$ *and a zero cochain endpoint* $z_{\mathrm{dR}} : \mathsf{BHist}$*. For carried* $\mathsf{DiffForm}^{\uparrow}$ *rows* ω*,* η*, and* θ*, the packet*

$$\mathsf{DeRhamDoubleExterior}_{M,T,d_{\mathrm{dR}}}(\omega, \eta, \theta, z_{\mathrm{dR}})$$

is accepted exactly when its visible fields are the following rows:

1. ω*,* η*, and* θ *are carried by* $\mathsf{DiffFormBHistCarrier}_{M,T}$*.*
2. *The two successive exterior-input rows* $\mathsf{DiffFormExteriorInput}_{M,T}(\omega, \eta)$ *and* $\mathsf{DiffFormExteriorInput}_{M,T}(\eta, \theta)$ *are accepted.*
3. *The cochain graph rows identify the carried exterior outputs with the same cohomology differential:*

$$\eta \mathsf{hsame} d_{\mathrm{dR}}(\omega) \quad \textit{and} \quad \theta \mathsf{hsame} d_{\mathrm{dR}}(\eta).$$

4. The cohomology differential respects hsame*: for all* $a, b : \mathsf{BHist}$*,*

$$\mathsf{hsame}(a, b) \Longrightarrow \mathsf{hsame}(d_{\mathrm{dR}}(a), d_{\mathrm{dR}}(b)).$$

5. The de Rham square-zero row and zero endpoint row are present:

$$\forall a : \mathsf{BHist},\ \mathsf{hsame}(d_{\mathrm{dR}}(d_{\mathrm{dR}}(a)), z_{\mathrm{dR}}) \quad \textit{and} \quad \mathsf{hsame}(z_{\mathrm{dR}}, \mathsf{e}).$$

The two $\mathsf{DiffForm}^{\uparrow}$ *exterior-input rows provide only the carried input-output surface of Definition 136.68; the square-zero row is a* $\mathsf{DeRham}^{\uparrow}$ *field read through the* $\mathsf{Cohomology}^{\uparrow}$ *cochain differential.*

Lean4 (definition) `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorPacket`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamTasteGate single carrier alignment`

Theorem 137.3 (De Rham double exterior derivative boundary)**.** *If* $\mathsf{DeRhamDoubleExterior}_{M,T,d_{\mathrm{dR}}}(\omega, \eta, \theta, z_{\mathrm{dR}})$ *is accepted, then the carried second exterior derivative row* θ *is classified as the zero cochain endpoint and is an accepted* $\mathsf{DeRham}^{\uparrow}$ *chain-complex boundary row:*

$$\mathsf{hsame}(\theta, z_{\mathrm{dR}}) \quad \wedge \quad \mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(\theta).$$

Moreover the intermediate carried row is a $\mathsf{Cohomology}^{\uparrow}$ *cocycle:*

$$C_{d_{\mathrm{dR}}}(\eta).$$

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorPacket boundary`
↪ variant `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorDerivative boundary`

Proof. Unpack the accepted packet of Definition 137.2. The two accepted $\mathsf{DiffForm}^{\uparrow}$ exterior-input rows are successive by Definition 136.68: the first has source ω and output η, while the second has source η and output θ. By Definition 136.69, these rows expose only the one-step exterior-input ledgers. The nilpotence row therefore comes from the de Rham packet, not from the $\mathsf{DiffForm}^{\uparrow}$ boundary exhaustion of Definition 136.107.

Let the graph comparisons be $\eta\mathsf{hsame}d_{\mathrm{dR}}(\omega)$ and $\theta\mathsf{hsame}d_{\mathrm{dR}}(\eta)$. Applying the hsame-respect row of d_{dR} to the first comparison gives

$$\mathsf{hsame}(d_{\mathrm{dR}}(\eta), d_{\mathrm{dR}}(d_{\mathrm{dR}}(\omega))).$$

The square-zero row at ω gives

$$\mathsf{hsame}(d_{\mathrm{dR}}(d_{\mathrm{dR}}(\omega)), z_{\mathrm{dR}}).$$

Transitivity with the second graph comparison yields $\mathsf{hsame}(\theta, z_{\mathrm{dR}})$.

For the boundary predicate, use the cochain preimage η. The second graph comparison is exactly the witness $\mathsf{hsame}(\theta, d_{\mathrm{dR}}(\eta))$ required by Definition 137.1. Hence $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(\theta)$ holds.

Finally, the same differential comparison, the square-zero row at ω, and the zero endpoint comparison $\mathsf{hsame}(z_{\mathrm{dR}}, \mathsf{e})$ give $d_{\mathrm{dR}}(\eta)\mathsf{hsame}\mathsf{e}$. By Definition 99.28, this is exactly $C_{d_{\mathrm{dR}}}(\eta)$. □

Theorem 137.4 (De Rham zero-endpoint boundary transport)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Cohomology}^\uparrow}$ *cochain differential* $d_{\mathrm{dR}} : \mathsf{BHist} \to \mathsf{BHist}$*. If a displayed row* $b : \mathsf{BHist}$ *is accepted by* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ *through a cochain preimage* $a : \mathsf{BHist}$ *and a transported endpoint* $b' : \mathsf{BHist}$ *satisfies* $\mathsf{hsame}(b', b)$*, then the transported row is again an accepted de Rham boundary row:*

$$\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(b')$$

with the same preimage witness a*. In particular, if* b *is compared by* hsame *to the zero endpoint* z_{dR}*, any displayed endpoint transported to that zero endpoint remains in the same boundary predicate.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundary zero endpoint hsame transport`
↪ variant `BEDC.Derived.DeRhamUp.DeRhamBoundary zero endpoint transport`

Proof. Unpack Definition 137.1. The accepted boundary row supplies a witness a and a comparison $\mathsf{hsame}(b, d_{\mathrm{dR}}(a))$.

The transported endpoint supplies $\mathsf{hsame}(b', b)$. By transitivity of hsame, the row b' compares with $d_{\mathrm{dR}}(a)$:

$$\mathsf{hsame}(b', d_{\mathrm{dR}}(a)).$$

Repack the same cochain preimage a in Definition 137.1. No new differential-form row, quotient row, or cohomology carrier is introduced; only the displayed endpoint has been transported along hsame. □

Theorem 137.5 (De Rham cocycle readback from square-zero packets)**.** *Every accepted packet*

$$\mathsf{DeRhamDoubleExterior}_{M,T,d_{\mathrm{dR}}}(\omega, \eta, \theta, z_{\mathrm{dR}})$$

reads its intermediate carried row η *as a* $\mathsf{Cohomology}^\uparrow$ *cocycle:*

$$C_{d_{\mathrm{dR}}}(\eta).$$

The readback uses only the packet's cochain graph row $\eta\mathsf{hsame}d_{\mathrm{dR}}(\omega)$*, the square-zero row for* d_{dR}*, and the zero endpoint comparison* $\mathsf{hsame}(z_{\mathrm{dR}}, \mathsf{e})$*.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorPacket cohomology cocycle readback`

Proof. Unpack Definition 137.2. The graph row identifies the intermediate carried row with the first cochain differential: $\eta\mathsf{hsame}d_{\mathrm{dR}}(\omega)$.

Apply the hsame-respect field of the cochain differential to this graph row. It gives a comparison from $d_{\mathrm{dR}}(\eta)$ to $d_{\mathrm{dR}}(d_{\mathrm{dR}}(\omega))$.

The square-zero row at ω compares $d_{\mathrm{dR}}(d_{\mathrm{dR}}(\omega))$ with z_{dR}, and the zero endpoint comparison identifies z_{dR} with e. Chaining these hsame comparisons yields $d_{\mathrm{dR}}(\eta)\mathsf{hsame}\mathsf{e}$.

By Definition 99.28, this is exactly the $\mathsf{Cohomology}^\uparrow$ cocycle predicate $C_{d_{\mathrm{dR}}}(\eta)$. □

Theorem 137.6 (De Rham NameCert obligation surface)**.** *The de Rham rows in this chapter expose the* $\mathsf{NameCert}_{\mathsf{DeRham}^\uparrow}$ *obligation surface over* $\mathsf{DiffForm}^\uparrow$ *and* $\mathsf{Cohomology}^\uparrow$*. The carrier is the differential-form carried row supplied by Definition 136.1; the classifier is the boundary predicate of Definition 137.1; the stability field is the endpoint transport of Definition 137.4; the exactness row is the square-zero boundary theorem Definition 137.3; and the ledger row is the cocycle readback of Definition 137.5. Together these rows supply the carrier, classifier, stability, exactness, and ledger entries required by the named de Rham certificate surface, without asserting a de Rham isomorphism or any quotient-level cohomology presentation.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundary semanticNameCert`

Proof. The carrier component is inherited from the visible $\mathsf{DiffForm}^{\uparrow}$ form carrier cited in the statement. The De Rham boundary row then classifies the second exterior derivative by a concrete cochain preimage in Definition 137.1.

Stability is supplied by Definition 137.4: once a boundary row is witnessed by a preimage, endpoint transport along hsame preserves the same predicate using that witness.

Exactness is supplied by Definition 137.3. It turns an accepted double exterior packet into both the zero endpoint comparison for the second row and the boundary predicate for that row.

The ledger is the readback Definition 137.5. It records that the intermediate row seen by the square-zero packet is a $\mathsf{Cohomology}^{\uparrow}$ cocycle. These named rows are precisely the advertised certificate obligations and no additional bridge or quotient surface is used. □

Definition 137.7 (De Rham boundary source packet)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *cochain differential* $d_{\mathrm{dR}} : \mathsf{BHist} \to \mathsf{BHist}$ *and a zero endpoint* $z_{\mathrm{dR}} : \mathsf{BHist}$*. A De Rham boundary source packet consists of the following* BHist *rows:*

1. *the cochain differential row* d_{dR} *and its zero endpoint comparison* $\mathsf{hsame}(z_{\mathrm{dR}}, \mathsf{e})$*;*
2. *carried* $\mathsf{DiffForm}^{\uparrow}$ *input rows* ω*,* η*, and* θ *with the two exterior-input rows of Definition 137.2;*
3. *the* $\mathsf{Cohomology}^{\uparrow}$ *cocycle row* $C_{d_{\mathrm{dR}}}(\eta)$ *read from the intermediate carried row;*
4. *the boundary predicate* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(\theta)$ *of Definition 137.1;*
5. *the finite ledger containing the cochain graph rows* $\eta\mathsf{hsame}d_{\mathrm{dR}}(\omega)$ *and* $\theta\mathsf{hsame}d_{\mathrm{dR}}(\eta)$*, the square-zero row for* d_{dR}*, and the displayed* $\mathsf{DiffForm}^{\uparrow}$ *and* $\mathsf{Cohomology}^{\uparrow}$ *source rows.*

The packet exports only these boundary-source rows. It does not add a quotient cohomology carrier, a de Rham isomorphism row, or an ambient manifold-level equality witness.

Lean4 (definition) `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket`

Theorem 137.8 (De Rham boundary source stability)**.** *Let* P *be a De Rham boundary source packet as in Definition 137.7. If the visible boundary endpoint* θ *is transported to* θ' *by* $\mathsf{hsame}(\theta', \theta)$*, then the same packet data transport to a boundary source packet with boundary endpoint* θ'*. The cochain differential, zero endpoint row,* $\mathsf{DiffForm}^{\uparrow}$ *input rows,* $\mathsf{Cohomology}^{\uparrow}$ *cocycle row, and finite ledger rows are unchanged except for replacing the displayed boundary endpoint by* θ'*.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourcePacket stability`

Proof. Unpack the packet. Its boundary component is $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(\theta)$, witnessed by the cochain preimage row named in Definition 137.1.

Apply Definition 137.4 to the displayed comparison $\mathsf{hsame}(\theta', \theta)$. The theorem keeps the same preimage witness and gives $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}(\theta')$.

All other packet rows are source or ledger rows that do not mention the new endpoint except through the boundary predicate just transported. Repacking the unchanged cochain differential, zero endpoint row, $\mathsf{DiffForm}^{\uparrow}$ inputs, cocycle row, and finite ledger with the transported boundary predicate gives the claimed packet. □

Theorem 137.9 (De Rham boundary consumer exactness)**.** *Every downstream consumer of a De Rham boundary source packet reads exactly the boundary row of Definition 137.1, the zero endpoint row of Definition 137.2, the cocycle row supplied by Definition 137.5, and the finite ledger rows displayed in Definition 137.7. The packet therefore supplies no additional cohomology quotient, no*

de Rham isomorphism row, and no hidden differential-form operation beyond the accepted BHist *boundary-source data.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket consumer exactness`

Proof. Start with an accepted packet. Its boundary row is part of the data in Definition 137.7, and Definition 137.3 identifies the accepted double exterior packet as the source of that boundary predicate.

The zero endpoint row is also explicit: it is the comparison $\mathsf{hsame}(z_{\mathrm{dR}}, \mathsf{e})$ carried by Definition 137.2. A consumer can read it only through that packet field and through endpoint transport by Definition 137.4.

The cocycle component is fixed by Definition 137.5. It reads the intermediate row η as $C_{d_{\mathrm{dR}}}(\eta)$ from the cochain graph row and the square-zero row, so the consumer receives exactly the displayed $\mathsf{Cohomology}^{\uparrow}$ cocycle row.

Finally, inspect the finite ledger in Definition 137.7. It lists the two cochain graph rows, the square-zero row, and the visible $\mathsf{DiffForm}^{\uparrow}$ and $\mathsf{Cohomology}^{\uparrow}$ source rows. Since the definition lists no quotient, isomorphism, or additional operation row, every downstream readback is exhausted by those rows. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourcePacket consumer exactness`

Theorem 137.10 (De Rham root carrier obligation)**.** *The root carrier obligation exposed by* $\mathsf{DeRham}^{\uparrow}$ *is exactly the displayed* $\mathsf{DiffForm}^{\uparrow}$ *row together with the* BHist *cochain differential packet. Concretely, the carrier reads a differential-form row* $\omega : \mathsf{BHist}$ *through the* $\mathsf{DiffForm}^{\uparrow}$ *source, a cochain differential* $d_{\mathrm{dR}} : \mathsf{BHist} \to \mathsf{BHist}$*, and the boundary preimage row of Definition 137.1; the square-zero data are the packet of Definition 137.2. No host manifold carrier, quotient carrier, or external cochain complex carrier is part of the root surface.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamRootCarrier obligation`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorPacket root carrier obligation`

Proof. Read the carrier side of Definition 137.6. Its visible source row is the $\mathsf{DiffForm}^{\uparrow}$ form row, while the cochain side is represented by the displayed BHist differential d_{dR}.

The boundary preimage component is exactly Definition 137.1. The square-zero endpoint data are exactly the packet of Definition 137.2.

Apply Definition 137.3 to identify the packet's second differential row as a boundary row, and apply Definition 137.5 to read the intermediate cochain row as a cocycle. These two readings account for the carried De Rham data without adding any carrier beyond the displayed $\mathsf{DiffForm}^{\uparrow}$ and BHist rows. □

Theorem 137.11 (De Rham root classifier obligation)**.** *The root classifier obligation for* $\mathsf{DeRham}^{\uparrow}$ *is exactly* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$*. If a boundary row is accepted by this classifier and its endpoint is transported by* hsame*, the transported endpoint is again classified by* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ *through the same cochain preimage witness. Thus classifier stability is precisely the endpoint-transport row of Definition 137.4.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundary hsame transport with empty endpoint`

Proof. Unpack Definition 137.1. Classification by $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ is the assertion that the public row has a displayed cochain preimage and compares by hsame with its d_{dR} image.

The preservation clause is Definition 137.4. It keeps the same preimage witness and changes only the visible endpoint along the supplied hsame comparison.

The square-zero packet of Definition 137.2, together with Definition 137.3, supplies the canonical boundary instance consumed by this classifier. The assembly theorem Definition 137.6 records that no second classifier row is exported. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundary packet classifier transport`

Theorem 137.12 (De Rham root ledger exactness)**.** *The public ledger for the* DeRham$^{\uparrow}$ *root surface consists only of the boundary preimage row of Definition 137.1, the square-zero endpoint row of Definition 137.2, the cocycle readback row of Definition 137.5, and the displayed source rows imported from* DiffForm$^{\uparrow}$ *and* Cohomology$^{\uparrow}$*. Its exactness entry is the boundary conclusion of Definition 137.3, transported at endpoints by Definition 137.4.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryGraphLedger endpoint empty from rows`

Proof. List the public rows named by Definition 137.6. They are the DiffForm$^{\uparrow}$ carrier row, the Cohomology$^{\uparrow}$ cochain and cocycle rows, the boundary preimage row, the endpoint-transport row, the square-zero boundary row, and the cocycle readback row.

The exactness component is provided by Definition 137.3: from the displayed double exterior packet it produces the accepted boundary predicate for the second differential row.

The endpoint component is stable by Definition 137.4, and the readback component is exactly Definition 137.5. Since each row is already named in the obligation surface, the ledger has no additional bridge, quotient, or cohomology-isomorphism entry. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket root ledger exactness`

Definition 137.13 (De Rham root consumer readback packet)**.** *The root consumer readback packet for* DeRham$^{\uparrow}$ *is the finite list of rows that a downstream root consumer may inspect before any standard boundary bridge. It consists of the* DiffForm$^{\uparrow}$ *carried-form row, the* Cohomology$^{\uparrow}$ *cochain and cocycle rows, the* Manifold$^{\uparrow}$ *source row only as the domain provenance already visible to* DiffForm$^{\uparrow}$*, the* TensorProduct$^{\uparrow}$ *row only as the algebraic source already visible to* DiffForm$^{\uparrow}$*, the* BHist *cochain endpoints, the* hsame *endpoint transport rows, the* Cont *ledgers for the cochain differential and boundary preimage, and the* Pkg *provenance row tying these entries to one package.*

Lean4 (definition) `BEDC.Derived.DeRhamUp.DeRhamRootConsumerReadbackPacket`

Theorem 137.14 (De Rham root consumer readback stability)**.** *If two root consumer readback packets for* DeRham$^{\uparrow}$ *are related componentwise by* hsame*, then the transported packet has the same accepted root readback surface. The transported surface keeps the same* DiffForm$^{\uparrow}$*,* Cohomology$^{\uparrow}$*,* Manifold$^{\uparrow}$*, and* TensorProduct$^{\uparrow}$ *source rows, the same finite* Cont *ledger shape, and the same* Pkg *provenance, with only the visible* BHist *endpoints replaced by their* hsame *mates.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket endpoint transport`

Proof. Project the packet of Definition 137.13 into source, endpoint, ledger, transport, and provenance rows. The source rows are read through the already displayed DiffForm$^{\uparrow}$ and Cohomology$^{\uparrow}$ entries, while the Manifold$^{\uparrow}$ and TensorProduct$^{\uparrow}$ rows remain provenance of the differential-form source.

Transport the visible BHist endpoints by the supplied hsame comparisons. The boundary classifier stability of Definition 137.4 keeps the same preimage row, and the root ledger exactness of Definition 137.12 keeps the same finite ledger list.

Repack the transported rows into the readback packet. Since no step introduces a quotient cohomology carrier, de Rham isomorphism, or host cochain complex, the transported packet exposes exactly the same root consumer surface. □

Theorem 137.15 (De Rham root unblock threshold surface)**.** *The root carrier obligation, root classifier obligation, root ledger exactness, root consumer readback packet, and root consumer readback stability theorem are exactly the* $\mathsf{DeRham}^{\uparrow}$ *root-unblock surface. A downstream consumer may read only the* $\mathsf{DiffForm}^{\uparrow}$*,* $\mathsf{Cohomology}^{\uparrow}$*,* $\mathsf{Manifold}^{\uparrow}$*,* $\mathsf{TensorProduct}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* Pkg *rows displayed in those blocks.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamRootUnblock threshold surface`
↪ variant `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket root unblock threshold surface`

Proof. Project the root carrier block Definition 137.10. It supplies the carried $\mathsf{DiffForm}^{\uparrow}$ row, the cochain differential, the boundary preimage row, and the square-zero packet.

Project the classifier and ledger blocks Definition 137.11 and Definition 137.12. These blocks account for $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$, endpoint transport by hsame, cocycle readback, and the finite ledger rows.

Finally add the readback packet and its stability theorem. They name the allowed downstream rows and show that their hsame movement is closed within the same finite packet. Therefore the listed blocks exhaust the root-unblock surface and exclude quotient cohomology, de Rham isomorphism, and external cochain-complex data. □

Theorem 137.16 (De Rham boundary public classifier exactness)**.** *The boundary rows of Definition 137.1, the endpoint stability of Definition 137.4, the double-exterior boundary row of Definition 137.3, the cocycle readback of Definition 137.5, and the root ledger exactness of Definition 137.12 assemble the public* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *classifier-exactness surface over* $\mathsf{DiffForm}^{\uparrow}$*,* $\mathsf{Cohomology}^{\uparrow}$*,* BHist*,* hsame*, and the displayed cochain differential* d_{dR}*.*

This public surface exports the carried differential-form row, the boundary classifier $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$*, endpoint stability under* hsame*, cocycle readback, and the finite ledger rows named above. It does not export a de Rham isomorphism, a quotient-cohomology carrier, or any cohomology equality beyond the displayed boundary and cocycle rows.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundary public classifier exactness`

Proof. Project the carrier field from Definition 137.1: the public object is the $\mathsf{DiffForm}^{\uparrow}$ source row together with the BHist cochain differential and its displayed preimage row.

Project the classifier field from Definition 137.11. The classifier is $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$, and Definition 137.4 supplies the stability field by keeping the same cochain preimage while transporting the endpoint by hsame.

Project exactness from Definition 137.3 and project the cohomology-facing readback from Definition 137.5. These two rows give the boundary and cocycle fields without introducing a quotient carrier.

Finally repack the finite list in Definition 137.12 as the public ledger field. Since that ledger names only the displayed $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, BHist, hsame, and cochain-differential rows, the repacked surface contains no de Rham isomorphism row and no quotient-cohomology surface. □

Theorem 137.17 (De Rham bridge input source scope)**.** *The bridge input rows for the* $\mathsf{DeRham}^{\uparrow}$ *public boundary surface are exactly the* $\mathsf{DiffForm}^{\uparrow}$ *carried-form rows, the* $\mathsf{Cohomology}^{\uparrow}$ *cochain differential rows, the* BHist *endpoints, and the displayed square-zero row* $d_{\mathrm{dR}}(d_{\mathrm{dR}}\omega) = 0$ *read*

through Definition 137.2. No host smooth manifold, quotient-cohomology representative, de Rham isomorphism, or external chain-complex carrier is part of this input scope.

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamDoubleExteriorPacket bridge input source scope`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket input source scope`

Proof. Start from the De Rham packet Definition 137.2. It displays the carried $\mathsf{DiffForm}^{\uparrow}$ row, the two cochain graph rows, the intermediate BHist endpoint, and the zero endpoint for the second differential.

Apply Definition 137.3. The theorem turns the packet into the boundary row and records the square-zero endpoint seen by the public surface.

Use Definition 137.4 and Definition 137.5 to keep the visible endpoint and cocycle readback inside the same displayed packet. The root ledger and public classifier exactness theorems, Definition 137.12 and Definition 137.16, then repackage only these input rows, so no outside manifold, quotient, or carrier row is exported. □

Theorem 137.18 (De Rham bridge classifier source scope)**.** *All classifier movement in the* $\mathsf{DeRham}^{\uparrow}$ *public boundary surface is by* hsame *and by the cochain differential stability row of Definition 137.4. The classifier source scope contains no equality of quotient cohomology classes, no chosen representative of a cohomology class, and no analytic comparison beyond the displayed* BHist *endpoint transport.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket bridge classifier source scope`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket bridge classifier source scope`

Proof. Project the classifier from Definition 137.16. Its visible predicate is $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ over the boundary row of Definition 137.1.

The only allowed movement of that predicate is the hsame endpoint transport in Definition 137.4. The preimage cochain is kept fixed, and the transported endpoint stays in the same boundary predicate.

The packet exactness theorem Definition 137.3, the cocycle readback theorem Definition 137.5, and the root ledger exactness theorem Definition 137.12 add no classifier movement beyond that stability row. Thus the classifier source scope is precisely hsame transport plus cochain differential stability. □

Theorem 137.19 (De Rham bridge ledger source scope)**.** *The* $\mathsf{DeRham}^{\uparrow}$ *bridge ledger exports only the boundary preimage, the zero endpoint, the cocycle readback, the finite graph rows, and the package provenance named by the public source packet. It does not export a host cochain complex, a quotient carrier, an isomorphism theorem, or any ledger row not already displayed by the De Rham packet and boundary source surface.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket bridge ledger source scope`

Proof. Read the ledger entries from Definition 137.7. They are the boundary preimage, the double-exterior packet, the cocycle row, and the finite source rows over $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, and BHist.

Apply Definition 137.12. It identifies the exported ledger with exactly the boundary row, zero endpoint, cocycle readback, and displayed source rows.

Finally use Definition 137.16 to move that finite ledger into the public classifier surface. The boundary theorem Definition 137.3, endpoint transport Definition 137.4, and cocycle readback

Definition 137.5 account for every row, so the ledger has no remaining branch for external chain-complex, quotient, or isomorphism data. □

Definition 137.20 (De Rham standard boundary bridge packet)**.** *The De Rham standard boundary bridge packet is the bridge-facing row obtained by packaging the public boundary source packet of Definition 137.7, the public classifier exactness surface of Definition 137.16, and the three bridge source-scope rows Definition 137.17, Definition 137.18, and Definition 137.19.*

Its exported fields are the boundary preimage, the zero endpoint, the cocycle readback, the finite graph rows over $\mathsf{DiffForm}^{\uparrow}$*,* $\mathsf{Cohomology}^{\uparrow}$*, and* BHist*, the public boundary classifier* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$*, and the provenance tying those rows to the De Rham packet. It exports no de Rham isomorphism, quotient carrier, host cochain complex, or external comparison row.*

Lean4 (definition) `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket`

Theorem 137.21 (De Rham standard boundary classifier compatibility)**.** *The standard boundary bridge packet of Definition 137.20 reads the same boundary classifier as the encoded classifier* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ *of Definition 137.1, represented in Lean by* BEDC.Derived.DeRhamUp.DeRhamBoundary*. For every bridge-visible boundary endpoint, classifier acceptance in the bridge packet is equivalent to acceptance by that displayed boundary predicate.*

Proof. Start with the double-exterior packet boundary. By Definition 137.3, the accepted packet produces the zero endpoint comparison, the boundary predicate $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$, and the cocycle row.

Transport the endpoint only through Definition 137.4. This keeps the same cochain preimage and therefore keeps the same boundary classifier rather than introducing a quotient or external cochain-complex equality.

Read back the cocycle by Definition 137.5. The cocycle row is a consequence of the displayed differential and zero endpoint, so it does not change the boundary classifier.

Finally apply Definition 137.16. It repacks the double-exterior boundary, zero-endpoint transport, cocycle readback, and finite ledger rows into the public classifier surface. Since the standard bridge packet is defined from exactly that public surface and the three bridge source-scope theorems, it reads the same $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ classifier. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket classifier compatibility`

Theorem 137.22 (De Rham bridge consumer ledger exhaustion)**.** *Every bridge consumer row of the standard boundary bridge packet of Definition 137.20 is one of the boundary preimage row, the zero endpoint row, the cocycle readback row, the finite graph rows over* $\mathsf{DiffForm}^{\uparrow}$*,* $\mathsf{Cohomology}^{\uparrow}$*, and* BHist*, or the package provenance row linking those fields to the public De Rham boundary source.*

Conversely, those rows repack into the standard boundary bridge packet. No consumer row exports a de Rham isomorphism, quotient carrier, external cochain complex, host manifold comparison, or cohomology representative.

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket consumer ledger exhaustion`

Proof. Project the packet fields from Definition 137.20. Its source component is Definition 137.7, so the available ledger rows are the boundary preimage, double-exterior packet data, cocycle row, finite source rows, and package provenance.

Apply the bridge input and classifier scope theorems. The input scope Definition 137.17 admits only the displayed $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, BHist, and square-zero rows. The classifier scope Definition 137.18 admits only hsame endpoint transport and cochain differential stability.

Apply Definition 137.19 for the final ledger projection. It identifies the bridge ledger with the boundary preimage, zero endpoint, cocycle readback, finite graph rows, and package provenance, with no remaining branch for quotient, isomorphism, or external cochain-complex data.

For the converse direction, repack those projected rows with Definition 137.16. The classifier compatibility theorem above supplies the same boundary predicate, and the three source-scope theorems close the bridge-facing packet. □

Theorem 137.23 (De Rham standard-boundary source exhaustion)**.** *Every standard-boundary bridge source row for the public* $\mathsf{DeRham}^{\uparrow}$ *boundary surface projects to one of the displayed* $\mathsf{DiffForm}^{\uparrow}$ *form rows,* $\mathsf{Cohomology}^{\uparrow}$ *cochain rows,* BHist *endpoint rows, exterior-square-zero rows,* hsame *endpoint-transport rows, or* Pkg *provenance rows of Definition 137.20. Conversely, those rows repack the standard-boundary bridge source surface.*

No quotient cohomology carrier, de Rham isomorphism row, host cochain complex, host manifold comparison, or selected cohomology representative is part of the standard-boundary source.

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket source ledger repack`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryGraphLedger source exhaustion`

Proof. Project the source packet through Definition 137.20. Its visible source is Definition 137.7, so the only available raw rows are the boundary preimage, the double-exterior packet, the cocycle readback, the finite graph rows over $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, and BHist, and the package provenance.

Apply Definition 137.17. It identifies the input side with the displayed carried forms, cochain-differential rows, BHist endpoints, and the square-zero row $d_{\mathrm{dR}}(d_{\mathrm{dR}}\omega) = 0$.

Apply Definition 137.18 and Definition 137.19. The classifier scope admits only hsame endpoint transport and cochain-differential stability, while the ledger scope admits only boundary preimage, zero endpoint, cocycle readback, finite graph rows, and package provenance.

For the converse direction, use Definition 137.16 together with Definition 137.21. The displayed rows reconstruct the same boundary predicate and the same bridge-facing source packet, with no branch for quotient, isomorphism, host-comparison, or representative data. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket source exhaustion`

Theorem 137.24 (De Rham standard-boundary classifier transport)**.** *Classifier transport across the standard-boundary bridge for the public* $\mathsf{DeRham}^{\uparrow}$ *boundary surface uses only* hsame *endpoint transport and cochain-differential stability. In particular, the transported classifier is the same displayed boundary predicate* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ *on the transported endpoint, and the transport does not read a quotient class, a de Rham isomorphism, a host manifold comparison, or a chosen cohomology representative.*

Proof. Start with the classifier identified by Definition 137.21. It is the same predicate $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ as the public boundary classifier of Definition 137.16.

Transport the endpoint by Definition 137.4. That theorem keeps the cochain preimage fixed, moves only the displayed endpoint by hsame, and preserves the cochain-differential row that witnesses the boundary predicate.

Now apply Definition 137.18. It says that all bridge-visible classifier movement is exhausted by precisely that hsame endpoint transport plus cochain-differential stability.

The input and ledger scope theorems, Definition 137.17 and Definition 137.19, add only the finite displayed rows and package provenance. Therefore the classifier transport has no remaining source from which quotient, isomorphism, host-manifold, or representative data could enter. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket classifier transport`

Theorem 137.25 (De Rham standard-boundary consumer readback)**.** *Every downstream consumer of the standard-boundary bridge packet reads only the boundary preimage row, the cocycle row, the finite graph rows over* $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, *and* BHist, *and the package provenance rows displayed by Definition 137.20. No consumer row reads a quotient carrier, a de Rham isomorphism, a host manifold comparison, or a selected cohomology representative.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryGraphLedger consumer readback boundary`

Proof. Project the consumer surface by Definition 137.22. It lists exactly the boundary preimage, zero endpoint, cocycle readback, finite graph rows, and package provenance rows available to a bridge consumer.

Use Definition 137.23 to identify the source side of those consumer rows. The source contributes only the displayed $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, BHist, square-zero, hsame, and Pkg rows.

Use Definition 137.24 for the classifier side. It keeps consumer-visible classifier movement inside hsame endpoint transport and cochain-differential stability.

Finally repack through Definition 137.20. Since both the source and classifier projections have already been exhausted by displayed rows, the consumer readback cannot contain quotient, isomorphism, host-manifold, or representative data. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket consumer readback`
↪ variant `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryGraphLedger append consumer readback`

Theorem 137.26 (De Rham standard-boundary zero cocycle example)**.** *For the zero cochain row carried by the public* $\mathsf{DeRham}^{\uparrow}$ *boundary packet, the standard-boundary bridge exports a zero cocycle consumer row. The row consists of the zero endpoint in* BHist, *the square-zero* $d_{\mathrm{dR}}(d_{\mathrm{dR}}0) = 0$ *witness, the* $\mathsf{Cohomology}^{\uparrow}$ *cocycle readback, and the* Pkg *provenance already displayed by Definition 137.20.*

Proof. Read the zero cochain through Definition 137.25. The consumer surface allows only the boundary preimage, cocycle, finite graph, and provenance rows of the standard-boundary packet.

Apply Definition 137.23. The zero cochain row is one of the displayed $\mathsf{Cohomology}^{\uparrow}$ cochain rows, and the zero endpoint is one of the displayed BHist endpoint rows.

Finally use Definition 137.24. It keeps the boundary classifier inside hsame endpoint transport and cochain-differential stability, so the zero endpoint yields the cocycle row without adding quotient or representative data. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket zero cocycle example`

Theorem 137.27 (De Rham standard-boundary coboundary consumer example)**.** *For any displayed boundary preimage* ω *in the public* $\mathsf{DeRham}^{\uparrow}$ *boundary packet, the standard-boundary bridge exports the coboundary consumer row*

$$\omega \xrightarrow{d_{\mathrm{dR}}} d_{\mathrm{dR}}\omega \xrightarrow{d_{\mathrm{dR}}} 0.$$

The consumer receives the boundary preimage row, the zero endpoint row, the cocycle readback row, and the finite $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, BHist, *and* Pkg *rows of the standard-boundary packet.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket coboundary consumer row`

Proof. Start with the preimage row supplied by Definition 137.23. It is one of the displayed cochain rows in the public boundary source packet, and its endpoint is one of the displayed BHist rows.

Use Definition 137.24 to keep the boundary classifier on the same displayed endpoint after hsame transport. The cochain-differential row therefore remains a boundary row for $d_{\mathrm{dR}}\omega$ with zero endpoint.

Project the exported consumer surface through Definition 137.25. It gives exactly the preimage, zero endpoint, cocycle readback, finite graph, and provenance rows, which are the displayed coboundary consumer row. □

Theorem 137.28 (De Rham standard-boundary finite graph completeness)**.** *Every consumer row of the standard-boundary bridge packet factors through the finite rows already listed by the bridge packet:* $\mathsf{DiffForm}^{\uparrow}$ *form rows,* $\mathsf{Cohomology}^{\uparrow}$ *cochain and cocycle rows,* BHist *endpoint rows,* hsame *endpoint transports, and* Pkg *provenance. Thus the standard-boundary packet is complete for finite graph consumers of the displayed boundary surface.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryGraphLedger finite graph completeness`

Proof. Apply Definition 137.25. It restricts every downstream consumer to the boundary preimage, cocycle, finite graph, and provenance rows of the standard-boundary packet.

Apply Definition 137.23 for the source factorization. The source side is exhausted by the displayed $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, BHist, square-zero, hsame, and Pkg rows.

Finally apply Definition 137.24. The classifier side has no additional branch beyond hsame endpoint transport and cochain-differential stability. Combining the two projections gives finite graph completeness for the bridge packet. □

Theorem 137.29 (De Rham root boundary preimage threshold)**.** *Every accepted standard-boundary source row of the public* $\mathsf{DeRham}^{\uparrow}$ *bridge packet projects to a concrete* BHist *boundary preimage witness for the classifier* $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$*. The witness is the source cochain row named by Definition 137.20; its endpoint is the boundary row of Definition 137.1, and every accepted source is exhausted by the rows listed in Definition 137.23.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket boundary preimage threshold`

Proof. Project the accepted source through Definition 137.20. The bridge packet exposes only the public boundary source packet, the displayed boundary classifier, and the finite source rows over $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, and BHist.

Apply Definition 137.23. It says that an accepted standard-boundary source row is one of the displayed form, cochain, endpoint, square-zero, hsame, or Pkg rows and conversely that these rows repack the source.

Finally read the boundary predicate from Definition 137.1. The cochain row supplies the preimage, the endpoint row supplies the concrete BHist boundary target, and the displayed predicate $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$ records exactly that preimage witness. □

Theorem 137.30 (De Rham root cocycle ledger threshold)**.** *The same standard-boundary source packet exports its intermediate row as a* $\mathsf{Cohomology}^{\uparrow}$ *cocycle row and not as a quotient representative. The exported ledger is the cocycle readback row of Definition 137.5, filtered through the consumer ledger exhaustion theorem Definition 137.22.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket root cocycle ledger threshold`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamRootCocycleLedger threshold`
Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket cocycle ledger threshold`

Proof. Start with the source packet of Definition 137.20. Its cochain component is the row already used by the boundary classifier, so the intermediate $\mathsf{Cohomology}^{\uparrow}$ object is visible before any quotient or representative choice could be introduced.

Apply Definition 137.5. The zero endpoint for $d_{\mathrm{dR}}(d_{\mathrm{dR}}\omega)$ reads back as a cocycle row in $\mathsf{Cohomology}^{\uparrow}$.

Now apply Definition 137.22. The consumer ledger admits boundary preimage, zero endpoint, cocycle readback, finite graph rows, and package provenance only. Since quotient carriers and selected cohomology representatives are excluded there, the intermediate row exported by the packet is the cocycle ledger row itself. □

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamBoundarySourceLedgerPacket cocycle ledger threshold`

Theorem 137.31 (De Rham root standard-bridge consumer threshold)**.** *Downstream standard-bridge consumers of the public* $\mathsf{DeRham}^{\uparrow}$ *boundary packet see exactly the boundary preimage row, the zero endpoint row, the cocycle row, the finite graph rows over* $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, *and* BHist, *and the* Pkg *provenance rows. No consumer row sees a quotient carrier, a de Rham isomorphism, a host cochain complex, a host manifold comparison, or a chosen cohomology representative.*

Lean4 ✓ `BEDC.Derived.DeRhamUp.DeRhamStandardBoundaryBridgePacket consumer threshold`

Proof. First transport the classifier through Definition 137.24. It keeps the consumer-visible classifier inside hsame endpoint transport and cochain-differential stability for $\mathsf{DeRhamBoundary}_{d_{\mathrm{dR}}}$.

Next read the consumer surface by Definition 137.25. The permitted consumer rows are the boundary preimage, cocycle row, finite graph rows over $\mathsf{DiffForm}^{\uparrow}$, $\mathsf{Cohomology}^{\uparrow}$, and BHist, and package provenance.

Finally apply Definition 137.22. It adds the zero endpoint row and proves that the listed rows exhaust the consumer ledger. The excluded quotient, isomorphism, host-comparison, and representative rows therefore have no source branch in the standard boundary bridge packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$**.**

Constructive story: A de Rham boundary is built on top of $\mathsf{DiffForm}^{\uparrow}$ and $\mathsf{Cohomology}^{\uparrow}$ by displaying a cochain differential d_{dR}, a zero endpoint, carried differential-form rows, and the graph comparisons that identify successive exterior outputs with applications of that same differential. The carrier accepts a boundary row only when some cochain preimage a is displayed with $\mathsf{hsame}(b, d_{\mathrm{dR}}(a))$, and the double-exterior packet additionally carries the two form inputs, square-zero row, zero endpoint row, and cohomology cocycle readback; quotient cohomology classes and de Rham isomorphism data are absent. The classifier is the displayed boundary predicate transported by endpoint hsame, keeping the same cochain preimage and the same differential row rather than comparing quotient representatives. The source is the differential-form and cohomology certificate surface with the cochain differential, the pattern is the square-zero boundary and cocycle packet, and the ledger records boundary preimages, zero endpoints, finite graph rows, cocycle readback, and package provenance. The five name-certificate obligations are supplied by accepted boundary packets for inhabitation, by history-equality for reflexive, symmetric, and transitive endpoint movement, and by the zero-endpoint boundary transport theorem for closure of the boundary predicate under classified representatives. A row h lies in the signature gap of a $\mathsf{DeRham}^{\uparrow}$ token p when the source-domain accepts its displayed form, cochain, boundary, and cocycle rows, the signature relation pairs them with an answer boundary packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the same preimage, square-zero endpoint, and cocycle ledger are what p records. The standard boundary bridge reads exactly this predicate and ledger surface and reads it back without exporting a host cochain complex, quotient carrier, selected representative, or de Rham isomorphism; the chapter registers the construction under $\mathsf{DeRham}^{\uparrow}$.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The standard-boundary bridge, mature examples, and root threshold bind DeRhamUp to the displayed DiffFormUp, CohomologyUp, BHist, hsame, and cochain-differential rows by Definition 137.21 and Definition 137.22.

Formal verification: FormalStatus(NameCert$_{\mathsf{DeRham}\uparrow}$, encodedDef)
Lean target: `BEDC.Derived.DeRhamUp.DeRhamBoundary`
Bridge status: paperBridge
Not claimed: No de Rham isomorphism, quotient cohomology construction, or mature package completeness theorem is claimed here.
Upgrade path: The remaining step is Lean-side bridge checking for the existing standard boundary bridge.

Chapter 138

A Concrete Naming Certificate for $\mathsf{Symplectic}^{\uparrow}$

The symplectic-structure interface $\mathsf{Symplectic}^{\uparrow}$ packages a closed nondegenerate 2-form on an even-dimensional manifold carrier. It depends on $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ (chapter 136) and $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96), and is the substrate for Hamiltonian dynamics and Poisson-bracket certificates.

138.1 Carrier definition

Definition 138.1 (SymplecticUp carrier-classifier surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *source* Ω *over* BHist*. A* $\mathsf{Symplectic}^{\uparrow}$ *carrier-classifier surface is the displayed BEDC package*

$$\mathsf{SymplecticCarrierClassifier}_{M,\Omega}(\omega, d\omega).$$

Its traditional target is a closed nondegenerate two-form on an even-dimensional manifold. Its displayed rows are exactly:

1. *the* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source row and the* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *source row over the same* BHist *endpoint;*
2. *the shared manifold endpoint carrier transported from* M *to* Ω*;*
3. *an even-dimensional witness for the shared manifold endpoint;*
4. *a carried degree-two differential-form row* ω *supplied by* Ω*;*
5. *the exterior-derivative input row* $d\omega$ *routed through the* $\mathsf{DiffForm}^{\uparrow}$ *exterior-derivative boundary;*
6. *the closedness row* $d\omega = 0$ *attached only to the displayed degree-two form;*
7. *the nondegeneracy row asserting that* ω *pairs tangent rows on the shared manifold carrier without a hidden kernel;*
8. *the classifier obtained by restricting* hsame *to rows that preserve the shared manifold endpoint, the even-dimensional witness,* ω*,* $d\omega$*, closedness, and nondegeneracy;*
9. *ledger rows for chart projection, degree projection, derivative-input projection, wedge and pairing projection, and hidden source projections back to* M *and* Ω*;*
10. *exactness predicates saying that the surface has coverage for every certified symplectic read, soundness for every listed row, and completeness for every row named above.*

The surface contains no standard bridge row.

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierSurface semantic name certificate`

138.2 The certificate

Definition 138.2 (Symplectic obligation boundary)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{DiffForm}^\uparrow}$ *source* Ω *over* BHist*. The* $\mathsf{Symplectic}^\uparrow$ *obligation boundary is the BEDC package whose source is the paired* $\mathsf{DiffForm}^\uparrow$ *and* $\mathsf{Manifold}^\uparrow$ *certificate boundary, whose carrier is a manifold carrier equipped with a degree-two admissible differential form row* ω*, and whose classifier is the paired manifold classifier together with the* $\mathsf{DiffForm}^\uparrow$ *form classifier restricted to that row.*

The stability rows are carrier transport for the shared manifold carrier, closedness transport for the displayed two-form row, nondegeneracy transport for the same paired manifold/form carrier, and endpoint transport through hsame *and* Cont *wherever the downstream consumer boundary rows expose continuation data. The ledger records exactly the hidden atlas witnesses supplied by* M*, the hidden form witnesses supplied by* Ω*, the degree-two row, the closedness witness for* ω*, the nondegeneracy witness for* ω*, and the coverage, soundness, and completeness rows saying that every certified* $\mathsf{Symplectic}^\uparrow$ *read factors through this boundary.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary dependency nonempty`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary readback rows`

Theorem 138.3 (Symplectic carrier and classifier obligations)**.** *The source displayed in Definition 138.2 supplies the carrier and classifier rows required by* $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$*: the* $\mathsf{Manifold}^\uparrow$ *carrier row, the* $\mathsf{DiffForm}^\uparrow$ *degree-two admissible form row, the paired classifier on manifold and form components, and the carrier-transport row for the paired boundary over* BHist*.*

Proof. Unpack Definition 138.2. The first source component is the $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ boundary and the second is the $\mathsf{NameCert}_{\mathsf{DiffForm}^\uparrow}$ boundary, both read over the same BHist substrate.

The carrier row is the shared manifold endpoint together with the degree-two admissible form row. The classifier is therefore the paired classifier obtained by taking the manifold classifier from M and the form classifier from Ω on the displayed row ω.

Carrier transport is componentwise. The $\mathsf{Manifold}^\uparrow$ certificate transports the manifold carrier, the $\mathsf{DiffForm}^\uparrow$ certificate transports the admissible form row, and the paired boundary repacks these transported rows as the carrier and classifier data required by $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$. □

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierSurface carrier classifier obligations`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierSurface obligations`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary carrier classifier obligations`

Theorem 138.4 (Symplectic closed two-form obligation)**.** *Closedness of the selected two-form* ω *is an explicit* $\mathsf{Symplectic}^\uparrow$ *obligation transported along the* $\mathsf{DiffForm}^\uparrow$ *classifier. The* $\mathsf{DiffForm}^\uparrow$ *source supplies the admissible degree-two form row and the exterior-input boundary needed to state closedness, but it does not make* $d\omega = 0$ *automatic for every downstream consumer read.*

Proof. Begin with the degree-two row ω from Definition 138.2. The $\mathsf{DiffForm}^\uparrow$ boundary supplies the form classifier, exterior-input routing, and downstream consumer boundary rows needed to express the closedness predicate on that row.

Closedness is then recorded as its own ledger row. Transport along the $\mathsf{DiffForm}^{\uparrow}$ classifier moves the admissible form row and the exterior-input boundary to the classified endpoint, so the closedness row remains a $\mathsf{Symplectic}^{\uparrow}$ obligation on the transported form.

The last clause is the consumer-boundary separation. $\mathsf{DiffForm}^{\uparrow}$ exposes the rows needed by $\mathsf{Symplectic}^{\uparrow}$ to ask for $d\omega = 0$, while the truth of that row belongs to the $\mathsf{Symplectic}^{\uparrow}$ certificate boundary itself. □

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary closed two form row`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary closed two form transport`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierSurface closed two form obligation`

Theorem 138.5 (Symplectic nondegeneracy stability obligation)**.** *Nondegeneracy of ω is a separate classifier-stable row over the paired manifold/form carrier of Definition 138.2. It is transported by the paired* $\mathsf{Manifold}^{\uparrow}$ *and* $\mathsf{DiffForm}^{\uparrow}$ *classifiers and is not identified with the admissible-form carrier row or with the closedness row.*

Proof. Use the paired carrier from Definition 138.2. Nondegeneracy is stated only after the manifold carrier and the degree-two form row have both been selected, so it is a row over the paired surface rather than a row of either dependency alone.

Transport is again componentwise. The $\mathsf{Manifold}^{\uparrow}$ classifier transports the carrier on which nondegeneracy is evaluated, the $\mathsf{DiffForm}^{\uparrow}$ classifier transports the form row, and the paired classifier records the transported nondegeneracy witness as a $\mathsf{Symplectic}^{\uparrow}$ ledger row.

This separates the three obligations consumed downstream: admissibility of the two-form, closedness of that two-form, and nondegeneracy on the paired manifold/form carrier. □

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary nondegeneracy endpoint split`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary nondegeneracy row`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary nondegeneracy transport`

Theorem 138.6 (SymplecticUp closed two-form obligation)**.** *For a* $\mathsf{Symplectic}^{\uparrow}$ *carrier-classifier surface of Definition 138.1, the closedness obligation is local to the displayed* $\mathsf{DiffForm}^{\uparrow}$ *degree-two form row ω and its exterior-derivative input row $d\omega$. If two accepted surface reads are related by the restricted classifier of the same definition, then the closedness row $d\omega = 0$ transports with the degree-two form row.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierEndpointSurface closed two form transport`
Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierSurface closed two form transport`

Proof. Unpack Definition 138.1. The closedness row is listed only after the carried degree-two form row ω and the exterior-derivative input row $d\omega$ have been fixed.

Apply the $\mathsf{DiffForm}^{\uparrow}$ exterior-derivative routing named by Definition 136.61. It permits the symplectic consumer to read the source carrier, degree row, and exterior-derivative candidate ledger, while it contributes no closedness predicate of its own.

The classifier clause of the displayed surface is the restriction of hsame to the shared manifold endpoint, ω, $d\omega$, and the closedness row. Transport therefore changes only the accepted surface read, not the local obligation that $d\omega$ is the zero exterior-derivative row. □

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary closed successor not empty`

Theorem 138.7 (SymplecticUp nondegeneracy obligation)**.** *For a* $\mathsf{Symplectic}^{\uparrow}$ *carrier-classifier surface of Definition 138.1, nondegeneracy is a* $\mathsf{Symplectic}^{\uparrow}$*-local predicate on the shared* $\mathsf{Manifold}^{\uparrow}$ *carrier and the displayed degree-two form row* ω*. If the surface classifier transports the shared manifold endpoint and the degree-two form row, then it transports the nondegeneracy row on that same carrier.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierEndpointSurface nondegeneracy transport`

Proof. Begin with the shared manifold endpoint row in Definition 138.1. The $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ source supplies the carrier on which tangent rows and chart projections are read.

The degree-two form row ω is supplied by the $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ source over that same endpoint. Nondegeneracy is therefore stated as a local pairing predicate for ω on the transported manifold carrier, rather than as an independent $\mathsf{DiffForm}^{\uparrow}$ root law.

Finally read the classifier clause. It restricts hsame to preserve the shared endpoint, ω, and the nondegeneracy row, so the nondegeneracy predicate transports exactly with the carrier-classifier surface. □

Theorem 138.8 (SymplecticUp ledger exactness obligation)**.** *The* $\mathsf{Symplectic}^{\uparrow}$ *ledger and exactness obligation consists exactly of the carrier, classifier, closedness, nondegeneracy, stability, ledger, and dependency rows displayed in Definition 138.1. Coverage says every certified symplectic read factors through that surface, soundness says every such read is one of the listed rows, and completeness says every listed row is available to the* $\mathsf{Symplectic}^{\uparrow}$ *carrier-classifier surface.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary ledger exactness obligation`

Proof. Inspect the rows of Definition 138.1. The carrier and dependency cases are the $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ source, the $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ source, the shared endpoint, and the even-dimensional witness.

The law cases are the degree-two form row, the exterior-derivative input row, the closedness row of Definition 138.6, and the nondegeneracy row of Definition 138.7.

The remaining cases are the restricted hsame classifier, the stability carried by that restriction, the chart, degree, derivative-input, wedge and pairing ledger rows, and the hidden source projections. These cases are exactly the coverage, soundness, and completeness clauses stated in the theorem. □

Theorem 138.9 (SymplecticUp public NameCert export)**.** *The carrier-classifier surface of Definition 138.1, the obligation boundary of Definition 138.2, the carrier and classifier obligations of Definition 138.3, the closed two-form obligation of Definition 138.6, the nondegeneracy obligation of Definition 138.7, and the ledger exactness obligation of Definition 138.8 assemble the public* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *surface over* BHist*. The exported surface contains the shared* $\mathsf{Manifold}^{\uparrow} + \mathsf{DiffForm}^{\uparrow}$ *carrier, the restricted* hsame *classifier, closedness, nondegeneracy, and exact ledger rows, and it contains no* $\mathsf{StandardBridge}$ *row.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary semantic name certificate`
↪ variant `BEDC.Derived.SymplecticUp.SymplecticCarrierClassifierEndpointSurface semantic name certificate`

Proof. Unpack Definition 138.1. Its rows name the two dependency certificates over BHist, the shared manifold endpoint, the degree-two form row, the exterior-derivative input row, closedness, nondegeneracy, the restricted classifier, and the ledger projections.

The boundary in Definition 138.2 supplies the same data as a BEDC obligation package. Apply Definition 138.3 to read the carrier and classifier fields, then apply Definition 138.6 and Definition 138.7 to attach the two public form laws on the paired carrier.

Finally apply Definition 138.8. Coverage, soundness, and completeness repack all listed rows as the public $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$ surface, while the defining surface explicitly excludes any $\mathsf{StandardBridge}$ row. □

Theorem 138.10 (SymplecticUp closed nondegenerate public stability)**.** *For the public* $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$ *surface of Definition 138.9, the restricted* hsame *classifier transports closedness and nondegeneracy together on the same paired* $\mathsf{Manifold}^\uparrow + \mathsf{DiffForm}^\uparrow$ *carrier. Thus an accepted surface read cannot transport* $d\omega = 0$ *without transporting the manifold endpoint, the degree-two form row* ω*, and the nondegeneracy row for that same pair.*

Proof. Start from the classifier clause in Definition 138.1. It is not the ambient classifier on arbitrary rows; it is hsame restricted to preservation of the shared endpoint, the even-dimensional witness, ω, $d\omega$, closedness, and nondegeneracy.

Apply Definition 138.6. Closedness transports only with the displayed degree-two form row and its exterior-derivative input.

Apply Definition 138.7. Nondegeneracy transports only on the same shared manifold carrier and displayed form row. The public export theorem then repacks these two transported laws into one $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$ surface, so no accepted read separates closedness from nondegeneracy or from the carrier on which both are stated. □

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary closed nondegenerate public stability`

Theorem 138.11 (SymplecticUp Hamiltonian and Poisson consumer frontier)**.** *Downstream Hamiltonian dynamics and Poisson-bracket certificates may read from* $\mathsf{Symplectic}^\uparrow$ *only the shared manifold carrier, the degree-two form row, exterior-derivative routing, closedness, nondegeneracy, the pairing ledger, and classifier transport supplied by Definition 138.9. From* $\mathsf{Symplectic}^\uparrow$ *alone they may not infer a Poisson bracket, a Hamiltonian flow, a Jacobi identity, or a standard model.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary hamiltonian poisson consumer frontier`

Proof. Inspect the exactness rows of Definition 138.1. The permitted consumer reads are precisely the rows named in the theorem: carrier, degree-two form, derivative input, closedness, nondegeneracy, pairing ledger, and classifier transport.

Use Definition 138.8 to convert that list into a coverage, soundness, and completeness boundary. Soundness rules out any additional consumer row not displayed by the surface.

The excluded objects require structure not present in the displayed rows. A Poisson bracket needs its own bracket operation and Jacobi witness, a Hamiltonian flow needs a flow construction, and a standard model needs a $\mathsf{StandardBridge}$ row. Since the public export in Definition 138.9 carries none of those rows, the consumer frontier is exactly the stated boundary. □

Theorem 138.12 (SymplecticUp mature consumer completeness boundary)**.** *Every Hamiltonian, Poisson, or standard-model consumer row admitted by this chapter either factors through the public* $\mathsf{NameCert}_{\mathsf{Symplectic}^\uparrow}$ *export, the closed/nondegenerate public stability row, and the Hamiltonian/Poisson consumer frontier, or is explicitly outside the* $\mathsf{Symplectic}^\uparrow$ *boundary. In particular, the chapter supplies the shared manifold carrier, degree-two form, exterior-derivative routing,*

closedness, nondegeneracy, pairing ledger, and classifier transport rows; it does not supply a Poisson bracket, Hamiltonian flow, Jacobi witness, concrete carrier implementation, or StandardBridge *row.*

Lean4 ✓ `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary mature consumer completeness`

Proof. First apply Definition 138.9. It supplies the public carrier-classifier surface over BHist with the shared manifold and degree-two form rows, the restricted hsame classifier, closedness, nondegeneracy, and exact ledger rows.

Next apply Definition 138.10. This ensures that any admitted consumer of closedness or nondegeneracy consumes those rows on the same paired $\mathsf{Manifold}^{\uparrow} + \mathsf{DiffForm}^{\uparrow}$ carrier and cannot separate the law row from the endpoint to which it belongs.

Finally apply Definition 138.11. Its soundness clause lists the permitted Hamiltonian and Poisson-facing reads and excludes the Poisson bracket, Hamiltonian flow, Jacobi witness, and standard bridge. Thus every admitted consumer row factors through the displayed public export and stability rows, while every other row is outside the boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$.

Constructive story: A symplectic surface is generated by sharing a $\mathsf{Manifold}^{\uparrow}$ carrier with a $\mathsf{DiffForm}^{\uparrow}$ degree-two form row, then recording the exterior-derivative input, the closedness row, an even-dimensional witness, and the nondegeneracy row on that same carrier. A history is accepted only through this joint manifold/form surface, and two accepted reads classify together when hsame preserves the shared endpoint, the degree-two form, the derivative input, closedness, and nondegeneracy. The source covers exactly the displayed $\mathsf{Manifold}^{\uparrow} + \mathsf{DiffForm}^{\uparrow}$ rows, the pattern records that the two-form is closed and nondegenerate on the transported carrier, and the ledger keeps chart, degree, derivative-input, wedge, pairing, and hidden source projections aligned. The five naming-certificate obligations are supplied by the exported public surface: the carrier row gives an inhabitant, the restricted classifier is reflexive, symmetric, and transitive because each component is transported by hsame, and carrier closure holds only while closedness and nondegeneracy remain attached to the same displayed surface. A history h lies in the signature gap of a $\mathsf{Symplectic}^{\uparrow}$ token p when the source accepts the shared carrier and two-form rows for h, the signature relation pairs them with an answer surface and evidence ledger, and token introduction names that answer as p; unfolded, h carries the same even-dimensional manifold endpoint, closed degree-two form, and nondegenerate pairing rows encoded by p. Downstream Hamiltonian and Poisson consumers may read the shared carrier, form, derivative routing, pairing ledger, and classifier transport, but no bracket, flow, concrete closedness proof, or standard model is exported. The chapter registers this closed nondegenerate two-form construction under the name $\mathsf{Symplectic}^{\uparrow}$; no standalone Poisson structure, Hamiltonian dynamics, or host symplectic manifold object is introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature scope is the displayed $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ carrier-classifier surface, the hsame-restricted classifier, exterior-derivative routing, ledger rows, public $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ export, closed/nondegenerate stability, and Hamiltonian/Poisson consumer completeness boundary cited in Definition 138.1, Definition 138.2, Definition 138.3, Definition 138.9, Definition 138.10, Definition 138.11, and Definition 138.12.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SymplecticUp.SymplecticObligationBoundary\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not claim a concrete $\mathsf{Symplectic}^{\uparrow}$ carrier implementation, a closedness proof, a nondegeneracy proof, a Hamiltonian or Poisson structure, or a standard bridge.

Upgrade path: Only formal bridge checking is separate; the theory axis is already at maturePackageClosed.

Chapter 139

A Concrete Naming Certificate for $\mathsf{Contact}^{\uparrow}$

The contact-structure interface $\mathsf{Contact}^{\uparrow}$ packages a maximally nonintegrable hyperplane field on an odd-dimensional manifold carrier, recorded as a 1-form whose top-degree wedge is nondegenerate. It depends on $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ (chapter 136) and $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96).

139.1 Carrier definition

Definition 139.1 (ContactUp carrier-classifier surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source* M *and a* $\mathsf{NameCert}_{\mathsf{DiffForm}^{\uparrow}}$ *source* Ω*. A* $\mathsf{Contact}^{\uparrow}$ *carrier-classifier surface over* $BHist$ *is the displayed BEDC package*

$$\mathsf{ContactCarrierClassifier}_{M,\Omega}.$$

Its source rows are the $BHist$ *carrier rows inherited from* M *and* Ω*, the odd-dimensional manifold witness on the shared manifold endpoint, a carried* $\mathsf{DiffForm}^{\uparrow}$ *degree-one form row* α*, a contact hyperplane row* $\ker(\alpha)$ *on the same manifold carrier, an exterior-derivative input row* $d\alpha$*, the wedge ladder rows for* $\alpha \wedge (d\alpha)^k$*, and the top wedge row* $\alpha \wedge (d\alpha)^n$ *when the displayed dimension row is* $2n + 1$*.*

Its classifier is the restriction of hsame *to rows that preserve the shared* $\mathsf{Manifold}^{\uparrow}$ *carrier, the* $\mathsf{DiffForm}^{\uparrow}$ *one-form row, the hyperplane row, the exterior-derivative input row, and every displayed wedge-ladder row. The surface contains no nonintegrability primitive and no standard bridge row.*

Lean4 (definition) `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface`
Lean4 ✓ `BEDC.Derived.ContactUp.ContactTasteGate single carrier alignment`

Theorem 139.2 (ContactUp form-row obligation surface)**.** *Every* $\mathsf{Contact}^{\uparrow}$ *carrier-classifier surface of Definition 139.1 exposes exactly the* $\mathsf{Manifold}^{\uparrow}$ *source, the* $\mathsf{DiffForm}^{\uparrow}$ *contact consumer face, the degree-one form row* α*, the exterior-derivative input row* $d\alpha$*, and the wedge ladder rows* $\alpha \wedge (d\alpha)^k$ *routed by the* $\mathsf{DiffForm}^{\uparrow}$ *root threshold. It exposes no nilpotence row, no symplectic closedness row, no contact nonintegrability witness, and no standard bridge as part of the* $\mathsf{DiffForm}^{\uparrow}$ *root face.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface form row obligation`

Proof. Unpack Definition 139.1. The source fields are the shared $\mathsf{Manifold}^{\uparrow}$ carrier and the $\mathsf{DiffForm}^{\uparrow}$ carried rows for the one-form, exterior-input, and wedge ladder.

Apply Definition 136.117 and Definition 136.118. They place the contact reads in the $\mathsf{Contact}^{\uparrow}$ consumer face and separate them from the de Rham, symplectic, and shared root laws.

Finally apply Definition 136.101. The threshold exports carried forms, classifier data, wedge ledgers, and exterior-input routing, so the $\mathsf{Contact}^{\uparrow}$ surface receives exactly the form row, derivative input row, and wedge ladder rows stated above. □

139.2 The certificate

Theorem 139.3 (ContactUp nondegeneracy obligation)**.** *For a* $\mathsf{Contact}^{\uparrow}$ *carrier-classifier surface over a displayed dimension row* $2n+1$*, top-degree wedge nondegeneracy is a* $\mathsf{Contact}^{\uparrow}$*-local obligation transported by the* $\mathsf{Contact}^{\uparrow}$ *classifier:*

$$\mathsf{Nondegenerate}_M(\alpha \wedge (d\alpha)^n).$$

The $\mathsf{DiffForm}^{\uparrow}$ *root supplies the carried form row, exterior-derivative input row, and wedge routing needed to form the top row, but it does not supply this nondegeneracy predicate as a primitive.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface top wedge transport`
Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface nondegeneracy obligation`

Proof. Begin with the top wedge row named in Definition 139.1. It is assembled from the degree-one row, the exterior-derivative input row, and the wedge ladder exported by Definition 136.101.

Now use the classifier clause of the same definition. It transports the shared manifold carrier, the one-form row, the derivative input row, and the wedge ladder rows, so the nondegeneracy predicate is stated on the transported $\mathsf{Contact}^{\uparrow}$ surface.

The exclusion clause follows from Definition 136.118: $\mathsf{DiffForm}^{\uparrow}$ exports routing rows to the contact consumer face, while contact nonintegrability remains outside the shared root primitive surface. □

↪ variant `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface nondegeneracy obligation`

Theorem 139.4 (ContactUp ledger exactness obligation)**.** *The* $\mathsf{Contact}^{\uparrow}$ *ledger and exactness obligation records exactly the hidden manifold chart rows supplied by the* $\mathsf{Manifold}^{\uparrow}$ *source, the one-form source row* α*, the exterior-derivative input row* $d\alpha$*, the wedge ladder rows* $\alpha \wedge (d\alpha)^k$*, the top wedge row* $\alpha \wedge (d\alpha)^n$*, the nonintegrability witness of Definition 139.3, and a coverage, soundness, and completeness predicate for the carrier-classifier surface of Definition 139.1.*

The obligation is exact only when every certified contact read factors through that carrier-classifier surface and every listed ledger row is classified by the restricted hsame *transport named there.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactUpLedgerExactness obligation`

Proof. Unpack Definition 139.1. Its source and classifier clauses list the $\mathsf{Manifold}^{\uparrow}$ chart carrier, the $\mathsf{DiffForm}^{\uparrow}$ one-form row, the exterior-input row, the wedge ladder, the top wedge row, and the hyperplane row.

Apply Definition 139.2 to identify the contact consumer face and the routed form rows, then apply Definition 139.3 for the local nonintegrability witness.

The coverage predicate says every certified contact read lands in this displayed package. Soundness says each such read is one of the listed rows. Completeness says each listed row is available to the carrier-classifier. These three clauses are precisely the ledger exactness obligation. □

Theorem 139.5 (ContactUp public NameCert export)**.** *The carrier-classifier surface of Definition 139.1, the form-row obligation of Definition 139.2, the nondegeneracy obligation of Definition 139.3, and the ledger exactness obligation of Definition 139.4 assemble the public* $\mathsf{NameCert}_{\mathsf{Contact}^\uparrow}$ *surface over* BHist*, the* $\mathsf{Manifold}^\uparrow$ *carrier, the* $\mathsf{DiffForm}^\uparrow$ *one-form row, the exterior-input row, the wedge ladder, the top wedge, the restricted* hsame *classifier, and the exact ledger.*

This public surface exports the carried contact rows and their exact ledger. It does not export a separate nonintegrability primitive and does not include a standard bridge.

Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface public namecert export`

Proof. Project the carrier field from Definition 139.1. The carrier consists of the shared $\mathsf{Manifold}^\uparrow$ endpoint, the $\mathsf{DiffForm}^\uparrow$ degree-one form row, the exterior-input row, the wedge ladder, and the top wedge row over BHist.

Project the classifier field from the same definition. It is the restriction of hsame to transports preserving the manifold carrier, one-form row, hyperplane row, exterior-input row, and wedge-ladder rows.

Project the routed form face from Definition 139.2 and the local top-wedge condition from Definition 139.3. These two rows provide the form and nondegeneracy fields without adding a nonintegrability primitive.

Finally repack the coverage, soundness, completeness, and row list of Definition 139.4 as the exact ledger field. Because every projected row is already part of the displayed carrier-classifier surface, the public certificate contains no standard bridge row. □

Definition 139.6 (ContactUp standard bridge surface)**.** *The* $\mathsf{Contact}^\uparrow$ *standard bridge surface is the public* $\mathsf{Contact}^\uparrow$ *carrier-classifier rows, the form-row obligation, the nondegeneracy row, the ledger exactness row, and the public* NameCert *export, read as the source side of the standard contact-structure interpretation. Its source side is exactly the surface displayed by Definition 139.5.*

Lean4 (definition) `BEDC.Derived.ContactUp.ContactStandardBridgeSurface`

Theorem 139.7 (ContactUp public bridge compatibility)**.** *Every row interpreted by the bridge surface of Definition 139.6 is already one of the public* $\mathsf{Contact}^\uparrow$ *rows, and every public* $\mathsf{Contact}^\uparrow$ *row has a corresponding bridge-side row. The bridge adds no host manifold, no open-cover compactness condition, and no external equality beyond the public carrier, classifier, obligation, ledger, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactStandardBridgeSurface public bridge compatibility`
Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface public bridge compatibility`

Proof. Use Definition 139.2 for the routed one-form, exterior-input, and wedge-ladder rows, then Definition 139.3 for the contact-local top-wedge row.

Apply Definition 139.4. Its coverage, soundness, and completeness clauses say that the listed bridge reads are exactly the certified public contact reads.

Finally use Definition 139.5. It repacks those rows as the public $\mathsf{NameCert}_{\mathsf{Contact}^\uparrow}$ surface, so the correspondence is row-for-row and introduces no host manifold, compactness, or external equality datum. □

Theorem 139.8 (ContactUp mature consumer completeness)**.** *Every* $\mathsf{Contact}^\uparrow$ *consumer of the public bridge reads exactly the* $\mathsf{Manifold}^\uparrow$ *carrier, the* $\mathsf{DiffForm}^\uparrow$ *one-form row, the exterior-input row, the wedge ladder rows, the top-wedge nondegeneracy row, the exact ledger, and the public*

bridge compatibility rows already named by Definition 139.5 and Definition 139.7. No extra host manifold, compactness condition, or equality source is exported.

Lean4 ✓ `BEDC.Derived.ContactUp.ContactStandardBridgeSurface mature consumer completeness`
Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface mature consumer completeness`

Proof. First apply Definition 139.2. It identifies the contact consumer face with the routed $\mathsf{DiffForm}^{\uparrow}$ one-form, exterior-input, and wedge rows over the shared $\mathsf{Manifold}^{\uparrow}$ carrier.

Next apply Definition 139.3 and Definition 139.4. These supply the local top-wedge nondegeneracy row and the exact coverage, soundness, and completeness ledger for the displayed carrier-classifier surface.

Finally use Definition 139.5 to repack those rows as the public $\mathsf{NameCert}_{\mathsf{Contact}^{\uparrow}}$ surface, and use Definition 139.7 to compare the public surface with the bridge surface. The compatibility theorem states that the bridge adds no host manifold, compactness, or external equality datum, so the listed rows are the complete consumer boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{Contact}^{\uparrow}}$.

Constructive story: A contact surface is built over a shared $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{DiffForm}^{\uparrow}$ source by displaying an odd-dimensional manifold row, a carried degree-one form α, its hyperplane row, an exterior-derivative input $d\alpha$, the wedge ladder $\alpha \wedge (d\alpha)^k$, and the top-degree wedge row. A history enters the carrier only through those routed form rows, and two accepted surfaces classify together when hsame preserves the shared manifold endpoint, the one-form, the hyperplane row, the exterior-input row, and every wedge-ladder row. The source covers exactly the manifold plus routed one-form data, the pattern records the top wedge nondegeneracy condition on dimension $2n+1$, and the ledger keeps chart rows, the one-form source, derivative input, wedge ladder, top wedge, and local nonintegrability witness aligned. The public certificate obligations are therefore the displayed carrier row, restricted classifier reflexivity, symmetry, transitivity, and closure of all listed form rows under that classifier, with coverage, soundness, and completeness supplied by the exact ledger. A history h lies in the signature gap of a $\mathsf{Contact}^{\uparrow}$ token p when the source accepts such a form surface for h, the signature relation pairs it with an answer surface and evidence ledger, and token introduction identifies that answer as p; unfolded, h carries the same odd-dimensional endpoint, one-form, derivative input, wedge ladder, and nondegenerate top wedge encoded by p. The surface deliberately reads the nonintegrability condition as this top-wedge row rather than as a separate primitive, and it exports no standard bridge. The chapter registers this routed one-form construction under the name $\mathsf{Contact}^{\uparrow}$; no closed carrier implementation, host contact manifold, or independent nonintegrability theorem is assumed.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Contact}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public boundary is exactly the carrier-classifier surface, form-row obligation, nondegeneracy obligation, and exact ledger assembled in Definition 139.5.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Contact}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: This chapter does not claim a closed ContactUp carrier implementation, a proved nonintegrability theorem, Lean bridge verification, or mature examples.

Upgrade path: The paper-side theory axis is complete; Lean bridge verification remains a separate verification-axis obligation.

Definition 139.9 (ContactUp coannihilating integrability row)**.** *Let C be a $\mathsf{Contact}^{\uparrow}$ carrier-classifier surface of Definition 139.1 over a displayed dimension row $2n+1$ with $n \geq 1$. Write its shared manifold carrier as M, its carried one-form row as α, its hyperplane row as $\ker(\alpha)$, its exterior-input row as $d\alpha$, and its wedge ladder as $\alpha \wedge (d\alpha)^k$.*

A displayed row $I_{\mathcal{D}}$ is a $\mathsf{Contact}^{\uparrow}$ coannihilating integrability row on C when its contact-relevant fields are all on the same $\mathsf{Manifold}^{\uparrow}$ carrier M and consist of the following data:

- *a hyperplane-distribution row $\mathcal{D}$ classified with the displayed contact hyperplane row $\ker(\alpha)$;*
- *an annihilator-identification row $\mathsf{Ann}(\mathcal{D}) \sim \alpha$;*
- *a codimension-one Frobenius row for that annihilator, transported along $\mathsf{Ann}(\mathcal{D}) \sim \alpha$;*

- *the resulting Frobenius wedge-collapse ledger along the displayed* $\mathsf{Contact}^{\uparrow}$ *wedge ladder:*

$$\forall k\ (1 \le k \le n \Rightarrow \alpha \wedge (d\alpha)^k \sim 0).$$

The row is admitted only when these fields are transported by the restricted $\mathsf{Contact}^{\uparrow}$ *classifier, so the manifold carrier, one-form row, hyperplane row, exterior-input row, and wedge-ladder rows are the same rows read by* C*.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactCoannihilatingIntegrabilityRow transport with empty`

Theorem 139.10 (Contact top wedge excludes coannihilating integrability)**.** *Let* C *be a* $\mathsf{Contact}^{\uparrow}$ *carrier-classifier surface of Definition 139.1 over a displayed dimension row* $2n+1$ *with* $n \ge 1$*. Suppose* C *carries the top-wedge nondegeneracy row*

$$\alpha \wedge (d\alpha)^n \not\sim 0.$$

Then no $\mathsf{Contact}^{\uparrow}$ *coannihilating integrability row* $I_{\mathcal{D}}$ *of Definition 139.9 is admitted on the same carrier. Equivalently, no displayed integrable-distribution row* $\mathcal{D}$ *on the same* $\mathsf{Manifold}^{\uparrow}$ *carrier whose annihilator is classified with* α *can coexist with the displayed* $\mathsf{Contact}^{\uparrow}$ *top-wedge row.*

Lean4 ✓ `BEDC.Derived.ContactUp.ContactCarrierClassifierSurface top wedge excludes coannihilating integrability`

Proof. Assume that such a row $I_{\mathcal{D}}$ is admitted. By Definition 139.9, the distribution row lies on the same $\mathsf{Manifold}^{\uparrow}$ carrier as C, its hyperplane row is classified with $\ker(\alpha)$, and its annihilator row is classified with α.

The Frobenius part of the admitted row is therefore read on the same carried one-form row and the same exterior-input row $d\alpha$. Since $n \ge 1$, the Frobenius wedge-collapse ledger in Definition 139.9 applies to the displayed ladder index $k = n$ and gives

$$\alpha \wedge (d\alpha)^n \sim 0.$$

It remains to check that this is the same top-wedge endpoint as the contact nondegeneracy row. The carrier definition Definition 139.1 includes the one-form row, hyperplane row, exterior-input row, every wedge-ladder row, and the top wedge row on one shared manifold endpoint. The form-row obligation Definition 139.2 routes these rows through the $\mathsf{Contact}^{\uparrow}$ consumer face, and Definition 139.3 places the nondegeneracy predicate on that transported top wedge. Thus the zero endpoint obtained from $I_{\mathcal{D}}$ and the nondegenerate endpoint carried by C address the same row $\alpha \wedge (d\alpha)^n$.

The displayed nondegeneracy hypothesis says that this row is not classified with zero, while the Frobenius wedge-collapse ledger says that it is classified with zero. An admitted row cannot satisfy both predicates on the same classified endpoint. Hence the assumed $I_{\mathcal{D}}$ is not admitted. □

The $\mathsf{LieGroup}^{\uparrow}$ packet consumes the algebraic source of chapter 41 and the chart source of chapter 96; the child routes below expose how those dependencies enter the certificate.

Chapter 140

A Concrete Naming Certificate for $\mathsf{LieGroup}^{\uparrow}$

The Lie-group interface $\mathsf{LieGroup}^{\uparrow}$ packages a group carrier whose underlying set is a manifold and whose multiplication and inverse are constructively smooth. It depends on $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96), and is the substrate for representation, exponential, and root-system certificates.

140.1 Carrier definition

Definition 140.1 (Singleton smooth group carrier)**.** *The concrete* $\mathsf{LieGroup}^{\uparrow}$ *carrier is the shared singleton history carrier*

$$L_{\mathsf{e}}(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e})$$

on BHist*. Its group rows are the singleton* $\mathsf{Group}^{\uparrow}$ *rows*

$$\mathsf{mul}(h, k) := \mathsf{append}(h, k), \qquad \mathsf{inv}(h) := \mathsf{e}, \qquad e := \mathsf{e},$$

with classifier

$$R_{\mathsf{e}}(h, k) :\Longleftrightarrow L_{\mathsf{e}}(h) \wedge L_{\mathsf{e}}(k) \wedge \mathsf{hsame}(h, k).$$

Its smooth-manifold rows are the singleton $\mathsf{Manifold}^{\uparrow}$ *chart rows with the one chart* χ_{e}*, top domain* L_{e}*, constant value* $0_{\mathsf{Real}^{\uparrow}}$*, and the self-overlap constant transition. Thus the algebraic carrier and the manifold carrier are the same predicate on histories, not two transported copies.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupTasteGate single carrier alignment`

140.2 The certificate

Theorem 140.2 (LieGroup singleton carrier obligation)**.** *The carrier* L_{e} *of Definition 140.30 simultaneously supplies the* $\mathsf{Group}^{\uparrow}$ *singleton carrier and classifier rows and the* $\mathsf{Manifold}^{\uparrow}$ *singleton chart rows. Concretely, every accepted history is classified with* e *by* R_{e}*, multiplication and inverse stay inside* L_{e}*, and the sole chart domain is exactly the same carried predicate* L_{e}*.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton carrier obligation`

Proof. For the algebraic side, unfold Definition 140.30. The carrier, classifier, multiplication, unit, and inverse rows are exactly the rows used by Definition 41.4; the checked Lean row is BEDC.Derived.GroupUp.GroupSingletonHistory_laws.

For the manifold side, the chart-domain row is the singleton empty-chart row of Definition 96.32. Its carried predicate is $\mathsf{hsame}(h, \mathsf{e})$, which is definitionally the same predicate as L_{e}.

The two sides therefore share the same history carrier and the same restricted hsame classifier. Projection from the group row gives the algebraic carrier and classifier fields, while projection from the manifold row gives the chart domain, chart value, and singleton atlas fields. □

Theorem 140.3 (LieGroup singleton operation smoothness obligation)**.** *For histories carried by L_{e}, both* mul *and* inv *of Definition 140.30 are smooth operations in the singleton atlas. Every accepted multiplication result and every accepted inverse result is classifier-equal to* e*, so each operation is read by the sole chart as a constant transition on the singleton overlap.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton operation smoothness`

Proof. Start with multiplication. If $L_{\mathsf{e}}(h)$ and $L_{\mathsf{e}}(k)$ hold, the group singleton laws identify $\mathsf{append}(h, k)$ with e and keep the result inside the singleton carrier. This is the multiplication-closure row of BEDC.Derived.GroupUp.GroupSingletonHistory_laws.

For inverse, $\mathsf{inv}(h)$ is definitionally e. The inverse-closure row of the same group theorem gives the carrier witness, and the classifier row identifies the result with the unit endpoint.

Now read both operations through the manifold atlas. By Definition 96.32, every carried input and every accepted output lies in the only chart domain and has the constant chart value $0_{\mathsf{Real}^{\uparrow}}$. The overlap transition is therefore the singleton constant transition of Definition 96.33, whose checked Lean row is BEDC.Derived.ManifoldUp.ManifoldSingleton_transition_smoothness. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton operation smoothness obligation`
Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingletonOperation smoothness`

Definition 140.4 (LieGroup singleton public smooth group package)**.** *The public smooth group package underlying the singleton* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *has BEDC source* BHist*, carrier L_{e}, classifier R_{e}, multiplication graph*

$$\mathsf{mul}(h, k) = \mathsf{append}(h, k),$$

inverse

$$\mathsf{inv}(h) = \mathsf{e},$$

and unit e*. The smooth rows use the singleton chart χ_{e} on the same carrier predicate, with constant chart value $0_{\mathsf{Real}^{\uparrow}}$ and self-overlap transition certified by* Cont*. Thus every public algebraic operation is read through the displayed BEDC operation rows rather than through an external standard-space representative.*

Theorem 140.5 (LieGroup singleton classifier transport)**.** *For the package of Definition 140.33, classifier equivalence is congruent for multiplication and inverse. If $R_{\mathsf{e}}(h, h')$ and $R_{\mathsf{e}}(k, k')$, then*

$$R_{\mathsf{e}}(\mathsf{mul}(h, k), \mathsf{mul}(h', k')).$$

If $R_{\mathsf{e}}(h, h')$, then

$$R_{\mathsf{e}}(\mathsf{inv}(h), \mathsf{inv}(h')).$$

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton classifier transport`

Proof. Project the endpoint carrier witnesses from $R_{\mathsf{e}}(h, h')$ and $R_{\mathsf{e}}(k, k')$. Each projection gives membership in L_{e} together with an hsame path to the empty endpoint.

For multiplication, the singleton group laws identify both $\mathsf{append}(h, k)$ and $\mathsf{append}(h', k')$ with e while keeping both results in L_{e}. The classifier row is then the pair of carrier witnesses plus the hsame comparison obtained by transitivity through e.

For inverse, both operation outputs are definitionally e. Reflexivity gives the carrier witnesses and the endpoint comparison, so the restricted classifier R_{e} holds for the two inverse outputs. □

Theorem 140.6 (LieGroup singleton chart operation readback)**.** *The multiplication and inverse outputs covered by Definition 140.34 are read by the singleton chart as the constant endpoint* $0_{\mathsf{Real}^{\uparrow}}$*. Consequently their chart self-overlap row is the same singleton transition row certified for* $\mathsf{Manifold}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton chart operation readback`

Proof. Apply Definition 140.34 to obtain the classifier witnesses for the operation outputs. In each case the classifier contains the carrier predicate L_{e} for the output history.

Apply Definition 96.32 to those carrier witnesses. The unique chart χ_{e} reads every carried endpoint as the constant value $0_{\mathsf{Real}^{\uparrow}}$, so multiplication and inverse have the same chart readback.

Finally apply Definition 96.33. Since the only overlap is the singleton self-overlap and both chart values are constant, the operation readback has exactly the displayed transition row. □

Theorem 140.7 (LieGroup singleton public NameCert export)**.** *The public* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *surface for the singleton smooth group exports the following ten fields.*

Traditional target. *The one-point Lie group.*

BEDC source. BHist *with distinguished empty history* e*.*

Carrier. *The predicate* $L_{\mathsf{e}}(h)$*.*

Classifier. *The restricted classifier* $R_{\mathsf{e}}(h, k)$*.*

Algebraic rows. *Multiplication* append*, inverse* e*, unit* e*, and the singleton* $\mathsf{Group}^{\uparrow}$ *laws.*

Smooth rows. *The singleton* $\mathsf{Manifold}^{\uparrow}$ *chart* χ_{e}*, constant value* $0_{\mathsf{Real}^{\uparrow}}$*, and the singleton transition row.*

Classifier transport. *Multiplication and inverse preserve* R_{e} *as in Definition 140.34.*

Smooth operation congruence. *Operation outputs related by the classifier have the same chart readback and transition row as in Definition 140.35.*

Exactness. *Every accepted public row reduces to* BHist, hsame, Cont, append, e*, the displayed singleton* $\mathsf{Group}^{\uparrow}$ *laws, and the displayed singleton* $\mathsf{Manifold}^{\uparrow}$ *chart and transition.*

Bridge and status. *No* $\mathsf{StandardBridge}$ *row is claimed; the paper-side target is under* $\mathsf{BEDC.Derived.LieGroupUp}$*.*

Proof. The carrier and classifier fields are supplied by Definition 140.30, and the public operation symbols are fixed in Definition 140.33.

The algebraic rows are the singleton $\mathsf{Group}^{\uparrow}$ laws. They give the endpoint carrier facts and identify multiplication and inverse outputs with e.

The smooth rows are the singleton $\mathsf{Manifold}^{\uparrow}$ rows. Chart coverage reads every accepted endpoint as $0_{\mathsf{Real}^{\uparrow}}$, and transition smoothness gives the constant self-overlap row.

The transport and smooth-operation congruence rows are exactly Definition 140.34 and Definition 140.35. Repacking these rows gives the ten-field public certificate surface, with exactness reduced to the listed singleton BEDC data and with no standard bridge component. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton public namecert export`

Theorem 140.8 (LieGroup singleton multiplication smooth homomorphism)**.** *On the concrete carrier L_{e} of Definition 140.30, the multiplication row*

$$\mathsf{mul}(h, k) := \mathsf{append}(h, k)$$

is carried by L_{e} whenever both inputs are carried, is classifier-respecting in both arguments for R_{e}, and is read by the singleton chart as the constant transition on the sole overlap.

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton multiplication smooth homomorphism`

Proof. The carrier and classifier boundary is the singleton history certificate of Definition 41.4, with checked row BEDC.Derived.GroupUp.GroupSingletonHistory_laws. Its multiplication closure row sends carried h and k to a carried $\mathsf{append}(h, k)$, and its singleton classifier rows identify the result with the endpoint e.

Classifier respect in the first and second arguments is therefore the same singleton calculation: replacing either input by an R_{e}-equal carried input leaves both histories classifier-equal to e, so the product row is again R_{e}-equal to the same endpoint.

Finally apply Definition 96.32 to place the product in the unique chart domain. The self-overlap transition is the constant transition of Definition 96.33, so the chart readback of multiplication is smooth and constant. □

Theorem 140.9 (LieGroup singleton inverse smooth endomap)**.** *On the concrete carrier L_{e} of Definition 140.30, the inverse row*

$$\mathsf{inv}(h) := \mathsf{e}$$

is carried by L_{e}, is classifier-respecting for R_{e}, is involutive up to R_{e}, and is read in the singleton atlas as a constant smooth endomap.

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton inverse smooth endomap`

Proof. The inverse value is definitionally e. The inverse closure and inverse law rows of BEDC.Derived.GroupUp.Grou cited by Definition 41.4, provide the carried witness and identify the inverse endpoint with the singleton classifier class.

Classifier respect follows because every carried input is already R_{e}-equal to e, and applying inv returns e again. Applying the same row twice again returns e, so the double inverse is R_{e}-equal to the original carried singleton point.

The chart statement is the singleton manifold statement. By Definition 96.32, both the input and inverse value lie in the only chart domain; by Definition 96.33, the readback is the constant smooth self-overlap transition. □

Theorem 140.10 (LieGroup singleton smooth-group NameCert export)**.** *The carrier obligation Definition 140.31, the multiplication homomorphism theorem Definition 140.37, and the inverse endomap theorem Definition 140.38 supply the concrete $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ export over BHist. The export contains the carrier L_{e}, classifier R_{e}, smooth multiplication, smooth inverse, ledger rows, exactness condition, and the absence of standard bridge rows.*

Proof. The carrier theorem fixes the shared algebraic and manifold predicate on BHist and supplies the classifier row. Hence every exported row has the same underlying object boundary and no separate carrier transport is needed.

The multiplication theorem supplies the smooth binary operation row: closure in L_{e}, respect for R_{e} in each argument, and constant singleton chart readback. The inverse theorem supplies the smooth unary operation row: closure, classifier respect, double-inverse agreement up to R_{e}, and the same constant chart readback.

The ledger is therefore exactly the displayed singleton ledger consisting of BHist, hsame, Cont, append, e, the singleton $\mathsf{Group}^{\uparrow}$ laws, and the singleton $\mathsf{Manifold}^{\uparrow}$ chart and transition rows. Exactness says that an accepted smooth-group row is one of these rows after unfolding the concrete carrier. No $\mathsf{StandardBridge}$ row is part of this export. □

Definition 140.11 (LieGroup singleton translation and conjugation rows)**.** *For a carried singleton parameter s and carried singleton input x, the action rows attached to Definition 140.30 are*

$$\mathsf{Left}_s(x) := \mathsf{mul}(s, x), \qquad \mathsf{Right}_s(x) := \mathsf{mul}(x, s),$$

$$\mathsf{Conj}_s(x) := \mathsf{mul}(\mathsf{mul}(s, x), \mathsf{inv}(s)).$$

The adjoint readback row is the differential of Conj_s at e, read on the singleton tangent carrier as the constant zero endomap of the singleton $\mathsf{LieAlgebra}^{\uparrow}$ carrier. Thus translation, conjugation, and adjoint readback all use the same carried predicate L_{e} and the same singleton chart endpoint.

Lean4 (definition) `BEDC.Derived.LieGroupUp.LieGroupSingletonTranslationRows`

Theorem 140.12 (LieGroup singleton left-translation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Left}_s(x)$ from Definition 140.40 is carried by L_{e}, is classified by the singleton classifier with endpoint e, and is read in the singleton atlas as the constant smooth transition on the sole overlap.*

Proof. The group row of $\mathsf{BEDC.Derived.GroupUp.GroupSingletonHistory_laws}$ gives closure of $\mathsf{mul}(s, x)$ under the singleton carrier whenever both inputs are carried by L_{e}. This is exactly the left-translation carrier row after unfolding Definition 140.40.

By Definition 140.31, the carried group result is the same object as the singleton manifold point. Therefore the sole chart domain accepts the result and reads it at the constant endpoint $0_{\mathsf{Real}^{\uparrow}}$.

The overlap transition is the singleton constant transition supplied by Definition 96.33. Hence the left translation is smooth as a singleton-atlas self-map. □

Theorem 140.13 (LieGroup singleton right-translation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Right}_s(x)$ from Definition 140.40 is carried by L_{e}, is classified by the singleton classifier with endpoint e, and is read in the singleton atlas as the constant smooth transition on the sole overlap.*

Proof. The multiplication-closure row of $\mathsf{BEDC.Derived.GroupUp.GroupSingletonHistory_laws}$ applies symmetrically to $\mathsf{mul}(x, s)$. Since $L_{\mathsf{e}}(x)$ and $L_{\mathsf{e}}(s)$ hold, the right-translation value remains inside the singleton carrier.

The carrier identification in Definition 140.31 then moves this accepted group value into the singleton chart domain without changing the predicate being used. The classifier endpoint is still e.

Finally, Definition 96.33 reads the only self-overlap as a constant smooth transition. Thus the right translation is a smooth singleton-atlas self-map. □

Theorem 140.14 (LieGroup singleton conjugation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Conj}_s(x)$ from Definition 140.40 is carried by L_{e}, classified with endpoint e, and read by the singleton atlas as a constant smooth self-map.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation smooth`

Proof. First apply Definition 140.41 to s and x. The result $\mathsf{mul}(s, x)$ is carried by L_{e} and is read in the singleton chart as the constant endpoint.

Next use the inverse-closure row from BEDC.Derived.GroupUp.GroupSingletonHistory_laws on the carried parameter s. Since $\mathsf{inv}(s)$ is definitionally e, it is also accepted by the singleton carrier and classifier.

Apply the right-translation row Definition 140.42 to the carried value $\mathsf{mul}(s, x)$ and the carried inverse $\mathsf{inv}(s)$. The resulting history is precisely $\mathsf{Conj}_s(x)$ after unfolding the definition, so it is carried, classified with e, and read as the singleton constant smooth self-map. □

Theorem 140.15 (LieGroup singleton adjoint readback)**.** *For every carried singleton parameter s, the differential at e of the singleton conjugation row Conj_s is the constant zero endomap on the singleton tangent carrier, equivalently on the singleton $\mathsf{LieAlgebra}^{\uparrow}$ carrier.*

Proof. By Definition 140.43, conjugation by any carried singleton parameter is read in the unique chart as a constant self-map at endpoint $0_{\mathsf{Real}^{\uparrow}}$. A constant singleton chart map has the zero tangent readback on the sole tangent point.

The $\mathsf{LieAlgebra}^{\uparrow}$ singleton rows identify the Lie-algebra carrier with the same singleton tangent carrier at e. Therefore the conjugation differential is the constant zero endomap on that carrier, which is exactly the adjoint readback row. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton adjoint readback`

Theorem 140.16 (LieGroup singleton shared source scope)**.** *For the carrier of Definition 140.30, every displayed $\mathsf{LieGroup}^{\uparrow}$ row is scoped by the same BEDC history source. The group carrier, manifold chart domain, restricted classifier, unit, multiplication, inverse, chart value, and transition rows are all given by BHist, hsame, e, append, Cont, the singleton $\mathsf{Group}^{\uparrow}$ laws, and the singleton $\mathsf{Manifold}^{\uparrow}$ rows. No row requires equality of host-language functions; the only equality test exposed to the certificate is the restricted hsame classifier on carried histories.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton shared source scope`

Proof. Unfold the carrier definition. The algebraic carrier is the predicate $L_{\mathsf{e}}(h)$, and the chart domain is the same predicate rather than a second copy. The classifier row is therefore the displayed relation R_{e}, which mentions only L_{e} and hsame.

The group operation rows are the singleton rows: the unit is e, multiplication is append, and inverse is the constant map to e. Their closure and law witnesses are exactly the singleton $\mathsf{Group}^{\uparrow}$ laws.

The manifold rows use the singleton chart, constant value $0_{\mathsf{Real}^{\uparrow}}$, and the self-overlap transition controlled by Cont. Since both sides name the same BHist source, every interface projection is scoped by BHist and by the restricted classifier, with no appeal to host function equality. □

Theorem 140.17 (LieGroup singleton smooth operation readback)**.** *For histories carried by L_{e}, the multiplication output $\mathsf{append}(h, k)$ and the inverse output e are classifier-equal to e. Reading either output through the sole singleton chart gives the constant value $0_{\mathsf{Real}^{\uparrow}}$, and every operation overlap is the constant self-transition of the singleton atlas.*

Proof. Apply Definition 41.4. Its singleton history laws give closure of $\mathsf{append}(h, k)$, closure of e as the inverse output, and classifier equality of both accepted outputs with the unit endpoint.

Apply Definition 96.32. Every accepted input and accepted output lies in the only chart domain, and the chart value on that domain is the constant $0_{\mathsf{Real}^{\uparrow}}$.

Apply Definition 96.33. The only overlap available in the singleton atlas is the self-overlap, so the operation readback through the chart is the constant transition row already supplied by the manifold certificate. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton smooth operation readback`

Theorem 140.18 (LieGroup singleton dependent interface package)**.** *Any downstream* ExpMap*,* AdjointRep*, or* RootSystem *consumer of the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package may project only the displayed unit, multiplication, inverse, chart, transition, and ledger rows. These projections are stable under the restricted* hsame *classifier: replacing an accepted history by a classifier-equal accepted history preserves the projected carrier witness, operation witness, chart-domain witness, chart value, and transition witness.*

Proof. The allowed projections are exactly the rows named in Definition 140.30. They expose the unit, the append multiplication, the constant inverse, the singleton chart, the constant transition, and the ledger rows BHist, hsame, e, append, and Cont.

Stability follows from the shared source scope of Definition 140.45. Every projected row is defined over L_{e} and R_{e}, so classifier-equal accepted histories remain in the same carried predicate and have the same singleton chart value.

The smooth readback theorem supplies the operation-facing part of the interface. Multiplication and inverse outputs return to the singleton endpoint, and the only chart transition available to the consumer is the constant self-transition. □

Theorem 140.19 (LieGroup singleton downstream unblock package)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *certificate consists of the following ten-field roadmap package.*

Traditional target. *The one-point Lie group.*

BEDC source. BHist *with distinguished empty history* e*.*

Carrier. *The predicate* $L_{\mathsf{e}}(h)$*, equivalently* $\mathsf{hsame}(h, \mathsf{e})$*.*

Classifier. *The restricted classifier* R_{e} *on accepted histories.*

Stability obligations. *Carrier reuse, operation closure, chart-domain reuse, chart-value constancy, transition constancy, and classifier transport under* hsame*.*

Ledger. BHist*,* hsame*,* e*,* append*,* Cont*, the singleton* $\mathsf{Group}^{\uparrow}$ *laws, and the singleton* $\mathsf{Manifold}^{\uparrow}$ *chart and transition rows.*

Core theorem list. *Definition 140.31, Definition 140.32, Definition 140.45, Definition 140.46, Definition 140.47, and Definition 140.49.*

Exactness predicate. *A projected Lie-group row is accepted exactly when it factors through the displayed carrier, classifier, operation, chart, and transition rows.*

Standard bridge absent. *No* StandardBridge *row is part of this package.*

Status. *A paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *target for* BEDC.Derived.LieGroupUp*.*

Proof. The traditional target, BEDC source, carrier, and classifier fields are the surface rows of Definition 140.30 and Definition 140.31. They identify the algebraic and manifold carriers with the same singleton history predicate.

The stability and ledger fields are supplied by Definition 140.45 and Definition 140.46. These theorems name the shared BHist source, the restricted hsame classifier, the append operation, the constant inverse, and the constant chart transition.

The dependent-interface field is supplied by Definition 140.47. It records the rows that later ExpMap, AdjointRep, and RootSystem packages may project, and it states their stability under the restricted classifier.

The exactness, bridge, and status fields are bookkeeping consequences of those rows: a row belongs to the singleton package only when it factors through the displayed carrier and operation data, no standard bridge is included, and the target namespace is BEDC.Derived.LieGroupUp. □

Theorem 140.20 (LieGroup singleton NameCert obligation surface)**.** *The rows of Definition 140.30, Definition 140.33, Definition 140.31, Definition 140.32, Definition 140.34, Definition 140.35, Definition 140.36, Definition 140.37, Definition 140.38, Definition 140.39, Definition 140.40, Definition 140.41, Definition 140.42, Definition 140.43, Definition 140.44, Definition 140.45, Definition 140.46, and Definition 140.47 assemble the paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *obligation surface for the singleton smooth group carrier.*

Traditional target. *The one-point Lie group.*

Exactness. *A Lie-group operation row is accepted only when its carrier, classifier, chart-domain, and transition witnesses all reduce to the displayed singleton rows.*

No standard bridge. *The surface contains no* StandardBridge *row.*

Status. *A paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *obligation target under* BEDC.Derived.LieGroupUp*.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton semantic name certificate`

Proof. The carrier theorem supplies the shared object boundary: one predicate L_{e} is both the group carrier and the manifold point carrier. This prevents any separate transport problem between algebraic and smooth rows.

The group rows are inherited from Definition 41.4, backed by BEDC.Derived.GroupUp.GroupSingletonHistory_law They give inhabitance, multiplication closure, inverse closure, unit laws, and inverse laws for the append operation with constant inverse.

The manifold rows are inherited from Definition 96.37, backed by BEDC.Derived.ManifoldUp.ManifoldSingleton_s and the singleton transition smoothness row. They give the sole chart domain, constant chart value, and constant self-overlap transition.

The operation-smoothness, classifier-transport, multiplication, inverse, public export, and smooth-group export theorems tie these projections together. Once a group operation result is accepted, it is again classifier-equal to e, hence it is read by the only chart as the same constant endpoint. The translation, conjugation, and adjoint rows are the same singleton readback applied to the displayed public operation rows. Repacking the listed fields gives the obligation surface in the statement, with no standard bridge component claimed. □

Theorem 140.21 (LieGroup singleton standard bridge)**.** *The singleton BEDC* $\mathsf{LieGroup}^{\uparrow}$ *packet of Definition 140.33 interprets as the standard one-point Lie group. The bridge sends the carrier* L_{e} *to the singleton carrier, reads multiplication and inverse from the singleton* $\mathsf{Group}^{\uparrow}$ *rows, and reads smoothness from the singleton* $\mathsf{Manifold}^{\uparrow}$ *chart rows. It carries no non-singleton Lie theory, exponential theory, representation theory, root-system theory, or host quotient data.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton standard bridge`

Proof. The carrier bridge is the singleton carrier of Definition 140.31. Every accepted history is R_{e}-classified with e, so the target carrier has one point.

The algebraic operation bridge is supplied by Definition 140.37 and Definition 140.38. Multiplication and inverse stay in L_{e} and are classifier-equal to the singleton endpoint.

The smooth bridge is supplied by Definition 140.35. The only chart is the singleton chart, and every operation readback is the constant smooth self-overlap row. Repacking these rows gives the standard one-point Lie group interpretation and no further Lie-group structure. □

Theorem 140.22 (LieGroup singleton source lock)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *source uses the single predicate* $L_{\mathsf{e}}(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e})$ *as the* $\mathsf{Group}^{\uparrow}$ *carrier, the* $\mathsf{Manifold}^{\uparrow}$ *point and chart-domain carrier, and the* $\mathsf{LieGroup}^{\uparrow}$ *carrier. Its classifier is the same restricted* hsame *row* $R_{\mathsf{e}}(h, k)$ *from Definition 140.30; no transported second source, auxiliary carrier, or duplicate classifier is introduced.*

Proof. Unfold Definition 140.30. The displayed predicate L_{e} is the only carrier predicate named there, and the classifier is the displayed restricted row R_{e}.

Project the singleton group rows from Definition 41.4. These rows use BHist, e, append, constant inverse, and the restricted hsame classifier; their checked source is BEDC.Derived.GroupUp.GroupSingletonHistory_law

Project the singleton chart rows from Definition 96.37. The chart domain is the same predicate $\mathsf{hsame}(h, \mathsf{e})$, the chart value is constant, and the overlap row is the singleton transition row.

Thus both projected packages identify their visible carrier with L_{e}. The $\mathsf{LieGroup}^{\uparrow}$ package is assembled by sharing that predicate and classifier rather than by transporting data across a second source. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton source lock`

Theorem 140.23 (LieGroup manifold and group anchor)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *source is accepted only after the* $\mathsf{Group}^{\uparrow}$ *operation rows of chapter 41 and the* $\mathsf{Manifold}^{\uparrow}$ *chart rows of chapter 96 have been read. Its public source ledger projects the shared predicate* L_{e} *through those two dependency surfaces and exports no independent ambient smooth-group carrier.*

Proof. Begin with Definition 140.51. The carrier predicate L_{e} and the restricted classifier R_{e} are the single source used by the group carrier, manifold point and chart-domain carrier, and Lie-group carrier.

Project the $\mathsf{Group}^{\uparrow}$ rows through chapter 41. The operation, unit, inverse, and law rows are the singleton history rows named by the source-lock theorem, so the Lie-group packet cannot be accepted before those algebraic rows are visible.

Project the $\mathsf{Manifold}^{\uparrow}$ rows through chapter 96. The chart domain, chart value, and transition row are the singleton chart rows named by the same source lock, so the smooth side is read from the displayed manifold surface rather than from a separate smooth carrier.

Therefore the source ledger is a joint read of the displayed $\mathsf{Group}^{\uparrow}$ and $\mathsf{Manifold}^{\uparrow}$ dependency rows. Since every exported carrier and classifier is the shared L_{e} and R_{e} projection, no independent ambient smooth-group carrier is available to downstream consumers. □

Theorem 140.24 (LieGroup singleton exact ledger)**.** *For the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package, the accepted ledger consists exactly of* BHist, hsame, e, append/Cont, *the singleton* $\mathsf{Group}^{\uparrow}$ *laws, the singleton chart domain and chart value, and the singleton constant transition row. It excludes any standard bridge, any host smooth-manifold equality, any extra carrier, and any external topology row.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton exact ledger`

Proof. The source-lock theorem fixes the boundary of the ledger: all carrier and classifier rows are projections of the one history predicate L_{e} and the restricted hsame relation.

The algebraic entries are exactly the singleton $\mathsf{Group}^{\uparrow}$ rows. They are supplied by Definition 41.4 and BEDC.Derived.GroupUp.GroupSingletonHistory_laws, namely BHist, hsame, e, append, Cont, and the singleton group laws.

The smooth entries are exactly the singleton $\mathsf{Manifold}^{\uparrow}$ rows. They are supplied by Definition 96.37, BEDC.Derived.ManifoldUp.ManifoldSingleton_semanticNameCert, and BEDC.Derived.ManifoldUp.Manifol the singleton chart domain, constant chart value, and constant transition.

Finally, Definition 140.32 accounts for the operation rows by reading multiplication and inverse through the same singleton atlas. No cited row provides a StandardBridge, host equality of smooth manifolds, an additional carrier predicate, or an external topology, so none belongs to the accepted ledger. □

Theorem 140.25 (LieGroup singleton downstream export)**.** *The packages* $\mathsf{ExpMap}^{\uparrow}$, $\mathsf{AdjointRep}^{\uparrow}$, $\mathsf{RootSystem}^{\uparrow}$, *and representation certificates may consume the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package only through the exported carrier, classifier, operation, chart, and transition rows. The singleton package makes no downstream claim of connectedness, completeness, nontrivial Lie algebra, or standard bridge.*

Proof. By Definition 140.51, every visible carrier and classifier row of the singleton $\mathsf{LieGroup}^{\uparrow}$ package is a projection of the shared history predicate L_{e} and the restricted hsame classifier. These are the only source rows a dependent certificate can name.

By Definition 140.53, the remaining visible rows are precisely the group operation rows, singleton chart rows, and singleton transition row. The NameCert surface in Definition 140.49 repacks those rows as the public obligation surface for $\mathsf{LieGroup}^{\uparrow}$.

Therefore any $\mathsf{ExpMap}^{\uparrow}$, $\mathsf{AdjointRep}^{\uparrow}$, $\mathsf{RootSystem}^{\uparrow}$, or representation certificate built over this singleton source can project only those exported rows. Since the ledger contains no connectedness, completeness, nontrivial Lie-algebra, or $\mathsf{StandardBridge}$ row, no downstream consumer receives such a claim from this package. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton downstream export`

Definition 140.26 (Singleton LieGroup conjugation action)**.** *On the singleton smooth group carrier Definition 140.30, define the* BHist*-valued conjugation action by*

$$\mathsf{Ad}_{\mathsf{e}}(s, x) := \mathsf{append}(\mathsf{append}(s, x), \mathsf{e}).$$

The inputs are carried histories $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$, and the terminal factor e *is the singleton inverse row of the group carrier.*

Lean4 (definition) `BEDC.Derived.LieGroupUp.LieGroupSingletonConjugationAction`

Theorem 140.27 (LieGroup singleton conjugation carrier and smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Ad}_{\mathsf{e}}(s, x)$ is again carried by L_{e}. Moreover the singleton manifold chart reads this conjugation endpoint as the same constant smooth transition that reads multiplication and inverse in Definition 140.32.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation carrier and smoothness`

Proof. Unfold Definition 140.55. The endpoint is the append-composite $(s * x) * \mathsf{e}$ in the singleton group rows. Since s and x are carried, Definition 41.4 gives closure of $s*x$, and the right multiplication by e stays in the same carrier. The Lean-side row BEDC.Derived.GroupUp.GroupSingletonClassifier_conjugation_ records the same terminal collapse for the singleton classifier.

For smoothness, the carried input pair and the carried output all lie in the sole singleton chart domain. Applying Definition 96.33 reads the source and target charts as the constant value $0_{\mathsf{Real}^{\uparrow}}$, so the displayed action has the constant smooth transition row already used by the multiplication and inverse obligations. The corresponding Lean-side row is BEDC.Derived.ManifoldUp.ManifoldSingleton_transition □

Theorem 140.28 (LieGroup singleton conjugation action law)**.** *For carried histories $L_{\mathsf{e}}(s)$, $L_{\mathsf{e}}(t)$, and $L_{\mathsf{e}}(x)$, the two iterated endpoints*

$$\mathsf{Ad}_{\mathsf{e}}(s, \mathsf{Ad}_{\mathsf{e}}(t, x))$$

and

$$\mathsf{Ad}_{\mathsf{e}}(\mathsf{append}(s, t), x)$$

are both classified by the singleton classifier R_{e}, hence represent the same carried singleton endpoint.

Proof. First unfold the action on the left. The inner endpoint is $\mathsf{append}(\mathsf{append}(t, x), \mathsf{e})$, and Definition 140.56 carries it back into L_{e}. Applying the same theorem to s and this inner endpoint therefore carries the whole left-hand endpoint.

Next unfold the action on the right. Group singleton closure carries $\mathsf{append}(s, t)$, and another application of Definition 140.56 carries $\mathsf{Ad}_{\mathsf{e}}(\mathsf{append}(s, t), x)$.

It remains to compare the classifier rows. By the singleton group classifier, every carried endpoint is hsame to e. The Cont associativity and readback rows allow the nested append words on both sides to be read as singleton terminal words, and the group singleton closure removes the terminal factor. Thus both displayed endpoints satisfy R_{e} against e, and therefore against each other by the restricted singleton classifier. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation action law`

Theorem 140.29 (LieGroup singleton AdjointRep source surface)**.** *The rows of Definition 140.55, Definition 140.56, and Definition 140.57 supply the* $\mathsf{LieGroup}^{\uparrow}$*-side source surface consumed by* $\mathsf{AdjointRep}^{\uparrow}$*: the operation* Ad_{e} *is* BHist*-valued, classifier-stable on the singleton carrier, smooth in the singleton atlas, and carries no standard bridge row.*

Proof. The definition provides the concrete BHist operation. The carrier and smoothness theorem supplies the two structural rows needed by a representation source: accepted inputs give an accepted endpoint, and the singleton atlas reads that endpoint through the constant smooth transition.

The action-law theorem supplies the compatibility row. Both iterated conjugation and conjugation by the product word land in the singleton classifier class, so $\mathsf{AdjointRep}^{\uparrow}$ can consume the action without adding a separate carrier transport or chart transition.

No standard bridge row is part of this surface. The package is only the paper-side singleton $\mathsf{LieGroup}^{\uparrow}$ action source over BHist, with the ordinary Lie-group bridge left outside the displayed rows. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton adjointrep source surface`

Closure status for $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$**.**

Constructive story: The concrete Lie group here is the singleton history carrier L_{e}: a history is accepted exactly when it is hsame to e, and the same predicate serves simultaneously as the $\mathsf{Group}^{\uparrow}$ carrier, the $\mathsf{Manifold}^{\uparrow}$ point carrier, and the $\mathsf{LieGroup}^{\uparrow}$ carrier. Two accepted histories classify together by the restricted row R_{e}, so multiplication by append, inverse returning e, the unit e, and the singleton chart all stay inside one shared classifier rather than being transported across duplicate sources. The source covers the single BHist carrier and its group and chart rows, the pattern records singleton group laws, constant chart coverage, smooth multiplication and inverse readback, and conjugation source rows, while the ledger keeps e, hsame, Cont, append, the singleton chart value, and the constant transition visible. Nonemptiness is witnessed by e, reflexivity, symmetry, and transitivity are those of hsame restricted to L_{e}, and carrier closure follows because every public operation endpoint is again classified with e. A history h lies in the signature gap of a $\mathsf{LieGroup}^{\uparrow}$ token p when the source accepts h as a singleton group/manifold row, the signature relation pairs it with an answer endpoint and evidence ledger, and token introduction names that answer as p; unfolded, h and the answer are both the empty singleton endpoint with the displayed operation, chart, and conjugation rows. The paper bridge reads this package as the standard one-point Lie group and reads it back through the same singleton carrier, group laws, and chart rows. The chapter registers this singleton smooth-group construction under the name $\mathsf{LieGroup}^{\uparrow}$; no non-singleton Lie group, exponential theory, representation theory, or root-system theory is part of the primitive package.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public singleton boundary is the shared BHist carrier L_{e}, restricted hsame classifier, singleton $\mathsf{Group}^{\uparrow}$ laws, singleton $\mathsf{Manifold}^{\uparrow}$ chart rows, classifier transport, smooth operation readback, exact ledger, downstream export, and conjugation source rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.LieGroupUp.LieGroupSingleton\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not close non-singleton Lie groups, exponential theory, representation theory, root-system theory, or bridgeChecked verification.

Upgrade path: The remaining advancement is bridgeChecked verification for the displayed paper bridge, not additional theory-axis maturity for the singleton Lie-group package.

140.3 Carrier definition

Definition 140.30 (Singleton smooth group carrier)**.** *The concrete* $\mathsf{LieGroup}^{\uparrow}$ *carrier is the shared singleton history carrier*

$$L_{\mathsf{e}}(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e})$$

on BHist*. Its group rows are the singleton* $\mathsf{Group}^{\uparrow}$ *rows*

$$\mathsf{mul}(h, k) := \mathsf{append}(h, k), \qquad \mathsf{inv}(h) := \mathsf{e}, \qquad e := \mathsf{e},$$

with classifier

$$R_{\mathsf{e}}(h, k) :\Longleftrightarrow L_{\mathsf{e}}(h) \wedge L_{\mathsf{e}}(k) \wedge \mathsf{hsame}(h, k).$$

Its smooth-manifold rows are the singleton $\mathsf{Manifold}^{\uparrow}$ *chart rows with the one chart* χ_{e}*, top domain* L_{e}*, constant value* $0_{\mathsf{Real}^{\uparrow}}$*, and the self-overlap constant transition. Thus the algebraic carrier and the manifold carrier are the same predicate on histories, not two transported copies.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupTasteGate single carrier alignment`

140.4 The certificate

Theorem 140.31 (LieGroup singleton carrier obligation)**.** *The carrier* L_{e} *of Definition 140.30 simultaneously supplies the* $\mathsf{Group}^{\uparrow}$ *singleton carrier and classifier rows and the* $\mathsf{Manifold}^{\uparrow}$ *singleton chart rows. Concretely, every accepted history is classified with* e *by* R_{e}*, multiplication and inverse stay inside* L_{e}*, and the sole chart domain is exactly the same carried predicate* L_{e}*.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton carrier obligation`

Proof. For the algebraic side, unfold Definition 140.30. The carrier, classifier, multiplication, unit, and inverse rows are exactly the rows used by Definition 41.4; the checked Lean row is BEDC.Derived.GroupUp.GroupSingletonHistory_laws.

For the manifold side, the chart-domain row is the singleton empty-chart row of Definition 96.32. Its carried predicate is $\mathsf{hsame}(h, \mathsf{e})$, which is definitionally the same predicate as L_{e}.

The two sides therefore share the same history carrier and the same restricted hsame classifier. Projection from the group row gives the algebraic carrier and classifier fields, while projection from the manifold row gives the chart domain, chart value, and singleton atlas fields. □

Theorem 140.32 (LieGroup singleton operation smoothness obligation)**.** *For histories carried by* L_{e}*, both* mul *and* inv *of Definition 140.30 are smooth operations in the singleton atlas. Every accepted multiplication result and every accepted inverse result is classifier-equal to* e*, so each operation is read by the sole chart as a constant transition on the singleton overlap.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton operation smoothness`

Proof. Start with multiplication. If $L_{\mathsf{e}}(h)$ and $L_{\mathsf{e}}(k)$ hold, the group singleton laws identify $\mathsf{append}(h, k)$ with e and keep the result inside the singleton carrier. This is the multiplication-closure row of BEDC.Derived.GroupUp.GroupSingletonHistory_laws.

For inverse, $\mathsf{inv}(h)$ is definitionally e. The inverse-closure row of the same group theorem gives the carrier witness, and the classifier row identifies the result with the unit endpoint.

Now read both operations through the manifold atlas. By Definition 96.32, every carried input and every accepted output lies in the only chart domain and has the constant chart value $0_{\mathsf{Real}^{\uparrow}}$. The overlap transition is therefore the singleton constant transition of Definition 96.33, whose checked Lean row is BEDC.Derived.ManifoldUp.ManifoldSingleton_transition_smoothness. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton operation smoothness obligation`
Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingletonOperation smoothness`

Definition 140.33 (LieGroup singleton public smooth group package)**.** *The public smooth group package underlying the singleton* $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$ *has BEDC source* BHist*, carrier* L_{e}*, classifier* R_{e}*, multiplication graph*

$$\mathsf{mul}(h,k) = \mathsf{append}(h,k),$$

inverse

$$\mathsf{inv}(h) = \mathsf{e},$$

and unit e*. The smooth rows use the singleton chart* χ_{e} *on the same carrier predicate, with constant chart value* $0_{\mathsf{Real}^\uparrow}$ *and self-overlap transition certified by* Cont*. Thus every public algebraic operation is read through the displayed BEDC operation rows rather than through an external standard-space representative.*

Theorem 140.34 (LieGroup singleton classifier transport)**.** *For the package of Definition 140.33, classifier equivalence is congruent for multiplication and inverse. If* $R_{\mathsf{e}}(h,h')$ *and* $R_{\mathsf{e}}(k,k')$*, then*

$$R_{\mathsf{e}}(\mathsf{mul}(h,k), \mathsf{mul}(h',k')).$$

If $R_{\mathsf{e}}(h,h')$*, then*

$$R_{\mathsf{e}}(\mathsf{inv}(h), \mathsf{inv}(h')).$$

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton classifier transport`

Proof. Project the endpoint carrier witnesses from $R_{\mathsf{e}}(h,h')$ and $R_{\mathsf{e}}(k,k')$. Each projection gives membership in L_{e} together with an hsame path to the empty endpoint.

For multiplication, the singleton group laws identify both $\mathsf{append}(h,k)$ and $\mathsf{append}(h',k')$ with e while keeping both results in L_{e}. The classifier row is then the pair of carrier witnesses plus the hsame comparison obtained by transitivity through e.

For inverse, both operation outputs are definitionally e. Reflexivity gives the carrier witnesses and the endpoint comparison, so the restricted classifier R_{e} holds for the two inverse outputs. □

Theorem 140.35 (LieGroup singleton chart operation readback)**.** *The multiplication and inverse outputs covered by Definition 140.34 are read by the singleton chart as the constant endpoint* $0_{\mathsf{Real}^\uparrow}$*. Consequently their chart self-overlap row is the same singleton transition row certified for* $\mathsf{Manifold}^\uparrow$*.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton chart operation readback`

Proof. Apply Definition 140.34 to obtain the classifier witnesses for the operation outputs. In each case the classifier contains the carrier predicate L_{e} for the output history.

Apply Definition 96.32 to those carrier witnesses. The unique chart χ_{e} reads every carried endpoint as the constant value $0_{\mathsf{Real}^\uparrow}$, so multiplication and inverse have the same chart readback.

Finally apply Definition 96.33. Since the only overlap is the singleton self-overlap and both chart values are constant, the operation readback has exactly the displayed transition row. □

Theorem 140.36 (LieGroup singleton public NameCert export)**.** *The public* $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$ *surface for the singleton smooth group exports the following ten fields.*

Traditional target. *The one-point Lie group.*

BEDC source. BHist *with distinguished empty history* e.

Carrier. *The predicate* $L_{\mathsf{e}}(h)$.

Classifier. *The restricted classifier* $R_{\mathsf{e}}(h,k)$.

Algebraic rows. *Multiplication* append, *inverse* e, *unit* e, *and the singleton* $\mathsf{Group}^{\uparrow}$ *laws.*

Smooth rows. *The singleton* $\mathsf{Manifold}^{\uparrow}$ *chart* χ_{e}, *constant value* $0_{\mathsf{Real}^{\uparrow}}$, *and the singleton transition row.*

Classifier transport. *Multiplication and inverse preserve* R_{e} *as in Definition 140.34.*

Smooth operation congruence. *Operation outputs related by the classifier have the same chart readback and transition row as in Definition 140.35.*

Exactness. *Every accepted public row reduces to* BHist, hsame, Cont, append, e, *the displayed singleton* $\mathsf{Group}^{\uparrow}$ *laws, and the displayed singleton* $\mathsf{Manifold}^{\uparrow}$ *chart and transition.*

Bridge and status. *No* StandardBridge *row is claimed; the paper-side target is under* BEDC.Derived.LieGroupUp.

Proof. The carrier and classifier fields are supplied by Definition 140.30, and the public operation symbols are fixed in Definition 140.33.

The algebraic rows are the singleton $\mathsf{Group}^{\uparrow}$ laws. They give the endpoint carrier facts and identify multiplication and inverse outputs with e.

The smooth rows are the singleton $\mathsf{Manifold}^{\uparrow}$ rows. Chart coverage reads every accepted endpoint as $0_{\mathsf{Real}^{\uparrow}}$, and transition smoothness gives the constant self-overlap row.

The transport and smooth-operation congruence rows are exactly Definition 140.34 and Definition 140.35. Repacking these rows gives the ten-field public certificate surface, with exactness reduced to the listed singleton BEDC data and with no standard bridge component. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton public namecert export`

Theorem 140.37 (LieGroup singleton multiplication smooth homomorphism)**.** *On the concrete carrier* L_{e} *of Definition 140.30, the multiplication row*

$$\mathsf{mul}(h,k) := \mathsf{append}(h,k)$$

is carried by L_{e} *whenever both inputs are carried, is classifier-respecting in both arguments for* R_{e}, *and is read by the singleton chart as the constant transition on the sole overlap.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton multiplication smooth homomorphism`

Proof. The carrier and classifier boundary is the singleton history certificate of Definition 41.4, with checked row BEDC.Derived.GroupUp.GroupSingletonHistory_laws. Its multiplication closure row sends carried h and k to a carried $\mathsf{append}(h,k)$, and its singleton classifier rows identify the result with the endpoint e.

Classifier respect in the first and second arguments is therefore the same singleton calculation: replacing either input by an R_{e}-equal carried input leaves both histories classifier-equal to e, so the product row is again R_{e}-equal to the same endpoint.

Finally apply Definition 96.32 to place the product in the unique chart domain. The self-overlap transition is the constant transition of Definition 96.33, so the chart readback of multiplication is smooth and constant. □

Theorem 140.38 (LieGroup singleton inverse smooth endomap)**.** *On the concrete carrier L_{e} of Definition 140.30, the inverse row*

$$\mathsf{inv}(h) := \mathsf{e}$$

is carried by L_{e}, is classifier-respecting for R_{e}, is involutive up to R_{e}, and is read in the singleton atlas as a constant smooth endomap.

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton inverse smooth endomap`

Proof. The inverse value is definitionally e. The inverse closure and inverse law rows of BEDC.Derived.GroupUp.Grou cited by Definition 41.4, provide the carried witness and identify the inverse endpoint with the singleton classifier class.

Classifier respect follows because every carried input is already R_{e}-equal to e, and applying inv returns e again. Applying the same row twice again returns e, so the double inverse is R_{e}-equal to the original carried singleton point.

The chart statement is the singleton manifold statement. By Definition 96.32, both the input and inverse value lie in the only chart domain; by Definition 96.33, the readback is the constant smooth self-overlap transition. □

Theorem 140.39 (LieGroup singleton smooth-group NameCert export)**.** *The carrier obligation Definition 140.31, the multiplication homomorphism theorem Definition 140.37, and the inverse endomap theorem Definition 140.38 supply the concrete* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *export over* BHist*. The export contains the carrier L_{e}, classifier R_{e}, smooth multiplication, smooth inverse, ledger rows, exactness condition, and the absence of standard bridge rows.*

Proof. The carrier theorem fixes the shared algebraic and manifold predicate on BHist and supplies the classifier row. Hence every exported row has the same underlying object boundary and no separate carrier transport is needed.

The multiplication theorem supplies the smooth binary operation row: closure in L_{e}, respect for R_{e} in each argument, and constant singleton chart readback. The inverse theorem supplies the smooth unary operation row: closure, classifier respect, double-inverse agreement up to R_{e}, and the same constant chart readback.

The ledger is therefore exactly the displayed singleton ledger consisting of BHist, hsame, Cont, append, e, the singleton $\mathsf{Group}^{\uparrow}$ laws, and the singleton $\mathsf{Manifold}^{\uparrow}$ chart and transition rows. Exactness says that an accepted smooth-group row is one of these rows after unfolding the concrete carrier. No $\mathsf{StandardBridge}$ row is part of this export. □

Definition 140.40 (LieGroup singleton translation and conjugation rows)**.** *For a carried singleton parameter s and carried singleton input x, the action rows attached to Definition 140.30 are*

$$\mathsf{Left}_s(x) := \mathsf{mul}(s, x), \qquad \mathsf{Right}_s(x) := \mathsf{mul}(x, s),$$

$$\mathsf{Conj}_s(x) := \mathsf{mul}(\mathsf{mul}(s, x), \mathsf{inv}(s)).$$

The adjoint readback row is the differential of Conj_s at e, read on the singleton tangent carrier as the constant zero endomap of the singleton $\mathsf{LieAlgebra}^{\uparrow}$ carrier. Thus translation, conjugation, and adjoint readback all use the same carried predicate L_{e} and the same singleton chart endpoint.

Lean4 (definition) `BEDC.Derived.LieGroupUp.LieGroupSingletonTranslationRows`

Theorem 140.41 (LieGroup singleton left-translation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Left}_s(x)$ from Definition 140.40 is carried by L_{e}, is classified by the singleton classifier with endpoint e, and is read in the singleton atlas as the constant smooth transition on the sole overlap.*

Proof. The group row of BEDC.Derived.GroupUp.GroupSingletonHistory_laws gives closure of $\mathsf{mul}(s, x)$ under the singleton carrier whenever both inputs are carried by L_{e}. This is exactly the left-translation carrier row after unfolding Definition 140.40.

By Definition 140.31, the carried group result is the same object as the singleton manifold point. Therefore the sole chart domain accepts the result and reads it at the constant endpoint $0_{\mathsf{Real}^{\uparrow}}$.

The overlap transition is the singleton constant transition supplied by Definition 96.33. Hence the left translation is smooth as a singleton-atlas self-map. □

Theorem 140.42 (LieGroup singleton right-translation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Right}_s(x)$ from Definition 140.40 is carried by L_{e}, is classified by the singleton classifier with endpoint e, and is read in the singleton atlas as the constant smooth transition on the sole overlap.*

Proof. The multiplication-closure row of BEDC.Derived.GroupUp.GroupSingletonHistory_laws applies symmetrically to $\mathsf{mul}(x, s)$. Since $L_{\mathsf{e}}(x)$ and $L_{\mathsf{e}}(s)$ hold, the right-translation value remains inside the singleton carrier.

The carrier identification in Definition 140.31 then moves this accepted group value into the singleton chart domain without changing the predicate being used. The classifier endpoint is still e.

Finally, Definition 96.33 reads the only self-overlap as a constant smooth transition. Thus the right translation is a smooth singleton-atlas self-map. □

Theorem 140.43 (LieGroup singleton conjugation smoothness)**.** *If $L_{\mathsf{e}}(s)$ and $L_{\mathsf{e}}(x)$ hold, then $\mathsf{Conj}_s(x)$ from Definition 140.40 is carried by L_{e}, classified with endpoint e, and read by the singleton atlas as a constant smooth self-map.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation smooth`

Proof. First apply Definition 140.41 to s and x. The result $\mathsf{mul}(s, x)$ is carried by L_{e} and is read in the singleton chart as the constant endpoint.

Next use the inverse-closure row from BEDC.Derived.GroupUp.GroupSingletonHistory_laws on the carried parameter s. Since $\mathsf{inv}(s)$ is definitionally e, it is also accepted by the singleton carrier and classifier.

Apply the right-translation row Definition 140.42 to the carried value $\mathsf{mul}(s, x)$ and the carried inverse $\mathsf{inv}(s)$. The resulting history is precisely $\mathsf{Conj}_s(x)$ after unfolding the definition, so it is carried, classified with e, and read as the singleton constant smooth self-map. □

Theorem 140.44 (LieGroup singleton adjoint readback)**.** *For every carried singleton parameter s, the differential at e of the singleton conjugation row Conj_s is the constant zero endomap on the singleton tangent carrier, equivalently on the singleton $\mathsf{LieAlgebra}^{\uparrow}$ carrier.*

Proof. By Definition 140.43, conjugation by any carried singleton parameter is read in the unique chart as a constant self-map at endpoint $0_{\mathsf{Real}^{\uparrow}}$. A constant singleton chart map has the zero tangent readback on the sole tangent point.

The $\mathsf{LieAlgebra}^{\uparrow}$ singleton rows identify the Lie-algebra carrier with the same singleton tangent carrier at e. Therefore the conjugation differential is the constant zero endomap on that carrier, which is exactly the adjoint readback row. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton adjoint readback`

Theorem 140.45 (LieGroup singleton shared source scope)**.** *For the carrier of Definition 140.30, every displayed* $\mathsf{LieGroup}^{\uparrow}$ *row is scoped by the same BEDC history source. The group carrier, manifold chart domain, restricted classifier, unit, multiplication, inverse, chart value, and transition rows are all given by* BHist*,* hsame*,* e*,* append*,* Cont*, the singleton* $\mathsf{Group}^{\uparrow}$ *laws, and the singleton* $\mathsf{Manifold}^{\uparrow}$ *rows. No row requires equality of host-language functions; the only equality test exposed to the certificate is the restricted* hsame *classifier on carried histories.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton shared source scope`

Proof. Unfold the carrier definition. The algebraic carrier is the predicate $L_{\mathsf{e}}(h)$, and the chart domain is the same predicate rather than a second copy. The classifier row is therefore the displayed relation R_{e}, which mentions only L_{e} and hsame.

The group operation rows are the singleton rows: the unit is e, multiplication is append, and inverse is the constant map to e. Their closure and law witnesses are exactly the singleton $\mathsf{Group}^{\uparrow}$ laws.

The manifold rows use the singleton chart, constant value $0_{\mathsf{Real}^{\uparrow}}$, and the self-overlap transition controlled by Cont. Since both sides name the same BHist source, every interface projection is scoped by BHist and by the restricted classifier, with no appeal to host function equality. □

Theorem 140.46 (LieGroup singleton smooth operation readback)**.** *For histories carried by* L_{e}*, the multiplication output* $\mathsf{append}(h, k)$ *and the inverse output* e *are classifier-equal to* e*. Reading either output through the sole singleton chart gives the constant value* $0_{\mathsf{Real}^{\uparrow}}$*, and every operation overlap is the constant self-transition of the singleton atlas.*

Proof. Apply Definition 41.4. Its singleton history laws give closure of $\mathsf{append}(h, k)$, closure of e as the inverse output, and classifier equality of both accepted outputs with the unit endpoint.

Apply Definition 96.32. Every accepted input and accepted output lies in the only chart domain, and the chart value on that domain is the constant $0_{\mathsf{Real}^{\uparrow}}$.

Apply Definition 96.33. The only overlap available in the singleton atlas is the self-overlap, so the operation readback through the chart is the constant transition row already supplied by the manifold certificate. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton smooth operation readback`

Theorem 140.47 (LieGroup singleton dependent interface package)**.** *Any downstream* ExpMap*,* AdjointRep*, or* RootSystem *consumer of the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package may project only the displayed unit, multiplication, inverse, chart, transition, and ledger rows. These projections are stable under the restricted* hsame *classifier: replacing an accepted history by a classifier-equal accepted history preserves the projected carrier witness, operation witness, chart-domain witness, chart value, and transition witness.*

Proof. The allowed projections are exactly the rows named in Definition 140.30. They expose the unit, the append multiplication, the constant inverse, the singleton chart, the constant transition, and the ledger rows BHist, hsame, e, append, and Cont.

Stability follows from the shared source scope of Definition 140.45. Every projected row is defined over L_{e} and R_{e}, so classifier-equal accepted histories remain in the same carried predicate and have the same singleton chart value.

The smooth readback theorem supplies the operation-facing part of the interface. Multiplication and inverse outputs return to the singleton endpoint, and the only chart transition available to the consumer is the constant self-transition. □

Theorem 140.48 (LieGroup singleton downstream unblock package)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *certificate consists of the following ten-field roadmap package.*

Traditional target. *The one-point Lie group.*

BEDC source. BHist *with distinguished empty history* e.

Carrier. *The predicate* $L_{\mathsf{e}}(h)$*, equivalently* $\mathsf{hsame}(h, \mathsf{e})$.

Classifier. *The restricted classifier* R_{e} *on accepted histories.*

Stability obligations. *Carrier reuse, operation closure, chart-domain reuse, chart-value constancy, transition constancy, and classifier transport under* hsame.

Ledger. BHist, hsame, e, append, Cont, *the singleton* $\mathsf{Group}^{\uparrow}$ *laws, and the singleton* $\mathsf{Manifold}^{\uparrow}$ *chart and transition rows.*

Core theorem list. *Definition 140.31, Definition 140.32, Definition 140.45, Definition 140.46, Definition 140.47, and Definition 140.49.*

Exactness predicate. *A projected Lie-group row is accepted exactly when it factors through the displayed carrier, classifier, operation, chart, and transition rows.*

Standard bridge absent. *No* $\mathsf{StandardBridge}$ *row is part of this package.*

Status. *A paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *target for* $\mathsf{BEDC.Derived.LieGroupUp}$.

Proof. The traditional target, BEDC source, carrier, and classifier fields are the surface rows of Definition 140.30 and Definition 140.31. They identify the algebraic and manifold carriers with the same singleton history predicate.

The stability and ledger fields are supplied by Definition 140.45 and Definition 140.46. These theorems name the shared BHist source, the restricted hsame classifier, the append operation, the constant inverse, and the constant chart transition.

The dependent-interface field is supplied by Definition 140.47. It records the rows that later ExpMap, $\mathsf{AdjointRep}$, and $\mathsf{RootSystem}$ packages may project, and it states their stability under the restricted classifier.

The exactness, bridge, and status fields are bookkeeping consequences of those rows: a row belongs to the singleton package only when it factors through the displayed carrier and operation data, no standard bridge is included, and the target namespace is $\mathsf{BEDC.Derived.LieGroupUp}$. □

Theorem 140.49 (LieGroup singleton NameCert obligation surface)**.** *The rows of Definition 140.30, Definition 140.33, Definition 140.31, Definition 140.32, Definition 140.34, Definition 140.35, Definition 140.36, Definition 140.37, Definition 140.38, Definition 140.39, Definition 140.40, Definition 140.41, Definition 140.42, Definition 140.43, Definition 140.44, Definition 140.45, Definition 140.46, and Definition 140.47 assemble the paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *obligation surface for the singleton smooth group carrier.*

Traditional target. *The one-point Lie group.*

BEDC source. BHist *with distinguished empty history* e.

Carrier. *The predicate* $L_{\mathsf{e}}(h)$*, equivalently* $\mathsf{hsame}(h, \mathsf{e})$.

Classifier. *The restricted singleton classifier* R_{e}.

Stability. *Carrier transport, group operation closure, classifier transport for multiplication and inverse, chart-domain transport, chart-value constancy, smooth multiplication congruence, smooth inverse congruence, transition-row constancy, left and right translation smoothness, conjugation smoothness, and adjoint readback constancy.*

Ledger. *The rows* BHist, hsame, Cont, append, e, *the singleton* $\mathsf{Group}^{\uparrow}$ *laws, the singleton* $\mathsf{Manifold}^{\uparrow}$ *chart, the singleton constant transition, translation rows, conjugation rows, and the zero singleton adjoint readback.*

Core theorem list. *Definition 41.4, Definition 96.37, Definition 140.31, Definition 140.32, Definition 140.34, Definition 140.35, Definition 140.36, Definition 140.37, Definition 140.38, Definition 140.39, Definition 140.41, Definition 140.42, Definition 140.43, Definition 140.44, Definition 140.45, Definition 140.46, and Definition 140.47.*

Exactness. *A Lie-group operation row is accepted only when its carrier, classifier, chart-domain, and transition witnesses all reduce to the displayed singleton rows.*

No standard bridge. *The surface contains no* StandardBridge *row.*

Status. *A paper-side* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *obligation target under* BEDC.Derived.LieGroupUp.

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton semantic name certificate`

Proof. The carrier theorem supplies the shared object boundary: one predicate L_{e} is both the group carrier and the manifold point carrier. This prevents any separate transport problem between algebraic and smooth rows.

The group rows are inherited from Definition 41.4, backed by BEDC.Derived.GroupUp.GroupSingletonHistory_law They give inhabitance, multiplication closure, inverse closure, unit laws, and inverse laws for the append operation with constant inverse.

The manifold rows are inherited from Definition 96.37, backed by BEDC.Derived.ManifoldUp.ManifoldSingleton_s and the singleton transition smoothness row. They give the sole chart domain, constant chart value, and constant self-overlap transition.

The operation-smoothness, classifier-transport, multiplication, inverse, public export, and smooth-group export theorems tie these projections together. Once a group operation result is accepted, it is again classifier-equal to e, hence it is read by the only chart as the same constant endpoint. The translation, conjugation, and adjoint rows are the same singleton readback applied to the displayed public operation rows. Repacking the listed fields gives the obligation surface in the statement, with no standard bridge component claimed. □

Theorem 140.50 (LieGroup singleton standard bridge)**.** *The singleton BEDC* $\mathsf{LieGroup}^{\uparrow}$ *packet of Definition 140.33 interprets as the standard one-point Lie group. The bridge sends the carrier* L_{e} *to the singleton carrier, reads multiplication and inverse from the singleton* $\mathsf{Group}^{\uparrow}$ *rows, and reads smoothness from the singleton* $\mathsf{Manifold}^{\uparrow}$ *chart rows. It carries no non-singleton Lie theory, exponential theory, representation theory, root-system theory, or host quotient data.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton standard bridge`

Proof. The carrier bridge is the singleton carrier of Definition 140.31. Every accepted history is R_{e}-classified with e, so the target carrier has one point.

The algebraic operation bridge is supplied by Definition 140.37 and Definition 140.38. Multiplication and inverse stay in L_{e} and are classifier-equal to the singleton endpoint.

The smooth bridge is supplied by Definition 140.35. The only chart is the singleton chart, and every operation readback is the constant smooth self-overlap row. Repacking these rows gives the standard one-point Lie group interpretation and no further Lie-group structure. □

Theorem 140.51 (LieGroup singleton source lock)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *source uses the single predicate* $L_{\mathsf{e}}(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e})$ *as the* $\mathsf{Group}^{\uparrow}$ *carrier, the* $\mathsf{Manifold}^{\uparrow}$ *point and chart-domain carrier, and the* $\mathsf{LieGroup}^{\uparrow}$ *carrier. Its classifier is the same restricted* hsame *row* $R_{\mathsf{e}}(h, k)$ *from Definition 140.30; no transported second source, auxiliary carrier, or duplicate classifier is introduced.*

Proof. Unfold Definition 140.30. The displayed predicate L_{e} is the only carrier predicate named there, and the classifier is the displayed restricted row R_{e}.

Project the singleton group rows from Definition 41.4. These rows use BHist, e, append, constant inverse, and the restricted hsame classifier; their checked source is BEDC.Derived.GroupUp.GroupSingletonHistory_lav

Project the singleton chart rows from Definition 96.37. The chart domain is the same predicate $\mathsf{hsame}(h, \mathsf{e})$, the chart value is constant, and the overlap row is the singleton transition row.

Thus both projected packages identify their visible carrier with L_{e}. The $\mathsf{LieGroup}^{\uparrow}$ package is assembled by sharing that predicate and classifier rather than by transporting data across a second source. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton source lock`

Theorem 140.52 (LieGroup manifold and group anchor)**.** *The singleton* $\mathsf{LieGroup}^{\uparrow}$ *source is accepted only after the* $\mathsf{Group}^{\uparrow}$ *operation rows of chapter 41 and the* $\mathsf{Manifold}^{\uparrow}$ *chart rows of chapter 96 have been read. Its public source ledger projects the shared predicate* L_{e} *through those two dependency surfaces and exports no independent ambient smooth-group carrier.*

Proof. Begin with Definition 140.51. The carrier predicate L_{e} and the restricted classifier R_{e} are the single source used by the group carrier, manifold point and chart-domain carrier, and Lie-group carrier.

Project the $\mathsf{Group}^{\uparrow}$ rows through chapter 41. The operation, unit, inverse, and law rows are the singleton history rows named by the source-lock theorem, so the Lie-group packet cannot be accepted before those algebraic rows are visible.

Project the $\mathsf{Manifold}^{\uparrow}$ rows through chapter 96. The chart domain, chart value, and transition row are the singleton chart rows named by the same source lock, so the smooth side is read from the displayed manifold surface rather than from a separate smooth carrier.

Therefore the source ledger is a joint read of the displayed $\mathsf{Group}^{\uparrow}$ and $\mathsf{Manifold}^{\uparrow}$ dependency rows. Since every exported carrier and classifier is the shared L_{e} and R_{e} projection, no independent ambient smooth-group carrier is available to downstream consumers. □

Theorem 140.53 (LieGroup singleton exact ledger)**.** *For the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package, the accepted ledger consists exactly of* BHist, hsame, e, $\mathsf{append}/\mathsf{Cont}$, *the singleton* $\mathsf{Group}^{\uparrow}$ *laws, the singleton chart domain and chart value, and the singleton constant transition row. It excludes any standard bridge, any host smooth-manifold equality, any extra carrier, and any external topology row.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton exact ledger`

Proof. The source-lock theorem fixes the boundary of the ledger: all carrier and classifier rows are projections of the one history predicate L_{e} and the restricted hsame relation.

The algebraic entries are exactly the singleton $\mathsf{Group}^{\uparrow}$ rows. They are supplied by Definition 41.4 and BEDC.Derived.GroupUp.GroupSingletonHistory_laws, namely BHist, hsame, e, append, Cont, and the singleton group laws.

The smooth entries are exactly the singleton $\mathsf{Manifold}^{\uparrow}$ rows. They are supplied by Definition 96.37, BEDC.Derived.ManifoldUp.ManifoldSingleton_semanticNameCert, and BEDC.Derived.ManifoldUp.Manifol the singleton chart domain, constant chart value, and constant transition.

Finally, Definition 140.32 accounts for the operation rows by reading multiplication and inverse through the same singleton atlas. No cited row provides a StandardBridge, host equality of smooth manifolds, an additional carrier predicate, or an external topology, so none belongs to the accepted ledger. □

Theorem 140.54 (LieGroup singleton downstream export)**.** *The packages* $\mathsf{ExpMap}^{\uparrow}$, $\mathsf{AdjointRep}^{\uparrow}$, $\mathsf{RootSystem}^{\uparrow}$, *and representation certificates may consume the singleton* $\mathsf{LieGroup}^{\uparrow}$ *package only through the exported carrier, classifier, operation, chart, and transition rows. The singleton package makes no downstream claim of connectedness, completeness, nontrivial Lie algebra, or standard bridge.*

Proof. By Definition 140.51, every visible carrier and classifier row of the singleton $\mathsf{LieGroup}^{\uparrow}$ package is a projection of the shared history predicate L_{e} and the restricted hsame classifier. These are the only source rows a dependent certificate can name.

By Definition 140.53, the remaining visible rows are precisely the group operation rows, singleton chart rows, and singleton transition row. The NameCert surface in Definition 140.49 repacks those rows as the public obligation surface for $\mathsf{LieGroup}^{\uparrow}$.

Therefore any $\mathsf{ExpMap}^{\uparrow}$, $\mathsf{AdjointRep}^{\uparrow}$, $\mathsf{RootSystem}^{\uparrow}$, or representation certificate built over this singleton source can project only those exported rows. Since the ledger contains no connectedness, completeness, nontrivial Lie-algebra, or StandardBridge row, no downstream consumer receives such a claim from this package. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton downstream export`

Definition 140.55 (Singleton LieGroup conjugation action)**.** *On the singleton smooth group carrier Definition 140.30, define the* BHist*-valued conjugation action by*

$$\mathsf{Ad}_{\mathsf{e}}(s, x) := \mathsf{append}(\mathsf{append}(s, x), \mathsf{e}).$$

The inputs are carried histories $L_{\mathsf{e}}(s)$ *and* $L_{\mathsf{e}}(x)$*, and the terminal factor* e *is the singleton inverse row of the group carrier.*

Lean4 (definition) `BEDC.Derived.LieGroupUp.LieGroupSingletonConjugationAction`

Theorem 140.56 (LieGroup singleton conjugation carrier and smoothness)**.** *If* $L_{\mathsf{e}}(s)$ *and* $L_{\mathsf{e}}(x)$ *hold, then* $\mathsf{Ad}_{\mathsf{e}}(s, x)$ *is again carried by* L_{e}*. Moreover the singleton manifold chart reads this conjugation endpoint as the same constant smooth transition that reads multiplication and inverse in Definition 140.32.*

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation carrier and smoothness`

Proof. Unfold Definition 140.55. The endpoint is the append-composite $(s * x) * \mathsf{e}$ in the singleton group rows. Since s and x are carried, Definition 41.4 gives closure of $s*x$, and the right multiplication by e stays in the same carrier. The Lean-side row BEDC.Derived.GroupUp.GroupSingletonClassifier_conjugation_
records the same terminal collapse for the singleton classifier.

For smoothness, the carried input pair and the carried output all lie in the sole singleton chart domain. Applying Definition 96.33 reads the source and target charts as the constant value $0_{\mathsf{Real}^{\uparrow}}$, so the displayed action has the constant smooth transition row already used by the multiplication and inverse obligations. The corresponding Lean-side row is BEDC.Derived.ManifoldUp.ManifoldSingleton_transition
□

Theorem 140.57 (LieGroup singleton conjugation action law)**.** *For carried histories $L_{\mathsf{e}}(s)$, $L_{\mathsf{e}}(t)$, and $L_{\mathsf{e}}(x)$, the two iterated endpoints*

$$\mathsf{Ad}_{\mathsf{e}}(s, \mathsf{Ad}_{\mathsf{e}}(t, x))$$

and

$$\mathsf{Ad}_{\mathsf{e}}(\mathsf{append}(s, t), x)$$

are both classified by the singleton classifier R_{e}, hence represent the same carried singleton endpoint.

Proof. First unfold the action on the left. The inner endpoint is $\mathsf{append}(\mathsf{append}(t, x), \mathsf{e})$, and Definition 140.56 carries it back into L_{e}. Applying the same theorem to s and this inner endpoint therefore carries the whole left-hand endpoint.

Next unfold the action on the right. Group singleton closure carries $\mathsf{append}(s, t)$, and another application of Definition 140.56 carries $\mathsf{Ad}_{\mathsf{e}}(\mathsf{append}(s, t), x)$.

It remains to compare the classifier rows. By the singleton group classifier, every carried endpoint is hsame to e. The Cont associativity and readback rows allow the nested append words on both sides to be read as singleton terminal words, and the group singleton closure removes the terminal factor. Thus both displayed endpoints satisfy R_{e} against e, and therefore against each other by the restricted singleton classifier. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton conjugation action law`

Theorem 140.58 (LieGroup singleton AdjointRep source surface)**.** *The rows of Definition 140.55, Definition 140.56, and Definition 140.57 supply the* $\mathsf{LieGroup}^{\uparrow}$*-side source surface consumed by* $\mathsf{AdjointRep}^{\uparrow}$*: the operation* Ad_{e} *is* BHist*-valued, classifier-stable on the singleton carrier, smooth in the singleton atlas, and carries no standard bridge row.*

Proof. The definition provides the concrete BHist operation. The carrier and smoothness theorem supplies the two structural rows needed by a representation source: accepted inputs give an accepted endpoint, and the singleton atlas reads that endpoint through the constant smooth transition.

The action-law theorem supplies the compatibility row. Both iterated conjugation and conjugation by the product word land in the singleton classifier class, so $\mathsf{AdjointRep}^{\uparrow}$ can consume the action without adding a separate carrier transport or chart transition.

No standard bridge row is part of this surface. The package is only the paper-side singleton $\mathsf{LieGroup}^{\uparrow}$ action source over BHist, with the ordinary Lie-group bridge left outside the displayed rows. □

Lean4 ✓ `BEDC.Derived.LieGroupUp.LieGroupSingleton adjointrep source surface`

Theorem 140.59 (LieGroup singleton TopGroup sibling route)**.** *The singleton smooth-group package of* $\mathsf{LieGroup}^{\uparrow}$ *is readable by the* $\mathsf{TopGroup}^{\uparrow}$ *sibling surface through the same singleton* $\mathsf{Group}^{\uparrow}$ *operation rows. The product and inverse rows of Definition 140.32 land on the continuous product and inverse obligation families of chapter 204, as organized by Definition 204.18 and Definition 204.22. This route exports no non-singleton Lie theory, ambient topology beyond the displayed continuous operation rows, or* bridgeChecked *claim.*

Proof. By Definition 140.51, the $\mathsf{LieGroup}^{\uparrow}$ carrier and classifier are the singleton history predicate L_{e} and the restricted hsame row already used by the singleton $\mathsf{Group}^{\uparrow}$ package. Thus the operation side of the package exposes multiplication, inverse, and unit through the same finite group rows rather than through a separate Lie-theoretic carrier.

The smoothness obligation Definition 140.32 reads those two operation graphs through the singleton chart as constant smooth maps. The $\mathsf{TopGroup}^{\uparrow}$ chapter reads exactly the analogous public operation boundary as product-neighbourhood and inverse-neighbourhood continuity rows; its Definition 204.18 repacks carrier compatibility, product transport, and inverse transport, and Definition 204.22 exhausts the finite Cont ledger by those two operation families.

Therefore the sibling route is the common singleton $\mathsf{Group}^{\uparrow}$ operation surface together with the displayed continuity rows. The route does not add a non-singleton Lie group, external topology source, exponential or representation theory, or a verified standard bridge. □

Theorem 140.60 (LieGroupUp manifold and topological-group route)**.** *Every accepted* $\mathsf{LieGroup}^{\uparrow}$ *carrier first exposes the* $\mathsf{Manifold}^{\uparrow}$ *chart and atlas rows of chapter 96, then exposes the* $\mathsf{TopGroup}^{\uparrow}$ *multiplication and inversion continuity rows of chapter 204, before it presents the combined group-manifold* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *surface. Thus a downstream smooth-group consumer reads chart domains, chart transport, group multiplication, inverse, continuity, smoothness, replay, provenance, and local naming through the displayed sibling rows, not through an ambient manifold object or an external topological group.*

Proof. Project the accepted $\mathsf{LieGroup}^{\uparrow}$ packet to its smooth rows. The chart-domain, chart-readback, atlas-transition, and smoothness entries are exactly the $\mathsf{Manifold}^{\uparrow}$ rows already carried by the singleton source surface, so the manifold side is read before any smooth-group export is available.

Project the same packet to its group-operation rows. Multiplication, inverse, unit, and their continuity readbacks are the $\mathsf{TopGroup}^{\uparrow}$-facing rows consumed by the topological-group sibling surface.

The local $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ row packages these two routes together with the shared BHist classifier, componentwise hsame transport, displayed Cont replay, and Pkg provenance. Since the carrier contains no separate ambient manifold object or external topological group coordinate, every smooth-group read factors through the named $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{TopGroup}^{\uparrow}$ dependency rows. □

Theorem 140.61 (LieGroup group and manifold sibling route)**.** *Every accepted* $\mathsf{LieGroup}^{\uparrow}$ *carrier reads the* $\mathsf{Group}^{\uparrow}$ *multiplication, inverse, and unit rows of chapter 41 together with the* $\mathsf{Manifold}^{\uparrow}$ *chart, atlas, and transition rows of chapter 96 before exporting the smooth-group* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *surface. The exported route packages group operations, manifold chart data, smooth multiplication and inverse readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local naming; it does not add a second group carrier, a second manifold carrier, or an ambient smooth object outside the sibling rows.*

In particular, the smooth multiplication and inversion names are downstream labels: the carrier first consumes the $\mathsf{Group}^{\uparrow}$ *multiplication/inverse obligation row and the* $\mathsf{Manifold}^{\uparrow}$ *chart-*

compatibility row, and only then records their smooth compatibility inside the local $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *route.*

Proof. Project the accepted $\mathsf{LieGroup}^{\uparrow}$ carrier to its algebraic rows. The multiplication, inverse, and unit data are read as the $\mathsf{Group}^{\uparrow}$ operation surface before the smoothness rows are exported.

Project the same carrier to its geometric rows. The chart domains, atlas compatibility, and transition data are read as the $\mathsf{Manifold}^{\uparrow}$ surface before any smooth-group NameCert is formed.

The local $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ row then binds these two sibling routes with the displayed smooth multiplication and inverse readback, transport, replay, and provenance rows. Since the carrier has no independent ambient group or manifold coordinate, every exported smooth-group certificate factors through the cited $\mathsf{Group}^{\uparrow}$ and $\mathsf{Manifold}^{\uparrow}$ rows. □

Chapter 141

A Concrete Naming Certificate for $\mathsf{LieAlgebra}^{\uparrow}$

The Lie-algebra interface $\mathsf{LieAlgebra}^{\uparrow}$ packages a vector-space carrier endowed with an antisymmetric bilinear bracket satisfying the Jacobi identity. It depends on $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47), and is both the tangent-space-at-identity datum of a Lie group and the algebraic object on which root-system certificates are built.

141.1 Carrier definition

141.2 The certificate

Definition 141.1 (Lie-algebra adjoint action)**.** *Let L carry a $\mathsf{LieAlgebra}^{\uparrow}$ certificate. Write C_L for its vector carrier, $\sim_L$ for its carrier classifier, and $[-,-]_L$ for its bilinear bracket. For each carried endpoint $x : C_L$, define the adjoint action determined by x on carried endpoints by*

$$\mathrm{ad}_x^L(t) := [x, t]_L.$$

Bracket closure makes $\mathrm{ad}_x^L(t)$ carried, and bracket classifier congruence makes this a classifier-respecting endomap of the vector carrier. This is the Lie-algebra side of the ad *coordinate named in chapter 143.*

Lean4 (definition) `BEDC.Derived.LieAlgebraUp.LieAlgebraAdjointAction`
Lean4 (definition) `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjointAction`

Theorem 141.2 (Adjoint action derivation from Jacobi)**.** *Let L carry a $\mathsf{LieAlgebra}^{\uparrow}$ certificate as in chapter 141. Write $+_L$, 0_L, and $-_L$ for the additive vector-space operations inherited from chapter 47. If x, y, z are carried by C_L, then*

$$\mathrm{ad}_x^L([y, z]_L) \sim_L [\mathrm{ad}_x^L(y), z]_L +_L [y, \mathrm{ad}_x^L(z)]_L.$$

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint derivation from jacobi`

Proof. All bracketed endpoints below are carried by the bracket-closure field, and all displayed sums and negatives are carried by the vector-space reduct. Set

$$A := [x, [y, z]_L]_L, \qquad B := [[x, y]_L, z]_L, \qquad C := [y, [x, z]_L]_L.$$

The Jacobi field of the $\mathsf{LieAlgebra}^{\uparrow}$ certificate gives

$$(A +_L [y, [z, x]_L]_L) +_L [z, [x, y]_L]_L \sim_L 0_L.$$

Antisymmetry gives $[z, x]_L \sim_L -_L[x, z]_L$ and $[z, [x, y]_L]_L \sim_L -_L B$. By bracket congruence and linearity in the second argument, the first comparison transports through $[y, -]_L$ and gives

$$[y, [z, x]_L]_L \sim_L -_L C.$$

Transporting the Jacobi comparison along these two classifier equalities yields

$$(A +_L (-_L C)) +_L (-_L B) \sim_L 0_L.$$

Using associativity and commutativity of the additive vector-space law, this is the same classifier comparison as

$$A +_L (-_L(B +_L C)) \sim_L 0_L.$$

Add $B +_L C$ to both sides and use additive congruence:

$$(A +_L (-_L(B +_L C))) +_L (B +_L C) \sim_L 0_L +_L (B +_L C).$$

The additive inverse and unit laws reduce the left endpoint to A and the right endpoint to $B +_L C$, all inside the classifier $\sim_L$. Substituting the definitions of A, B, and C, and unfolding Definition 141.1, gives the displayed adjoint derivation law. □

Theorem 141.3 (Inner derivation commutator identity)**.** *Let L carry a $\mathsf{LieAlgebra}^{\uparrow}$ certificate as in chapter 141. Write $+_L$, 0_L, and $-_L$ for the additive vector-space operations inherited from chapter 47, write $\sim_L$ for the carrier classifier, and write $[-, -]_L$ for the Lie bracket. For carried endpoints x, y, z of C_L, read the bracket of adjoint endomaps pointwise as*

$$[\mathrm{ad}^L_x, \mathrm{ad}^L_y](t) := \mathrm{ad}^L_x(\mathrm{ad}^L_y(t)) +_L (-_L \mathrm{ad}^L_y(\mathrm{ad}^L_x(t))).$$

Then $[\mathrm{ad}^L_x, \mathrm{ad}^L_y](z)$ and $\mathrm{ad}^L_{[x,y]_L}(z)$ are carried by C_L, and

$$[\mathrm{ad}^L_x, \mathrm{ad}^L_y](z) \sim_L \mathrm{ad}^L_{[x,y]_L}(z).$$

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint commutator identity`

Proof. Bracket closure carries $[x, y]_L$, $\mathrm{ad}^L_y(z)$, $\mathrm{ad}^L_x(z)$, $\mathrm{ad}^L_x(\mathrm{ad}^L_y(z))$, $\mathrm{ad}^L_y(\mathrm{ad}^L_x(z))$, and $\mathrm{ad}^L_{[x,y]_L}(z)$. The additive closure and negation closure of the vector-space reduct therefore carry the displayed endomap commutator endpoint.

Set

$$P := \mathrm{ad}^L_x(\mathrm{ad}^L_y(z)), \qquad Q := \mathrm{ad}^L_y(\mathrm{ad}^L_x(z)), \qquad R := \mathrm{ad}^L_{[x,y]_L}(z).$$

Unfolding Definition 141.1, the comparison in Definition 141.2 applied to x, y, z gives

$$P \sim_L R +_L Q.$$

Add $-_L Q$ on the right by additive congruence:

$$P +_L (-_L Q) \sim_L (R +_L Q) +_L (-_L Q).$$

Associativity in the additive vector-space law rewrites the right endpoint as $R +_L (Q +_L (-_L Q))$. The inverse law and the additive unit law classify this endpoint with R. By transitivity of $\sim_L$,

$$P +_L (-_L Q) \sim_L R.$$

Substituting the definitions of P, Q, and R, and using the pointwise endomap-commutator reading above, gives the displayed identity. □

Theorem 141.4 (Adjoint action preserves vector addition)**.** *Let L carry a* $\mathsf{LieAlgebra}^{\uparrow}$ *certificate. Write C_L for its vector carrier, $\sim_L$ for its carrier classifier, $+_L$ for vector addition in the vector-space reduct, and $[-,-]_L$ for the Lie bracket. If x, y, z are carried by C_L, then $\mathrm{ad}^L_x(y +_L z)$ and $\mathrm{ad}^L_x(y) +_L \mathrm{ad}^L_x(z)$ are carried by C_L, and*

$$\mathrm{ad}^L_x(y +_L z) \sim_L \mathrm{ad}^L_x(y) +_L \mathrm{ad}^L_x(z).$$

Proof. The additive closure field of the vector-space reduct carries $y +_L z$. The bracket-closure field of the $\mathsf{LieAlgebra}^{\uparrow}$ certificate therefore carries $[x, y +_L z]_L$, and it also carries $[x, y]_L$ and $[x, z]_L$. Applying additive closure once more carries $[x, y]_L +_L [x, z]_L$.

The second-argument additivity field in the bilinear bracket, applied to the carried endpoints x, y, z, gives

$$[x, y +_L z]_L \sim_L [x, y]_L +_L [x, z]_L.$$

Unfolding the adjoint action from Definition 141.1 on the three bracket endpoints identifies this comparison with the displayed adjoint additive-linearity law, and the closure statements above identify both sides as carried endpoints of C_L. □

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint additive linearity`

Theorem 141.5 (Adjoint action preserves scalar multiplication)**.** *Let L carry a* $\mathsf{LieAlgebra}^{\uparrow}$ *certificate. Write S_L for its scalar-field carrier, C_L for its vector carrier, $\sim_L$ for its vector carrier classifier, $\odot_L$ for the scalar action in the vector-space reduct, and $[-,-]_L$ for the Lie bracket. If r is carried by S_L and x, y are carried by C_L, then $\mathrm{ad}^L_x(r \odot_L y)$ and $r \odot_L \mathrm{ad}^L_x(y)$ are carried by C_L, and*

$$\mathrm{ad}^L_x(r \odot_L y) \sim_L r \odot_L \mathrm{ad}^L_x(y).$$

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint scalar linearity`

Proof. Scalar-action closure in the $\mathsf{VecSpace}^{\uparrow}$ reduct carries $r \odot_L y$. Bracket closure in the $\mathsf{LieAlgebra}^{\uparrow}$ certificate therefore carries $[x, r \odot_L y]_L$. The same bracket-closure field carries $[x, y]_L$, and scalar-action closure carries $r \odot_L [x, y]_L$.

The second-argument scalar-linearity field in the bilinear bracket, applied to the carried scalar endpoint r and carried vector endpoints x, y, gives

$$[x, r \odot_L y]_L \sim_L r \odot_L [x, y]_L.$$

Unfolding the adjoint action from Definition 141.1 on both bracket endpoints identifies this comparison with the displayed scalar-linearity law for ad^L_x, and the closure statements above identify both sides as carried endpoints of C_L. □

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint scalar endpoint closure`

Theorem 141.6 (Adjoint action acting-endpoint scalar linearity)**.** *Let L carry a* $\mathsf{LieAlgebra}^{\uparrow}$ *certificate. Write S_L for its scalar-field carrier, C_L for its vector carrier, $\sim_L$ for its vector carrier classifier, $\odot_L$ for the scalar action in the vector-space reduct, and $[-,-]_L$ for the Lie bracket. If r is carried by S_L and x, y are carried by C_L, then $\mathrm{ad}^L_{r \odot_L x}(y)$ and $r \odot_L \mathrm{ad}^L_x(y)$ are carried by C_L, and*

$$\mathrm{ad}^L_{r \odot_L x}(y) \sim_L r \odot_L \mathrm{ad}^L_x(y).$$

Proof. Scalar-action closure in the $\mathsf{VecSpace}^{\uparrow}$ reduct carries $r \odot_L x$. Bracket closure in the $\mathsf{LieAlgebra}^{\uparrow}$ certificate therefore carries $[r \odot_L x, y]_L$. The same bracket-closure field carries $[x, y]_L$, and scalar-action closure carries $r \odot_L [x, y]_L$.

The first-argument scalar-linearity field in the bilinear bracket, applied to the carried scalar endpoint r and carried vector endpoints x, y, gives

$$[r \odot_L x, y]_L \sim_L r \odot_L [x, y]_L.$$

Unfolding the adjoint action from Definition 141.1 on both bracket endpoints identifies this comparison with the displayed scalar-linearity law for the acting endpoint of ad^L, and the closure statements above identify both sides as carried endpoints of C_L. □

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint acting endpoint scalar linearity`

Theorem 141.7 (Lie-algebra adjoint LinearMap endomap package)**.** *Let L carry a $\mathsf{LieAlgebra}^{\uparrow}$ certificate. Write F_L for the scalar field of its vector-space reduct, $F_{L,\mathsf{Ring}}$ for the ring reduct of that scalar field, C_L for the vector carrier, $\sim_L$ for the vector classifier, $+_L$ and 0_L for vector addition and zero, $\odot_L$ for scalar action, and $[-,-]_L$ for the Lie bracket. If x is carried by C_L, define the endomap identifier*

$$\mathsf{adEnd}^L_x(t) := \mathrm{ad}^L_x(t) = [x, t]_L.$$

Then adEnd^L_x carries the $\mathsf{LinMap}^{\uparrow}$ endomap package on the vector carrier. Equivalently, after the vector-space reduct is read through Definition 47.24,

$$\mathsf{LinearMapCert}_{F_{L,\mathsf{Ring}}}(C_L, C_L; \mathsf{adEnd}^L_x)$$

holds.

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint endomap package`

Proof. The $\mathsf{LieAlgebra}^{\uparrow}$ certificate contains a $\mathsf{VecSpace}^{\uparrow}(F_L, C_L)$ reduct. By Definition 47.24, deleting only the inverse-indexed field rows gives a $\mathsf{Module}^{\uparrow}(F_{L,\mathsf{Ring}}, C_L)$ certificate with the same vector carrier, classifier, vector addition, zero, scalar action, and non-inverse ledgers. These are the source and target module carriers used by Definition 48.59.

For output closure, let t be carried by C_L. Bracket closure in the $\mathsf{LieAlgebra}^{\uparrow}$ certificate carries $[x, t]_L$, so $\mathsf{adEnd}^L_x(t)$ is carried by C_L.

For source-classifier descent, assume $t \sim_L u$ between carried vector endpoints. Classifier reflexivity gives $x \sim_L x$, and the bracket classifier-congruence row cited in Definition 141.1 transports these two comparisons to

$$[x, t]_L \sim_L [x, u]_L.$$

Unfolding the endomap identifier gives

$$\mathsf{adEnd}^L_x(t) \sim_L \mathsf{adEnd}^L_x(u).$$

For additivity, Definition 141.4 gives, for carried $y, z : C_L$,

$$\mathsf{adEnd}^L_x(y +_L z) \sim_L \mathsf{adEnd}^L_x(y) +_L \mathsf{adEnd}^L_x(z).$$

For scalar compatibility, Definition 141.5 gives, for each carried scalar $r : F_L$ and carried $y : C_L$,

$$\mathsf{adEnd}^L_x(r \odot_L y) \sim_L r \odot_L \mathsf{adEnd}^L_x(y).$$

The scalar carrier and scalar action are unchanged by the ring reduct, so this is exactly the scalar row required over $F_{L,\mathsf{Ring}}$.

It remains to record the zero row. The vector-space additive unit law gives

$$0_L +_L 0_L \sim_L 0_L.$$

The descent row just proved transports this comparison through adEnd_x^L, and the additive row at $0_L, 0_L$ gives

$$\mathsf{adEnd}_x^L(0_L) \sim_L \mathsf{adEnd}_x^L(0_L) +_L \mathsf{adEnd}_x^L(0_L).$$

By Definition 47.25, the additive vector carrier of C_L is an $\mathsf{AbGroup}^\uparrow$ certificate with the same $+_L$, 0_L, and $\sim_L$. Applying Definition 48.56 to $w = \mathsf{adEnd}_x^L(0_L)$ yields

$$\mathsf{adEnd}_x^L(0_L) \sim_L 0_L.$$

Thus output closure, source-classifier descent, additive preservation, scalar compatibility, zero preservation, and ledger data are all available: the ledger records the identifier adEnd_x^L, the fixed carried input x, the bracket-closure and bracket-congruence witnesses, and the two second-argument bilinearity rows. By Definition 48.59, these rows form $\mathsf{LinearMapCert}_{F_{L,\mathsf{Ring}}}(C_L, C_L; \mathsf{adEnd}_x^L)$. Since Definition 48.47, Definition 48.48, Definition 48.49, Definition 48.50, and Definition 48.52 read the vector-space endomap package as precisely this function-with-law formation over a common scalar source, the same rows carry the $\mathsf{LinMap}^\uparrow$ endomap package on C_L. □

Theorem 141.8 (Adjoint action acting-endpoint additive linearity)**.** *Let L carry a $\mathsf{LieAlgebra}^\uparrow$ certificate. Write C_L for its vector carrier, $\sim_L$ for its vector carrier classifier, $+_L$ for vector addition in the vector-space reduct, and $[-,-]_L$ for the Lie bracket. If x, z, y are carried by C_L, then $\mathrm{ad}^L_{x+_L z}(y)$ and $\mathrm{ad}^L_x(y) +_L \mathrm{ad}^L_z(y)$ are carried by C_L, and*

$$\mathrm{ad}^L_{x+_L z}(y) \sim_L \mathrm{ad}^L_x(y) +_L \mathrm{ad}^L_z(y).$$

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint acting endpoint additive linearity`

Proof. The additive vector law retained in the $\mathsf{VecSpace}^\uparrow$ reduct, read through Definition 47.19 and Definition 46.18, carries $x +_L z$. Bracket closure in the $\mathsf{LieAlgebra}^\uparrow$ certificate therefore carries $[x +_L z, y]_L$. The same bracket-closure row carries $[x, y]_L$ and $[z, y]_L$, and additive vector closure carries $[x, y]_L +_L [z, y]_L$.

The first-input additivity row of the bilinear bracket, applied to the carried endpoints x, z, y, gives

$$[x +_L z, y]_L \sim_L [x, y]_L +_L [z, y]_L.$$

Unfolding the adjoint action from Definition 141.1 at the three bracket endpoints turns this comparison into the displayed acting-endpoint additive-linearity law, and the carrier statements above identify both sides as endpoints carried by C_L. □

Theorem 141.9 (Lie bracket left-zero annihilation)**.** *Let L carry a $\mathsf{LieAlgebra}^\uparrow$ certificate. Write C_L for its vector carrier, $\sim_L$ for its vector classifier, $+_L$ and 0_L for vector addition and zero in the vector-space reduct, and $[-,-]_L$ for the Lie bracket. If x is carried by C_L, then $[0_L, x]_L$ is carried by C_L and*

$$[0_L, x]_L \sim_L 0_L.$$

The right-zero endpoint is carried and classified with zero as well:

$$[x, 0_L]_L \sim_L 0_L.$$

Lean4 ✓ `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonBracket left zero annihilation`

Proof. The $\mathsf{LieAlgebra}^{\uparrow}$ certificate contains a $\mathsf{VecSpace}^{\uparrow}$ reduct on C_L. Its zero-closure row carries 0_L, its additive closure row carries $0_L +_L 0_L$, and its additive unit law gives

$$0_L +_L 0_L \sim_L 0_L.$$

Bracket closure therefore carries $[0_L, x]_L$ and $[x, 0_L]_L$. By Definition 47.25, the additive vector carrier of C_L is an $\mathsf{AbGroup}^{\uparrow}$ certificate with the same $+_L$, 0_L, and $\sim_L$.

Set $a := [0_L, x]_L$. Apply Definition 141.8 with acting endpoints 0_L and 0_L and target endpoint x. After unfolding Definition 141.1, this gives

$$[0_L +_L 0_L, x]_L \sim_L a +_L a.$$

The bracket classifier-congruence row, applied to $0_L +_L 0_L \sim_L 0_L$ and classifier reflexivity for the carried endpoint x, gives

$$[0_L +_L 0_L, x]_L \sim_L a.$$

Classifier symmetry from Definition 9.7 and transitivity from Definition 9.8 compose the last two comparisons into

$$a \sim_L a +_L a.$$

Since a is carried, Definition 48.56 applied in the additive vector carrier yields

$$[0_L, x]_L = a \sim_L 0_L.$$

Set $b := [x, 0_L]_L$. Apply Definition 141.4 with fixed acting endpoint x and target endpoints 0_L and 0_L. Unfolding Definition 141.1 gives

$$[x, 0_L +_L 0_L]_L \sim_L b +_L b.$$

Bracket classifier congruence, using classifier reflexivity for x and the additive unit comparison $0_L +_L 0_L \sim_L 0_L$, gives

$$[x, 0_L +_L 0_L]_L \sim_L b.$$

Again symmetry and transitivity give $b \sim_L b +_L b$, and duplicate cancellation in the same $\mathsf{AbGroup}^{\uparrow}$ reduct gives

$$[x, 0_L]_L = b \sim_L 0_L.$$

□

Closure status for $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$.

Constructive story: A Lie algebra is accepted by first taking the certified $\mathsf{VecSpace}^{\uparrow}$ carrier, then attaching a bilinear antisymmetric bracket whose outputs remain in that same vector carrier and whose Jacobi row can be read by the classifier. Two algebra packets classify together when the vector endpoints are classified by the $\mathsf{VecSpace}^{\uparrow}$ reduct and every bracket, additive, scalar, and adjoint-endomap endpoint transports through that same carrier classifier. The source covers carried vector endpoints with bracket rows, the pattern records closure, bilinearity, antisymmetry, Jacobi, zero-bracket annihilation, and the inner derivation identities, while the ledger keeps the bracket provenance and the $\mathsf{LinMap}^{\uparrow}$ adjoint-endomap package visible to downstream consumers. The carrier is inhabited by the zero vector row, and the five certificate obligations follow because the vector classifier is reflexive, symmetric, transitive, and stable under addition, scalar action, bracket formation, and transported bracket endpoints. A history h lies in the signature gap of a $\mathsf{LieAlgebra}^{\uparrow}$ token p when the source accepts the vector-plus-bracket packet for h, the signature relation pairs it with an answer algebra packet and evidence ledger, and token introduction names that answer as p; unfolded, the vector carrier, bracket endpoint, Jacobi-derived adjoint action, and linear endomap rows match the data encoded by p. The paper bridge exposes these rows to adjoint-representation and root-system consumers, but it does not supply a Lie-group integration bridge or

classification theorem. The chapter registers this bracket-on-vector-carrier construction under the name LieAlgebra$^{\uparrow}$; no ambient algebra object, hidden tangent space, or external Lie-theoretic classification is assumed.

Theory closure: TheoryGate(NameCert$_{\mathsf{LieAlgebra}\uparrow}$, maturePackageClosed)

Scope closed: The mature package surface is bound to bracket closure, the VecSpace$^{\uparrow}$ reduct, the adjoint-endomap LinMap$^{\uparrow}$ package, inner derivation identities, zero-bracket annihilation, and the downstream bridge consumers exposed by the chapter.

Formal verification: FormalStatus(NameCert$_{\mathsf{LieAlgebra}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.LieAlgebraUp.LieAlgebraSingletonAdjoint\_endomap\_package`

Bridge status: paperBridge

Not claimed: It does not claim a LieGroup$^{\uparrow}$ bridge, a RootSystem$^{\uparrow}$ bridge, or downstream Lie-theoretic classification.

Upgrade path: Bridge-checked closure requires a checked standard bridge from the mature Lie-algebra package inventory to its downstream bridge consumers.

Chapter 142

A Concrete Naming Certificate for $\mathsf{ExpMap}^{\uparrow}$

The exponential-map interface $\mathsf{ExpMap}^{\uparrow}$ packages the canonical map $\mathfrak{g} \to G$ from the Lie algebra to the Lie group of a connected Lie-group carrier. It depends on $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140) and $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ (chapter 141).

142.1 Carrier definition

Definition 142.1 (Certified exponential-map interface carrier)**.** *A certified* $\mathsf{ExpMap}^{\uparrow}$ *interface carrier is a tuple*

$$\mathcal{E} = (\mathcal{G}, \mathcal{L}, \tau, \gamma, \phi, \eta_{\mathcal{G}}, \eta_{\mathcal{L}})$$

where $\mathcal{G}$ *is a* $\mathsf{LieGroup}^{\uparrow}$ *source certificate,* $\mathcal{L}$ *is a* $\mathsf{LieAlgebra}^{\uparrow}$ *source certificate,* $\tau : \mathsf{BHist}$ *is the tangent input row,* $\gamma : \mathsf{BHist}$ *is the group endpoint row,* ϕ *is a local-flow witness from* τ *to* γ*, and* $\eta_{\mathcal{G}}$ *and* $\eta_{\mathcal{L}}$ *are the corresponding* NameCert *source witnesses. The interface classifier is the restricted* hsame *relation on the tangent, endpoint, and local-flow rows. The carrier is accepted exactly when these rows are scoped through the two source* NameCert *witnesses and the local-flow witness records the exponential endpoint determined by the tangent history.*

Lean4 (definition) `BEDC.Derived.ExpMapUp.ExpMapCertifiedInterfaceCarrier`

Theorem 142.2 (ExpMap carrier obligation surface)**.** *The* $\mathsf{ExpMap}^{\uparrow}$ *carrier is the* BHist *graph package whose source projection is licensed by the* $\mathsf{LieAlgebra}^{\uparrow}$ *tangent carrier and whose target projection is licensed by the* $\mathsf{LieGroup}^{\uparrow}$ *carrier. A carried row consists of a source tangent row* x*, a target group row* g*, and a displayed finite BEDC flow ledger connecting them through* Cont *and* hsame *rows. The graph row is generated only by that finite ledger; it does not assert equality of host functions, analytic exponentials, or ambient manifold maps.*

Its ten-field fit is: traditional target the exponential graph $\mathfrak{g} \to G$*; BEDC source the paired* $\mathsf{LieAlgebra}^{\uparrow}/\mathsf{LieGroup}^{\uparrow}$ *certificates; carrier the* BHist *graph package; classifier the componentwise source-target classifier with ledger transport; stability the transport fields supplied by the two dependencies together with* hsame *on the ledger; ledger the finite* Cont *flow display; core theorem list this carrier surface, classifier stability, and zero-flow composition; exactness the assertion that every public row is one such graph package; standard bridge none; status proof target for the* $\mathsf{NameCert}_{\mathsf{ExpMap}^{\uparrow}}$ *obligation surface.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapGraphCarrier obligation surface`

↪ variant `BEDC.Derived.ExpMapUp.ExpMapFlowLedger carrier obligation surface`

↪ variant `BEDC.Derived.ExpMapUp.ExpMapCarrier obligation surface`

Proof. Project the $\mathsf{LieAlgebra}^{\uparrow}$ NameCert surface to obtain the admissible tangent-source rows, and project the $\mathsf{LieGroup}^{\uparrow}$ NameCert surface to obtain the admissible target group rows. These two projections give the endpoints of the graph package without mentioning a host-level function.

Unfold the graph package as a source row, a target row, and a finite ledger of Cont steps with hsame endpoint transport. The displayed ledger is then recorded as the hidden data in the per-object certificate template, so every carried $\mathsf{ExpMap}^{\uparrow}$ row is generated by BEDC rows alone. □

Theorem 142.3 (ExpMap classifier stability obligation surface)**.** *Two* $\mathsf{ExpMap}^{\uparrow}$ *graph rows are classified exactly by agreement of their* $\mathsf{LieAlgebra}^{\uparrow}$ *source classifiers, agreement of their* $\mathsf{LieGroup}^{\uparrow}$ *target classifiers, and* hsame *transport of the displayed finite flow ledger. The classifier is reflexive, symmetric, transitive, and carrier-transporting by the corresponding source certificate field, target certificate field, and* hsame *transport field.*

Its ten-field fit is: traditional target graph equality for the exponential map; BEDC source the source classifier, target classifier, and finite ledger classifier; carrier the graph package of Definition 142.2; classifier the three-part relation just displayed; stability componentwise transport for source, target, and ledger rows; ledger the transported finite flow display; core theorem list the carrier surface and this stability surface; exactness public graph classification by the three visible components; standard bridge none; status proof target for classifier stability in $\mathsf{NameCert}_{\mathsf{ExpMap}^{\uparrow}}$.

Proof. Apply the classifier fields from the $\mathsf{LieAlgebra}^{\uparrow}$ and $\mathsf{LieGroup}^{\uparrow}$ dependency certificates componentwise. Reflexivity, symmetry, transitivity, and carrier transport for the source and target projections are inherited from those two fields.

For the ledger component, use hsame reflexivity for the unchanged ledger, hsame symmetry to reverse a displayed transport, and hsame transitivity to concatenate transports. Repacking the three transported components gives exactly the graph-row classifier and its carrier-transport clause. □

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapClassifier stability obligation surface`

Theorem 142.4 (ExpMap zero and flow-composition obligation surface)**.** *The zero-tangent row of the* $\mathsf{LieAlgebra}^{\uparrow}$ *source maps to the identity row of the* $\mathsf{LieGroup}^{\uparrow}$ *target, and composable finite* $\mathsf{ExpMap}^{\uparrow}$ *flow rows compose by* Cont *associativity up to* hsame*. The ledger provenance for the composed row is restricted to the zero row, the two displayed flow rows, and the* Cont *associativity witness; no host flow equation or analytic uniqueness principle is part of the obligation.*

Its ten-field fit is: traditional target zero-to-identity and exponential-flow composition; BEDC source the $\mathsf{LieAlgebra}^{\uparrow}$ *zero row, the* $\mathsf{LieGroup}^{\uparrow}$ *identity row, and finite* Cont *ledgers; carrier the graph package of Definition 142.2; classifier the stability surface of Definition 142.3; stability* hsame *transport for zero, identity, and composed ledgers; ledger the empty ledger and the two composable finite ledgers; core theorem list zero, unit, and associativity rows; exactness every composed public row has precisely that provenance; standard bridge none; status proof target for zero and local-flow compatibility in* $\mathsf{NameCert}_{\mathsf{ExpMap}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapGraphCarrier zero flow composition obligation`

↪ variant `BEDC.Derived.ExpMapUp.ExpMapFlowLedger zero flow composition obligations`

↪ variant `BEDC.Derived.ExpMapUp.ExpMapZeroFlow obligation surface`

Proof. Represent the zero tangent by the empty finite flow ledger. Reading this ledger through cont_left_unit and cont_right_unit identifies its target endpoint with the LieGroup$^{\uparrow}$ identity row up to hsame.

For two composable flow rows, concatenate their finite Cont ledgers. The associativity witness cont_assoc_hsame transports the concatenated display to the carried graph row, and the classifier stability surface transports the source and target endpoints along with it. Thus the composed row has exactly the displayed ledger provenance. □

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapZeroFlow composition obligation`
Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapFlowLedger zero composition obligation`

142.2 The certificate

Theorem 142.5 (Exponential-map carrier source obligations)**.** *Every certified* ExpMap$^{\uparrow}$ *interface carrier in Definition 142.1 projects the* LieGroup$^{\uparrow}$ *source row, the* LieAlgebra$^{\uparrow}$ *source row, the tangent* BHist *row, and the group-endpoint* BHist *row required by the exponential-map certificate.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapCarrier source obligations`

Proof. Unpack the carrier tuple. The first two components are already the source certificates for LieGroup$^{\uparrow}$ and LieAlgebra$^{\uparrow}$, and the last two source witnesses are the named NameCert scopes for those components.

The tangent and endpoint rows are the third and fourth components of the same tuple. Since the carrier definition accepts the tuple only when these histories are scoped through the source witnesses, projecting them gives exactly the four required rows: group source, algebra source, tangent input, and group endpoint. □

Theorem 142.6 (Exponential-map classifier stability obligations)**.** *For the certified* ExpMap$^{\uparrow}$ *carrier, the restricted* hsame *classifier on tangent, endpoint, and local-flow rows has reflexivity, symmetry, transitivity, and carrier transport obligations supplied by* hsame *and by the two source* NameCert *certificates.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapClassifier stability obligations`
Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapGraphCarrier hsame transport`
↪ variant `BEDC.Derived.ExpMapUp.ExpMapGraphCarrier classifier transport`

Proof. Reflexivity, symmetry, and transitivity are the corresponding structural clauses of hsame restricted to the rows named in Definition 142.1. The restriction does not change the witnesses; it only records that their endpoints are tangent, endpoint, or local-flow rows of the same carrier.

Carrier transport uses the two source certificates. Transport across the LieAlgebra$^{\uparrow}$ source keeps tangent histories in the accepted algebra row, and transport across the LieGroup$^{\uparrow}$ source keeps endpoint histories in the accepted group row. The local-flow component is transported by applying these two transports to its source and target histories and retaining the same hsame comparison as the interface classifier witness. □

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapGraphClassifier stability obligations`

Theorem 142.7 (Exponential-map flow and zero obligations)**.** *The certified* ExpMap$^{\uparrow}$ *carrier has two flow obligations: the zero tangent history is classified with the identity group endpoint, and* Cont*-composition of local-flow histories is compatible with the exponential endpoint classifier.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapFlowAndZero obligations`

Proof. The zero tangent obligation is the local-flow row whose input is the zero row of the $\mathsf{LieAlgebra}^{\uparrow}$ source certificate. Its endpoint is the identity row of the $\mathsf{LieGroup}^{\uparrow}$ source certificate, and the accepted local-flow witness records the hsame comparison between this endpoint and the carried group endpoint.

For composition, take two compatible local-flow witnesses whose middle endpoint rows are hsame-classified. The Cont row composes the two histories, the $\mathsf{LieGroup}^{\uparrow}$ source certificate transports the composed endpoint through the middle comparison, and the $\mathsf{LieAlgebra}^{\uparrow}$ source certificate transports the tangent input row along the algebra classifier. The resulting composed local-flow witness has the same source and target rows required by the exponential endpoint classifier. □

Theorem 142.8 (Exponential-map ledger and dependency obligations)**.** *The certified* $\mathsf{ExpMap}^{\uparrow}$ *obligation ledger contains exactly the* $\mathsf{LieGroup}^{\uparrow}$ *source, the* $\mathsf{LieAlgebra}^{\uparrow}$ *source, the tangent* BHist *row, the endpoint* BHist *row, the restricted* hsame *classifier rows, the* Cont *local-flow composition rows, and the two source* NameCert *witnesses.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapLedger dependency obligations`
Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapFlowLedger dependency exactness`

Proof. Soundness is by reading each accepted ledger row from the carrier tuple or from the source certificate named in the tuple. No further row is needed to state the exponential-map obligations: the carrier projections give the sources and histories, hsame gives the classifier witnesses, Cont gives composition of local-flow histories, and the two NameCert witnesses scope all source transport.

Exactness is the reverse reading. Any row accepted by the $\mathsf{ExpMap}^{\uparrow}$ ledger must be one of the rows listed in the definition of the certified carrier or one of the structural rows named by its source certificates. Therefore the dependency surface is exactly $\mathsf{LieGroup}^{\uparrow}$, $\mathsf{LieAlgebra}^{\uparrow}$, BHist, hsame, Cont, and NameCert, with no additional bridge or Lean verification target claimed here. □

Theorem 142.9 (ExpMap standard-flow bridge surface)**.** *The public* $\mathsf{ExpMap}^{\uparrow}$ *graph package over* BHist *has a standard-flow bridge whose source rows are exactly the* $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ *row, the* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *row, the tangent row, the endpoint row, the finite* Cont *flow ledger, and the componentwise* hsame *classifier. Its exported standard reading is the finite graph of the exponential-flow interface, not a host analytic exponential map.*

Lean4 ✓ `BEDC.Derived.ExpMapUp.ExpMapUp StdBridge`

Proof. Start with Definition 142.2. It identifies the carrier as a BHist graph package with a $\mathsf{LieAlgebra}^{\uparrow}$ tangent source, a $\mathsf{LieGroup}^{\uparrow}$ endpoint target, and a finite BEDC flow ledger.

Use Definition 142.3 to transport the source row, target row, and ledger componentwise. This gives exactly the hsame classifier row required by the standard-flow reading.

Next apply Definition 142.4. The zero and composition rows show that the displayed graph behaves as a finite flow interface under Cont composition, with no appeal to host uniqueness of analytic flows.

Finally project the dependency rows through Definition 142.8. The ledger names precisely $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, the tangent row, the endpoint row, finite Cont, and componentwise hsame. Repacking these projections gives the standard-flow bridge surface, and its standard reading is only the finite graph carried by the same tuple. □

Closure status for $\mathsf{NameCert}_{\mathsf{ExpMap}^\uparrow}$**.**

Constructive story: An exponential-map row is generated as a graph packet over the two dependency certificates: a $\mathsf{LieAlgebra}^\uparrow$ tangent-source history, a $\mathsf{LieGroup}^\uparrow$ target history, and a finite local-flow ledger connecting them through Cont and hsame. A packet is accepted only when both endpoints are licensed by those source certificates and the flow witness is part of the displayed history data; two packets classify together componentwise by the algebra source classifier, the group target classifier, and transport of the finite flow ledger. The source covers exactly these tangent–group graph packages, the pattern records zero tangent to identity, composable flow rows, and graph stability, and the ledger keeps the two dependency certificates, tangent row, endpoint row, finite continuation route, and componentwise history-sameness visible. Nonemptiness is supplied by the zero-flow graph, while reflexivity, symmetry, transitivity, and carrier closure are inherited from the two source classifiers together with hsame transport and Cont associativity of displayed flow rows. A history h lies in the signature gap of an $\mathsf{ExpMap}^\uparrow$ token p when the source accepts a graph packet for h, the signature relation pairs it with an answer graph and evidence ledger, and token introduction names that answer as p; unfolded, the tangent input, group endpoint, and finite flow route are exactly the graph encoded by p. The paper bridge reads the package as the standard finite-flow graph surface from $\mathfrak{g}$ to G, but only through the same dependency, source, target, and ledger rows. The chapter registers this finite-flow graph construction under the name $\mathsf{ExpMap}^\uparrow$; analytic exponential uniqueness and host-level smooth map equality are not assumed.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ExpMap}^\uparrow}$, maturePackageClosed)

Scope closed: The bridged paper boundary is exactly the carrier graph package, componentwise classifier, zero/flow composition row, ledger/dependency surface, and standard-flow bridge witness over $\mathsf{LieGroup}^\uparrow$, $\mathsf{LieAlgebra}^\uparrow$, BHist, hsame, Cont, and NameCert in Definition 142.2, Definition 142.3, Definition 142.4, Definition 142.8, and Definition 142.9.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ExpMap}^\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.ExpMapUp.ExpMapLedger\_dependency\_obligations`

Bridge status: bridgeChecked

Not claimed: This chapter does not claim analytic exponential uniqueness or host-level smooth map equality for $\mathsf{ExpMap}^\uparrow$.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 143

A Concrete Naming Certificate for $\mathsf{AdjointRep}^{\uparrow}$

The adjoint-representation interface $\mathsf{AdjointRep}^{\uparrow}$ packages the conjugation action $\mathrm{Ad}\colon G \to \mathrm{Aut}(\mathfrak{g})$ together with its differential ad. It depends on $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140) and $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ (chapter 141).

143.1 The certificate

Theorem 143.1 (AdjointRep dependency source obligation)**.** *The dependency source for* $\mathsf{AdjointRep}^{\uparrow}$ *is exactly the displayed* $\mathsf{LieGroup}^{\uparrow}$ *surface of chapter 140 together with the displayed* $\mathsf{LieAlgebra}^{\uparrow}$ *surface of chapter 141. Every* $\mathsf{AdjointRep}^{\uparrow}$ *row is read from these two* NameCert *sources: the group source supplies the carrier, classifier, identity, multiplication, inverse, and conjugation surface, while the algebra source supplies the carrier, classifier, bracket, and adjoint endomap surface.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepDependencySource obligation`

Proof. Unpack the $\mathsf{AdjointRep}^{\uparrow}$ interface as a dependent certificate over the two cited public surfaces. No third ambient carrier is named in the chapter, and no host equality is used to identify the two dependency rows.

The BEDC package discipline therefore fixes the source boundary before the action rows are interpreted. The group side contributes only $\mathsf{LieGroup}^{\uparrow}$-classified histories, and the algebra side contributes only $\mathsf{LieAlgebra}^{\uparrow}$-classified histories.

Thus every subsequent Ad, ad, transport, stability, and target row has these two sources as its complete input surface. □

Theorem 143.2 (AdjointRep conjugation carrier obligation)**.** *The* Ad *row is carried by the* $\mathsf{LieGroup}^{\uparrow}$ *singleton conjugation carrier. For each accepted group history and accepted algebra history, the conjugation endpoint remains a* BHist *action endpoint rather than a host function outside the BEDC ledger.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepConjugation carrier obligation`

Proof. Start with the $\mathsf{LieGroup}^{\uparrow}$ source surface fixed by Definition 143.1. Its singleton carrier already contains the conjugation source row and the classifier that licenses group histories.

Feed an accepted algebra history from the $\mathsf{LieAlgebra}^{\uparrow}$ source into that row. The result is recorded as a BEDC history endpoint, so the visible action does not leave the BHist carrier.

The obligation is exactly this carrier check: Ad must be displayed as an action endpoint in the ledger, with all representative choices hidden behind hsame transport. □

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepConjugationCarrier obligation`

Theorem 143.3 (AdjointRep differential action obligation)**.** *The* ad *row is the* LieAlgebra$^{\uparrow}$ *adjoint endomap package generated by the bracket. Its input and output endpoints are classified by the* LieAlgebra$^{\uparrow}$ *surface, and the row is not a separate derivative object over an unlicensed tangent carrier.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepDifferentialAction obligation`

Proof. Use the LieAlgebra$^{\uparrow}$ dependency named in Definition 143.1. That source already exposes the bracket classifier and the adjoint endomap package used by the algebra carrier.

Reading the differential at the identity group endpoint can therefore only select the displayed adjoint endomap row. It does not create a second tangent carrier, because the source package has no public row for one.

The certificate obligation is to keep ad attached to this bracket endomap package and to record its endpoints through the same BHist and hsame classifier discipline as the algebra source. □

Theorem 143.4 (AdjointRep automorphism target obligation)**.** *The target row for* Ad *is an automorphism-style carrier over the* LieAlgebra$^{\uparrow}$ *classifier. Its inverse and composition data are read from the* LieGroup$^{\uparrow}$ *inverse and multiplication rows together with the* LieAlgebra$^{\uparrow}$ *endomap rows.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepAutomorphism target obligation`

Proof. Apply the conjugation carrier obligation to obtain the visible Ad endpoint. Apply the group inverse and multiplication rows from LieGroup$^{\uparrow}$ to read inverse and composite group histories inside the same classifier boundary.

Next use the LieAlgebra$^{\uparrow}$ endomap package. It supplies the target classifier over which composition of algebra endpoints is interpreted.

The automorphism-style row is then a repacking of these two source surfaces: group inverse gives the inverse action endpoint, group multiplication gives composition of action endpoints, and algebra endomaps keep the target over the Lie-algebra classifier. □

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepAutomorphismTarget obligation`

Theorem 143.5 (AdjointRep classifier stability obligation)**.** *Transported* LieGroup$^{\uparrow}$ *and* LieAlgebra$^{\uparrow}$ *inputs preserve the displayed* Ad *and* ad *endpoints through* hsame*,* Cont*, and NameCert classifier transport. Consequently the action row, differential row, and automorphism-target row are stable under the two source classifiers.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepSingleton classifier stability obligation`
↪ variant `BEDC.Derived.AdjointRepUp.AdjointRepClassifier stability obligation`

Proof. First transport the group input along the LieGroup$^{\uparrow}$ classifier and hsame. The conjugation carrier obligation reads the resulting Ad endpoint from the same singleton action row, so the endpoint is unchanged up to the displayed BEDC classifier.

Next transport the algebra input along the LieAlgebra$^{\uparrow}$ classifier, hsame, and the continuation ledger Cont. The differential action obligation keeps ad inside the bracket endomap package, and the automorphism target obligation keeps Ad inside the algebra endomap target.

These two transports are the whole stability check. No row is stabilized by host equality; every preserved endpoint is read through the two NameCert classifiers and the BEDC continuation relation. □

Closure status for $\mathsf{NameCert}_{\mathsf{AdjointRep}^\uparrow}$.

Constructive story: An adjoint-representation row is generated only after the $\mathsf{LieGroup}^\uparrow$ and $\mathsf{LieAlgebra}^\uparrow$ sources are fixed: the group side supplies carrier, multiplication, inverse, and conjugation rows, while the algebra side supplies the bracket carrier, classifier, and adjoint endomap package. A displayed Ad endpoint is accepted when conjugation sends a carried group history and carried algebra history to a BHist action endpoint, and the ad endpoint is accepted when it is the bracket-generated adjoint endomap already present in the Lie-algebra package. Two accepted rows classify together by transporting the group input, algebra input, action endpoint, differential endpoint, and automorphism target through the two source classifiers, hsame, and the visible Cont ledger. The source covers exactly the two dependency surfaces, the pattern records conjugation carrier, differential action, automorphism target, and classifier stability, and the ledger keeps the group, algebra, action, differential, inverse, composition, and source-provenance rows aligned. The five naming-certificate obligations are inherited from the two dependencies plus the stability theorem: accepted source rows inhabit the carrier, classifier reflexivity, symmetry, and transitivity are componentwise, and transported endpoints remain within the displayed action and endomap packages. A history h lies in the signature gap of an $\mathsf{AdjointRep}^\uparrow$ token p when the source accepts its dependency/action packet, the signature relation pairs it with an answer representation row and evidence ledger, and token introduction names that answer as p; unfolded, h carries the same Ad, ad, automorphism-target, and classifier-stability rows encoded by p. The chapter registers this dependency-driven conjugation-and-differential construction under the name $\mathsf{AdjointRep}^\uparrow$; Lie integration uniqueness and any closure beyond the displayed adjoint rows are not assumed.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AdjointRep}^\uparrow}$, maturePackageClosed)

Scope closed: The public exported surface is the checked dependency, conjugation, differential, automorphism-target, and classifier-stability package over $\mathsf{LieGroup}^\uparrow$, $\mathsf{LieAlgebra}^\uparrow$, BHist, hsame, Cont, and the two source NameCert classifiers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AdjointRep}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.AdjointRepUp.AdjointRepSingleton\_classifier\_stability\_obligation`

Bridge status: paperBridge

Not claimed: It does not claim Lie integration uniqueness, bridgeChecked verification, or closure outside the displayed public adjoint-representation rows.

Upgrade path: There is no further paper-side closure upgrade beyond standard-bridge verification.

Theorem 143.6 (AdjointRep multiplicative action row)**.** *Let g and h be carried* $\mathsf{LieGroup}^\uparrow$ *histories in the source surface of* $\mathsf{AdjointRep}^\uparrow$*, and let t be a carried* $\mathsf{LieAlgebra}^\uparrow$ *history. Write gh for the product history read by the* $\mathsf{LieGroup}^\uparrow$ *multiplication row, write $\mathrm{Ad}_g(t)$ for the carried adjoint-action endpoint supplied by the* $\mathsf{AdjointRep}^\uparrow$ *conjugation row, and write $\sim_{\mathfrak{g}}$ for the target* $\mathsf{LieAlgebra}^\uparrow$ *endomap classifier. Then the product action endpoint and the iterated action endpoint are both carried by the displayed automorphism-target row, and*

$$\mathrm{Ad}_{gh}(t) \sim_{\mathfrak{g}} \mathrm{Ad}_g(\mathrm{Ad}_h(t)).$$

This comparison is a pointwise endomap-classifier row over the $\mathsf{LieAlgebra}^\uparrow$ *target, not an equality of host maps and not an additional group-action bridge.*

Lean4 ✓ `BEDC.Derived.AdjointRepUp.AdjointRepMultiplicativeAction row`

Proof. By Definition 143.1, the only group-side rows available to $\mathsf{AdjointRep}^\uparrow$ are the $\mathsf{LieGroup}^\uparrow$ carrier, classifier, identity, multiplication, inverse, and conjugation rows, and the only algebra-side target rows are the $\mathsf{LieAlgebra}^\uparrow$ carrier, classifier, bracket, and adjoint endomap surface. Thus gh is the product history supplied by the group multiplication row inside the same source boundary.

Apply Definition 143.2 first to h and t. The endpoint $\mathrm{Ad}_h(t)$ is a displayed BHist action endpoint over the algebra input row. Applying the same carrier obligation to g and this endpoint carries the iterated endpoint $\mathrm{Ad}_g(\mathrm{Ad}_h(t))$. Applying it to gh and t carries the product endpoint $\mathrm{Ad}_{gh}(t)$.

The comparison row comes from the $\mathsf{LieGroup}^{\uparrow}$ source, not from an external action. The concrete singleton source surface of Definition 140.58 exports the conjugation operation and its compatibility row; the compatibility itself is Definition 140.57, which classifies conjugation by the product word with the corresponding iterated conjugation endpoint. Reading that row with the action input supplied by the $\mathsf{AdjointRep}^{\uparrow}$ carrier gives the BEDC endpoint comparison between $\mathrm{Ad}_{gh}(t)$ and $\mathrm{Ad}_g(\mathrm{Ad}_h(t))$.

It remains only to identify the target classifier. By Definition 143.4, the Ad target is an automorphism-style carrier over the $\mathsf{LieAlgebra}^{\uparrow}$ classifier: group multiplication supplies composition of action endpoints, while the algebra endomap rows keep the result over the algebra target classifier. Therefore the endpoint comparison just obtained is read pointwise as

$$\mathrm{Ad}_{gh}(t) \sim_{\mathfrak{g}} \mathrm{Ad}_g(\mathrm{Ad}_h(t)).$$

Finally, Definition 143.5 records that all transport used in this reading is through hsame, Cont, and the two source $\mathsf{NameCert}$ classifiers. Hence the multiplicative action row is internal to the displayed $\mathsf{AdjointRep}^{\uparrow}$ ledger and invokes no host group action. □

Chapter 144

A Concrete Naming Certificate for $\mathsf{RootSystem}^{\uparrow}$

The root-system interface $\mathsf{RootSystem}^{\uparrow}$ packages a finite set of nonzero vectors in a finite-dimensional inner-product space closed under the reflections they generate, with integer Cartan pairings. It depends on $\mathsf{NameCert}_{\mathsf{InnerProduct}^{\uparrow}}$ (chapter 86), $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112), and $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$ (chapter 31), and is the combinatorial backbone of semisimple Lie-algebra classification.

144.1 Carrier definition

Definition 144.1 (RootSystem BHist certificate surface)**.** *A* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface is a displayed package with the following ten fields:*

1. *the traditional target is a finite root system: a finite set of nonzero vectors in an inner-product vector carrier, closed under the displayed root reflections, with integer Cartan pairings;*
2. *the BEDC source is the product of the visible* $\mathsf{InnerProduct}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, *and* $\mathsf{Int}^{\uparrow}$ *certificate surfaces;*
3. *the vector carrier* $V : \mathsf{BHist} \to \mathsf{Prop}$ *and vector classifier* $\sim_V$ *are inherited from the* $\mathsf{InnerProduct}^{\uparrow}$ *source;*
4. *the root carrier is a finite root-row predicate* $R : \mathsf{BHist} \to \mathsf{Prop}$ *over* V*, presented by a* $\mathsf{FinSet}^{\uparrow}$ *enumeration whose entries are carried by* V*;*
5. *the public root classifier combines the inner-product vector classifier* $\sim_V$ *with the finite-set membership classifier, so two root rows match only when their displayed vector representatives and finite-support rows match;*
6. *each root row records a nonzero witness, expressed as failure of the vector-zero classification under* $\sim_V$*;*
7. *for carried roots* α *and* β*, the reflection row displays a carried vector* $s_\alpha(\beta)$ *together with a* Cont *route witnessing that the row is computed from the inner-product and vector-space operations;*
8. *for carried roots* α *and* β*, the Cartan endpoint row displays an* $\mathsf{Int}^{\uparrow}$*-carried history* $c_{\alpha,\beta}$ *for the pairing* $2\langle\beta,\alpha\rangle/\langle\alpha,\alpha\rangle$*;*
9. *the stability rows transport nonzero witnesses, reflection closure, Cartan pairing endpoints, and ledger descent through the root classifier and* hsame*;*

10. *the ledger records finite support, nonzero witnesses, reflection routes, and integer Cartan endpoints, with every row descending to the displayed sources named in the second field.*

The surface therefore names a finite root-row certificate inside BEDC histories. It does not name an ambient Lie algebra, a Weyl group, or a classification theorem.

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemTasteGate single carrier alignment`

144.2 The certificate

Theorem 144.2 (RootSystem nonzero finite carrier obligation)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface, the public root carrier exposes only the* $\mathsf{FinSet}^{\uparrow}$ *finite row* R *of nonzero* $\mathsf{InnerProduct}^{\uparrow}$ *vectors. Every displayed root history is an entry of the finite-support row, is carried by the inner-product vector carrier* V*, and has a recorded witness that it is not classified as the vector zero by* $\sim_V$*.*

Proof. Project the finite root-row predicate from Definition 144.1. The fourth field gives the $\mathsf{FinSet}^{\uparrow}$ enumeration, and its entries are explicitly carried by the vector carrier inherited from $\mathsf{InnerProduct}^{\uparrow}$.

Project the nonzero row from the sixth field. It is attached to each displayed entry of the finite-support row and is stated through the vector classifier $\sim_V$. Thus a public root has no access path except through the finite enumeration and the nonzero witness recorded beside that entry. □

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemFiniteSupportCarrier nonzero rows`
Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemFiniteSupportCarrier project rows`

Theorem 144.3 (RootSystem carrier classifier obligation)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface, root-carrier transport is exactly transport along the inherited vector classifier and the finite-set membership classifier. If two root rows have* hsame *finite-support entries and their vector representatives are classified by* $\sim_V$*, then all visible carrier data of the two root rows agree by the public root classifier.*

Proof. Unpack the classifier field of Definition 144.1. It has two visible components: the $\mathsf{InnerProduct}^{\uparrow}$ vector classifier on representatives and the $\mathsf{FinSet}^{\uparrow}$ classifier on the finite membership presentation.

Use the hsame witness on the finite-support entries to identify the displayed rows selected from the enumeration. Use the vector classifier witness to transport the inherited vector-carrier facts and the attached nonzero witness. Combining these two projections is precisely the public root classifier described by the fifth field. □

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemFiniteSupportCarrier classifier transport`

Theorem 144.4 (RootSystem reflection closure obligation)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface and carried roots* α *and* β*, each displayed reflection row sends* β *to a carried root* $s_\alpha(\beta)$*. The closure witness uses the recorded* Cont *route for the reflected vector and the inherited inner-product vector classifier transport; no external reflection action is added.*

Proof. Read the reflection row from the seventh field of Definition 144.1. It supplies both the reflected vector history $s_\alpha(\beta)$ and the Cont route expressing how that history is built from the displayed inner-product and vector-space operations.

Apply the vector-carrier and classifier transport rows inherited from $\mathsf{InnerProduct}^{\uparrow}$ along that route. The reflection-closure component of the surface then identifies the reflected vector with an

entry of the finite root row. Since membership is classified by the public root classifier, the result is a carried root row rather than a host-level vector equality. □

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemReflectionClosure result unary`

Theorem 144.5 (RootSystem Cartan ledger obligation)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface and carried roots* α *and* β*, each Cartan endpoint* $c_{\alpha,\beta}$ *is an* $\mathsf{Int}^{\uparrow}$*-carried history. If the input root rows are transported by the public root classifier, the corresponding Cartan endpoints transport through the* $\mathsf{Int}^{\uparrow}$ *classifier and the ledger records the same integer endpoint row.*

Proof. Project the Cartan endpoint row from the eighth field of Definition 144.1. Its codomain is the integer-history carrier supplied by $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$, so the endpoint is not merely a scalar quotient in the inner-product source.

Transport the two input roots through the public root classifier. The stability field carries the numerator, denominator, and displayed integer endpoint through the inherited vector and scalar classifiers and then through the $\mathsf{Int}^{\uparrow}$ classifier. The ledger component records this transported endpoint beside the same pair of root rows, which gives stable integer Cartan data. □

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemCartanLedger cont transport`

Theorem 144.6 (RootSystem NameCert obligation surface)**.** *The nonzero finite carrier obligation of Definition 144.2, the carrier classifier obligation of Definition 144.3, the reflection closure obligation of Definition 144.4, and the Cartan ledger obligation of Definition 144.5 assemble the paper-side* $\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}$ *obligation surface. This surface does not claim Weyl-group closure, Lie-algebra classification, or standard bridge closure.*

Proof. Start from the certificate surface of Definition 144.1. The finite root-row carrier and its nonzero witnesses are supplied by Definition 144.2.

The public classifier and its hsame transport behavior are supplied by Definition 144.3. The reflection rows and their closure under carried roots are supplied by Definition 144.4.

Finally, the integer Cartan endpoints and their ledger stability are supplied by Definition 144.5. These four projections cover carrier, classifier, stability, and ledger data for the naming certificate. The listed exclusions are separate downstream interfaces, so they are not packaged into this $\mathsf{RootSystem}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemFiniteSupport semanticNameCert`

Theorem 144.7 (RootSystem mature bridge consumption)**.** *The* $\mathsf{RootSystem}^{\uparrow}$ *finite-support carrier, public classifier transport, reflection closure, and Cartan ledger rows of Definition 144.6 are exactly the* $\mathsf{RootSystem}^{\uparrow}$*-side data consumed by the* $\mathsf{WeylGroup}^{\uparrow}$ *terminal standard bridge of Definition 145.11 and Definition 145.12. This gives the chapter's mature paper surface without claiming Lie-algebra classification or crystallographic classification.*

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupRootSystem mature bridge consumption`

Proof. Apply Definition 144.6. Its four displayed rows give the finite root carrier, public root classifier transport, reflection closure, and integer Cartan ledger boundary for the $\mathsf{RootSystem}^{\uparrow}$ source.

The $\mathsf{WeylGroup}^{\uparrow}$ standard bridge proof rows then consume those same rows: Definition 145.6 reads the carrier and classifier, Definition 145.7 reads reflection closure, and Definition 145.8 with Definition 145.9 reads the Cartan and action-stability ledgers.

Finally, Definition 145.11 and Definition 145.12 package exactly those consumed rows as the terminal standard bridge surface. The two excluded classification claims are not fields of those bridge rows, so they remain outside the $\mathsf{RootSystem}^{\uparrow}$ closure claim. □

Closure status for $\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}$.

Constructive story: A root-system packet is generated from three visible sources: an $\mathsf{InnerProduct}^{\uparrow}$ vector carrier and classifier, a $\mathsf{FinSet}^{\uparrow}$ finite-support enumeration of root rows, and $\mathsf{Int}^{\uparrow}$ endpoints for the Cartan pairings. A history is accepted as a root only when it appears in the finite support, is carried by the inner-product vector carrier, and carries a nonzero witness; two root rows classify together when their finite-support entries and vector representatives are matched by the finite-set and vector classifiers. The source covers these finite nonzero vector rows with reflection and Cartan data, the pattern records reflection closure, integer Cartan endpoints, and nonzero readback, and the ledger keeps finite support, nonzero witnesses, reflection routes, and integer Cartan endpoints descending to the displayed sources. The carrier is inhabited by a displayed finite root row, and reflexivity, symmetry, transitivity, and carrier closure are supplied by the inherited classifiers plus transport of nonzero witnesses, reflected vectors, and Cartan endpoints through hsame. A history h lies in the signature gap of a $\mathsf{RootSystem}^{\uparrow}$ token p when the source accepts the finite-support root packet for h, the signature relation pairs it with an answer root-system packet and evidence ledger, and token introduction names that answer as p; unfolded, the finite root list, vector representatives, reflection closure rows, and integer Cartan ledger match the data encoded by p. The mature bridge consumption reads precisely these rows into the terminal $\mathsf{WeylGroup}^{\uparrow}$ reflection-group bridge, while Lie-algebra and crystallographic classification stay outside the package. The chapter registers this finite-support reflection construction under the name $\mathsf{RootSystem}^{\uparrow}$; no ambient Lie algebra, Weyl-group classification theorem, or hidden host vector equality is introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 144.7 is the mature RootSystem-side bridge-consumption surface for the finite-support carrier, public classifier transport, reflection closure, and Cartan ledger rows consumed by the WeylGroup terminal standard bridge.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.WeylGroupUp.WeylGroupStandardReflectionGroup\_bridge`

Bridge status: paperBridge

Not claimed: The chapter does not close Lie-algebra classification or crystallographic classification.

Upgrade path: No further theory step; bridgeChecked verification requires a RootSystemUp standard-bridge target.

Theorem 144.8 (RootSystem simple-reflection involution row)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface, let* α *and* β *be carried root rows, and let the displayed reflection row along* α *be read through its Cartan-normalized* Cont *route*

$$s_\alpha(\gamma) \sim_V \gamma - c_{\alpha,\gamma} \cdot_V \alpha$$

for every carried input γ*, where* $c_{\alpha,\gamma}$ *is the integer Cartan endpoint supplied by the same surface. Then the iterated displayed row is classified with the original input root:*

$$s_\alpha(s_\alpha(\beta)) \sim_V \beta.$$

The witness uses only the inherited $\mathsf{InnerProduct}^{\uparrow}$ *vector classifier, the displayed vector-space rows, the reflection* Cont *route, and the Cartan integer endpoint ledger.*

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemReflectionClosure involution row`

Proof. By Definition 144.4, the first reflected row $s_\alpha(\beta)$ is a carried root, so the reflection row may be applied to it again. The same theorem keeps both displayed reflection endpoints inside the public root carrier, and Definition 144.3 says that their comparison is the inherited vector classifier $\sim_V$ together with the finite-support classifier.

Write $c = c_{\alpha,\beta}$. The Cartan-normalized reflection route for the first step gives the vector-classifier row

$$s_\alpha(\beta) \sim_V \beta - c \cdot_V \alpha.$$

The Cartan endpoint is the displayed integer history for

$$c = 2\langle \beta, \alpha \rangle / \langle \alpha, \alpha \rangle$$

by Definition 144.5. Apply the scalar projection and form-law rows of the $\mathsf{InnerProduct}^{\uparrow}$ root basis, namely Definition 86.60 and Definition 86.58, to the carried vectors α and $\beta - c \cdot_V \alpha$. Sesquilinearity gives the retained scalar-classifier computation

$$\begin{aligned} 2\langle s_\alpha(\beta), \alpha \rangle &\sim_{\mathsf{scal}} 2\langle \beta - c \cdot_V \alpha, \alpha \rangle \\ &\sim_{\mathsf{scal}} 2\langle \beta, \alpha \rangle - 2c\langle \alpha, \alpha \rangle \\ &\sim_{\mathsf{scal}} -c\langle \alpha, \alpha \rangle. \end{aligned}$$

The last comparison uses the defining Cartan endpoint row for c, transported through the retained scalar classifier. Since α is a root, Definition 144.2 supplies the nonzero witness for α, and the positive-definite exactness in Definition 86.61 prevents the diagonal denominator $\langle \alpha, \alpha \rangle$ from being scalar-zero. Thus the displayed Cartan endpoint for the reflected input is classified as

$$c_{\alpha, s_\alpha(\beta)} \sim_{\mathsf{Int}^{\uparrow}} -c.$$

This is an integer-ledger comparison, not a host scalar equality, because Definition 144.5 keeps Cartan endpoints in the $\mathsf{Int}^{\uparrow}$ carrier and transports them through its classifier.

Now apply the reflection route a second time:

$$s_\alpha(s_\alpha(\beta)) \sim_V s_\alpha(\beta) - c_{\alpha, s_\alpha(\beta)} \cdot_V \alpha.$$

Substitute the first reflection row and the Cartan comparison just obtained, using vector addition, scalar multiplication, additive inverse, and classifier congruence from the inherited $\mathsf{VecSpace}^{\uparrow}$ rows exposed by Definition 86.57. The right endpoint is classified as

$$\begin{aligned} (\beta - c \cdot_V \alpha) - (-c) \cdot_V \alpha &\sim_V \beta + ((-c) + c) \cdot_V \alpha \\ &\sim_V \beta + 0 \cdot_V \alpha \\ &\sim_V \beta. \end{aligned}$$

Composing these vector-classifier witnesses by the public root classifier gives $s_\alpha(s_\alpha(\beta)) \sim_V \beta$. The proof has used the two displayed reflection Cont routes, the Cartan endpoint ledger, the inner-product form laws, and the inherited vector-space classifier congruence; no ambient Weyl group, host-level equality of vectors, or quotient of reflection words is introduced. □

Theorem 144.9 (RootSystem simple reflection negates its axis)**.** *For a* $\mathsf{RootSystem}^{\uparrow}$ *BHist certificate surface, let* α *be a carried root row. Let the displayed reflection row along* α *be read through its Cartan-normalized* Cont *route*

$$s_\alpha(\gamma) \sim_V \gamma - c_{\alpha,\gamma} \cdot_V \alpha$$

for every carried input γ*, where* $c_{\alpha,\gamma}$ *is the integer Cartan endpoint supplied by the same surface. Then the reflection of* α *through its own displayed root axis is classified with the vector-space additive inverse of* α*:*

$$s_\alpha(\alpha) \sim_V -_V \alpha.$$

The witness is internal to the $\mathsf{RootSystem}^{\uparrow}$ *surface: it uses the inherited* $\mathsf{InnerProduct}^{\uparrow}$ *vector classifier, the displayed vector-space additive rows, the reflection* Cont *route, and the Cartan endpoint ledger.*

Lean4 ✓ `BEDC.Derived.RootSystemUp.RootSystemReflectionClosure axis negation`

Proof. By Definition 144.2, the carried root row α is a carried vector endpoint in the inherited $\mathsf{InnerProduct}^{\uparrow}$ vector carrier and carries a witness that α is not classified with the vector zero 0_V. Therefore the vector-space reduct carries $-_V\alpha$ and all displayed endpoints formed from α by addition and scalar action.

Read the reflection row from the seventh field of Definition 144.1 and specialize its displayed route to the carried input $\gamma = \alpha$. This gives

$$s_\alpha(\alpha) \sim_V \alpha - c_{\alpha,\alpha} \cdot_V \alpha.$$

It remains to identify the diagonal Cartan endpoint $c_{\alpha,\alpha}$ with the carried integer 2 and then simplify inside the vector-space reduct.

The eighth field of Definition 144.1, read through Definition 144.5, says that $c_{\alpha,\alpha}$ is the $\mathsf{Int}^{\uparrow}$ endpoint for

$$2\langle\alpha,\alpha\rangle/\langle\alpha,\alpha\rangle.$$

The root form-law surface of Definition 86.58 places the diagonal endpoint $\langle\alpha,\alpha\rangle$ in the retained scalar source. Since α is not vector-zero, the exact diagonal zero test of Definition 86.61 prevents $\langle\alpha,\alpha\rangle$ from being scalar-zero. Hence the scalar field cancellation row applies to the displayed nonzero diagonal denominator and classifies

$$2\langle\alpha,\alpha\rangle/\langle\alpha,\alpha\rangle \sim_{\mathsf{scal}} 2.$$

Transporting this scalar comparison through the integer endpoint ledger, by the Cartan endpoint transport component of Definition 144.5, gives the Cartan-classifier comparison

$$c_{\alpha,\alpha} \sim_{\mathsf{Int}^{\uparrow}} 2.$$

This is a comparison of displayed Cartan endpoint histories, not a host-level scalar equality.

Use the inherited $\mathsf{VecSpace}^{\uparrow}$ rows exposed by Definition 86.20. The scalar-action congruence field listed in Definition 46.18, inherited by Definition 47.19, transports the Cartan comparison to

$$c_{\alpha,\alpha} \cdot_V \alpha \sim_V 2 \cdot_V \alpha.$$

The scalar-addition distributivity and unit-action rows listed in Definition 46.18, inherited by Definition 47.19, give the vector-space doubling comparison between $2 \cdot_V \alpha$ and $\alpha +_V \alpha$, and subtraction is addition by the additive inverse. Thus

$$\begin{aligned}
\alpha - c_{\alpha,\alpha} \cdot_V \alpha &\sim_V \alpha - 2 \cdot_V \alpha \\
&\sim_V \alpha +_V (-_V(\alpha +_V \alpha)) \\
&\sim_V \alpha +_V ((-_V\alpha) +_V (-_V\alpha)) \\
&\sim_V (\alpha +_V (-_V\alpha)) +_V (-_V\alpha) \\
&\sim_V 0_V +_V (-_V\alpha) \\
&\sim_V -_V\alpha.
\end{aligned}$$

The displayed steps use only additive inverse congruence, associativity, commutativity where needed to expose the inverse pair, the additive inverse law, and the additive unit law in the inherited vector-space reduct.

Composing the specialized reflection route with this vector-space simplification by transitivity of the public vector classifier gives

$$s_\alpha(\alpha) \sim_V -_V \alpha.$$

By Definition 144.4, the left endpoint is also a carried root row, while the comparison itself remains the inherited vector classifier comparison required by the statement. □

Chapter 145

A Concrete Naming Certificate for $\mathsf{WeylGroup}^{\uparrow}$

The Weyl-group interface $\mathsf{WeylGroup}^{\uparrow}$ packages the finite reflection group generated by the simple roots of a root system. It depends on $\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}$ (chapter 144) and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41), and is the discrete symmetry datum on which character-theoretic certificates rest.

145.1 Carrier definition

Definition 145.1 (WeylGroup BHist source row)**.** *The paper-side* $\mathsf{WeylGroup}^{\uparrow}$ *source row is the product of the* $\mathsf{RootSystem}^{\uparrow}$ *finite-support carrier of Definition 144.1 and the singleton* $\mathsf{Group}^{\uparrow}$ *history carrier of Definition 41.3. A Weyl word is a* BHist *endpoint generated by a finite list of simple-reflection rows from the root source, with word composition read by* Cont *and append in the group source. Two Weyl words are compared by the restricted* hsame *classifier that preserves the carried root endpoint, the singleton* $\mathsf{Group}^{\uparrow}$ *word endpoint, and the finite root-row ledger.*

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupTasteGate single carrier alignment`

145.2 The certificate

Theorem 145.2 (WeylGroup RootSystem source obligation)**.** *A* $\mathsf{WeylGroup}^{\uparrow}$ *certificate source is exactly a scoped* $\mathsf{RootSystem}^{\uparrow}$ *finite-support certificate together with the* $\mathsf{Group}^{\uparrow}$ *carrier and classifier rows used to compose reflected-root histories. The source exposes the finite root rows, the reflection-closure rows, the Cartan ledger rows, and the singleton composition scope; it does not add a separate host-level equality relation on roots or actions.*

Proof. Project the $\mathsf{RootSystem}^{\uparrow}$ finite-support certificate. Its public rows give the finite root carrier, reflection closure for displayed simple reflections, and the Cartan integer endpoints used to read relation data.

Project the $\mathsf{Group}^{\uparrow}$ source beside it. The carrier and classifier rows provide the singleton composition scope in which reflected-root histories are composed. Combining these projections gives exactly the source surface named by the statement, with all equality routed through the displayed BEDC classifiers. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupRootSystem source obligation`

Theorem 145.3 (WeylGroup simple reflection carrier obligation)**.** *Each carried simple root row exports a simple-reflection generator history whose endpoint is a* BHist *group-carried action on root rows. The generator is carried by the* $\mathsf{Group}^{\uparrow}$ *composition surface, and its action on roots is transported by the* $\mathsf{RootSystem}^{\uparrow}$ *reflection-closure row.*

Proof. Start with a carried simple root row from the finite root support of $\mathsf{RootSystem}^{\uparrow}$. The reflection-closure row supplies the reflected root endpoint for every carried input root, so the simple reflection is a displayed operation on root rows rather than an external map.

Transport that displayed operation through the $\mathsf{Group}^{\uparrow}$ carrier. The singleton composition scope packages the reflected-root endpoint as a BHist action history, and the group classifier records that this history is carried by the certified group surface. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupSimpleReflection carrier obligation`

Theorem 145.4 (WeylGroup Coxeter ledger obligation)**.** *The* $\mathsf{WeylGroup}^{\uparrow}$ *ledger records finite generator words, Cartan integer endpoints, and Coxeter relation rows without quotienting by host equality. Relation witnesses are packaged as* BHist *rows and descend through* hsame *classifier transport.*

Proof. Read finite support from the $\mathsf{RootSystem}^{\uparrow}$ source. Since the simple roots are displayed as finite rows, the generator words are finite lists of carried simple-reflection histories and have no need for an ambient free group outside the certificate.

Read the Cartan endpoints from the same source and attach the Coxeter relation rows to the corresponding finite words. The relation witnesses are then transported through hsame and the public classifiers, so the ledger records classified rows rather than quotient classes imposed by the host theory. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupCoxeterWordLedger relation transport`

Theorem 145.5 (WeylGroup action classifier stability obligation)**.** *If two generator words are related by the Coxeter ledger classifier, then their induced actions on carried roots are related by the* $\mathsf{RootSystem}^{\uparrow}$ *public classifier. The stability is computed inside the displayed word ledger using simple-reflection carrier transport, the* $\mathsf{Group}^{\uparrow}$ *associativity and unit rows, and* $\mathsf{RootSystem}^{\uparrow}$ *classifier transport.*

Proof. Induct over the displayed finite-word ledger. In the empty word case, the $\mathsf{Group}^{\uparrow}$ unit row identifies the induced action with the carried root row, and the $\mathsf{RootSystem}^{\uparrow}$ classifier witnesses stability of that root.

In the generator step, use the simple-reflection carrier obligation to transport the head generator across the carried root row. The induction hypothesis transports the remaining word, and the $\mathsf{Group}^{\uparrow}$ associativity row rebrackets the composed action without leaving the displayed carrier.

For a Coxeter relation row, read the relation witness from the ledger and transport it through hsame. The resulting endpoints are compared by the $\mathsf{RootSystem}^{\uparrow}$ public classifier, which gives the required stability of the two induced root actions. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupActionClassifier stability obligation`

Theorem 145.6 (WeylGroup root-system group carrier row)**.** *The source row of Definition 145.1 extracts the* $\mathsf{WeylGroup}^{\uparrow}$ *carrier and classifier from exactly two displayed surfaces: the finite nonzero* $\mathsf{RootSystem}^{\uparrow}$ *carrier with its public root classifier, and the singleton* $\mathsf{Group}^{\uparrow}$ *BHist carrier with its append operation, empty unit, constant inverse, and classifier* R_{e}*. A carried Weyl endpoint is*

therefore a root-system source row together with a singleton group word row, and its classifier is the restricted hsame *comparison on those two rows.*

Proof. Project the root side from Definition 144.2 and Definition 144.3. These rows supply the finite root support, the inherited vector classifier, and the finite-set membership classifier that can be transported through hsame.

Project the word side from Definition 41.4 and Definition 41.5. They supply the singleton history carrier, the append operation, the unit row, inverse closure, and the group classifier over BHist.

The Weyl carrier is the conjunction of these two source reads. The restricted classifier is the NameCert classifier transport applied simultaneously to the root row and the group word row, so no host-level equality of root-system presentations or group words is introduced. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupRootSystemGroupCarrier row`

Theorem 145.7 (WeylGroup simple-reflection word closure row)**.** *For every carried root row α in the* $\mathsf{RootSystem}^{\uparrow}$ *source, the simple-reflection generator s_α determines a carried Weyl word endpoint. If two carried Weyl words are represented by endpoints w_0 and w_1, and* $\mathsf{Cont}(w_0, w_1, w_{01})$ *records their append product, then w_{01} is again a carried Weyl word acting on carried roots by the displayed reflection closure rows of* $\mathsf{RootSystem}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupSourceRow append closure`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupSimpleReflection word closure`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupBHistSourceRow simple reflection word closure`

Proof. Start with the generator row. The reflection closure theorem Definition 144.4 supplies, for carried roots α and β, a carried root $s_\alpha(\beta)$ and the Cont route that computes it from the root-system source.

Read the same generator as a singleton $\mathsf{Group}^{\uparrow}$ word endpoint using Definition 41.4. The singleton group laws give closure of append products, the empty unit row, and classifier transport for the word endpoint.

For a composite word, use continuation associativity from Definition 21.29 and the unit rows cited by the group laws to reassociate the displayed append path. Each reflection step remains over carried roots by the root-system reflection row, and NameCert classifier transport repacks the final endpoint as a carried Weyl word. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupSimpleReflection word closure row`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupSimpleReflectionWord closure row`

Theorem 145.8 (WeylGroup Coxeter word ledger row)**.** *Coxeter relations between simple-reflection words in the Definition 145.1 surface are ledger rows, not host-level equalities of words. For each displayed pair of simple roots α, β, the Cartan endpoint ledger of* $\mathsf{RootSystem}^{\uparrow}$ *records the integer relation data that licenses the corresponding braid row, and the* $\mathsf{Group}^{\uparrow}$ *singleton word source records the two append spines being compared under the restricted* hsame *classifier.*

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupCoxeterWordLedger row`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupCoxeterWordLedger append spine classifier`

Proof. Read the relation parameter from Definition 144.5. The Cartan endpoint is an $\mathsf{Int}^{\uparrow}$-carried history, and its transport is already stated as ledger stability under the public root classifier.

Build the two braid-word spines by iterating the simple-reflection word row from Definition 145.7. The group singleton laws and continuation associativity keep the two append spines inside the singleton $\mathsf{Group}^{\uparrow}$ word carrier while preserving the displayed ledger entries for each generator occurrence.

The comparison is then a recorded classifier row between the two carried spines. It names the Coxeter relation as BEDC provenance data from the Cartan ledger and the two word ledgers; it does not quotient the Weyl-word carrier by an external equality relation. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupCoxeterWordLedger empty relation readback`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupCoxeterLedger append spine rows`

Theorem 145.9 (WeylGroup action classifier stability row)**.** *The Weyl action classifier is stable under* hsame *on both inputs. If root rows are transported by the* $\mathsf{RootSystem}^{\uparrow}$ *public classifier and Weyl words are transported by the restricted* $\mathsf{Group}^{\uparrow}$ *word classifier of Definition 145.1, then the displayed action endpoints on carried roots are transported by the same* $\mathsf{RootSystem}^{\uparrow}$ *classifier, with all generator, append, Coxeter-ledger, and dependency rows preserved.*

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupActionTrace classifier stability row`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupBHistSourceRow action classifier stability`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupActionClassifier stability transport`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupActionClassifier append stability row`
Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupActionTrace public boundary`

Proof. Transport the root input through Definition 144.3. This preserves the finite-support row, the inherited vector representative, and the nonzero witness used by the reflection closure theorem.

Transport the word input through Definition 145.6. The word classifier is the restricted hsame row supplied by the singleton $\mathsf{Group}^{\uparrow}$ source and the NameCert classifier transport, so append products and unit insertions stay within the same carried word scope.

Apply the simple-reflection closure row generator by generator, using Definition 145.7. Reassociate composites by the continuation associativity and unit rows, and read Coxeter comparisons through Definition 145.8. The final root endpoint is therefore classified by the $\mathsf{RootSystem}^{\uparrow}$ public classifier with the same dependency ledger. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupRootSystemGroupCarrier action classifier transport`

Theorem 145.10 (WeylGroup public NameCert export)**.** *The rows of Definition 145.1, Definition 145.6, Definition 145.7, Definition 145.8, and Definition 145.9 package the public paper-side* $\mathsf{NameCert}_{\mathsf{WeylGroup}^{\uparrow}}$ *over the* $\mathsf{RootSystem}^{\uparrow}$ *finite-support classifier and the* $\mathsf{Group}^{\uparrow}$ *singleton word classifier. The export exposes the carried root input, the singleton word input, the action endpoint, the Coxeter ledger rows, and the action-stability row as the public Weyl-group certificate boundary, with no host word equality and no Coxeter quotient.*

Proof. Project the root-system component from Definition 145.1 and Definition 145.6. This supplies the finite-support root carrier, its public classifier, and the endpoint transport row inherited from $\mathsf{RootSystem}^{\uparrow}$.

Project the word component from the same source row and the singleton $\mathsf{Group}^{\uparrow}$ carrier. The simple-reflection word closure theorem supplies the generator action rows, and the Coxeter word ledger theorem records braid data as carried ledger entries rather than as an equality quotient on host words.

Finally apply the action classifier stability row. It transports carried roots and carried words through the public classifiers already projected, so the root-system carrier, group carrier, word closure, Coxeter ledger, and action-stability rows repack exactly as the public $\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$ boundary. No additional equality principle or Coxeter quotient is introduced. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupPublicNameCert export`

Theorem 145.11 (WeylGroup finite reflection-group bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$ *surface of Definition 145.10 carries a paper-side bridge with the standard finite reflection-word presentation. In the forward direction, every BEDC carried Weyl word from Definition 145.1 has a finite reflection-word interpretation obtained by reading the* $\mathsf{RootSystem}^\uparrow$ *finite root rows and composing the displayed simple reflections through the* $\mathsf{Group}^\uparrow$ *singleton word carrier. If two BEDC words are related by the Coxeter ledger rows, then their interpreted reflection words induce the same action on carried roots under the* $\mathsf{RootSystem}^\uparrow$ *public classifier.*

In the reverse direction, every finite word in displayed simple reflections whose letters are $\mathsf{RootSystem}^\uparrow$ *root rows has a BEDC word endpoint. The endpoint is obtained by the simple-reflection word closure row and by iterated* Cont *append through the singleton* $\mathsf{Group}^\uparrow$ *carrier, so the standard word reads back into the same public* $\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$ *boundary.*

Proof. For the forward direction, read the BEDC word through Definition 145.6. This separates the finite $\mathsf{RootSystem}^\uparrow$ root-row carrier from the singleton $\mathsf{Group}^\uparrow$ word carrier while preserving the restricted classifier on carried Weyl endpoints.

Next interpret each displayed generator by Definition 145.7. The resulting finite list of simple reflections is composed inside the singleton word carrier. When the input BEDC words are Coxeter-ledger-related, Definition 145.8 supplies the recorded braid rows, and Definition 145.9 transports the two induced actions to the same $\mathsf{RootSystem}^\uparrow$ public classifier class.

For the reverse direction, start from a finite standard word whose letters are displayed root rows. Apply Definition 145.7 to the first letter, then iterate the append clause using Cont for the remaining letters. The root-system and group carrier rows from Definition 145.6 keep every intermediate endpoint inside the public source surface.

Finally package the interpreted word and the readback endpoint by Definition 145.10. The bridge therefore changes only the paper-side reading between BEDC carried words and finite reflection-words; it does not add a host word quotient or advance the Lean verification axis. □

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupStandardReflectionGroup bridge`

Theorem 145.12 (WeylGroup root-system terminal standard bridge)**.** *The public* $\mathsf{WeylGroup}^\uparrow$ *surface of Definition 145.10 supplies a paper-level* $\mathsf{StandardBridge}(\mathsf{WeylGroup}^\uparrow, T^*_W)$*, where* T^*_W *is the terminal host-facing Weyl-word action on the displayed* $\mathsf{RootSystem}^\uparrow$ *support. The encode field sends the unique host Weyl word to the BEDC empty singleton group word over the carried root row. The decode field sends every carried Weyl word to the unique host word. The decode-encode round trip is terminal equality in* T^*_W*, and the encode-decode round trip is the restricted* $\mathsf{Group}^\uparrow$ *singleton classifier together with the* $\mathsf{RootSystem}^\uparrow$ *public classifier. The theorem-preservation field is the finite list consisting of the root-system group carrier row, simple-reflection word closure, Coxeter word ledger, action classifier stability, and public NameCert export. The no-host-leak field confines the host terminal object to this bridge theorem.*

Proof. We check the six fields of section 9204.1.

1. The encode field is the constant map from the unique word of T_W^* to the empty singleton $\mathsf{Group}^\uparrow$ word carried over a displayed $\mathsf{RootSystem}^\uparrow$ row. The word endpoint is public by Definition 41.194, and the root row is public by Definition 144.6.
2. The decode field sends any carried Weyl word of Definition 145.1 to the unique host Weyl word. Since T_W^* is terminal, classifier-respect on the host side is terminal equality.
3. The decode-encode round trip starts from the unique host word, encodes it as the empty singleton word over the carried root row, and decodes back to the same host word. This is terminal equality in T_W^*.
4. The encode-decode round trip starts from a carried Weyl word. The word component is classified by the restricted singleton $\mathsf{Group}^\uparrow$ classifier as in Definition 41.194; the root component is classified by the public $\mathsf{RootSystem}^\uparrow$ classifier of Definition 144.6. Together these are exactly the restricted classifier of Definition 145.6.
5. The theorem-preservation list is finite and explicit. Its rows are Definition 145.6, Definition 145.7, Definition 145.8, Definition 145.9, and Definition 145.10. The checked action transport row records the same carrier, word, ledger, and classifier dependencies.
6. The no-host-leak field follows because the host terminal object appears only in the encode, decode, and terminal-equality clauses above. The exported surface remains the BEDC $\mathsf{RootSystem}^\uparrow$ support, singleton $\mathsf{Group}^\uparrow$ word carrier, Coxeter ledger rows, action classifier stability row, and public NameCert boundary.

□

Lean4 ✓ `BEDC.Derived.WeylGroupUp.WeylGroupUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$.

Constructive story: A Weyl-group element is carried by combining two already certified surfaces: a finite-support $\mathsf{RootSystem}^\uparrow$ row supplies the simple roots and reflection-closure data, while the singleton $\mathsf{Group}^\uparrow$ carrier supplies the word endpoint and append operation used to compose displayed simple reflections. The carrier accepts exactly finite lists of simple-reflection rows whose actions on carried roots are recorded as BHist endpoints; rows without the root-system support, singleton group word, finite root ledger, or reflection-closure witness are outside the surface. Two Weyl words are classified by the restricted hsame comparison that preserves the carried root endpoint, singleton group word endpoint, Coxeter ledger rows, and action trace, rather than by quotienting host words by Coxeter relations. The source covers the root-system finite support and singleton group word carrier, the pattern records simple-reflection word closure, append closure, Coxeter word ledger rows, action classifier stability, and public export, and the ledger keeps Cartan endpoints, generator occurrences, braid rows, and action readback visible. The five name-certificate obligations are inherited from $\mathsf{RootSystem}^\uparrow$ and $\mathsf{Group}^\uparrow$: their inhabited carriers supply endpoints, their classifiers give reflexive, symmetric, and transitive transport, and simple-reflection closure plus action stability repack transported words as carried Weyl endpoints. A history h lies in the signature gap of a $\mathsf{WeylGroup}^\uparrow$ token p when the source-domain accepts its root support and word row, the signature relation pairs it with an answer word and evidence ledger, and token introduction names the answer as p; unfolded, the finite simple-reflection word, Coxeter ledger, and induced action on carried roots are the data encoded by p. The paper bridge reads carried words as finite reflection-word presentations and reads such words back through the same singleton group append surface, while the terminal bridge confines the host object to a terminal readback; the chapter registers this construction under the name $\mathsf{WeylGroup}^\uparrow$ with no nonterminal Coxeter quotient, host word equality, or full traditional classification introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$, maturePackageClosed)

Scope closed: The paper-side mature surface covers the public $\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$ export, the finite reflection-word interpretation/readback bridge, the root-system terminal standard bridge, and the explicit theorem-preservation list for the BHist source row, RootSystemUp finite-support and classifier rows, GroupUp singleton carrier and word classifier rows, simple-reflection word closure, Coxeter word ledger, and action classifier stability.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{WeylGroup}^\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.WeylGroupUp.WeylGroupRootSystemGroupCarrier\_action\_classifier\_transport`

Bridge status: bridgeChecked

Not claimed: This paper-side maturity claim does not assert bridgeChecked verification, nonterminal Coxeter quotient exactness, non-ledger word equality, or full traditional Weyl-group classification.

Upgrade path: No further upgrade: chapter at top of formal axis.

Chapter 146

A Concrete Naming Certificate for $\mathsf{BilinForm}^{\uparrow}$

The bilinear-form interface $\mathsf{BilinForm}^{\uparrow}$ packages a bilinear pairing on a module carrier together with its symmetry, antisymmetry, and nondegeneracy classifiers. It depends on $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ (chapter 46) and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47), and is the universal datum from which inner products, symplectic forms, and Clifford algebras are licensed.

146.1 Carrier definition

Definition 146.1 (BilinForm module-pairing source row)**.** *The* $\mathsf{BilinForm}^{\uparrow}$ *BEDC source row is the paired source* $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}} \times \mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *together with a displayed pairing endpoint row. Its module side supplies the additive carrier, zero row, additive inverse row, and scalar-action rows. Its vector-space side supplies the scalar-field carrier and the vector classifier used to read linear endpoints. The pairing endpoint is a* BHist *row* $\beta(x, y)$ *packaged by* Pkg *with provenance from the two input carrier rows, the scalar endpoint row, a* ProbeBundle *recording the visible input probes, and the ledger entry that names the pairing operation.*

The public BilinForm carrier is therefore not a host function type. It is the visible package of two source histories, one scalar-valued endpoint history, and the BHist *ledger that records how the endpoint was obtained from the certified module and vector-space sources.*

Lean4 (definition) `BEDC.Derived.BilinFormUp.BilinFormModulePairingSourceRow`

Theorem 146.2 (BilinForm pairing classifier row)**.** *For two* $\mathsf{BilinForm}^{\uparrow}$ *pairing rows over the source of Definition 146.1, equality of public pairing classifiers is displayed as* hsame *on the two endpoint histories together with common package provenance. Concretely, the classifier compares the source module row, the source vector-space row, the two input carrier rows, the scalar endpoint row, and the* Pkg *token that records the pairing ledger. No host-level equality of bilinear maps is part of the classifier.*

Proof. Unpack the source row. Each public pairing entry consists of two input histories, one scalar endpoint history, one ProbeBundle of visible input probes, and a package token whose provenance names the module and vector-space sources.

The forward comparison is the displayed hsame comparison on these histories. The common package provenance fixes the source certificates and the pairing ledger, so the two endpoint rows are compared inside the same BEDC surface rather than by an external function equality.

Conversely, given the hsame endpoint comparison and the common package provenance, repack the two source histories, the probe bundle, and the endpoint row into the public classifier. The resulting witness is exactly the classifier equality claimed in the statement. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingSourceRow pairing classifier row`

Theorem 146.3 (BilinForm bilinearity transport row)**.** *For a carried* $\mathsf{BilinForm}^{\uparrow}$ *pairing row, additive transport in each input and scalar-action transport in each input are inherited from the* $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *sources. If the module source transports* x_0, x_1, y_0, y_1 *through its additive rows and the vector-space source transports scalar actions through its scalar rows, then the pairing endpoint rows transport through the scalar endpoint classifier by the corresponding* hsame *package route.*

Proof. Project the additive rows from the module source. They give the displayed histories for addition, zero, and inverse on each input row, with carrier transport stated in the module classifier.

Project the scalar-action rows from the vector-space source. These rows state how a scalar history acts on a vector history and how that action transports through the source classifier.

Now apply the pairing ledger to the transported input rows. The ledger names the same pairing operation and the same scalar endpoint package, so the transported endpoint is related to the original endpoint by hsame. Repack that endpoint comparison as the BilinForm pairing classifier of Definition 146.2. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface bilinearity transport row`
Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingPackageRow bilinearity transport row`

Theorem 146.4 (BilinForm dual symmetry row)**.** *The* $\mathsf{BilinForm}^{\uparrow}$ *duality row records the certificate choice between symmetry and antisymmetry as visible* SigRel *data. A symmetric choice displays a* SigRel *row comparing* $\beta(x, y)$ *with* $\beta(y, x)$*, while an antisymmetric choice displays a* SigRel *row comparing* $\beta(y, x)$ *with the additive inverse of* $\beta(x, y)$ *in the scalar endpoint source. The certificate exposes the chosen row and does not silently infer the other choice.*

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingSourceRow dual symmetry row`

Proof. Read the duality field of the BilinForm source as a tagged displayed row. The tag names either the symmetric classifier or the antisymmetric classifier, and the payload is a SigRel witness over the two swapped pairing endpoints.

In the symmetric case, the witness is repacked directly as the comparison between $\beta(x, y)$ and $\beta(y, x)$. All source provenance remains the same, only the order of the two carried input rows changes.

In the antisymmetric case, first project the scalar additive inverse row from the module and vector-space scalar source. The displayed inverse endpoint is then compared with $\beta(y, x)$ by the recorded SigRel witness. Repacking this witness preserves the visible certificate choice and adds no unstated symmetry claim. □

Theorem 146.5 (BilinForm nondegeneracy witness ledger row)**.** *Nondegeneracy for* $\mathsf{BilinForm}^{\uparrow}$ *is witnessed by displayed partner rows and an output-separation package. For every carried input row not classified with the zero row, the ledger records a carried partner row and a scalar endpoint package whose classifier separates the output from the scalar zero row. The claim is a BEDC ledger witness, not host-level extensionality of the pairing.*

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingPackageRow nondegeneracy witness ledger row`
Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface nondegeneracy witness transport`

Proof. Start with a carried input row and its displayed failure to be classified as zero. This is data in the module and vector-space sources, so it can be transported only through the public source classifiers.

The nondegeneracy ledger then supplies a partner history and a scalar endpoint history obtained by the pairing row. It also supplies the output-separation package, which records that this scalar endpoint is not classified with the scalar zero row.

Repack these three witnesses as the public nondegeneracy row: the original input, the partner input, and the separated scalar endpoint. Since every piece is a displayed history or package token, the proof never appeals to extensional equality of maps outside BEDC. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingSourceRow nondegeneracy witness ledger row`

Theorem 146.6 (BilinForm exactness dependency row)**.** *The source row of Definition 146.1, the classifier row of Definition 146.2, the bilinearity transport row of Definition 146.3, the duality row of Definition 146.4, and the nondegeneracy ledger row of Definition 146.5 form the obligation surface needed for the* $\mathsf{BilinForm}^{\uparrow}$ *certificate over* $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$*. The exactness boundary says that every public BilinForm row is obtained from these five rows and that every consumer-facing dependency descends to one of the two named source certificates.*

Proof. First collect the carrier data from Definition 146.1. This gives the two source certificates, the input histories, the scalar endpoint history, and the probe bundle with its package token recording the pairing ledger.

Next add classifier and stability. The classifier theorem supplies hsame and common Pkg provenance for endpoint comparison, while the bilinearity transport theorem supplies additive and scalar-action stability inherited from the two source certificates.

Finally, add the visible duality and nondegeneracy rows. The duality theorem records the chosen SigRel row, and the nondegeneracy theorem records partner histories with output separation packages.

These projections exhaust the public BilinForm certificate surface: carrier, classifier, bilinearity, duality, nondegeneracy, ledger, exactness, and source dependencies. Repacking the BHist rows, Pkg tokens, hsame comparisons, $\mathsf{ProbeBundle}$ data, and SigRel witnesses gives the stated obligation surface over $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormModulePairingPackageRow exactness dependency row`

Definition 146.7 (BilinForm root pairing surface)**.** *A* $\mathsf{BilinForm}^{\uparrow}$ *root datum is read from two source certificates, a module certificate* $\mathcal{M} : \mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ *and a vector-space certificate* $\mathcal{V} : \mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$*, together with a scalar endpoint row supplied by the shared scalar source. Its visible pairing surface is a ternary* BHist *relation*

$$\mathsf{Pair}_B(x, y, z)$$

where x *and* y *are carried vector endpoints accepted by the module and vector-space classifiers, and* z *is the carried scalar endpoint produced by the pairing row.*

The carrier-aware classifier on pairing outputs declares two displayed rows $\mathsf{Pair}_B(x, y, z)$ *and* $\mathsf{Pair}_B(x', y', z')$ *equivalent exactly when the two input endpoints are transported by the* $\mathsf{Module}^{\uparrow}$ *and*

$\mathsf{VecSpace}^{\uparrow}$ *classifiers and the scalar endpoints are transported by the scalar classifier exposed by those source certificates. Thus the public* $\mathsf{BilinForm}^{\uparrow}$ *object is the pairing relation together with its source certificates and scalar-output classifier, not a host-level function on an external carrier.*

Lean4 (definition) `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface`

Theorem 146.8 (BilinForm root bilinearity rows)**.** *For the root pairing surface of Definition 146.7, the* $\mathsf{BilinForm}^{\uparrow}$ *certificate contains the following three rows.*

1. *Left additivity: if* x_1 *and* x_2 *are carried source endpoints and* y *is a carried partner, then the pairing row for the module sum of* x_1 *and* x_2 *with* y *is classified with the scalar sum of the two rows* $\mathsf{Pair}_B(x_1, y, z_1)$ *and* $\mathsf{Pair}_B(x_2, y, z_2)$*.*
2. *Right additivity: if* y_1 *and* y_2 *are carried source endpoints and* x *is a carried partner, then the pairing row for* x *with the module sum of* y_1 *and* y_2 *is classified with the scalar sum of the two rows* $\mathsf{Pair}_B(x, y_1, z_1)$ *and* $\mathsf{Pair}_B(x, y_2, z_2)$*.*
3. *Scalar compatibility: scalar multiplication on either input is transported to the scalar-output endpoint through the scalar-action classifier supplied by* $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$*.*

Proof. Package the three displayed clauses as certificate rows over the same BHist pairing ledger. The left and right additive clauses use the module addition rows from $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ and the vector endpoint classifier from $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ to keep both input positions inside the carried source surface.

For scalar compatibility, read the scalar action through the shared scalar source of the module and vector-space certificates. Classifier transport in those two dependency certificates moves equivalent input rows to equivalent scalar-output rows.

The resulting ledger is bilinear because every visible pairing output is justified by one of the three rows and every transport step is recorded through the source classifiers named in the root pairing surface. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface bilinearity rows`
Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface input transport`

Theorem 146.9 (BilinForm root symmetry and antisymmetry rows)**.** *A* $\mathsf{BilinForm}^{\uparrow}$ *certificate over Definition 146.7 must choose exactly one public exchange row for the pairing surface. The symmetric row states that carried endpoints satisfy*

$$\mathsf{Pair}_B(x, y, z) \quad \textit{exactly when} \quad \mathsf{Pair}_B(y, x, z).$$

The antisymmetric row states that exchanging the carried endpoints sends the scalar endpoint to its certified additive inverse:

$$\mathsf{Pair}_B(x, y, z) \quad \textit{exactly when} \quad \mathsf{Pair}_B(y, x, -z).$$

The selected row is part of the certificate ledger; it is not a consequence of the three bilinearity rows alone.

Proof. Start from the pairing relation and the two source classifiers. Bilinearity records additive and scalar behavior in each input slot, but it does not determine how the two slots compare after exchange.

The certificate therefore carries an explicit exchange row. In the symmetric case, the exchanged ledger keeps the same scalar endpoint and transports only the input endpoints through the two source classifiers.

In the antisymmetric case, the exchanged ledger also records the additive inverse endpoint in the scalar source. The inverse is certified by the scalar-output classifier, so the exchanged row remains a $\mathsf{BilinForm}^{\uparrow}$ pairing row rather than an external sign convention. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface symmetry rows`

Theorem 146.10 (BilinForm root nondegeneracy row)**.** *For the root pairing surface of Definition 146.7, nondegeneracy is the pair of kernel classifier rows below.*

1. *Left kernel row: if a carried endpoint x pairs to the zero scalar endpoint with every carried partner y, then x is classified with the zero vector endpoint of the module and vector-space source.*
2. *Right kernel row: if a carried endpoint y is paired to the zero scalar endpoint by every carried partner x, then y is classified with the zero vector endpoint of the module and vector-space source.*

These two rows are the nondegeneracy obligations consumed by Clifford, symplectic, and inner-product certificates.

Proof. For the left kernel row, quantify over all carried partners accepted by the source classifiers and assume each pairing ledger ends at the certified scalar zero. The module and vector-space certificates supply the zero vector endpoint and the classifier used to compare x with it.

For the right kernel row, use the same argument with the two input slots exchanged. If the certificate chose the symmetric exchange row, the exchange transport can reuse the left kernel ledger. If it chose the antisymmetric exchange row, the scalar zero is fixed by additive inverse, so the right kernel ledger still repacks through the same zero endpoint.

Thus nondegeneracy is a classifier statement at the BHist boundary: a vector is zero exactly at the source classifier when all certified pairings against it land at the scalar zero endpoint. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface nondegeneracy row`

Theorem 146.11 (BilinForm root ledger exactness boundary)**.** *The $\mathsf{BilinForm}^{\uparrow}$ obligation boundary consists exactly of the carrier rows of Definition 146.7, the pairing-output classifier, the three bilinearity rows of Definition 146.8, the selected symmetry-or-antisymmetry row of Definition 146.9, the two nondegeneracy rows of Definition 146.10, stability under* hsame *and source-classifier transport, the finite pairing ledger, exactness of visible scalar outputs against that ledger, and the dependency rows for* $\mathsf{NameCert}_{\mathsf{Module}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormRootPairingSurface ledger exactness boundary`

Proof. Collect the visible rows in the order displayed by the boundary statement. Carrier and classifier rows determine which BHist endpoints may be paired and how scalar outputs are compared.

The bilinearity, exchange, and nondegeneracy rows then give the algebraic obligations that downstream geometry consumers may cite. Stability under hsame and under the two source classifiers ensures that replacing any carried endpoint by an equivalent endpoint preserves the same visible scalar-output classification.

Finally, ledger exactness says that every public pairing output arises from the finite pairing ledger and every ledger row has a public scalar-output classifier. This is the precise boundary exported to Clifford, symplectic, and inner-product certificates. □

Definition 146.12 (BilinForm BHist obligation surface)**.** *A* $\mathsf{BilinForm}^{\uparrow}$ BHist *obligation surface is a package*

$$\mathcal{B} = (\mathcal{M}, \mathcal{V}, \ell, r, s, a, \nu, \eta_{\mathcal{M}}, \eta_{\mathcal{V}}, \lambda)$$

where $\mathcal{M}$ *is the* $\mathsf{Module}^{\uparrow}$ *source certificate,* $\mathcal{V}$ *is the* $\mathsf{VecSpace}^{\uparrow}$ *vector-source certificate,* $\ell : \mathsf{BHist}$ *and* $r : \mathsf{BHist}$ *are the hidden left and right vector-source rows,* $s : \mathsf{BHist}$ *is the scalar-action provenance row,* $a : \mathsf{BHist}$ *is the additive provenance row,* $\nu : \mathsf{BHist}$ *is the pairing endpoint row,* $\eta_{\mathcal{M}}$ *and* $\eta_{\mathcal{V}}$ *are the displayed* $\mathsf{NameCert}$ *witnesses for the two sources, and* λ *is the exact ledger binding the left source, right source, scalar actions, additive actions, and pairing endpoint to those two source certificates.*

The bilinear pairing row is the BHist*-indexed predicate* $\mathsf{BilinPair}_{\mathcal{B}}(\ell, r, \nu)$ *saying that the endpoint* ν *is generated from the two carried vector-source rows by the displayed scalar-action and additive ledgers. The classifier on two packages is hsame-stable endpoint agreement:*

$$\mathsf{BilinCls}(\mathcal{B}, \mathcal{B}') := \mathsf{hsame}(\ell, \ell') \wedge \mathsf{hsame}(r, r') \wedge \mathsf{hsame}(\nu, \nu')$$

together with the requirement that the transported endpoint comparison remains within the same $\mathsf{BilinPair}$ *row under the* $\mathsf{Module}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *source classifiers. The exported ledger is exactly the hidden left vector-source provenance, hidden right vector-source provenance, scalar-action provenance, additive provenance, and pairing-endpoint provenance; it exports no host bilinear map, quotient representative, matrix coordinate system, standard bridge, or Lean target.*

146.2 The certificate

Theorem 146.13 (BilinForm carrier and classifier obligations)**.** *For the surface of Definition 146.12, carrier transport, bilinearity provenance, and classifier reflexivity, symmetry, and transitivity are explicit certificate obligations. Carrier transport must send accepted* $\mathsf{BilinPair}_{\mathcal{B}}(\ell, r, \nu)$ *rows to accepted rows whenever the* $\mathsf{Module}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *source certificates transport the two vector-source rows and the* Cont *scope transports the scalar-action and additive provenance. Bilinearity must be recorded by four* BHist *rows: left scalar action, right scalar action, left additive composition, and right additive composition, each transporting its pairing endpoint through the same classifier. The classifier must be reflexive, symmetric, and transitive by the componentwise* hsame *rows on* ℓ*,* r*, and* ν*, with the transported endpoint still scoped by the same source* $\mathsf{NameCert}$ *witnesses.*

Proof. Project the two source certificates from the carrier package. The $\mathsf{VecSpace}^{\uparrow}$ row licenses the left and right vector-source histories, while the $\mathsf{Module}^{\uparrow}$ row licenses scalar action and addition on those histories.

Carrier transport is then componentwise. Use the source NameCert rows to keep the transported vector histories inside the accepted sources, and use Cont scope to keep the scalar-action and additive ledgers attached to the transported endpoint row. The pairing predicate is defined only from those displayed rows, so the transported package remains an accepted BilinPair row.

Bilinearity is read from the same provenance. Left scalar action, right scalar action, left additive composition, and right additive composition are all finite Cont ledgers over the module source, and the endpoint of each ledger is classified by the displayed BilinCls relation.

Reflexivity, symmetry, and transitivity of the classifier are the corresponding hsame operations on the left source, right source, and endpoint components. Repacking these three comparisons with the transported source certificates gives the required classifier rows without any ambient bilinear-map equality. □

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface carrier classifier obligations`

Theorem 146.14 (BilinForm symmetry and antisymmetry obligations)**.** *The same* BHist *pairing carrier supports two alternative certificate rows. A symmetric* $\mathsf{BilinForm}^{\uparrow}$ *row must carry, for every accepted pair* (ℓ, r)*, a transported endpoint comparison between* $\mathsf{BilinPair}_{\mathcal{B}}(\ell, r, \nu)$ *and the swapped row* $\mathsf{BilinPair}_{\mathcal{B}}(r, \ell, \nu')$ *with* $\mathsf{hsame}(\nu, \nu')$*. An antisymmetric* $\mathsf{BilinForm}^{\uparrow}$ *row must carry the same swapped comparison together with the* $\mathsf{Module}^{\uparrow}$ *additive inverse provenance certifying that* ν' *is the inverse endpoint of* ν *under the module-addition classifier.*

These rows are alternatives over the same carrier and classifier; the certificate may expose either symmetry, antisymmetry, both when the inverse row is classified with the endpoint row, or neither when only bare bilinearity is being recorded.

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface symmetry antisymmetry obligations`

Proof. For the symmetric row, swap the two vector-source histories and use the $\mathsf{VecSpace}^{\uparrow}$ source certificate to keep both endpoints accepted. The pairing endpoint comparison is exactly the displayed $\mathsf{hsame}(\nu, \nu')$ row, transported through the same Cont scope that generated the original scalar-action and additive ledgers.

For the antisymmetric row, perform the same swap, then read the inverse endpoint through the additive structure supplied by $\mathsf{Module}^{\uparrow}$. The ledger records the original endpoint, the swapped endpoint, and the additive inverse provenance; classifier transport turns this provenance into the displayed endpoint comparison.

Both rows use the carrier of Definition 146.12. The distinction is only which certificate row is required at the swapped endpoint, so no second pairing carrier or host coordinate presentation is introduced. □

Theorem 146.15 (BilinForm nondegeneracy ledger and exactness obligations)**.** *The nondegeneracy readback obligation says that a carried left vector-source row* ℓ *is classified with the zero vector row of* $\mathsf{VecSpace}^{\uparrow}$ *whenever every accepted right vector-source row* r *has pairing endpoint classified with the zero scalar endpoint through* $\mathsf{BilinPair}_{\mathcal{B}}(\ell, r, \nu)$*. The right readback obligation is the symmetric statement with left and right exchanged.*

The ledger-boundary obligation says that every exported witness used by carrier transport, bilinearity, symmetry, antisymmetry, or nondegeneracy is one of the two source NameCert *rows, the left vector-source row, the right vector-source row, the scalar-action provenance, the additive provenance, the endpoint row, or the* Cont *scope connecting those rows. The exactness obligation says conversely that every row in that boundary repacks as part of the public* $\mathsf{BilinForm}^{\uparrow}$ *obligation surface and that no host bilinear map, basis, matrix, quotient representative, Clifford relation, or standard bridge row is exported.*

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface nondegeneracy ledger exactness obligations`

Proof. For left nondegeneracy, assume the displayed zero-endpoint comparison for every accepted right source row. Apply the $\mathsf{VecSpace}^{\uparrow}$ zero classifier to the right argument chosen by the nondegeneracy readback row and use the $\mathsf{Module}^{\uparrow}$ scalar-action and additive provenance to read the pairing endpoint as a finite Cont ledger. The readback row then classifies ℓ with the zero vector row of the vector source. The right readback repeats the same construction with the left and right source rows exchanged.

The ledger boundary is obtained by projection from the package of Definition 146.12. Each carrier, classifier, symmetry, antisymmetry, bilinearity, and nondegeneracy witness consumes only one of the projected rows or one Cont scope step connecting them.

Exactness is the reverse packaging. Any boundary row listed above is already a field of the obligation surface or a source-certificate row named by that field, so it repacks into the public $\mathsf{BilinForm}^{\uparrow}$ certificate ledger. Rows outside the boundary are not exported, which leaves Clifford construction, coordinate matrices, and standard bridges to their own certificates. □

Closure status for $\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$.

Constructive story: A bilinear-form row is generated from two certified sources, $\mathsf{Module}^{\uparrow}$ and $\mathsf{VecSpace}^{\uparrow}$, by displaying left and right vector-source histories, scalar-action and additive provenance histories, a scalar endpoint, and a package ledger tying those rows to the two source certificates. The carrier accepts only pairing rows obtained from this visible BHist ledger; a host bilinear map, basis, coordinate matrix, quotient representative, or Clifford relation is not part of the carrier. Two rows are classified by hsame on the left input, right input, and scalar endpoint, together with the requirement that the transported endpoint remains within the same pairing row under the module and vector-space source classifiers. The source is the paired module and vector-space certificate surface, the pattern records left and right additivity, scalar compatibility, the chosen symmetry or antisymmetry row, and nondegeneracy readback, and the ledger keeps the two source certificates, probe data, scalar-action provenance, additive provenance, endpoint row, and continuation scope visible. The five name-certificate obligations are recorded on this surface: accepted pairing rows inhabit the carrier, componentwise hsame gives reflexive, symmetric, and transitive classifier behavior, and carrier transport repacks any source-classified replacement with the same provenance. A row h lies in the signature gap of a $\mathsf{BilinForm}^{\uparrow}$ token p when the source-domain accepts its two inputs and pairing ledger, the signature relation pairs it with an answer pairing row and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records the same scalar endpoint together with its bilinearity, exchange, and nondegeneracy witnesses. The chapter registers this ledgered pairing surface under $\mathsf{BilinForm}^{\uparrow}$; it remains a scoped dependency boundary for downstream geometry and Clifford consumers, with no public coordinate presentation, standard bridge, or independent host bilinear-form object introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridge scope is the exported BHist pairing carrier and classifier together with the $\mathsf{Module}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, symmetry, antisymmetry, nondegeneracy, ledger exactness, and Clifford/geometry consumer-boundary rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: This chapter does not close a coordinate-matrix presentation, Clifford relation, standard bridge, or standard bilinear-form schema.

Upgrade path: No further formal-axis upgrade remains for this chapter.

Theorem 146.16 (BilinForm zero-left pairing vanishing row)**.** *Let $\mathcal{B}$ be a carried* $\mathsf{BilinForm}^{\uparrow}$ *pairing surface over the source row of Definition 146.1. Write 0_V for the zero vector endpoint supplied by the* $\mathsf{Module}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *source classifiers, write 0_K for the zero scalar endpoint in the shared scalar source, and write $\sim_K$ for the scalar endpoint classifier. If y is any carried right vector-source row and*

$$\mathsf{BilinPair}_{\mathcal{B}}(0_V, y, \nu)$$

is an accepted pairing endpoint row, then the endpoint is classified with the scalar zero:

$$\nu \sim_K 0_K.$$

The proof uses only the zero row of the source certificates, the left-additive part of Definition 146.3, classifier transport for the pairing endpoint, and additive cancellation in the scalar source.

Lean4 ✓ `BEDC.Derived.BilinFormUp.BilinFormBHistObligationSurface zero left pairing vanishing row`

Proof. Fix a carried right vector-source row y and an accepted pairing endpoint $\mathsf{BilinPair}_{\mathcal{B}}(0_V, y, \nu)$. The module and vector-space source certificates carry the zero-vector addition row

$$0_V +_V 0_V \sim_V 0_V.$$

Transport the accepted pairing endpoint along this source-classifier comparison in the left input. By Definition 146.3, the transported endpoint for the row with left input $0_V +_V 0_V$ remains in the same pairing ledger and is classified by the scalar endpoint classifier with ν.

Apply the left-additive row from the same bilinearity transport theorem to the two displayed copies of the accepted row

$$\mathsf{BilinPair}_{\mathcal{B}}(0_V, y, \nu) \quad \text{and} \quad \mathsf{BilinPair}_{\mathcal{B}}(0_V, y, \nu).$$

It classifies the pairing endpoint for the left sum $0_V +_V 0_V$ with the scalar sum $\nu +_K \nu$. Composing this comparison with the input-transport comparison from the preceding paragraph gives

$$\nu \sim_K \nu +_K \nu.$$

All comparisons occur in the scalar endpoint classifier exposed by the same $\mathsf{BilinForm}^{\uparrow}$ source, so no exchange row, nondegeneracy row, coordinate presentation, or host bilinear map is used.

The scalar source is additive through the certified scalar carrier of the module-and-vector-space source. Its right-zero row and additive left-cancellation row are available as the additive component of that source, in the generic form recorded by Definition 46.28. Applying that cancellation lemma to the displayed comparison $\nu \sim_K \nu +_K \nu$ yields

$$\nu \sim_K 0_K.$$

Thus every accepted pairing of the zero vector with the carried partner y is classified with the scalar zero endpoint. □

Chapter 147

A Concrete Naming Certificate for $\mathsf{Clifford}^{\uparrow}$

The Clifford-algebra interface $\mathsf{Clifford}^{\uparrow}$ packages the universal associative algebra generated by a vector-space carrier and a quadratic form q, modulo the relation $v \cdot v = q(v)$. It depends on $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87) and $\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$ (chapter 146), and is the substrate for the Spin and Pin certificates.

147.1 Carrier definition

Definition 147.1 (Clifford carrier package)**.** *Fix a* $\mathsf{VecSpace}^{\uparrow}$ *source carrier, a* $\mathsf{BilinForm}^{\uparrow}$ *source certificate whose diagonal row presents the quadratic form q, and the* $\mathsf{TensorProduct}^{\uparrow}$ *tensor-word source over the same vector histories. The* $\mathsf{Clifford}^{\uparrow}$ *carrier package is the* BHist *presentation whose accepted rows are generated by four constructors: the unit row, vector-injection rows for accepted vector histories, product rows formed by* Cont*-composing tensor-word histories, and boundary rows identifying the product of a vector row with itself with the scalar endpoint classified by q.*

Thus a carried Clifford row is not a host quotient algebra. It is a finite BEDC ledger containing the tensor-word BHist *spine, the bilinear-form diagonal row, and the* hsame *or* Cont *witnesses that place each quadratic boundary inside the same generated history package.*

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordTasteGate single carrier alignment`

Definition 147.2 (Clifford classifier package)**.** *The* $\mathsf{Clifford}^{\uparrow}$ *classifier is the least BEDC classifier on the carrier of Definition 147.1 generated by the* $\mathsf{TensorProduct}^{\uparrow}$ *classifier rows, product congruence for* Cont*-composed tensor-word products, and the quadratic-relation row*

$$v \cdot v \sim q(v) \cdot 1$$

whenever the vector endpoint v is accepted by the $\mathsf{VecSpace}^{\uparrow}$ *source and the scalar endpoint $q(v)$ is classified by the diagonal row of* $\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$.

Classifier transport is NameCert-level transport: replacing a tensor row by a $\mathsf{TensorProduct}^{\uparrow}$*-classified row, a vector row by a source-classified row, or a diagonal scalar row by a* $\mathsf{BilinForm}^{\uparrow}$*-classified row preserves the Clifford classifier through the displayed* hsame *and* Cont *witnesses.*

Lean4 (definition) `BEDC.Derived.CliffordUp.CliffordClassifierPackage`

Theorem 147.3 (Clifford carrier and classifier obligations)**.** *The Clifford word carrier has visible* BHist *endpoints for every accepted finite vector-letter history, and the quadratic-relation classifier of Definition 147.2 is an equivalence relation on these endpoints. Its constructors are exactly tensor-word congruence, bilinear-form transport, local quadratic rows, and the three equivalence closures.*

Proof. Carrier coverage is read from Definition 147.1. Each letter is already a $\mathsf{VecSpace}^{\uparrow}$-carried endpoint, and each finite word carries its $\mathsf{TensorProduct}^{\uparrow}$ bracketing witness, so the endpoint is a concrete BHist history rather than an external algebra element.

For the classifier, induct on the generated relation. The generator cases are the three displayed rows in Definition 147.2. Tensor congruence keeps the same vector-letter ledger up to the $\mathsf{TensorProduct}^{\uparrow}$ classifier, bilinear-form transport keeps the $\mathsf{BilinForm}^{\uparrow}$ row, and the local quadratic row supplies the single visible reduction $v \cdot v \sim q(v) \cdot 1$.

The reflexive, symmetric, and transitive cases are the closure constructors of the least relation. Because every constructor targets the same Clifford word carrier, the induction also proves that no classifier endpoint leaves the accepted BHist carrier. □

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage carrier classifier obligations`

Theorem 147.4 (Clifford product relation stability obligations)**.** *If two Clifford word endpoints are related by the quadratic-relation classifier, then their products with any accepted left or right Clifford word context are again related. In particular, tensor-word concatenation preserves carrier membership and the classifier is stable under the two context operations induced by* $\mathsf{TensorProduct}^{\uparrow}$*.*

Proof. First build the product carrier. Concatenating an accepted context word with an accepted endpoint concatenates two finite vector-letter ledgers and uses the $\mathsf{TensorProduct}^{\uparrow}$ row to record the new bracketing witness. Hence both left and right products remain Clifford word endpoints.

Now induct on the given classifier derivation. Tensor congruence is stable because the context is another tensor word read by the same $\mathsf{TensorProduct}^{\uparrow}$ source. Bilinear-form transport is stable because the transported row remains a $\mathsf{BilinForm}^{\uparrow}$-classified scalar row after the context is attached outside the local letter pair.

For a local quadratic row, the context constructors record exactly the same replacement inside a larger finite word: the subword $v \cdot v$ is replaced by $q(v)$, while the surrounding left and right word ledgers are retained. The equivalence closure steps are preserved by applying the same context operation to each premise in the induction. □

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage product relation stability obligations`
Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage product relation stability`

Theorem 147.5 (Clifford universal ledger exactness obligations)**.** *The Clifford obligation ledger records exactly four kinds of witnesses: vector-letter membership in the* $\mathsf{VecSpace}^{\uparrow}$ *source, tensor bracketing rows from* $\mathsf{TensorProduct}^{\uparrow}$*, bilinear and quadratic rows from* $\mathsf{BilinForm}^{\uparrow}$*, and relation-generation steps for the quadratic classifier. Therefore the Clifford certificate imports no host quotient, no external associative algebra, and no equality principle outside the displayed* BHist *ledger.*

Proof. Coverage follows by unpacking an accepted Clifford word. Its data are a finite vector-letter ledger, the tensor bracketing row for that ledger, and the endpoint BHist. These are the first two witness kinds in the stated ledger.

Soundness of scalar and quadratic information is supplied by the $\mathsf{NameCert}_{\mathsf{BilinForm}^\uparrow}$ source. The bilinear transport row and the local quadratic row $v \cdot v \sim q(v)$ are recorded as rows of the generated classifier, so the scalar endpoint is never read from a host quotient.

Exactness is the induction principle for the least classifier relation. Every accepted relation step is either one of the listed generators or one of the equivalence and context closures already recorded by the relation-generation ledger. Thus any purported Clifford equality must expose one of these rows, which rules out imported algebraic equality as a hidden source. □

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage universal ledger exactness`

147.2 The certificate

Theorem 147.6 (Clifford quadratic relation obligation)**.** *For every accepted vector* BHist *row v in the* $\mathsf{VecSpace}^\uparrow$ *source and every diagonal scalar row classified by* $\mathsf{NameCert}_{\mathsf{BilinForm}^\uparrow}$ *as $q(v)$, the* $\mathsf{Clifford}^\uparrow$ *certificate contains a classifier witness identifying the product history $v \cdot v$ with the scalar-unit endpoint $q(v) \cdot 1$. The witness is transported along* hsame, Cont, *the* $\mathsf{TensorProduct}^\uparrow$ *tensor-word classifier, and the* $\mathsf{BilinForm}^\uparrow$ *diagonal classifier; no host-level quotient equality is part of the obligation.*

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordClassifierPackage quadratic relation obligation`

Proof. Start with the vector-injection constructor of Definition 147.1. Applying it twice gives two tensor-word endpoints in the $\mathsf{TensorProduct}^\uparrow$ source, and the product constructor records their product as a BHist row through Cont.

Use the $\mathsf{BilinForm}^\uparrow$ dependency to read the diagonal scalar row $q(v)$. The scalar endpoint is inserted into the Clifford carrier by the unit constructor and the scalar-row classifier supplied by the source certificate.

The quadratic boundary constructor then contributes the displayed classifier row. Transport of the vector representative uses hsame and the $\mathsf{TensorProduct}^\uparrow$ classifier; transport of the scalar endpoint uses the $\mathsf{BilinForm}^\uparrow$ classifier. Induction on the generated boundary witness has the unit and vector cases empty, the product case closed by congruence, and the boundary case exactly the relation above. □

Theorem 147.7 (Clifford quadratic boundary confluence)**.** *Suppose two accepted Clifford word histories are obtained from the same accepted tensor-word context by applying quadratic-boundary rows to two visible vector-square subwords, possibly in different orders, with accepted left and right tensor contexts around each local square. Then the two resulting endpoints are related by the generated* $\mathsf{Clifford}^\uparrow$ *classifier. The comparison uses only the local quadratic rows, tensor-context stability, and transitivity of the generated classifier; it does not use host quotient-algebra equality.*

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordClassifierPackage quadratic boundary confluence`

Proof. First isolate the two local visible squares inside the accepted tensor word. For each square, Definition 147.6 supplies the classifier row from $v \cdot v$ to the corresponding scalar-unit endpoint $q(v) \cdot 1$.

Next place each local classifier row back inside its accepted left and right tensor contexts. Apply Definition 147.4 to close the row under the surrounding product contexts, so each local reduction becomes a classifier row between accepted whole-word histories.

If the two reductions are disjoint, perform them in either order by applying the same context-stability step to the remaining visible square. If one context is nested in the other, first regard the inner reduction as a classifier row inside the outer tensor context, and then apply the outer quadratic row with the inner endpoint already transported.

In both cases the generated classifier contains the two contextualized local steps. Transitivity of the generated relation composes the first-order path with the reverse of the second-order path, yielding a classifier witness between the two endpoints. Since every step is generated inside the Clifford BHist carrier, no host quotient equality is read. □

Theorem 147.8 (Clifford product stability obligation)**.** *If a, a', b, b' are carried Clifford* BHist *rows, a is classified with a', and b is classified with b', then every product row classified from $a \cdot b$ is transported to a product row classified from $a' \cdot b'$. The transport uses* Cont *for product composition,* hsame *for endpoint replacement, the* $\mathsf{TensorProduct}^{\uparrow}$ *classifier on tensor-word spines, and NameCert-level classifier transport for every* $\mathsf{BilinForm}^{\uparrow}$ *quadratic boundary appearing in the witnesses.*

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage product stability obligation`

Proof. Induct on the classifier witness for the left factor. The reflexive generator keeps the product ledger unchanged, the tensor-product generator is transported by the $\mathsf{TensorProduct}^{\uparrow}$ classifier row, and the quadratic generator is transported by Definition 147.6.

Induct on the classifier witness for the right factor in the same product context. The Cont product row is held fixed while the endpoint is replaced by hsame, and product congruence repacks the resulting history as a Clifford product row.

For composite classifier witnesses, concatenate the two transported product ledgers. Associativity of the visible Cont spine supplies the endpoint comparison needed to read the concatenation as the same product history, so the final row remains inside the least classifier of Definition 147.2. □

Theorem 147.9 (Clifford universal factorization obligation)**.** *Let A be any BEDC algebra package whose multiplication is recorded by* BHist *product rows and whose classifier is stable under* hsame*,* Cont*, and NameCert-level transport. If a vector-row map from the shared* $\mathsf{VecSpace}^{\uparrow}$ *source into A sends each accepted vector v to an endpoint whose square is classified with the scalar endpoint $q(v)$ supplied by* $\mathsf{NameCert}_{\mathsf{BilinForm}^{\uparrow}}$*, then every Clifford carrier row has a unique induced classified image in A obtained by recursion on the generated tensor-word presentation. The recursion factors through the* $\mathsf{TensorProduct}^{\uparrow}$ *tensor-word source and respects the quadratic-relation classifier of Definition 147.2.*

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage universal factorization obligation`

Proof. Define the image on generators first. The unit row maps to the unit row of A, and a vector-injection row maps by the given vector-row map. These two clauses are compatible with the source classifiers by the assumed NameCert-level transport for A.

For a product row, use the multiplication row of A and the Cont ledger that composes the already constructed images of the two factors. The induction hypothesis supplies classified images for the factors, and product stability in A transports the composite image across representative changes.

For a quadratic boundary row, use the hypothesis that the square of the vector image is classified with the scalar endpoint $q(v)$. The $\mathsf{BilinForm}^{\uparrow}$ diagonal classifier transports the scalar representative, and Definition 147.6 supplies the corresponding Clifford-side boundary.

Uniqueness is by induction on the same generated presentation. Any factorization must agree on the unit and vector constructors, must preserve product rows because its multiplication is read through Cont, and must preserve the quadratic boundary because its square clause is exactly the diagonal $\mathsf{BilinForm}^{\uparrow}$ clause. □

Theorem 147.10 (Clifford ledger exactness obligation)**.** *The* $\mathsf{Clifford}^{\uparrow}$ *certificate ledger contains exactly the shared* $\mathsf{VecSpace}^{\uparrow}$ *source rows, the* $\mathsf{TensorProduct}^{\uparrow}$ *tensor-word rows, the* $\mathsf{BilinForm}^{\uparrow}$ *diagonal scalar rows, the unit, vector-injection, product, and quadratic-boundary constructors of Definition 147.1, and the classifier witnesses generated in Definition 147.2. Every accepted Clifford* BHist *row and every accepted classifier transport is obtained from this list by finite induction on the generated carrier and classifier witnesses.*

Proof. Soundness follows by reading each constructor. Unit and vector-injection rows are listed directly, product rows are listed with their Cont composition witness, and quadratic-boundary rows are listed with their $\mathsf{TensorProduct}^{\uparrow}$ and $\mathsf{BilinForm}^{\uparrow}$ source witnesses.

Classifier soundness is also by induction. Tensor-product classifier rows, product congruence, and the quadratic-relation row are exactly the three generators in Definition 147.2; reflexive, symmetric, and transitive uses only repack these finite witnesses through hsame.

For exactness, take any accepted Clifford ledger row. Inverting its generated carrier witness gives one of the four carrier constructors. Inverting any accepted classifier witness gives either a source classifier row, a product-congruence row, or a quadratic-boundary row. Hence no additional host quotient, analytic algebra, Spin-row, or Pin-row datum is present in the Clifford certificate. □

Lean4 ✓ `BEDC.Derived.CliffordUp.CliffordCarrierPackage ledger exactness obligation`

Closure status for $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$**.**

Constructive story: A Clifford row is generated as a finite BHist word package over a $\mathsf{VecSpace}^{\uparrow}$ source, a $\mathsf{TensorProduct}^{\uparrow}$ tensor-word source, and a $\mathsf{BilinForm}^{\uparrow}$ diagonal row presenting the quadratic form q. The carrier accepts exactly the unit row, vector-injection rows for accepted vector histories, product rows formed by Cont-composing tensor words, and boundary rows that place the visible square $v \cdot v$ beside the scalar-unit endpoint $q(v) \cdot 1$; host quotient algebras and analytic modules are outside the carrier. The classifier is the least displayed relation generated by tensor-word congruence, product congruence, bilinear-form transport, the local quadratic boundary row, and reflexive, symmetric, and transitive closure within the same accepted word surface. The source is the vector, tensor, and bilinear certificate triple, the pattern records finite word generation, product stability, quadratic confluence, and universal factorization, and the ledger records vector-letter membership, tensor bracketing, bilinear diagonal scalars, unit/vector/product constructors, and generated classifier witnesses. The five name-certificate obligations hold because the unit and vector constructors inhabit the carrier, the generated classifier supplies the equivalence rows by construction, and product-relation stability keeps every classified representative accepted under left and right tensor contexts. A word package h lies in the signature gap of a $\mathsf{Clifford}^{\uparrow}$ token p when the source-domain accepts its vector letters, tensor bracketing, and quadratic boundary rows, the signature relation pairs the word with an answer endpoint and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records exactly the generated word modulo the displayed $v \cdot v = q(v)$ boundary relation. The chapter registers this generated word-and-boundary construction under $\mathsf{Clifford}^{\uparrow}$; it exports no Spin or Pin group, host quotient algebra, analytic Clifford module, or standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface binds the universal factorization and ledger-exactness interface consumed by $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{PinGroup}^{\uparrow}$ to the concrete BHist, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{BilinForm}^{\uparrow}$, $\mathsf{TensorProduct}^{\uparrow}$, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CliffordUp.CliffordCarrierPackage\_product\_relation\_stability`

Bridge status: paperBridge

Not claimed: No Spin or Pin group, host quotient algebra, analytic Clifford module, or standard bridge is closed here.

Upgrade path: No further paper theory-axis grade is recorded for this Clifford word-and-boundary surface.

Chapter 148

A Concrete Naming Certificate for $\mathsf{SpinGroup}^{\uparrow}$

The Spin-group interface $\mathsf{SpinGroup}^{\uparrow}$ packages the connected double cover of the orthogonal group as a subgroup of the Clifford-algebra units. It depends on $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ (chapter 147) and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41).

148.1 Carrier definition

Definition 148.1 (SpinGroupUp BHist carrier packet)**.** *Fix the* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *source of chapter 147 and the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source of chapter 41. A* $\mathsf{SpinGroup}^{\uparrow}$ *carrier packet is the finite* BHist *packet whose visible rows consist of:*

1. *the Clifford unit row and its transported* $\mathsf{Group}^{\uparrow}$ *identity row;*
2. *vector rows accepted by the Clifford source and their norm-one classifier witnesses;*
3. *finite Clifford product rows closed under the carried group operation;*
4. *a cover row naming the induced orthogonal action on vector histories;*
5. *a subgroup row saying the accepted product histories lie inside the Clifford unit group surface;*
6. *an action row recording conjugation of vector histories by accepted spin histories;*
7. *a classifier row generated by the Clifford classifier, the Group classifier,* hsame *endpoint transport, and finite* Cont *product transport;*
8. Pkg *provenance rows for every Clifford source row, Group source row, cover row, subgroup row, action row, classifier row, and finite ledger row.*

The packet is a BEDC carrier presentation. It does not identify spin histories by a host quotient or by a topological connected-component predicate.

Definition 148.2 (SpinGroup root BHist carrier)**.** *The concrete* $\mathsf{SpinGroup}^{\uparrow}$ *root carrier is the finite* BHist *packet whose visible rows are all of the following:*

1. *a carried* $\mathsf{Clifford}^{\uparrow}$ *endpoint row supplied by* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$*;*
2. *a singleton-history* $\mathsf{Group}^{\uparrow}$ *law row supplied by* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *for the same visible endpoint shape;*

3. *a unit-like Clifford endpoint row, namely a Clifford carrier row classified with the Clifford unit endpoint;*
4. Cont *and* hsame *witnesses recording that the displayed multiplication and inverse rows are transported through the Clifford endpoint classifier.*

The packet contains no host orthogonal group, no quotient algebra, and no ambient matrix representation; its carrier evidence is exactly the listed BHist, Cont, hsame, NameCert, *and* UnaryHistory *data.*

Theorem 148.3 (SpinGroup source scope)**.** *Every row of Definition 148.2 is sourced through* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *or* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$*. The Clifford endpoint, unit-like endpoint, product transport, and inverse transport rows are read from the Clifford certificate; the singleton-history associativity, unit, and inverse law rows are read from the group certificate over* UnaryHistory*. No additional source row is admitted by the* $\mathsf{SpinGroup}^\uparrow$ *root carrier.*

Proof. Unpack the root carrier packet. Each constructor in the packet names either a Clifford carrier row, a Clifford classifier row, a group singleton-history law row, or a transport witness connecting these rows.

The Clifford rows are discharged by the carrier, unit, product, and classifier clauses of $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$. The group law rows are discharged by the singleton-history law surface of $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$, with the visible endpoint supplied by the same UnaryHistory spine.

It remains only to account for the transport witnesses. These are ordinary Cont and hsame rows whose endpoints are already present in the two certificates, so repacking them adds no third source. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier source scope`

Theorem 148.4 (Clifford unit lift for SpinGroup)**.** *If a* $\mathsf{Clifford}^\uparrow$ *carrier row is classified with the Clifford unit endpoint, then the same row lifts to the* $\mathsf{SpinGroup}^\uparrow$ *root carrier by pairing it with the singleton* $\mathsf{Group}^\uparrow$ *identity law row and the reflexive* Cont *and* hsame *transport witnesses. The lift preserves the visible Clifford endpoint classifier and records the row as unit-like inside the SpinGroup packet.*

Proof. Start with the displayed Clifford carrier row and its classifier witness to the unit endpoint. The carrier clause of $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ supplies the endpoint row, while classifier reflexivity supplies the stable unit comparison needed by the packet.

Next choose the singleton-history identity row from $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$. Since the endpoint spine is the same unary history, the group row and the Clifford unit row share the visible boundary required by the root carrier.

Finally repack the Clifford row, the singleton identity law, and the reflexive Cont and hsame witnesses into Definition 148.2. No multiplication or inverse row is consumed in this special case. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford unit lift`
Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier unit lift`

Theorem 148.5 (SpinGroup group-law transport)**.** *Let* a*,* b*,* a'*, and* b' *be* $\mathsf{SpinGroup}^\uparrow$ *root-carrier rows whose Clifford endpoints are classified by the* $\mathsf{Clifford}^\uparrow$ *endpoint classifier and whose group-law rows are singleton-history* $\mathsf{Group}^\uparrow$ *rows. If* $\mathsf{hsame}(a, a')$ *and* $\mathsf{hsame}(b, b')$ *hold through the Clifford classifier, then multiplication and inverse rows transported by* Cont *remain inside the* $\mathsf{SpinGroup}^\uparrow$ *root carrier and carry the corresponding* $\mathsf{Group}^\uparrow$ *multiplication and inverse laws.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier group law transport`

Proof. Unpack the two root-carrier rows. The Clifford parts expose carried endpoints and classifier witnesses, while the group parts expose the singleton-history multiplication and inverse law rows.

For multiplication, compose the two Clifford endpoint transports with the Clifford product transport supplied by $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$. The group singleton-history multiplication row is then read through $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and placed over the transported endpoint.

For inverse, use the same endpoint classifier transport with the Clifford inverse endpoint row. The singleton-history inverse law supplies the group side, and the Cont witness repacks the result as a root-carrier inverse row.

The final packet is again of the form in Definition 148.2: the visible Clifford endpoint has moved only by hsame, and every group-law row remains a $\mathsf{Group}^\uparrow$ row over the same unary history. □

Theorem 148.6 (SpinGroup NameCert obligation surface)**.** *The rows in Definition 148.2, together with Definition 148.3, Definition 148.4, and Definition 148.5, form the* $\mathsf{SpinGroup}^\uparrow$ *root* NameCert *obligation surface. The surface consists precisely of Clifford source scope, unit lift, multiplication transport, inverse transport, singleton-history group laws, and finite ledger exactness for these rows.*

Proof. Read the obligation surface row by row. Source scope is supplied by Definition 148.3; the unit face is supplied by Definition 148.4; multiplication and inverse transport are supplied by Definition 148.5.

The classifier side is finite because every row is a named component of the carrier packet. Inverting a proposed $\mathsf{SpinGroup}^\uparrow$ root obligation therefore yields either a Clifford carrier/classifier row, a singleton-history $\mathsf{Group}^\uparrow$ law row, or a displayed Cont or hsame witness between those endpoints.

Repacking these cases gives the stated root NameCert surface. No Spin or Pin global presentation, orthogonal action, matrix model, or host quotient algebra is used by this obligation surface. □

Theorem 148.7 (SpinGroup root ledger exhaustion)**.** *Every finite ledger row exposed by Definition 148.2 is one of the displayed* BHist *rows,* Cont *witnesses,* hsame *witnesses,* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *source rows,* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *source rows, or singleton* UnaryHistory *group-law rows. Conversely, each displayed row of these forms is accepted by the root carrier ledger.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier ledger semantic exhaustion`

Proof. Project an arbitrary ledger row from the root carrier packet. Constructor inversion leaves only the four packet coordinates listed in Definition 148.2: the Clifford endpoint row, the singleton-history group-law row, the unit-like Clifford endpoint row, and the displayed Cont/hsame transport witnesses.

Apply Definition 148.3 to the source rows. It confines the Clifford side to $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ and the group-law side to $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ over the same UnaryHistory spine.

For the converse direction, repack each displayed row through the same constructor projections. The unit-like case uses Definition 148.4, while product and inverse ledger rows use Definition 148.5. Thus no ledger row lies outside the concrete BEDC packet, and no displayed packet row is omitted. □

Theorem 148.8 (SpinGroup root transport closure)**.** *Let x and y be rows of the concrete* $\mathsf{SpinGroup}^\uparrow$ *root carrier of Definition 148.2. If x*hsame*y through the Clifford endpoint classifier and the connecting row is carried by* Cont *over the same* UnaryHistory *group-law spine, then every unit, multiplication, and inverse row admitted from x transports to an admitted root-carrier row over y.*

Proof. Unpack x and y as root carrier packets. Their Clifford endpoint rows are sourced by $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$, and their singleton-history group laws are sourced by $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ by Definition 148.3.

The unit row transports first. If the row is the unit-like Clifford endpoint, Definition 148.4 supplies the accepted target packet after the hsame comparison has moved the visible endpoint.

For multiplication and inverse, apply Definition 148.5. The theorem composes the Clifford endpoint transport with the product or inverse Cont row and then reads the matching singleton-history group law from $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$. The transported row is therefore again a row of Definition 148.2. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier transport closure`

Theorem 148.9 (SpinGroup root NameCert threshold package)**.** *The concrete root packet of Definition 148.2 reaches the* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *threshold determined by* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$*: its carrier rows are* BHist *rows, its classifier movement is by* hsame*, its transport rows are by* Cont*, its group-law evidence is singleton* UnaryHistory *evidence, and its ledger is exhausted by Definition 148.7.*

Proof. Start with the obligation surface of Definition 148.6. It identifies the required source, unit, multiplication, inverse, singleton-history group-law, and ledger faces of the root certificate.

The carrier and source faces are supplied by constructor projection from Definition 148.2 together with Definition 148.3. The unit face is supplied by Definition 148.4.

The transport faces are supplied by Definition 148.5 and Definition 148.8. Finally, Definition 148.7 shows that the ledger has exactly the displayed BEDC rows, so the package has no hidden orthogonal-group, matrix, or quotient-algebra obligation. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier root namecert threshold package`

Definition 148.10 (SpinGroup root public consumer boundary packet)**.** *The* $\mathsf{SpinGroup}^\uparrow$ *root public consumer boundary packet is the finite* BHist *packet whose visible rows are exactly the Clifford source row from* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$*, the singleton* $\mathsf{Group}^\uparrow$ *row from* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$*, the unit endpoint, product endpoint, and inverse endpoint rows, the even-parity* UnaryHistory *ledger, the displayed* Cont *transport rows, the displayed* hsame *classifier rows, and the* Pkg *provenance rows tying these entries to the root package.*

The packet has no field for a host orthogonal group, a Clifford quotient, a matrix model, or a standard bridge row.

Theorem 148.11 (SpinGroup root public consumer boundary coverage)**.** *Every public* $\mathsf{SpinGroup}^\uparrow$ *consumer row at the root boundary projects from Definition 148.10. In particular, the readable rows are the Clifford source row, singleton* $\mathsf{Group}^\uparrow$ *row, unit, product, inverse, even-parity ledger,* Cont*,* hsame*, and* Pkg *rows displayed by that packet.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier public consumer boundary coverage`

Proof. Start with the root threshold package of Definition 148.9. It confines the root certificate to the Clifford source, singleton group-law source, transport rows, classifier rows, unit/product/inverse endpoints, and finite ledger rows.

Project the consumer read through Definition 148.7. The ledger inversion leaves only displayed BHist rows, Cont rows, hsame rows, $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ source rows, $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ source rows, singleton UnaryHistory rows, and Pkg provenance.

Finally repack those projected rows into Definition 148.10. The packet contains exactly the row kinds left by the threshold package and ledger exhaustion, so every public root consumer row is covered by it. □

Theorem 148.12 (SpinGroup root public consumer boundary exhaustion)**.** *Every row displayed by Definition 148.10 repacks as a public* $\mathsf{SpinGroup}^{\uparrow}$ *root consumer row, and every public root consumer row is one of those displayed rows. Thus the root public boundary is exhausted by the Clifford source row, singleton* $\mathsf{Group}^{\uparrow}$ *row, unit/product/inverse endpoints, even-parity* UnaryHistory *ledger,* Cont*,* hsame*, and* Pkg *provenance.*

No host orthogonal group row, Clifford quotient row, matrix-model row, or standard bridge row is in scope for this public root boundary.

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier public consumer boundary exhaustion`

Proof. For coverage, use Definition 148.11. It projects each public root consumer row to one coordinate of the boundary packet.

For repacking, read the coordinates of Definition 148.10. The Clifford source and singleton group-law rows repack through Definition 148.3; the unit endpoint repacks through Definition 148.4; and the product and inverse endpoints repack through Definition 148.5.

The even-parity ledger, Cont, hsame, and Pkg rows repack through Definition 148.7 and then through the threshold package of Definition 148.9. The definition of the boundary packet provides no coordinate for host orthogonal groups, Clifford quotients, matrix models, or standard bridges, so the exhausted public surface cannot read any such row. □

Theorem 148.13 (SpinGroup root public boundary transport stability)**.** *Let r be a public* $\mathsf{SpinGroup}^{\uparrow}$ *root consumer row displayed by Definition 148.10. If r is transported by the displayed* hsame *and* Cont *rows while keeping the same Clifford source row, singleton* $\mathsf{Group}^{\uparrow}$ *row, even-parity* UnaryHistory *ledger, and* Pkg *provenance, then the transported row is again a public* $\mathsf{SpinGroup}^{\uparrow}$ *root consumer row.*

No host orthogonal group, matrix model, Clifford quotient, or standard bridge row enters this public boundary under the transport.

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier public boundary transport stability`

Proof. Project the original public row through Definition 148.11. The projected coordinates are exactly the Clifford source row, singleton $\mathsf{Group}^{\uparrow}$ row, unit, product, inverse, even-parity ledger, displayed Cont/hsame rows, and Pkg provenance.

Transport only the displayed classifier and continuation coordinates. The source coordinates remain fixed by Definition 148.3, and the product and inverse coordinates remain admitted by Definition 148.5 over the same singleton group-law row and unary ledger.

Repack the transported coordinates by Definition 148.12. Since the boundary packet has no coordinate for host orthogonal groups, matrix models, Clifford quotients, or standard bridges, the transported row is still a public root consumer row and no external row has entered the boundary. □

Theorem 148.14 (SpinGroup root public consumer NameCert boundary)**.** *The root public consumer surface for* $\mathsf{SpinGroup}^{\uparrow}$ *is exactly the finite* BHist NameCert *boundary consisting of the Clifford source row, the singleton* $\mathsf{Group}^{\uparrow}$ *row, unit, product, and inverse endpoints, the even-parity* UnaryHistory *ledger, the displayed* Cont *rows, the displayed* hsame *rows, and the* Pkg *provenance*

rows of Definition 148.10. Coverage, exhaustion, and transport stability are precisely the three public boundary fields for this surface.

No host orthogonal group, matrix model, Clifford quotient, or standard bridge row is exported by this public NameCert *boundary.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier public consumer namecert boundary`

Proof. The coverage field is Definition 148.11. It sends any public root consumer read to one of the displayed Clifford, singleton $\mathsf{Group}^{\uparrow}$, endpoint, parity-ledger, Cont, hsame, or Pkg rows.

The exhaustion field is Definition 148.12. It repacks each displayed coordinate as a public root consumer row and proves that no other coordinate is available at the root boundary.

The stability field is Definition 148.13. It shows that transport along the displayed Cont and hsame rows preserves the same finite public packet while keeping the Clifford source, singleton $\mathsf{Group}^{\uparrow}$ source, parity ledger, and Pkg provenance fixed.

Together these three fields are exactly the public consumer NameCert boundary for the finite packet of Definition 148.10. Since each field is formulated only in terms of that packet, the public boundary exports no host orthogonal group, matrix model, Clifford quotient, or standard bridge row. □

Theorem 148.15 (SpinGroup root public boundary no extra row)**.** *Every public* $\mathsf{SpinGroup}^{\uparrow}$ *root consumer row that is stable under the displayed* Cont *and* hsame *transports is one of the rows of Definition 148.10. In particular, no host orthogonal group row, matrix-model row, Clifford quotient row, or standard bridge row can be recovered by transport from this public boundary.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier public boundary no extra row`

Proof. Project the stable public consumer row through Definition 148.11. The projection lands in the finite packet containing only the Clifford source, singleton $\mathsf{Group}^{\uparrow}$ row, unit, product, inverse, even-parity ledger, Cont, hsame, and Pkg coordinates.

Use Definition 148.13 for the transport step. Stability keeps the row inside the same displayed packet and does not create a coordinate outside the packet.

Finally apply Definition 148.12. It says that the packet rows exhaust the public root boundary, so every transported stable row is one of the displayed coordinates. Because the packet has no coordinate for host orthogonal groups, matrix models, Clifford quotients, or standard bridges, none of those rows can be recovered by transport. □

Lemma 148.16 (SpinGroup root local consumer downstream coverage)**.** *Let c be an accepted local consumer of the* $\mathsf{SpinGroup}^{\uparrow}$ *root* BHist *packet. Then the consumer read is exhausted by the finite rows already displayed in Definition 148.2 and Definition 148.10. More precisely, c factors through one of the following local alternatives:*

1. *a* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *or* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source row covered by Definition 148.3;*
2. *a unit, product, inverse, singleton* $\mathsf{Group}^{\uparrow}$*, or even-parity* UnaryHistory *row covered by Definition 148.7;*
3. *a displayed* Cont*,* hsame*, or* Pkg *ledger coordinate of the root packet;*
4. *a public coverage coordinate of Definition 148.10, as covered by Definition 148.11 and Definition 148.12.*

Consequently every consumer request for a host orthogonal group, a Clifford quotient, a matrix model, an analytic covering datum, a connected-component predicate, or a bridge row has no accepted coordinate in the $\mathsf{SpinGroup}^{\uparrow}$ *root* BHist *packet.*

Proof. Start with an accepted local consumer read. By Definition 148.11, the read projects to the finite boundary packet of Definition 148.10. The projected coordinate is therefore one of the displayed Clifford source, singleton $\mathsf{Group}^{\uparrow}$, unit, product, inverse, even-parity $\mathsf{UnaryHistory}$, Cont, hsame, or Pkg rows.

Apply Definition 148.3 to the source coordinates. It confines every source row of the root carrier to $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ or $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ over the same unary group-law spine, so no third source can be read by the consumer.

Apply Definition 148.7 to the remaining ledger coordinates. It exhausts every finite ledger row exposed by the root carrier by the displayed BHist rows, Cont witnesses, hsame witnesses, the two $\mathsf{NameCert}$ source rows, and singleton $\mathsf{UnaryHistory}$ group-law rows. The unit case repacks through the displayed unit endpoint, while the product and inverse cases repack through the displayed transport rows already present in the same root packet.

It remains only to check that no accepted local consumer is omitted. This is the converse direction of Definition 148.12: every row displayed by the boundary packet repacks as a public $\mathsf{SpinGroup}^{\uparrow}$ root consumer row, and every public root consumer row is one of those displayed rows. Thus the four alternatives in the statement cover all accepted local consumer reads.

For the excluded requests, suppose a local consumer asks for a host orthogonal group, Clifford quotient, matrix model, analytic covering datum, connected-component predicate, or bridge row. Coverage would have to project that request to a coordinate of Definition 148.10. The definition has no such coordinate, Definition 148.3 admits no third source row, and Definition 148.7 admits no ledger row beyond the displayed finite alternatives. Hence those requests remain outside the accepted $\mathsf{SpinGroup}^{\uparrow}$ root BHist packet. □

Definition 148.17 (SpinGroup double-cover interface row)**.** *A* $\mathsf{SpinGroup}^{\uparrow}$ *double-cover interface row is the finite* BHist *packet over Definition 148.2 whose visible coordinates are the Clifford endpoint row, the singleton* $\mathsf{Group}^{\uparrow}$ *law row, the unit-like Clifford endpoint, the* Cont *and* hsame *transport witnesses between those endpoints, the* $\mathsf{UnaryHistory}$ *group-law spine, and the* Pkg *provenance rows used by the root carrier. The interface exports only these rows to the public double-cover boundary. It does not export a host Clifford quotient, a matrix realization, or an orthogonal-group primitive as an independent source.*

Theorem 148.18 (SpinGroup double-cover source exhaustion)**.** *Every public double-cover row admitted by Definition 148.17 projects through the* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$, Cont, hsame, $\mathsf{UnaryHistory}$, *and* Pkg *rows already named by Definition 148.3, Definition 148.5, and Definition 148.7. Conversely, any row obtained from those named sources and repacked into the finite interface packet is accepted as a public double-cover row.*

Proof. Project the public row from Definition 148.17. Constructor inversion leaves the same displayed coordinates as the root carrier: the Clifford endpoint, the singleton group-law row, the unit-like endpoint, the transport witnesses, the unary history spine, and the provenance row.

The source classification is then inherited without a new case split. Apply Definition 148.3 to the Clifford and group-facing coordinates, and apply Definition 148.5 to the product and inverse transport coordinates.

It remains to account for ledger visibility. Apply Definition 148.7; it says that the displayed BHist rows, Cont rows, hsame rows, $\mathsf{UnaryHistory}$ rows, and Pkg provenance rows exhaust the root

ledger. Repacking those rows into the double-cover interface gives the converse inclusion and leaves no host quotient, matrix, or orthogonal primitive outside the named BEDC sources. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier double cover source exhaustion`

Theorem 148.19 (SpinGroup NameCert root obligation package)**.** *The interface of Definition 148.17 forms a root* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *obligation package with the ten visible fields: carrier* BHist *row, Clifford source classifier, singleton* $\mathsf{Group}^\uparrow$ *source classifier,* hsame *stability,* Cont *stability, unit endpoint, multiplication endpoint, inverse endpoint, exact finite ledger, and absence of a standard bridge claim. Each field is read from Definition 148.2, Definition 148.9, and Definition 148.18.*

Proof. Start from the threshold package of Definition 148.9. It supplies the carrier, classifier movement, transport rows, singleton-history group-law evidence, and finite ledger exactness required of the root certificate.

Now refine the package into the ten visible fields. The carrier field is the finite BHist row of Definition 148.2. The two source classifiers are supplied by Definition 148.3. The hsame and Cont stability fields, together with unit, multiplication, and inverse endpoints, are supplied by Definition 148.5 and Definition 148.8.

The ledger and boundary fields are final projections. The ledger is exact by Definition 148.7, while Definition 148.18 shows that the public double-cover interface has no additional source row. Thus the obligation package contains the root certificate surface but does not assert a standard bridge. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier root namecert obligation package`

Theorem 148.20 (SpinGroup Clifford even-unit carrier obligation)**.** *The* $\mathsf{SpinGroup}^\uparrow$ *carrier is the* BHist*-coded row of Clifford unit data whose displayed product is even and whose projection lies in the orthogonal action boundary. Its visible carrier entries are inherited from* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$*: Clifford unit rows, even product witnesses, group operation and inverse rows,* hsame *transport,* Cont *and* Pkg *provenance, and ledger entries naming the projection to the orthogonal action interface. The carrier does not export a host Clifford algebra element apart from these certified rows.*

Proof. Read the Clifford unit rows from chapter 147. They provide the visible BHist product, unit, inverse, even-product, and projection rows used by the spin carrier.

Read the group-facing operation boundary from chapter 41. It supplies the multiplication, unit, inverse, carrier transport, and ledger slots needed to regard the Clifford unit rows as group rows.

Repack the shared hsame, Cont, Pkg, and ledger provenance as the carrier for $\mathsf{SpinGroup}^\uparrow$. The repacking keeps the Clifford and group rows visible and records the orthogonal projection as a boundary row, so it adds no analytic or host-level carrier beyond the displayed BEDC histories. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford even unit carrier obligation`

148.2 The certificate

Theorem 148.21 (SpinGroup carrier obligation)**.** *A* $\mathsf{SpinGroup}^\uparrow$ *certificate carries its object row as a* BHist *predicate over Clifford-even lift rows, rotation/projection endpoint rows, and a source row supplied by* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$*. The carrier is not a host spin group: every admitted spin row is a finite BEDC packet whose visible fields are a Clifford carrier row, an even-parity* UnaryHistory *ledger, a product-unit row, and a projection row into the already certified orthogonal surface.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier carrier obligation`

Proof. Read the carrier slot of the roadmap ten-field template. The traditional target is a spin lift, but the BEDC source is the $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ row together with the group operation rows named by $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$.

The BHist carrier predicate therefore accepts exactly the finite Clifford lift packet, the even-parity UnaryHistory ledger, and the projection endpoint row. The projection is read by Cont from the lift packet to the rotation endpoint, while hsame supplies only classifier transport between carried representatives.

No host spin group is introduced. The certificate surface exports the rows named by the NameCert dependencies and the displayed BEDC ledgers, so any downstream carrier use must project through those rows. □

Theorem 148.22 (SpinGroup classifier obligation)**.** *Two* $\mathsf{SpinGroup}^\uparrow$ *carrier rows are classified exactly when their Clifford lift rows, double-cover projection rows, and even-Clifford ledger rows are compared by* hsame *in the same* BHist *scope. The classifier is componentwise over the lift, projection, and parity ledger; it does not identify two rows by appealing to an external Lie-group equality.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier classifier obligation`

Proof. Use the classifier field of the roadmap ten-field template after Definition 148.21 has fixed the carried rows. The source classifier comes from $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$, and the visible projection endpoint is a BHist row, so the only available comparison is hsame.

For two carrier packets, project their Clifford lift rows, their projection rows, and their even-parity UnaryHistory ledgers. Componentwise hsame on these three rows is stable under the NameCert transport fields, and the Cont projection row keeps the lift endpoint attached to the same public rotation surface.

Conversely, any classifier row for $\mathsf{SpinGroup}^\uparrow$ must be readable through these same projections, because the carrier has no additional equality field. Hence the displayed componentwise comparison is the whole classifier obligation. □

Theorem 148.23 (SpinGroup lift parity ledger)**.** *The hidden ledger of a* $\mathsf{SpinGroup}^\uparrow$ *certificate records two rows: the even-Clifford parity row as* UnaryHistory *data over* BHist *words, and the two-to-one projection row as* Cont *data from the Clifford lift to the orthogonal endpoint. These rows are ledger data of the certificate, not new public carrier primitives.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier lift parity ledger`

Proof. Project the ledger field of the roadmap ten-field template. The Clifford source supplies word histories and product rows, while the spin certificate adds the parity and projection ledgers needed to read a lift as a double-cover point.

The parity row is unary because it records the even length of the Clifford word presentation. It is scoped as UnaryHistory over BHist rather than as an ambient integer parity predicate, and hsame transport is inherited from the Clifford word classifier.

The projection row is a Cont witness from the lift packet to the rotation endpoint. It is hidden ledger data because it witnesses how the public orthogonal row is read from the lift, while the public boundary remains the projection endpoint itself. □

Theorem 148.24 (SpinGroup concrete lift closure)**.** *If two admitted* $\mathsf{SpinGroup}^{\uparrow}$ *lift rows are composable through the Clifford product ledger, then* Cont*-composition of the two lift packets preserves the carrier and transports the classifier. The resulting packet has a Clifford-even lift row, a composed projection row, and a transported even-parity ledger in the same* BHist *certificate scope.*

Proof. Unpack the operation and stability fields of the roadmap ten-field template. Each input lift is already a BHist packet with a Clifford carrier row, an even UnaryHistory ledger, and a projection row.

Compose the lift packets using the Clifford product continuation supplied by $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$. The two even-parity ledgers compose to another even ledger inside the same unary history scope, and the two projection rows compose by Cont to the corresponding orthogonal endpoint.

Classifier transport is componentwise. The lift comparison is transported by the Clifford NameCert classifier, the projection comparison by the composed Cont rows, and the parity comparison by hsame on the unary ledger. These are exactly the carrier fields of Definition 148.21. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier concrete lift closure`

Theorem 148.25 (SpinGroup spin double cover boundary)**.** *The public boundary of* $\mathsf{SpinGroup}^{\uparrow}$ *is the double-cover projection row from a Clifford-even lift to the already certified orthogonal or special-orthogonal surface. The boundary is a* BHist *projection ledger classified by* hsame *and transported by* Cont*; it is not an external Lie group supplied outside the BEDC certificate.*

Proof. Read the exactness and boundary fields of the roadmap ten-field template. The carrier and ledger obligations have already fixed the Clifford lift, the even UnaryHistory row, and the projection endpoint as the complete visible surface.

The public row is therefore the projection endpoint, together with its Cont witness from the Clifford-even lift. The orthogonal or special-orthogonal target is already certified by its own NameCert row, so $\mathsf{SpinGroup}^{\uparrow}$ exports only the double-cover boundary into that surface.

Exactness runs in the reverse direction. Any public spin-boundary use must recover the lift row, parity ledger, and projection continuation from the same BHist packet; rows outside those fields are not part of this certificate. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier spin double cover boundary`

Theorem 148.26 (SpinGroupUp root obligation surface)**.** *The* $\mathsf{SpinGroup}^{\uparrow}$ *NameCert obligation surface consists exactly of the carrier packet of Definition 148.1, the generated classifier on its accepted histories, stability under* hsame *and finite* Cont *product transport, and the finite ledger rows naming unit, vector, product, cover, subgroup, action, classifier, and* Pkg *provenance data. In the roadmap ten-field template, the traditional target is the spin group inside the Clifford units; the BEDC sources are the cited* $\mathsf{Clifford}^{\uparrow}$ *and* $\mathsf{Group}^{\uparrow}$ *certificates; the carrier, classifier, stability, ledger, exactness, and status rows are precisely the rows displayed in the packet; the standard bridge row is empty.*

Proof. Read the carrier field from Definition 148.1. The unit, vector, and product rows are Clifford rows, while the identity and product laws are read through the $\mathsf{Group}^{\uparrow}$ source of chapter 41.

The classifier field is generated only from the two source classifiers, hsame endpoint replacement, and finite Cont product transport. Thus carrier stability follows componentwise: Clifford transport keeps the word-level rows inside chapter 147, and Group transport keeps the unit and product rows inside the group source.

The remaining roadmap fields are the finite ledger and exactness fields. The cover, subgroup, action, and provenance rows are named in the packet, so any public $\mathsf{SpinGroup}^{\uparrow}$ row is obtained by repacking those rows into the ten-field certificate surface. No additional row is available for topology, quotient equality, analytic connectedness, or a standard bridge. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier root namecert obligation surface`

Theorem 148.27 (SpinGroupUp Clifford unit carrier obligation)**.** *A* $\mathsf{SpinGroup}^{\uparrow}$ *carrier is a* BHist *packet whose visible rows are a* $\mathsf{Clifford}^{\uparrow}$ *unit row, an orthogonal-action endpoint row, and a* $\mathsf{Group}^{\uparrow}$ *carrier row. The packet exports no host Lie group, matrix equality, or ambient Clifford algebra equality beyond the displayed BEDC rows.*

Proof. Use the dependency surface stated at the start of this chapter. The $\mathsf{Clifford}^{\uparrow}$ certificate supplies the unit row inside the Clifford-algebra interface, while the $\mathsf{Group}^{\uparrow}$ certificate supplies the public group-carrier row read by downstream group consumers.

The $\mathsf{SpinGroup}^{\uparrow}$ carrier is the ten-field certificate packet that places those two dependency rows beside the orthogonal-action endpoint row. Since the carrier is a BHist packet, all equality and transport visible at the interface is through hsame and the named classifier rows, not through a host matrix or Lie-group equality. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford unit carrier obligation`

Theorem 148.28 (SpinGroupUp Clifford–Group consumer boundary)**.** *A downstream consumer of a* $\mathsf{SpinGroup}^{\uparrow}$ *certificate may read only the* $\mathsf{Clifford}^{\uparrow}$ *source rows, the* $\mathsf{Group}^{\uparrow}$ *source rows, the cover row, the subgroup row, the action row, the generated classifier row, the* hsame *and* Cont *transport witnesses, and the* Pkg *provenance rows appearing in Definition 148.1. In particular, every consumer request name factors through those rows and no request may inspect a host Lie group, a quotient representative, or an analytic connected-component object.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford group consumer boundary`

Proof. Unpack a consumer request against the displayed carrier packet. The only source rows named by the packet are the Clifford rows from chapter 147 and the Group rows from chapter 41.

The cover and action requests are finite ledger reads: the cover row names the induced action on vector histories, while the action row records conjugation by carried spin histories. Both rows retain their Pkg provenance and use the generated classifier for transport.

For a product or classifier request, the consumer must use the same finite Cont spine and hsame endpoint transport carried by the packet. Since no other row is present, the public surface exposes exactly the Clifford source, Group source, cover, action, subgroup, classifier, transport, and provenance rows listed in the statement. □

Theorem 148.29 (SpinGroupUp ledger exclusion)**.** *The public* $\mathsf{SpinGroup}^{\uparrow}$ *ledger excludes host Lie-group topology, quotient equality, analytic connectedness, and external double-cover data. Any accepted spin row must instead exhibit a finite* BHist *packet over the* $\mathsf{Clifford}^{\uparrow}$ *and* $\mathsf{Group}^{\uparrow}$ *sources, with cover, subgroup, action, classifier, transport, and* Pkg *provenance rows as in Definition 148.1.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier ledger exclusion`

Proof. Inspect the ledger rows of the carrier packet. The visible rows are all finite BEDC rows: Clifford unit and vector rows, Group unit and product rows, finite product spines, cover and action rows, subgroup rows, classifier rows, and provenance rows.

Host Lie-group topology and analytic connectedness have no row in this packet. A consumer cannot reconstruct them from hsame or Cont, since those witnesses only transport endpoints and finite product spines already present in the BEDC ledger.

Quotient equality and external double-cover data are also absent. The cover row is a named finite action row on vector histories, not a quotient object; the subgroup row is a carried Group row over Clifford units, not an imported subgroup equality. Therefore every public spin certificate is exactly the finite packet described above. □

Theorem 148.30 (SpinGroupUp double-cover ledger obligation)**.** *The double-cover ledger for a* SpinGroup$^{\uparrow}$ *packet records the Clifford unit endpoint, the projected orthogonal-action endpoint, and the kernel-sign witness as* BHist*,* hsame*,* Cont*, and* Pkg *rows. No additional covering space, topology, or host quotient is exported as public carrier data.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier double cover ledger obligation`

Proof. Read the same dependency rows through the NameCert ten-field template. The Clifford$^{\uparrow}$ side contributes the unit endpoint, and the projected orthogonal-action endpoint records the public target of the double-cover map.

The kernel-sign witness is ledger data: it is carried by BEDC rows using BHist endpoints, hsame transport, continuation provenance Cont, and package evidence Pkg. Repacking those rows into the ledger slot of the SpinGroup$^{\uparrow}$ certificate yields the stated double-cover ledger without adding a host quotient or topological covering object. □

Theorem 148.31 (SpinGroupUp group interface boundary)**.** *Any* Group$^{\uparrow}$ *consumer of a displayed* SpinGroup$^{\uparrow}$ *packet may read only the multiplication, identity, inverse, and classifier rows supplied by that packet. The Clifford multiplication rows, orthogonal projection rows, and kernel-sign witness remain ledger rows and are not exported as extra group operations.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier group interface boundary`

Proof. Project the Group$^{\uparrow}$ dependency from the carrier packet described in Definition 148.27. The public group interface consists of its multiplication, identity, inverse, and classifier rows, all carried through the same BHist packet.

The double-cover data is read separately through Definition 148.30. It supplies provenance for why the group rows come from Clifford units and the orthogonal projection, but it stays in the ledger slot of the ten-field NameCert template. Thus a Group$^{\uparrow}$ consumer receives exactly the group interface and no hidden Clifford or projection operation. □

Theorem 148.32 (SpinGroupUp Clifford-unit source obligation)**.** *A* SpinGroup$^{\uparrow}$ *source row is a displayed* Clifford$^{\uparrow}$ *unit endpoint together with even-product provenance, a* Group$^{\uparrow}$ *multiplication row, and* BHist*,* Cont*, and* Pkg *ledgers tying the unit read and the product read to the same carried source. The row records multiplication and inverse access only through the inherited Clifford-unit and group certificates, and it does not assert an uncarried host-level spin subgroup.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford unit source obligation`

Proof. Read the Clifford dependency as a unit endpoint in the Clifford$^{\uparrow}$ carrier. The even-product provenance is a finite BHist ledger whose factors are carried Clifford generators and whose product endpoint is the displayed unit row.

Read the group dependency as the multiplication and inverse package on those unit endpoints. The $\mathsf{Group}^{\uparrow}$ row supplies the operation laws only for the displayed carried endpoints, while Cont records the product computation and Pkg records the shared provenance.

Combining the two dependency reads gives the $\mathsf{SpinGroup}^{\uparrow}$ source row. Every field is inherited from $\mathsf{Clifford}^{\uparrow}$, $\mathsf{Group}^{\uparrow}$, BHist, Cont, and Pkg, so no ambient subgroup predicate or external Clifford algebra quotient is added. □

Theorem 148.33 (SpinGroupUp double-cover fiber classifier)**.** *The double-cover classifier for* $\mathsf{SpinGroup}^{\uparrow}$ *compares two carried spin endpoints by their Clifford-unit carrier rows together with the shared* $\mathsf{OrthogonalGroup}^{\uparrow}$ *action endpoint. Two spin rows are in the same fiber exactly when the Clifford-unit comparisons and the displayed orthogonal-action readback agree in the package ledger; the classifier does not quotient by host-level signs or by an unrecorded kernel object.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier double cover fiber classifier`

Proof. Unpack two $\mathsf{SpinGroup}^{\uparrow}$ source rows using Definition 148.32. Each row exposes a carried Clifford unit, even-product provenance, multiplication and inverse rows, and package provenance.

Compare the Clifford-unit coordinates with the inherited $\mathsf{Clifford}^{\uparrow}$ classifier. Then compare the displayed orthogonal-action endpoint using the shared action readback recorded in the same Pkg ledger.

The fiber classifier is the conjunction of these displayed comparisons. Since the sign ambiguity is represented only by carried Clifford-unit rows and their action endpoint, the construction never forms a host sign quotient or an unrecorded double-cover kernel. □

Theorem 148.34 (SpinGroupUp group consumer boundary)**.** *Downstream* $\mathsf{LieGroup}^{\uparrow}$ *or* $\mathsf{PinGroup}^{\uparrow}$ *consumers of* $\mathsf{SpinGroup}^{\uparrow}$ *may read only the Clifford unit row, multiplication and inverse rows, the double-cover classifier of Definition 148.33, and* NameCert *provenance. They may not inspect a host Lie group, a host sign quotient, or an uncarried Clifford algebra carrier outside the displayed BEDC source package.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier group consumer boundary`

Proof. The source obligation exposes the carried unit and the group operation rows. These are sufficient for group-style consumers to read multiplication, inverse, identity provenance, and the finite even-product ledger.

The double-cover classifier exposes exactly the additional fiber data used by geometry consumers: the Clifford-unit comparison and the shared orthogonal action endpoint. The consumer therefore reads a package of named BHist rows, not an ambient quotient.

The NameCert provenance binds these rows to the $\mathsf{SpinGroup}^{\uparrow}$ interface. Any $\mathsf{LieGroup}^{\uparrow}$ or $\mathsf{PinGroup}^{\uparrow}$ consumer that needs more structure must add its own displayed source rows rather than reading an unrecorded host object through this boundary. □

Theorem 148.35 (SpinGroup even-product classifier obligation)**.** *The* $\mathsf{SpinGroup}^{\uparrow}$ *classifier is inherited from the Clifford unit classifier together with group classifier transport. For carried spin rows it is stable under multiplication, inverse, and replacement of even-product witnesses, and it preserves the projection ledger into the orthogonal action boundary. The classifier surface uses only* BHist *rows,* hsame *transport,* Cont/Pkg *provenance,* NameCert *fields, and the Clifford and group ledgers.*

Proof. Apply chapter 147 to read the Clifford unit classifier and the even-product witness transport rows. These rows compare the displayed Clifford products through certified BHist data.

Apply chapter 41 to transport the same classifier through multiplication and inverse. The group boundary supplies the operation and inverse stability rows without replacing the BEDC comparison by host equality.

The projection ledger is carried along the same Cont and Pkg provenance used by the carrier theorem. Thus multiplication, inverse, and even-witness replacement preserve the classifier and leave the orthogonal action boundary unchanged. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier even product classifier obligation`

Theorem 148.36 (SpinGroup NameCert obligation surface)**.** *The carrier row of Definition 148.20 and the classifier row of Definition 148.35 assemble the* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *obligation surface. This surface contains the Clifford even-unit carrier, group transport rows, classifier stability, inverse and multiplication stability, even-product witness stability, projection ledger,* hsame *transport,* Cont/Pkg *provenance, and the exact visible ledger boundary. It explicitly does not assert connected Lie topology, smooth-manifold structure, analytic covering data, or a topological double cover theorem.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupUp StdBridge`

Proof. Start with the carrier theorem. It fixes the accepted histories as Clifford unit rows with even-product witnesses and an orthogonal-action projection ledger, all read through chapter 147 and chapter 41.

Then apply the classifier theorem. It supplies classifier transport under group multiplication and inverse and preserves the even-product and projection ledger rows.

Repack these rows into the NameCert fields: source, carrier, classifier, stability, exactness, and ledger. Since every row is a BHist, hsame, Cont, or Pkg row inherited from the Clifford and group boundaries, the resulting $\mathsf{SpinGroup}^{\uparrow}$ surface is a BEDC certificate surface only and carries no Lie-topological or analytic covering assertion. □

Theorem 148.37 (SpinGroup spin-boundary inclusion transport)**.** *Let a* $\mathsf{SpinGroup}^{\uparrow}$ *root carrier row be admitted by Definition 148.3. Transport it by* hsame *along the Clifford endpoint and by* Cont *along the shared unary group-law spine. The transported row is still an admitted Spin boundary row: its Clifford unit component, even-word component, and singleton group-law component remain inside the* BHist *surface named by the SpinGroup certificate.*

Proof. Start with the root source scope of Definition 148.3. It exposes the accepted row only as a Clifford source row together with the displayed group-law spine.

Apply Definition 148.8. The hsame Clifford endpoint transport preserves the unit and even-word witnesses, and the Cont group-law transport preserves the singleton group interface.

Finally apply Definition 148.31. It identifies the transported unary group-law spine with the same boundary read by the SpinGroup carrier. Repacking these transported rows gives an admitted Spin boundary row and adds no host orthogonal group or quotient row. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier spin boundary inclusion transport`

Theorem 148.38 (SpinGroup Clifford-unit ledger coverage)**.** *Every ledger row visible at the* $\mathsf{SpinGroup}^{\uparrow}$ *spin boundary is one of the following finite* BHist *rows: a Clifford unit row, a singleton Group law row, a* Cont *transport row, an* hsame *transport row, or a* Pkg *provenance row. No spin-boundary ledger row is supplied by an ambient orthogonal group, matrix model, quotient algebra, or analytic covering datum.*

Proof. Apply Definition 148.7. It exhausts the root ledger by the visible Clifford endpoint, even-product witness, group-law transport, Cont readback, hsame comparison, and Pkg provenance rows.

Then apply Definition 148.27. This identifies the Clifford side of the ledger with unit rows already accepted by the consumed $\mathsf{Clifford}^{\uparrow}$ certificate.

The remaining ledger entries are the singleton group-law row and the transport or provenance rows listed by the root exhaustion theorem. Hence every visible row has one of the five forms in the statement, and there is no further external ledger source to inspect. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier clifford unit ledger coverage`

Theorem 148.39 (SpinGroup PinGroup consumer source exactness)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *spin-inclusion consumer reads exactly the* $\mathsf{SpinGroup}^{\uparrow}$ *boundary rows: the Clifford unit rows, singleton group-law rows,* Cont *transport rows,* hsame *transport rows, and* Pkg *provenance rows exposed by the SpinGroup certificate. It reads no host orthogonal group, matrix model, quotient algebra, analytic covering datum, or separate source outside that boundary.*

Proof. First use Definition 148.37. It shows that the rows transported into the consumer remain Spin boundary rows rather than host-level Clifford or group equalities.

Next use Definition 148.38. The ledger visible to the consumer is exhausted by Clifford unit, singleton group-law, Cont, hsame, and Pkg rows.

Finally apply Definition 148.36 and Definition 149.7. The SpinGroup obligation surface is the exported boundary, and the PinGroup inclusion surface consumes that boundary as its source. Therefore the consumer source is exact and admits none of the excluded host, model, quotient, analytic, or covering data. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier pin consumer source exactness`

Theorem 148.40 (SpinGroup root threshold obligation triple)**.** *An accepted* $\mathsf{SpinGroup}^{\uparrow}$ *root packet exposes exactly three threshold rows: the* BHist *Clifford unit carrier row, the even-word parity row, and the group-law transport row. These rows are visible only through* Cont*,* hsame*, and* NameCert *provenance from Definition 148.1 and Definition 148.2. No additional root row is available outside the threshold package of Definition 148.9 and the obligation surface of Definition 148.36.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier threshold obligation triple`

Proof. Project the accepted packet through Definition 148.2. Its constructors expose only the Clifford endpoint row, the singleton group-law row, the unit-like Clifford row, and the displayed Cont/hsame transport witnesses.

Next compare this projection with the wider packet of Definition 148.1. The wider packet contributes the finite Clifford product rows and the parity ledger, while Definition 148.9 confines them to the same $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ provenance.

Finally use Definition 148.36. It repacks the carrier, classifier, stability, exactness, and ledger faces and leaves only the Clifford unit carrier, even-word parity, and group-law transport as the root threshold rows. Thus the packet has no host quotient, ambient orthogonal group equality, or matrix-model row. □

Theorem 148.41 (SpinGroup root even-word classifier inversion)**.** *Any accepted classifier comparison between* $\mathsf{SpinGroup}^{\uparrow}$ *root packets projects to the even Clifford word row, the inherited group*

carrier row, and the double-cover fiber row. The inversion is internal to the displayed BHist *packet: it reads the even-word component from Definition 148.1, the group carrier component from Definition 148.2, and the fiber component from Definition 148.33. It does not use a host quotient or an ambient orthogonal group equality.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier even word classifier inversion`

Proof. Start with the accepted classifier comparison and project it through Definition 148.36. The classifier face is a BEDC row assembled from hsame, Cont, Pkg, and the displayed Clifford and group certificate rows.

The even component is obtained by projecting the Clifford product part of Definition 148.1. Because Definition 148.9 fixes the root source surface, this projection is the even Clifford word row rather than an ambient parity predicate.

The inherited group carrier row is the singleton-history group-law component of Definition 148.2. The remaining projection is the double-cover fiber classifier supplied by Definition 148.33. These three projected rows exhaust the accepted comparison, so no host quotient or external orthogonal equality is read. □

Theorem 148.42 (SpinGroup root double-cover consumer exhaustion)**.** *A downstream* $\mathsf{PinGroup}^{\uparrow}$ *or* $\mathsf{Clifford}^{\uparrow}$ *consumer of the* $\mathsf{SpinGroup}^{\uparrow}$ *root double-cover boundary can read only the visible Clifford unit source, the parity classifier, inverse and product witnesses, the double-cover fiber classifier, finite* Cont *readbacks, and* Pkg *provenance. These are exactly the rows exposed by Definition 148.1, Definition 148.2, Definition 148.9, Definition 148.33, and Definition 148.36.*

Proof. Project a consumer read through Definition 148.36. The obligation surface lists the carrier, classifier, stability, exactness, and ledger rows available to any downstream consumer.

Apply Definition 148.9 to the root part. It confines carrier reads to the visible Clifford unit source, parity ledger, inverse and product witnesses, finite Cont transport, hsame comparison, and Pkg provenance. The concrete packet definitions provide no other constructor to inspect.

Finally apply Definition 148.33 to the projection boundary. The only extra classifier available there is the double-cover fiber classifier, and it is again a displayed finite BHist row. Repacking the projected rows gives exactly the consumer surface named in the statement, with no host quotient, ambient orthogonal group equality, analytic covering datum, or standard-bridge datum. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier double cover consumer exhaustion`

Corollary 148.43 (SpinGroup BHist packet strict obstruction)**.** *Let a displayed* $\mathsf{SpinGroup}^{\uparrow}$ BHist *packet row be used as a failure, refusal, separation, or countermodel row against a converse double-cover read or against reuse by a downstream consumer. Then the obstruction is strict and local: it blocks only the named route whose readback asks for one of the exported packet coordinates, namely the Clifford-even lift row, the even* UnaryHistory *parity ledger, the double-cover projection endpoint, the projection* Cont *witness, the* hsame *classifier row, or the cited* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source rows. It cannot be reinterpreted as a global impossibility for spin groups, as a host theorem about Clifford or orthogonal groups, or as hidden external validation of an unlisted route.*

Proof. Start with the displayed obstruction row and read it through the public double-cover boundary of Definition 148.25. That boundary has only one consumer-facing readback: the projection endpoint together with its Cont witness from the Clifford-even lift. Exactness in the same theorem forces any public spin-boundary use to recover the Clifford-even lift row, the even UnaryHistory

parity ledger, and the projection continuation from the same finite BHist packet. A row that is not one of these readback coordinates is therefore not a boundary coordinate for the converse route.

Now apply the source-scope theorem Definition 148.3. Every root carrier row is sourced through $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ or $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$: the Clifford endpoint, unit-like endpoint, product transport, and inverse transport rows are read from the Clifford certificate, while the singleton-history group-law rows are read from the group certificate over the same unary history. No third source row is admitted by the $\mathsf{SpinGroup}^\uparrow$ root carrier.

Consequently any consumer-facing use of the obstruction must factor through the displayed list: source rows from $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$, the Clifford-even lift, the parity ledger, the projection endpoint, the projection Cont witness, and the hsame classifier movement. If the proposed converse or reuse route asks for one of those rows and the displayed failure, refusal, separation, or countermodel row denies that coordinate, the route is blocked.

The same factorization also rejects stronger readings. A global impossibility statement would require a row ranging over spin groups outside this finite packet; a host theorem would require a Clifford, orthogonal, quotient, matrix, or topological source not supplied by the two certificates; and hidden external validation would require an accepted route not listed among the boundary readback and source-scope rows. The cited boundary and source-scope theorems provide none of those coordinates. The obstruction is therefore only a local negative certificate for the named converse or reuse route inside the displayed $\mathsf{SpinGroup}^\uparrow$ BHist packet. □

Theorem 148.44 (SpinGroup double-cover fiber ledger)**.** *The double-cover fiber ledger row exposed by* $\mathsf{SpinGroup}^\uparrow$ *is exactly the Clifford-unit comparison, the parity* UnaryHistory *row, the orthogonal-action endpoint, the* Cont *projection witness, and the* Pkg *provenance. These five rows are the fiber face of Definition 148.1 and Definition 148.33; no host sign quotient or ambient orthogonal-group equality is part of the ledger.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier double cover fiber ledger`

Proof. Project the carried packet through Definition 148.1. The visible coordinates include the Clifford unit data, parity history, action endpoint, continuation witness, and package provenance.

Apply Definition 148.33. It compares the two carried spin endpoints only by the Clifford-unit comparison and the shared orthogonal-action endpoint recorded in the package ledger.

The parity row and the Cont witness are the transport data that make this comparison a fiber row. Since the classifier theorem exposes no other constructor, the five displayed rows exhaust the ledger. □

Theorem 148.45 (SpinGroup conjugation action readback)**.** *The action row in Definition 148.1 reads conjugation only from the displayed Clifford product rows, Clifford inverse rows, and* hsame *transport. It does not read a host action, a matrix action, or an unrecorded orthogonal representation outside the* $\mathsf{SpinGroup}^\uparrow$ *packet.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier conjugation action readback`

Proof. Unpack the action coordinate of Definition 148.1. Its source rows are the Clifford-unit endpoint, the multiplication ledger, the inverse ledger, and the displayed hsame transports between the selected endpoints.

Use Definition 148.34 to restrict downstream reads to Clifford unit, multiplication, inverse, double-cover classifier, and provenance rows. The conjugation action is therefore reconstructed from the product-inverse-product spine already present in the packet.

The hsame rows transport the readback between classifier-equal endpoints. No host action row is available after this projection, so the action readback is exactly the displayed Clifford product and inverse readback. □

Theorem 148.46 (SpinGroup boundary consumer exactness)**.** *Every* $\mathsf{PinGroup}^{\uparrow}$, $\mathsf{LieGroup}^{\uparrow}$, *or* $\mathsf{Clifford}^{\uparrow}$ *consumer of the* $\mathsf{SpinGroup}^{\uparrow}$ *boundary reads precisely the exported Clifford-unit source, parity classifier, multiplication and inverse rows, conjugation readback, double-cover fiber ledger, finite* Cont *witnesses, and* Pkg *provenance. No host orthogonal group, host quotient, or additional Clifford carrier row is exported.*

Proof. Begin with Definition 148.42. It already confines root double-cover consumers to the visible Clifford unit, parity, inverse, product, fiber classifier, continuation, and provenance rows.

Apply Definition 148.44 to replace the fiber classifier by its exact ledger rows. Apply Definition 148.45 for the action coordinate; that readback contributes only Clifford product, inverse, and hsame transport rows.

Finally use Definition 148.34. Its consumer projection admits the same rows for $\mathsf{PinGroup}^{\uparrow}$, $\mathsf{LieGroup}^{\uparrow}$, and $\mathsf{Clifford}^{\uparrow}$ consumers and admits no host orthogonal group or quotient row. Thus the exported boundary is exact. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier boundary consumer exactness`

Theorem 148.47 (SpinGroup conjugation action product law)**.** *Let S and T be accepted* $\mathsf{SpinGroup}^{\uparrow}$ *packets of Definition 148.1. Let s and t be their visible Clifford-unit endpoints, let $s \cdot t$ be the endpoint supplied by the packet's finite Clifford product row, and let v be a Clifford-vector row accepted by the same* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *source. Write*

$$\mathsf{Act}_s(v) := (s \cdot v) \cdot s^{-1}$$

for the conjugation endpoint read by the action row, and write $\sim_{\mathsf{Clifford}^{\uparrow}}$ *for the generated* $\mathsf{Clifford}^{\uparrow}$ *classifier. Then the product action endpoint and the iterated action endpoint are both accepted Clifford-vector action rows in the* $\mathsf{SpinGroup}^{\uparrow}$ *packet, and*

$$\mathsf{Act}_{s\cdot t}(v) \sim_{\mathsf{Clifford}^{\uparrow}} \mathsf{Act}_s(\mathsf{Act}_t(v)).$$

The comparison keeps the same orthogonal-action endpoint and the same Pkg *provenance ledger. It is a Clifford-row classifier comparison, not equality of host linear maps, matrices, or an unrecorded orthogonal-group action.*

Proof. Project the two accepted packets through Definition 148.1. The visible data include the Clifford-unit endpoints s and t, the Clifford product row for $s \cdot t$, the inverse rows for s, t, and $s \cdot t$, the action row on Clifford-vector histories, the orthogonal-action endpoint, and the Pkg provenance rows. By Definition 148.28 and Definition 148.34, no other action source is available to the consumer.

Apply Definition 148.45. The action endpoint for the product packet is read as the Clifford word

$$((s \cdot t) \cdot v) \cdot (s \cdot t)^{-1}.$$

The iterated action endpoint is read as the Clifford word

$$(s \cdot ((t \cdot v) \cdot t^{-1})) \cdot s^{-1}.$$

Both words are accepted Clifford rows because the action readback uses only Clifford product rows, Clifford inverse rows, and hsame transport already present in the packet.

The word comparison is the same BEDC group calculation as Definition 41.96, now read inside the Clifford-unit surface. First, the inverse row for the product is the reversed inverse product row supplied by Definition 41.65:

$$(s \cdot t)^{-1} \sim_{\mathsf{Clifford}^{\uparrow}} t^{-1} \cdot s^{-1}.$$

Multiplication congruence and associativity for the displayed product spine transport this comparison through the outer Clifford products, so

$$((s \cdot t) \cdot v) \cdot (s \cdot t)^{-1} \sim_{\mathsf{Clifford}^{\uparrow}} ((s \cdot t) \cdot v) \cdot (t^{-1} \cdot s^{-1}).$$

Reassociating the same finite product spine gives

$$((s \cdot t) \cdot v) \cdot (t^{-1} \cdot s^{-1}) \sim_{\mathsf{Clifford}^{\uparrow}} (s \cdot ((t \cdot v) \cdot t^{-1})) \cdot s^{-1}.$$

The transport of each reassociation through the Clifford classifier is exactly the product-stability row of Definition 147.8 inside the generated classifier of Definition 147.2. Transitivity of that classifier gives the displayed comparison between $\mathsf{Act}_{s \cdot t}(v)$ and $\mathsf{Act}_s(\mathsf{Act}_t(v))$.

It remains to identify the endpoint and provenance read by the public spin boundary. The double-cover row is not recomputed from a host orthogonal group: Definition 148.33 compares spin packets by the Clifford-unit comparison together with the shared orthogonal-action endpoint in the package ledger. The calculation above changes only the parenthesization of the displayed Clifford product-inverse-product spine and uses the product inverse row already named by the packet. Therefore the orthogonal-action endpoint and the Pkg provenance row remain the same, and the action product law is internal to the displayed $\mathsf{SpinGroup}^{\uparrow}$ boundary. □

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier conjugation action product law`

Theorem 148.48 (SpinGroup conjugation action identity law)**.** *Let S be an accepted* $\mathsf{SpinGroup}^{\uparrow}$ *packet of Definition 148.1 whose visible Clifford-unit endpoint is the identity endpoint e. Let v be any Clifford-vector row accepted by the same* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *source. Write*

$$\mathsf{Act}_e(v) := (e \cdot v) \cdot e^{-1}$$

for the conjugation endpoint read by the action row, and write $\sim_{\mathsf{Clifford}^{\uparrow}}$ for the generated $\mathsf{Clifford}^{\uparrow}$ *classifier. Then $\mathsf{Act}_e(v)$ is an accepted Clifford-vector action row in the same* $\mathsf{SpinGroup}^{\uparrow}$ *packet and*

$$\mathsf{Act}_e(v) \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

The comparison uses only the displayed Clifford identity, inverse, product, hsame, Cont, *and* Pkg *rows; it does not use a host linear action, a matrix model, or an ambient orthogonal-group equality.*

Lean4 ✓ `BEDC.Derived.SpinGroupUp.SpinGroupRootCarrier conjugation action identity law`

Proof. Project S through Definition 148.1. The visible coordinates include the Clifford identity endpoint e, the inverse row for e, the finite product rows with Clifford-vector rows, the action row, the classifier row generated by the Clifford classifier and hsame transport, and the Pkg provenance for these rows. By Definition 148.28 and Definition 148.34, no other action source is available to the consumer.

Apply Definition 148.45. The action endpoint for the identity packet is read as the Clifford word

$$(e \cdot v) \cdot e^{-1}.$$

This word is an accepted Clifford action row because the readback uses only the packet's Clifford product rows, inverse rows, and endpoint transports.

The identity endpoint is carried as the same unit row on the Clifford and $\mathsf{Group}^{\uparrow}$ sides of the packet. The inverse row for the identity endpoint is therefore classified with the identity endpoint by the group inverse law over that carried Clifford-unit surface. Transporting this inverse comparison through the right product context gives

$$(e \cdot v) \cdot e^{-1} \sim_{\mathsf{Clifford}^{\uparrow}} (e \cdot v) \cdot e.$$

The transport is an instance of the product-stability row of Definition 147.8 inside the generated classifier of Definition 147.2.

Now apply the two displayed identity laws in the same finite product spine. The right identity law collapses the final factor:

$$(e \cdot v) \cdot e \sim_{\mathsf{Clifford}^{\uparrow}} e \cdot v.$$

The left identity law collapses the initial factor:

$$e \cdot v \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

Transitivity of the generated $\mathsf{Clifford}^{\uparrow}$ classifier composes these three rows and gives

$$(e \cdot v) \cdot e^{-1} \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

Substituting the action readback notation yields $\mathsf{Act}_e(v) \sim_{\mathsf{Clifford}^{\uparrow}} v$.

The calculation has changed only the displayed Clifford product-inverse-product word by inverse and unit rows already present in the packet. The orthogonal readback and Pkg provenance are not recomputed from any host representation, so the identity action law is internal to the public $\mathsf{SpinGroup}^{\uparrow}$ boundary. □

Theorem 148.49 (SpinGroup conjugation action inverse-involution law)**.** *Let S be an accepted $\mathsf{SpinGroup}^{\uparrow}$ packet of Definition 148.1 with visible Clifford-unit endpoint s, inverse endpoint s^{-1}, identity endpoint e, and displayed left-inverse row*

$$s^{-1} \cdot s \sim_{\mathsf{Clifford}^{\uparrow}} e.$$

Let v be a Clifford-vector row accepted by the same $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ source. Write

$$\mathsf{Act}_s(v) := (s \cdot v) \cdot s^{-1}$$

for the conjugation endpoint read by the action row, and write $\sim_{\mathsf{Clifford}^{\uparrow}}$ for the generated $\mathsf{Clifford}^{\uparrow}$ classifier. Then the iterated endpoint

$$\mathsf{Act}_{s^{-1}}(\mathsf{Act}_s(v))$$

is an accepted Clifford-vector action row in the same $\mathsf{SpinGroup}^{\uparrow}$ packet and

$$\mathsf{Act}_{s^{-1}}(\mathsf{Act}_s(v)) \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

The comparison is the displayed inverse-cancellation row of the Clifford-unit ledger transported through the conjugation readback; it is not equality of host linear maps, matrices, or an ambient orthogonal-group action.

Proof. Project S through Definition 148.1. The packet contains the Clifford-unit endpoint s, its inverse endpoint s^{-1}, the identity endpoint e, product rows for $s^{-1} \cdot s$, the action row on Clifford-vector histories, the generated $\mathsf{Clifford}^{\uparrow}$ classifier, and the Pkg provenance for these rows. By Definition 148.28 and Definition 148.34, this is the whole readable surface for the downstream action calculation.

Apply Definition 148.47 with outer spin endpoint s^{-1} and inner spin endpoint s. The product endpoint and the iterated action endpoint are accepted Clifford-vector action rows in the same packet, and the product law gives

$$\mathsf{Act}_{s^{-1} \cdot s}(v) \sim_{\mathsf{Clifford}^{\uparrow}} \mathsf{Act}_{s^{-1}}(\mathsf{Act}_s(v)).$$

By symmetry of the generated classifier, it is enough to compare $\mathsf{Act}_{s^{-1} \cdot s}(v)$ with v.

The displayed left-inverse row in the carried $\mathsf{Group}^{\uparrow}$ surface identifies the Clifford-unit product endpoint with the identity endpoint:

$$s^{-1} \cdot s \sim_{\mathsf{Clifford}^{\uparrow}} e.$$

This row is read on the Clifford side through the same multiplication and inverse coordinates used by the action readback. Applying Definition 148.45, the two action endpoints are the Clifford words

$$((s^{-1} \cdot s) \cdot v) \cdot (s^{-1} \cdot s)^{-1}$$

and

$$(e \cdot v) \cdot e^{-1}.$$

Transport the comparison $s^{-1} \cdot s \sim_{\mathsf{Clifford}^{\uparrow}} e$ through the left factor of the first word by Definition 147.8. For the inverse factor, apply inverse congruence from the carried $\mathsf{Group}^{\uparrow}$ rows, equivalently the inverse-congruence field listed in Definition 41.55, and then transport the resulting comparison through the right product context using the same Clifford product stability. Thus

$$\mathsf{Act}_{s^{-1} \cdot s}(v) \sim_{\mathsf{Clifford}^{\uparrow}} \mathsf{Act}_e(v).$$

Now apply Definition 148.48 to the identity endpoint in the same packet:

$$\mathsf{Act}_e(v) \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

Transitivity of the generated classifier composes the product-law comparison, the transported inverse-cancellation comparison, and the identity-action comparison, giving

$$\mathsf{Act}_{s^{-1}}(\mathsf{Act}_s(v)) \sim_{\mathsf{Clifford}^{\uparrow}} v.$$

The accepted-row assertion for the iterated endpoint was already supplied by the product-law application, and every transport used above is a displayed Clifford product, inverse, hsame, Cont, or Pkg row of the same $\mathsf{SpinGroup}^{\uparrow}$ packet. □

Theorem 148.50 (SpinGroup conjugation action classifier congruence)**.** *Let S be an accepted $\mathsf{SpinGroup}^{\uparrow}$ packet of Definition 148.1. Let s and s' be visible Clifford-unit endpoints of S with $s \sim_{\mathsf{Clifford}^{\uparrow}} s'$. Let v and v' be Clifford-vector rows accepted by the same $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ source with $v \sim_{\mathsf{Clifford}^{\uparrow}} v'$. Write*

$$\mathsf{Act}_s(v) := (s \cdot v) \cdot s^{-1}$$

for the conjugation endpoint read by the action row, and write $\sim_{\mathsf{Clifford}^\uparrow}$ *for the generated* $\mathsf{Clifford}^\uparrow$ *classifier. Then* $\mathsf{Act}_s(v)$ *and* $\mathsf{Act}_{s'}(v')$ *are accepted Clifford-vector action rows in the same* $\mathsf{SpinGroup}^\uparrow$ *packet, and*

$$\mathsf{Act}_s(v) \sim_{\mathsf{Clifford}^\uparrow} \mathsf{Act}_{s'}(v').$$

The comparison is the classifier transport of the displayed product-inverse-product word; it does not use equality of host linear maps, matrices, or an unrecorded orthogonal action.

Proof. Project S through Definition 148.1. The visible rows include the Clifford-unit endpoints s and s', the Clifford-vector rows v and v', the finite Clifford product rows, the inverse rows supplied through the carried $\mathsf{Group}^\uparrow$ surface, the action row on vector histories, the generated $\mathsf{Clifford}^\uparrow$ classifier, and the Pkg provenance tying these rows to the same packet. By Definition 148.28 and Definition 148.34, no other action source is available to a consumer of this packet.

Apply Definition 148.45. The two action endpoints are read as the Clifford words

$$(s \cdot v) \cdot s^{-1}$$

and

$$(s' \cdot v') \cdot (s')^{-1}.$$

These are accepted action rows because the readback uses only Clifford product rows, Clifford inverse rows, and hsame transport already present in S.

The displayed comparison $s \sim_{\mathsf{Clifford}^\uparrow} s'$ lies in the Clifford-unit surface carried by the same packet. The inverse-congruence row listed in Definition 41.55, read through that carried group surface, transports it to

$$s^{-1} \sim_{\mathsf{Clifford}^\uparrow} (s')^{-1}.$$

Now apply the product-stability row of Definition 147.8 inside the generated classifier of Definition 147.2. Applied first to $s \sim_{\mathsf{Clifford}^\uparrow} s'$ and $v \sim_{\mathsf{Clifford}^\uparrow} v'$, it gives

$$s \cdot v \sim_{\mathsf{Clifford}^\uparrow} s' \cdot v'.$$

Applied again to this product comparison and to the inverse comparison above, it gives

$$(s \cdot v) \cdot s^{-1} \sim_{\mathsf{Clifford}^\uparrow} (s' \cdot v') \cdot (s')^{-1}.$$

Substituting the action readback notation yields the asserted classifier row between $\mathsf{Act}_s(v)$ and $\mathsf{Act}_{s'}(v')$.

All rows used in the calculation are read from the same $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ source and the same accepted $\mathsf{SpinGroup}^\uparrow$ packet: the two input classifier comparisons, the inverse-congruence row, the two Clifford product-stability transports, the action readback, and the provenance ledger. Hence the congruence is internal to the packet and keeps the action endpoint within the same public $\mathsf{SpinGroup}^\uparrow$ boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$**.**

Constructive story: A spin row is generated by taking the displayed $\mathsf{Clifford}^\uparrow$ unit surface, pairing it with the singleton-history $\mathsf{Group}^\uparrow$ law surface, and keeping the Clifford endpoint, unit-like endpoint, multiplication and inverse transports, parity history, projection row, continuation witnesses, and provenance in one finite packet. The carrier accepts only those BHist rows whose Clifford, group, UnaryHistory, Cont, hsame, and Pkg fields are present; a host orthogonal group, matrix realization, Clifford quotient, or topological connected-component predicate is not part of the root boundary. Two accepted spin packets classify together by componentwise hsame on the Clifford lift, group-law row, parity ledger, projection endpoint, multiplication and inverse rows, and package provenance, with finite continuation routes carrying the double-cover and conjugation readbacks. The source specification is the combined $\mathsf{Clifford}^\uparrow$ and $\mathsf{Group}^\uparrow$ boundary, the

pattern specification records unit, multiplication, inverse, even-parity, double-cover fiber, and conjugation-action rows, and the ledger keeps the Clifford-unit comparison, parity row, orthogonal-action endpoint, projection witness, and provenance visible. The five name-certificate obligations are supplied by the root obligation package: an accepted packet inhabits the carrier, componentwise hsame gives reflexive, symmetric, and transitive classifier movement, and source-scope plus ledger-exhaustion repack every transported unit, product, inverse, and fiber row inside the same boundary. A packet history h lies in the signature gap of a $\mathsf{SpinGroup}^{\uparrow}$ token p when the source-domain accepts its Clifford-group boundary, the signature relation pairs it with an answer spin packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the unit, multiplication, inverse, parity, projection, and fiber rows are exactly those encoded by p. The chapter registers this Clifford-unit boundary construction under the name $\mathsf{SpinGroup}^{\uparrow}$; it introduces no full double-cover theorem, no topological connectedness proof, and no standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation surface binds the carrier, classifier, transport, unit, multiplication, inverse, and ledger rows over $\mathsf{Clifford}^{\uparrow}$, $\mathsf{Group}^{\uparrow}$, BHist, Cont, hsame, UnaryHistory, and Pkg.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$, bridgeChecked)

Chapter 149

A Concrete Naming Certificate for $\mathsf{PinGroup}^{\uparrow}$

The Pin-group interface $\mathsf{PinGroup}^{\uparrow}$ packages the double cover of the full orthogonal group, extending Spin by a reflection generator. It depends on $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ (chapter 148) and $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ (chapter 147).

149.1 Carrier definition

Definition 149.1 (PinGroupUp reflection-extension carrier)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *reflection-extension carrier is the finite* BHist *carrier obtained from the* $\mathsf{SpinGroup}^{\uparrow}$ *carrier of chapter 148 by adjoining one displayed reflection-generator row inside the* $\mathsf{Clifford}^{\uparrow}$ *carrier of chapter 147. Its classifier is inherited from* hsame*-compatible Clifford transport: two displayed pin rows are classified exactly when the underlying Clifford carrier rows are connected by the finite* Cont *ledger accepted by the source* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *and their spin subrows are classified by the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *surface.*

Theorem 149.2 (PinGroup BHist carrier obligation)**.** *Every* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *carrier is a* BHist *predicate built from the consumed* $\mathsf{SpinGroup}^{\uparrow}$ *and* $\mathsf{Clifford}^{\uparrow}$ *certificate rows. Its accepted histories record the Spin carrier row, the Clifford multiplication and grading rows, a finite reflection-generator ledger, and the classifier boundary used by the displayed orthogonal-action surface. It adds no host Pin-group carrier, host orthogonal group, or external Clifford algebra object.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionExtensionCarrier bhist carrier obligation`

Proof. Unpack the ten-field NameCert template. The source rows are the $\mathsf{SpinGroup}^{\uparrow}$ certificate of chapter 148 and the $\mathsf{Clifford}^{\uparrow}$ certificate of chapter 147, so the carrier field is read as a predicate on BHist histories already accepted by those rows.

The remaining fields attach only classifier, stability, exactness, and ledger information. The reflection generator and orthogonal-action boundary therefore enter as certificate rows inside the same history predicate, not as a host carrier.

Thus the Pin carrier is the displayed BHist predicate generated by Spin rows, Clifford rows, and the finite generator ledger. Since the template has no further carrier slot, no external Pin object is exported. □

Theorem 149.3 (PinGroup reflection-generator obligation)**.** *The reflection-generator row of a* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ *certificate is carried by a finite* Cont *ledger witness over the* $\mathsf{Clifford}^\uparrow$ *certificate rows. The row records a unary generator, its classifier-stable Clifford action, and its compatibility with the Pin carrier. It is not a host orthogonal transformation and does not import a host reflection group.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface reflection generator obligation`

↪ variant `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier reflection generator obligation`

Proof. Read the generator row inside the certificate ledger supplied by the $\mathsf{Clifford}^\uparrow$ source chapter (chapter 147). The ledger witness is a finite Cont entry whose endpoints are carried histories, so the generator is available only through BEDC rows.

Stability is then the stability field of the same ten-field template: replacing endpoints by hsame histories preserves the Clifford action row and the Pin carrier predicate. Exactness says that the generator row is accepted precisely when those carried Clifford and ledger witnesses are present.

Therefore the reflection generator is a finite ledger witness internal to the certificate. The displayed orthogonal meaning is a classifier boundary read from that row, not an imported host transformation. □

Theorem 149.4 (PinGroup Spin-extension obligation)**.** *The* $\mathsf{PinGroup}^\uparrow$ *carrier includes the consumed* $\mathsf{SpinGroup}^\uparrow$ *carrier as its even subcarrier. A Spin witness accepted by chapter 148 embeds into the Pin carrier through the Clifford even-grade rows and the shared classifier, and its image uses the identity reflection-generator ledger entry.*

Proof. Unpack the source field for the $\mathsf{SpinGroup}^\uparrow$ dependency. Its carrier, classifier, and exactness rows are already BEDC rows over BHist, so they may be copied into the Pin carrier field without changing their classifier.

Use the $\mathsf{Clifford}^\uparrow$ grading rows to identify these copied histories as the even subcarrier inside the Pin predicate. The generator ledger contributes the identity row, so no odd reflection generator is required for Spin witnesses.

The template's exactness field then states that the embedded Spin rows are accepted by the Pin carrier exactly through those even Clifford and identity ledger witnesses. This gives the Spin inclusion as a certificate row rather than a separate host subgroup. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier spin extension obligation`

Theorem 149.5 (PinGroup full-orthogonal projection obligation)**.** *The full-orthogonal projection row of a* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ *certificate records the classifier boundary from the Pin carrier to the displayed orthogonal-action surface. The row is sourced from the Clifford action and the finite reflection-generator ledger, and it exports only the carried action classifier, not a host orthogonal group element.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionExtensionCarrier full orthogonal projection obligation`

Proof. Start with a Pin carrier witness. By Definition 149.2, it consists of Spin and Clifford source rows together with the finite reflection-generator ledger.

Apply the classifier field of the ten-field template to read the displayed orthogonal-action surface from those rows. The Clifford action supplies the even part, and Definition 149.3 supplies the finite reflection-generator part.

The exactness field identifies the projection row with that classifier boundary. Hence the public projection records only the BEDC action classifier and its ledger provenance, while excluding a host orthogonal-group carrier. □

149.2 The certificate

Theorem 149.6 (PinGroupUp reflection-generator admission)**.** *The reflection-generator row displayed in Definition 149.1 is admitted by the* $\mathsf{PinGroup}^{\uparrow}$ *carrier precisely as a* BHist *row already carried by the source* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$*, together with the finite* Cont *provenance ledger identifying it as the non-spin generator row of the pin surface.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionGeneratorCarrier admission`

Proof. Project the generator from the Clifford carrier in chapter 147. The row is a displayed BHist carrier entry, so it is available to the pin carrier without forming any host orthogonal-group element.

The hsame classifier and finite Cont ledger carried by the Clifford certificate provide the admissibility certificate for transporting the generator row. Repacking those rows with the source $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ provenance gives the reflection-generator field of Definition 149.1.

No quotient of Clifford units and no equality in a host orthogonal group is used; the admitted object is only the displayed BHist generator row and its $\mathsf{NameCert}$ provenance. □

Theorem 149.7 (SpinGroupUp inclusion surface for PinGroupUp)**.** *Every* BHist *carrier row supplied by* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *embeds into the Definition 149.1 as the spin subrow of the* $\mathsf{PinGroup}^{\uparrow}$ *carrier. Its classifier,* Cont *transport ledger, and* $\mathsf{NameCert}$ *provenance are the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *rows, read inside the ambient Clifford carrier.*

Proof. Start with a carried spin row from chapter 148. By the construction of Definition 149.1, the pin carrier keeps the whole spin carrier and adds only the displayed reflection-generator row.

The spin classifier is not recomputed. It is copied as the inherited hsame-compatible classifier row and transported by the same finite Cont ledger already accepted by $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$.

The Clifford dependency supplies the ambient carrier in which both the spin subrow and the reflection-generator row live. Therefore the inclusion surface is a kernel-level BHist inclusion with $\mathsf{NameCert}$ provenance, not an identification with a host orthogonal subgroup. □

Theorem 149.8 (PinGroupUp Clifford conjugation ledger)**.** *The Clifford conjugation data visible to* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the finite ledger consisting of the spin subrow, the reflection-generator row, the* hsame *classifier transports between their Clifford carrier representatives, and the* Cont *provenance rows supplied by* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$*. This ledger records provenance for pin conjugation without exporting a quotient action or host orthogonal-group equality.*

Proof. Read the two source rows from Definition 149.1: the inherited $\mathsf{SpinGroup}^{\uparrow}$ carrier row and the displayed Clifford reflection-generator row. Both are already BHist rows in the Clifford carrier.

Apply the hsame-compatible transport surface of chapter 147. Its finite Cont ledger records how the Clifford representatives are transported under the displayed conjugation rows, and its $\mathsf{NameCert}$ provenance records the source of each projection.

Combining these projections gives the exact conjugation ledger exposed by $\mathsf{PinGroup}^{\uparrow}$. Since the ledger consists only of BHist, hsame, Cont, and $\mathsf{NameCert}$ rows, it exports no quotient of Clifford representatives and no equality in a host orthogonal group. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface clifford conjugation ledger`

Theorem 149.9 (PinGroupUp Clifford-reflection product closure)**.** *Let a displayed* $\mathsf{PinGroup}^{\uparrow}$ *carrier expose the inherited spin row* S*, the Clifford carrier row* C*, the reflection-generator row* R*, and the Clifford product ledger* μ *supplied by the source* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$*. If* x *is carried by* S *and* R *is carried by* C*, then the displayed product row* $\mu(x, R)$ *is again a carried* $\mathsf{PinGroup}^{\uparrow}$ *row. Its Clifford source is* C*, its reflection source is* R*, and its transport is exhausted by the* hsame *comparisons and* Cont *entries already present in the displayed carrier.*

Proof. Project the spin carrier row, Clifford carrier row, reflection row, product ledger, continuation ledger, and provenance row from Definition 149.1 and the source $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ certificate. These projections give all endpoints used by the product row $\mu(x, R)$.

The Clifford endpoint is read through C, and the reflection endpoint is read through R. The public classifier compares both endpoints only by hsame, so transported product endpoints remain in the displayed finite packet.

Repack the product row by appending the product entry already named by μ to the finite BHist ledger and transporting the same entry by the displayed Cont row. The resulting packet has the same source rows, reflection row, and provenance row, hence it is again a $\mathsf{PinGroup}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier reflection product closure`

Theorem 149.10 (PinGroup odd reflection coset exhaustion)**.** *Every carried non-spin* $\mathsf{PinGroup}^{\uparrow}$ *row is generated by the displayed Clifford reflection row, a* $\mathsf{SpinGroup}^{\uparrow}$ *source row, and the finite* Cont *ledger entries of Definition 149.1. The odd side contains no additional source row beyond the reflection generator and the already displayed Clifford product ledger.*

Proof. Start with a carried row whose classifier is not read through the inherited spin subcarrier. By Definition 149.1, the available non-spin data are the displayed Clifford reflection row, the inherited $\mathsf{SpinGroup}^{\uparrow}$ source row, and the finite Cont ledger.

Apply Definition 149.6 to identify the reflection endpoint as the generator row. Apply Definition 149.7 to keep the spin endpoint inside the inherited source row.

Finally apply Definition 149.9. It repacks the spin endpoint, the reflection endpoint, and the Clifford product ledger as a carried $\mathsf{PinGroup}^{\uparrow}$ row, so every non-spin row is exhausted by those finite entries. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier odd reflection coset exhaustion`

Theorem 149.11 (PinGroup reflection parity determinacy)**.** *The finite reflection ledger of Definition 149.1 determines whether a carried* $\mathsf{PinGroup}^{\uparrow}$ *row is read through the* $\mathsf{SpinGroup}^{\uparrow}$ *subcarrier or through the odd reflection side. This parity reading is invariant under* hsame *transport of the displayed Clifford representatives.*

Proof. Inspect the finite BHist ledger in Definition 149.1. A row with no active reflection-generator entry is read through the spin subcarrier by Definition 149.7.

When the reflection-generator entry is active, apply Definition 149.6. The row is then read on the odd reflection side, and Definition 149.9 records the same choice after multiplying by the displayed Clifford product row.

It remains to check transport. The classifier only compares Clifford representatives by hsame, and the continuation data are finite Cont entries already present in the same ledger. Transport therefore preserves which of the two displayed readings the row uses. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface reflection parity determinacy`

Theorem 149.12 (PinGroup source ledger coverage)**.** *Every public* $\mathsf{PinGroup}^{\uparrow}$ *source projection is covered by exactly the displayed* $\mathsf{SpinGroup}^{\uparrow}$ *and* $\mathsf{Clifford}^{\uparrow}$ *source rows together with the reflection-generator ledger of Definition 149.1. No further public source certificate is exported by the* $\mathsf{PinGroup}^{\uparrow}$ *boundary.*

Proof. Read the public source projections from Definition 149.1. The displayed source rows are the inherited $\mathsf{SpinGroup}^{\uparrow}$ row and the $\mathsf{Clifford}^{\uparrow}$ row carrying the reflection generator and Clifford product ledger.

Apply Definition 149.6 for the generator projection and Definition 149.7 for the spin projection. Apply Definition 149.9 to cover the product rows that combine those two displayed sources.

The remaining public entries are hsame comparisons and finite Cont provenance rows over the same ledger. They do not introduce a new source projection, so the listed SpinGroupUp, CliffordUp, and reflection-generator rows cover the whole public boundary. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface source ledger coverage`

Theorem 149.13 (PinGroupUp Spin and Clifford source scope)**.** *Every source row admitted by a* $\mathsf{PinGroup}^{\uparrow}$ *carrier is one of the displayed* $\mathsf{SpinGroup}^{\uparrow}$ *or* $\mathsf{Clifford}^{\uparrow}$ *source rows of Definition 149.1. The reflection-generator row, the Clifford-product row, and the spin-inclusion row are internal rows over those two sources and do not introduce a third source certificate.*

Proof. Induct over the finite BHist ledger underlying the displayed carrier. The initial source entries are exactly the inherited spin row and the Clifford row from Definition 149.1.

For a reflection-generator entry, the carrier definition reads its source and target through the Clifford row, so the entry contributes no new source. For a spin inclusion entry, the domain is the inherited spin row and the codomain is the displayed Clifford row.

For a Clifford-product entry, the ledger row is μ and its endpoints are the already carried spin and reflection rows. The continuation step preserves the same finite source list by Cont, so the induction closes with only the two displayed source certificates. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier spin clifford source scope`

Theorem 149.14 (PinGroup NameCert boundary surface)**.** *The* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *boundary packages the carrier, classifier, reflection-generator row, Spin inclusion, full-orthogonal projection, exactness, and ledger rows into one certificate surface. The carrier is the* BHist *predicate of Definition 149.2; the reflection row is the finite* Cont *witness of Definition 149.3; the Spin row is the even-subcarrier embedding of Definition 149.4; and the projection row is the classifier boundary of Definition 149.5.*

Proof. Collect the four obligation rows. The carrier row supplies the predicate over BHist, the reflection row supplies the finite generator ledger, the Spin-extension row supplies the even subcarrier, and the projection row supplies the classifier boundary to the orthogonal-action surface.

The ten-field template repacks these rows by placing the consumed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ certificates in the source field, the Pin classifier in the classifier field, the displayed transport clauses in the stability field, and the finite generator and projection witnesses in the ledger field.

Exactness is then the statement that a history is accepted exactly when the listed source, classifier, reflection, Spin-inclusion, projection, and ledger rows are present. This is the required PinGroup boundary surface and contains no host Pin group or host orthogonal transformation. □

Theorem 149.15 (PinGroupUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *obligation surface consists exactly of the reflection-extension carrier of Definition 149.1, its componentwise* hsame *classifier, the reflection-generator row, the Clifford-product ledger, the spin-inclusion surface, and the finite* Cont/Pkg *ledger scope. It claims no data beyond the displayed* $\mathsf{SpinGroup}^{\uparrow}$ *and* $\mathsf{Clifford}^{\uparrow}$ *source certificates.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier semantic name certificate`

Proof. Unpack the carrier packet. The projections expose the spin source, Clifford source, reflection generator, Clifford product, spin inclusion, continuation ledger, and provenance row.

Apply Definition 149.6 to identify the admitted reflection row. Apply Definition 149.9 to identify the product row as a carried $\mathsf{PinGroup}^{\uparrow}$ row. Apply Definition 149.13 to restrict all source rows to the displayed spin and Clifford surfaces.

The classifier contains only componentwise hsame transport and Cont transport of the finite ledger. Repacking those projections gives precisely the named obligation surface, with no additional carrier or source certificate available to downstream consumers. □

Definition 149.16 (PinGroupUp reflection-parity carrier)**.** *The visible reflection-parity carrier of* $\mathsf{PinGroup}^{\uparrow}$ *is the* BHist *predicate generated by two displayed packets: the Spin-inclusion row of Definition 149.4 and the finite reflection-generator ledger of Definition 149.3. A public row lies in the inherited Spin branch when its source projection factors through the Spin-inclusion row. It lies in the reflection branch when its source projection factors through one listed Clifford reflection generator and the Clifford-product ledger of Definition 149.9. The carrier contains no third parity source and no host-level parity predicate.*

Theorem 149.17 (PinGroupUp reflection-parity stability)**.** *The reflection-parity carrier of Definition 149.16 is stable under the transport rows already present in the public* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface. Transporting the Spin row by* hsame *preserves the inherited Spin branch, and transporting the finite reflection ledger by* Cont *preserves the reflection branch.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier stability`

Proof. For the inherited branch, unpack the Spin-inclusion row from Definition 149.15. Its public comparison is componentwise hsame, so an hsame transport of the Spin source and target is again read through the same Spin-inclusion row.

For the reflection branch, unpack the reflection generator and product ledger. Apply Definition 149.6 to identify the admitted generator row, then apply Definition 149.9 to keep products inside the displayed finite BHist ledger.

The continuation row is exactly the Cont field already exposed by Definition 149.15. Repacking the transported Spin row and the transported reflection ledger gives the same two-branch carrier of Definition 149.16. □

Theorem 149.18 (PinGroupUp reflection-parity exactness)**.** *The public* $\mathsf{PinGroup}^{\uparrow}$ *classifier distinguishes exactly the two branches of Definition 149.16. A public row is classified as inherited precisely when the listed* BHist, hsame, Cont, Pkg, *and* NameCert *rows factor through the Spin-inclusion source, and it is classified as reflective precisely when those same rows factor through the Clifford reflection-generator source and its product ledger.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier exactness`

Proof. Start from the public obligation packet of Definition 149.15. Its source fields are only the displayed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ certificates, and its classifier fields are componentwise hsame comparisons plus the finite Cont ledger.

If the row factors through the Spin-inclusion source, the classifier reads the row through the inherited Spin branch. The Pkg and $\mathsf{NameCert}$ projections name the same source certificate, so no reflection-generator witness is used.

If the row factors through a Clifford reflection generator, apply Definition 149.6 to obtain the generator row and Definition 149.9 to obtain the closed product row. The classifier then reads the row through the reflection branch, with the same Cont ledger and provenance row.

Conversely, any row classified by the public packet has one of those two factorizations, because Definition 149.13 exhausts all available source rows. Therefore the classifier is exact for the two visible parity branches. □

Theorem 149.19 (PinGroupUp source exhaustion)**.** *Every public* $\mathsf{PinGroup}^{\uparrow}$ *row is generated either by the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *source or by the* $\mathsf{Clifford}^{\uparrow}$ *reflection-generator source listed in Definition 149.1. No public row of the* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface has a source outside these two displayed origins.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier source exhaustion`

Proof. Unpack a public $\mathsf{PinGroup}^{\uparrow}$ row through Definition 149.15. The carrier, classifier, ledger, and provenance projections are exactly the projections of Definition 149.1.

Apply Definition 149.13. It states that the only admitted source rows are the inherited Spin source and the Clifford source, while reflection-generator, product, and Spin-inclusion rows are internal rows over those sources.

The reflection side is closed under the finite product ledger by Definition 149.9. Repacking the two cases gives source exhaustion for the whole public surface. □

Theorem 149.20 (PinGroup reflection ledger closure)**.** *Every reflection-generator row of the public* $\mathsf{PinGroup}^{\uparrow}$ *surface is a finite* Cont *ledger over carried* $\mathsf{Clifford}^{\uparrow}$ *rows, and this ledger remains stable under* hsame *transport. Thus the reflection branch is anchored in* BHist *rows supplied by the Clifford source certificate, with no external reflection object.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface reflection ledger closure`

Proof. Start from Definition 149.3. It reads the reflection-generator row as a finite Cont witness whose endpoints are carried by the consumed $\mathsf{Clifford}^{\uparrow}$ certificate.

Use the Clifford source certificate recorded in chapter 147. Its carrier and classifier rows are BHist rows stable under hsame and certificate-level transport, so the Pin reflection ledger inherits the same stability.

Repack the transported rows through the public packet of Definition 149.15. The result is exactly the finite reflection ledger visible to $\mathsf{PinGroup}^{\uparrow}$ consumers. □

Theorem 149.21 (PinGroup Spin boundary exhaustion)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *carrier reads the Spin subcarrier exactly through the consumed* $\mathsf{SpinGroup}^{\uparrow}$ *row together with the even-grade Clifford rows already carried by the source certificate. No additional Spin boundary is available outside the displayed* BHist *carrier, classifier, and* Cont *transport rows.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface spin boundary exhaustion`

Proof. Apply Definition 149.4. It embeds the consumed $\mathsf{SpinGroup}^{\uparrow}$ carrier as the Spin branch of the Pin reflection-extension carrier.

Next apply Definition 149.15. The public certificate surface exposes the Spin branch only through its source certificate, the Clifford even-grade rows used by that source, and the finite Cont ledger that transports those rows into the Pin carrier.

Since the surface lists no separate Spin object, every Spin-boundary row of $\mathsf{PinGroup}^{\uparrow}$ is exhausted by those consumed BHist rows and their hsame transports. □

Theorem 149.22 (PinGroup Clifford action consumer surface)**.** *Downstream consumers of the public* $\mathsf{PinGroup}^{\uparrow}$ *Clifford action may read only the reflection ledger, Clifford action row, Spin boundary,* Pkg *provenance,* Cont *transport, and* hsame *witnesses displayed by the* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface. They receive no host orthogonal group and no external Pin object beyond these* BHist*-anchored rows.*

Proof. Read the public action data from Definition 149.15. Its exported fields are the carrier, classifier, source certificates, finite Cont ledger, hsame transport witnesses, and Pkg provenance rows.

Apply Definition 149.20 for the reflection ledger and Definition 149.21 for the Spin boundary. The Clifford action row is the same carried source row used in Definition 149.8.

The source exhaustion theorem Definition 149.19 leaves no further public source. Therefore a downstream consumer cannot read a host orthogonal group or an external Pin object from the public $\mathsf{PinGroup}^{\uparrow}$ action surface. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupUp StdBridge`

Definition 149.23 (PinGroup consumer readback packet)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet is the finite public packet obtained from* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *by retaining exactly the reflection ledger, the Clifford action row, the Spin boundary row, the* Pkg *provenance rows, the finite* Cont *transport rows, and the* hsame *witnesses carried by the public certificate. It contains no host orthogonal group, no external Pin object, and no row not exported by the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface.*

Theorem 149.24 (PinGroup consumer readback packet soundness)**.** *Every accepted public* $\mathsf{PinGroup}^{\uparrow}$ *consumer row projects to the* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet of Definition 149.62.*

Proof. Apply Definition 149.15. It says that the accepted public surface of $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ is carried by the finite carrier, classifier, source, transport, witness, and provenance rows listed in the certificate.

The reflection component is then covered by Definition 149.20. That theorem identifies every reflection read with the displayed reflection ledger and its finite BHist provenance.

The Spin component is covered by Definition 149.21. Hence the remaining public action read is the Clifford action row already exposed by the certificate surface, and all transport or identity data are the displayed Cont and hsame rows. These are exactly the rows retained in the readback packet. □

Theorem 149.25 (PinGroup consumer readback packet exactness)**.** *Any* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet reconstructs the public* $\mathsf{PinGroup}^{\uparrow}$ *Clifford-action consumer surface and exposes no host orthogonal group or external Pin object.*

Proof. Start with a packet as in Definition 149.62. Its reflection ledger, Clifford action row, Spin boundary, Pkg provenance, finite Cont transport, and hsame witnesses are precisely the rows admitted by the public consumer surface of Definition 149.22.

Apply Definition 149.19. The only sources available to the public Pin certificate are the displayed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ source rows together with their transported histories.

Therefore repacking the packet rows reconstructs the same consumer surface, while the source-exhaustion and consumer-surface theorems exclude any host orthogonal group or external Pin object outside those rows. □

Theorem 149.26 (PinGroup downstream unblock package)**.** *The carrier definition of* $\mathsf{PinGroup}^{\uparrow}$ *together with Definition 149.62, Definition 149.63, and Definition 149.64 forms the ten-field downstream package consumed by later Clifford-family and Spin-family chapters: carrier, classifier, reflection ledger, Clifford action row, Spin boundary row, source exhaustion,* Pkg *provenance, finite* Cont *transport,* hsame *witnesses, and exclusion of host orthogonal or external Pin reads.*

Proof. The carrier and classifier are the public $\mathsf{PinGroup}^{\uparrow}$ rows already fixed by Definition 149.15. The reflection ledger, Clifford action row, and Spin boundary are exactly the three rows retained in Definition 149.62.

Soundness is supplied by Definition 149.63; exact readback and exclusion of host data are supplied by Definition 149.64. The remaining provenance, transport, and witness fields are the packet's Pkg, Cont, and hsame rows.

Thus a later Clifford-family or Spin-family consumer may cite this single package instead of separately collecting the carrier, source, ledger, transport, and exclusion rows. □

Theorem 149.27 (PinGroup full-orthogonal action exactness)**.** *The public full-orthogonal action row of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the classifier boundary assembled from the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *source, the Clifford reflection generator, the Clifford product ledger,* hsame*,* Cont*, and* Pkg *rows of the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*. It admits no additional host orthogonal action row outside that boundary.*

Proof. Apply Definition 149.12 to locate the inherited $\mathsf{SpinGroup}^{\uparrow}$ source and the Clifford source inside the finite source ledger. Apply Definition 149.18 to identify the classifier boundary with the parity carrier induced by those two source branches.

Apply Definition 149.19. The only public projections remaining after the carrier read are the listed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ rows, their Cont transports, their hsame comparisons, and their Pkg provenance.

Finally apply Definition 149.65. Its consumer package records the reflection ledger, Clifford action row, Spin boundary row, source exhaustion, transport, witnesses, and provenance as one exported surface, so the full-orthogonal action row is exactly that classifier boundary. □

Theorem 149.28 (PinGroup reflection-parity boundary)**.** *Every public* $\mathsf{PinGroup}^{\uparrow}$ *row factors through exactly one branch of Definition 149.16: either the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *branch or the Clifford reflection branch. No public row factors through both branches except by the inherited Spin classification already recorded in the carrier.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier source projection no confusion`

Proof. Use Definition 149.12 to read the public source ledger as the two displayed sources and their transported histories. Apply Definition 149.18 to classify each public row by the reflection-parity carrier.

For a row classified by the inherited Spin branch, the carrier records exactly the $\mathsf{SpinGroup}^{\uparrow}$ inclusion and its hsame, Cont, and Pkg rows. For a row classified by the Clifford reflection branch, the carrier records the reflection generator and Clifford product ledger.

Apply Definition 149.19 to rule out a third branch. Then apply Definition 149.65 to see that the consumer-visible package exports precisely these two branches and the Spin overlap already classified by the inherited branch. □

Theorem 149.29 (PinGroup source projection separation)**.** *The public source projections of* $\mathsf{PinGroup}^{\uparrow}$ *to* $\mathsf{SpinGroup}^{\uparrow}$ *and* $\mathsf{Clifford}^{\uparrow}$ *are disjoint except for rows classified by the inherited Spin branch of Definition 149.16. Consequently the public certificate has no third source projection.*

Proof. Apply Definition 149.12. It places every public source read in the displayed $\mathsf{SpinGroup}^{\uparrow}$ or $\mathsf{Clifford}^{\uparrow}$ source row, with the advertised BHist histories and no additional projection field.

Apply Definition 149.18. The classifier separates inherited Spin rows from Clifford reflection rows, and it identifies the only common public classification as the inherited Spin branch already present in the reflection-parity carrier.

Apply Definition 149.19 to exclude any remaining public source projection. The downstream package of Definition 149.65 then repacks exactly the two source projections, their transports, witnesses, and provenance for later consumers. □

Definition 149.30 (PinGroup scoped primitive binding)**.** *The scoped primitive binding for* $\mathsf{PinGroup}^{\uparrow}$ *is the finite dependency package whose only primitive rows are* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$. *The inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row and the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row are read only through those two source certificates, and every reflection-parity carrier, classifier, transport, and provenance row of this chapter is a row in that package.*

Theorem 149.31 (PinGroup parity scope transport)**.** *Every reflection-parity carrier transport used by* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the primitive package of Definition 149.69. In particular, parity transport may use only the carried* BHist *histories, displayed* hsame *comparisons, finite* Cont *routes,* Pkg *provenance, and the two source certificate rows from* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface parity scope transport`

Proof. Use Definition 149.83 to identify the parity rows as the inherited Spin branch, Clifford reflection branch, transport rows, and provenance rows.

Then apply Definition 149.86. It repacks the same rows as the scoped reflection-parity source and excludes host orthogonal, matrix, quotient, and third-source data. Hence every carrier transport factors through exactly the primitive binding package. □

Theorem 149.32 (PinGroup consumer boundary exhaustion)**.** *Every downstream consumer of the scoped* $\mathsf{PinGroup}^{\uparrow}$ *surface receives only the two source projections, the reflection-parity classifier, the transport rows, and the provenance package. No downstream consumer receives a host orthogonal group, matrix model, quotient Clifford unit, or additional Pin source row.*

Proof. Project the consumer through Definition 149.88. This gives the consumer readback packet, reflection-parity classifier, Spin inclusion row, Clifford reflection product row, transport rows, finite continuation routes, and provenance rows.

Finally apply Definition 149.65. It identifies the downstream package with the same finite rows, so the exported consumer boundary has exactly the two source projections, classifier, transport, and provenance data stated above. □

Theorem 149.33 (PinGroup reflection-generator transport closure)**.** *The* hsame *transport of the Clifford reflection-generator row preserves* $\mathsf{PinGroup}^{\uparrow}$ *carrier admission exactly through the finite* Cont *ledger of the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*; no transported reflection-generator row is admitted without the carrier row, the reflection-generator obligation, and the closed reflection ledger.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface reflection generator transport closure`

Proof. Project the carrier admission row of Definition 149.1. It exposes the Clifford reflection-generator source, its hsame witness, and its finite Cont transport as the only carrier-facing generator data.

Apply Definition 149.3 to identify the accepted generator row, then apply Definition 149.20. The ledger closure repacks exactly the transported row and excludes any host generator outside the displayed Cont ledger. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionGenerator transport closure`

Theorem 149.34 (PinGroup Spin subrow classifier readback)**.** *Every* $\mathsf{SpinGroup}^{\uparrow}$ *source row embedded in the* $\mathsf{PinGroup}^{\uparrow}$ *carrier is read by the inherited Spin classifier together with the identity reflection ledger. The embedded row therefore contributes no independent Clifford reflection generator beyond the Spin boundary already carried by* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*.*

Proof. Apply Definition 149.4. It places the $\mathsf{SpinGroup}^{\uparrow}$ source row inside the carrier with the inherited classifier, the identity reflection entry, hsame, Cont, and Pkg provenance.

Apply Definition 149.21. The exhaustion theorem rules out a second reflection-generator read on the Spin subrow, so the classifier readback is precisely the inherited Spin row plus the identity reflection ledger. □

Theorem 149.35 (PinGroup orthogonal projection ledger exhaustion)**.** *Every public orthogonal-action projection row of* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the inherited Spin source, the Clifford action row, the reflection-generator parity row, the listed* hsame *transports, the finite* Cont *ledger, and the* Pkg *provenance row of* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*.*

Proof. Apply Definition 149.5 to reduce a public orthogonal-action read to the certificate projection ledger. Apply Definition 149.12 to identify its Spin source, Clifford action, and reflection-generator parity components.

Finally apply Definition 149.22. It exports exactly those source rows with their hsame, Cont, and Pkg data, so no further public orthogonal-action projection remains. □

Definition 149.36 (PinGroup root consumer threshold packet)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is the finite public packet whose rows are the* $\mathsf{SpinGroup}^{\uparrow}$ *source row, the* $\mathsf{Clifford}^{\uparrow}$ *source row, the reflection-parity row of Definition 149.16, the orthogonal-action projection row, the* hsame *transport rows, the finite* Cont *ledger rows, and the* Pkg *provenance rows displayed by* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*. A downstream root consumer reads only this packet when it asks for the Pin reflection boundary.*

Theorem 149.37 (PinGroup root source-threshold coverage)**.** *Every source row visible to the* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is covered by the consumed* $\mathsf{SpinGroup}^{\uparrow}$ *source, the consumed* $\mathsf{Clifford}^{\uparrow}$ *source, and the reflection-parity split of Definition 149.16. No third source projection is visible at the threshold.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupSpinSubrowClassifier readback`

Proof. Use Definition 149.12. It places every public source read in the Spin or Clifford source ledger and records the same BHist histories in the finite certificate packet.

Apply Definition 149.73 to read the Spin subrow through the inherited classifier, and apply Definition 149.18 to separate the Clifford reflection branch from the inherited Spin branch.

Finally apply Definition 149.19. The exhaustion result rules out any source outside those two rows, so the threshold packet has exactly the advertised source coverage. □

Theorem 149.38 (PinGroup root reflection-threshold exactness)**.** *The reflection part of the* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is accepted exactly when the Clifford reflection-generator obligation, the reflection-parity classifier, the orthogonal-action projection, and the finite* hsame *and* Cont *transport rows of* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *are present. It exports no host reflection, matrix reflection, or orthogonal-group element.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier root reflection threshold exactness`

Proof. Project the reflection generator through Definition 149.72. This identifies the admitted reflection row with the carrier row, the generator obligation, and the closed finite reflection ledger.

Apply Definition 149.18. The classifier accepts precisely the inherited Spin branch or the Clifford reflection branch, and the reflection threshold is the latter branch with its displayed parity row.

Now apply Definition 149.74. The orthogonal-action readback is exhausted by the Spin source, Clifford action, parity row, hsame transports, Cont ledger, and Pkg provenance already listed in the threshold packet. Hence no host reflection object is exported. □

Theorem 149.39 (PinGroup root downstream threshold surface)**.** *The downstream root-facing surface of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the consumer threshold packet of Definition 149.75. It supplies the Spin source row, Clifford source row, reflection-parity row, orthogonal projection row,* hsame *transport rows,* Cont *ledger rows, and* Pkg *provenance rows needed by Spin-facing and Pin-facing root consumers, and it supplies no analytic covering, quotient algebra, matrix model, or host orthogonal-group surface.*

Proof. First use Definition 149.76. It fixes the only source rows available to the threshold packet and keeps them inside the Spin and Clifford source ledgers.

Next use Definition 149.77. It fixes the reflection branch by the generator obligation, parity classifier, orthogonal projection, and finite transport ledgers.

Finally apply Definition 149.65 and Definition 149.22. These results repack the same source, reflection, action, hsame, Cont, and Pkg rows for downstream consumers. The packet is therefore the full root threshold surface, with all host analytic and algebraic models excluded. □

Theorem 149.40 (PinGroup root carrier obligation scope)**.** *The carrier rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the* $\mathsf{SpinGroup}^{\uparrow}$ *source row, the* $\mathsf{Clifford}^{\uparrow}$ *source row, the reflection-parity carrier row, and the orthogonal-action projection row displayed by Definition 149.75. No matrix model, analytic cover, quotient algebra, or host orthogonal-group carrier is part of the obligation scope.*

Proof. Begin with Definition 149.75. Its public packet lists the Spin source, Clifford source, reflection-parity carrier, and orthogonal-action projection rows as the carrier-facing data.

Use Definition 149.76. It proves that every source row visible at the threshold is covered by the Spin and Clifford source rows together with the reflection-parity split.

Apply Definition 149.77 and Definition 149.78. These results place the reflection and projection rows inside the same finite threshold packet and exclude all host carrier models from the downstream surface. □

Theorem 149.41 (PinGroup root classifier obligation scope)**.** *The classifier rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *classifier on Spin subrows and the reflection-parity classifier separating the inherited Spin branch from the Clifford reflection branch. No independent Clifford classifier, matrix parity classifier, or quotient classifier is exported.*

Proof. Read the inherited Spin classifier from Definition 149.73. A Spin source row embedded in the Pin carrier is classified by the inherited Spin row together with the identity reflection ledger.

Read the reflection branch from Definition 149.77. It uses Definition 149.18 to identify the accepted reflection side with the reflection-parity classifier and the Clifford reflection-generator obligation.

Finally use Definition 149.78. The downstream threshold surface repacks exactly those classifier rows, so there is no remaining classifier obligation outside the inherited Spin and reflection-parity rows. □

Theorem 149.42 (PinGroup root ledger obligation scope)**.** *The ledger rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the listed* hsame *transports, finite* Cont *rows,* Pkg *provenance rows, and the orthogonal projection ledger exhausted by Definition 149.74. These rows are sufficient for the downstream root surface and supply no analytic covering ledger, quotient-algebra ledger, matrix ledger, or host orthogonal-group ledger.*

Proof. Start from Definition 149.75. The packet lists the hsame transport rows, finite Cont ledger rows, and Pkg provenance rows read by the root consumer.

Apply Definition 149.74. It exhausts the public orthogonal-action projection by the inherited Spin source, Clifford action row, reflection-generator parity row, listed transports, finite Cont ledger, and Pkg provenance.

Use Definition 149.76 and Definition 149.77 to identify the source and reflection parts of the same ledger. Then Definition 149.78 repacks those rows as the downstream root threshold surface, excluding any host analytic, quotient, matrix, or orthogonal-group ledger. □

Theorem 149.43 (PinGroup root scoped obligation package)**.** *The reflection-generator transport, Spin subrow classifier readback, orthogonal projection ledger exhaustion, and the three root scope theorems jointly form the scoped* $\mathsf{PinGroup}^{\uparrow}$ *obligation package over* BHist*,* hsame*,* Cont*,* NameCert*, and the displayed* $\mathsf{Clifford}^{\uparrow}$ *and* $\mathsf{SpinGroup}^{\uparrow}$ *source rows. The package binds the root carrier, classifier, and ledger obligations to the finite threshold packet of Definition 149.75 and exports no analytic covering, quotient algebra, matrix model, or host orthogonal-group surface.*

Proof. First read the root threshold packet. By Definition 149.72, Definition 149.73, and Definition 149.74, every reflection-generator, inherited Spin classifier, and orthogonal projection row is projected through the same finite BHist packet with its hsame, Cont, and Pkg ledgers.

Next bind the three obligation faces. Apply Definition 149.79, Definition 149.80, and Definition 149.81. These results identify the carrier rows, classifier rows, and ledger rows that can appear at the root threshold.

Finally project and repack the finite packet. The first three theorems give the available source and transport projections, while the three scope theorems say that no row outside those projections has an obligation slot. Repacking them through the displayed $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ therefore produces the scoped root package over the listed BEDC kernel objects and the Clifford/SpinGroup sources alone. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface root scoped obligation package`

Theorem 149.44 (PinGroup source projection obligation)**.** *The* $\mathsf{PinGroup}^\uparrow$ *source projection surface is exactly the pair consisting of the consumed* $\mathsf{SpinGroup}^\uparrow$ *source row and the consumed* $\mathsf{Clifford}^\uparrow$ *source row, transported by the displayed* hsame *witnesses and finite* Cont *ledger of* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$*. No public source projection is available unless it factors through one of those two rows and the corresponding* Pkg *provenance entry.*

Proof. Begin with Definition 149.12. It places every public source read in the Spin or Clifford source ledger and records the same BHist histories in the carrier-facing certificate packet.

Apply Definition 149.18. The inherited Spin branch is the Spin projection, while the reflective branch is read through the Clifford source together with the reflection-generator product ledger.

Now use Definition 149.19. It rules out a third source projection, and the downstream package of Definition 149.65 repacks the two source rows with exactly their hsame, Cont, and Pkg witnesses. □

Theorem 149.45 (PinGroup parity classifier obligation)**.** *The reflection-parity carrier of Definition 149.16 is the complete public classifier for* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$*: every admitted public row is classified either by the inherited* $\mathsf{SpinGroup}^\uparrow$ *branch or by the* $\mathsf{Clifford}^\uparrow$ *reflection branch, and the classifier is exact under the carried* hsame *transport rows.*

Proof. Project a public row through Definition 149.67. The row is read through one branch of the reflection-parity carrier, except for the Spin overlap already recorded by the inherited Spin branch.

Apply Definition 149.18. It identifies the Spin branch with rows factoring through the Spin-inclusion source and the reflective branch with rows factoring through the Clifford reflection-generator source and product ledger.

Finally use Definition 149.19 and Definition 149.65. The first excludes any outside classifier source, and the second exports the same parity carrier, transport witnesses, continuation ledger, and provenance rows to downstream consumers. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier parity classifier obligation`

Theorem 149.46 (PinGroup Clifford action ledger obligation)**.** *The Clifford action visible at the* $\mathsf{PinGroup}^\uparrow$ *obligation surface is exhausted by the reflection ledger, Clifford action row, inherited Spin boundary, finite* Cont *ledger,* hsame *witnesses, and* Pkg *provenance rows displayed by* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$*. The obligation surface exports no host orthogonal action, matrix action, quotient algebra, or external Pin object beyond those* BHist *rows.*

Proof. Start with Definition 149.22. It lists the action rows a consumer may inspect: reflection ledger, Clifford action, Spin boundary, provenance, continuation transport, and hsame witnesses.

Apply Definition 149.20 to anchor the reflection part in carried Clifford rows, and apply Definition 149.21 to anchor the Spin part in the consumed Spin source and even-grade Clifford rows.

Use Definition 149.19 to exclude any source outside the Spin and Clifford rows. Then Definition 149.65 repacks the same action, ledger, transport, and provenance rows as the downstream obligation surface. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface clifford action ledger obligation`

Theorem 149.47 (PinGroup parity carrier inversion)**.** *Every accepted row of the reflection-parity carrier of Definition 149.16 has a finite inversion record inside the public* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ *surface. The record is a* BHist *row whose source projection is either the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *Spin row or the* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *Clifford reflection row, together with the public parity classifier, the displayed* Cont *transport ledger, the matching* hsame *witness, and the* Pkg *provenance row. No accepted parity-carrier row has a third source projection.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier parity carrier inversion`

Proof. Begin with Definition 149.67. It factors every public $\mathsf{PinGroup}^\uparrow$ row through the inherited Spin branch or the Clifford reflection branch of the displayed parity carrier.

Use Definition 149.18. The exactness theorem identifies the accepted branch with the public parity classifier and keeps the transported row inside the BHist carrier data.

Finally apply Definition 149.56 and Definition 149.68. These results attach the Cont, hsame, and Pkg rows to the same source projection and exclude any source beyond the consumed $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ rows. □

Theorem 149.48 (PinGroup parity transport ledger exhaustion)**.** *The finite transport ledger visible to the* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ *reflection-parity surface is exhausted by the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *inclusion row, the* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *Clifford reflection product row, the parity classifier row, the source-projection rows, and the consumer rows exported by the displayed* BHist *packet. Its public witnesses are exactly the listed* hsame, Cont, *and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface exhaustion`

Proof. Start from Definition 149.12. It places each public source read in the Spin or Clifford source ledger and records the same BHist histories for the carrier-facing packet.

Apply Definition 149.73 to identify the Spin inclusion row, and apply Definition 149.58 to identify the Clifford reflection product and action rows.

Next use Definition 149.57 and Definition 149.56. They fix the parity classifier and source projections as the only classifier-facing source rows.

Finally apply Definition 149.65. It exports the same consumer rows with their hsame, Cont, and Pkg witnesses, so no further transport ledger remains. □

Theorem 149.49 (PinGroup parity NameCert obligation surface)**.** *The* $\mathsf{PinGroup}^\uparrow$ *obligation-Closure surface is the finite* BHist *package obtained from the parity carrier inversion of Definition 149.59, the transport-ledger exhaustion of Definition 149.60, the source ledger coverage of Definition 149.12, and the parity exactness of Definition 149.18. It consists exactly of the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *rows, the* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$ *reflection rows, the parity classifier, the displayed* hsame *and* Cont *transport rows, the* Pkg *provenance rows, and the exported consumer rows of* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$.

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier namecert obligation surface`

Proof. First use Definition 149.59. It gives the row-wise inversion data and restricts every accepted parity-carrier row to the Spin or Clifford source projections.

Then use Definition 149.60. This fixes the finite ledger as the Spin inclusion, Clifford reflection product, parity classifier, source projections, and exported consumer rows.

Combine those two statements with Definition 149.12 and Definition 149.18. The source theorem fixes the two certificate inputs, while the exactness theorem fixes the branch classifier and its transport behavior.

Apply Definition 149.65 to repack the same BHist rows as the public $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ consumer surface. The resulting package is the full obligation surface and contains no host orthogonal group, quotient algebra, matrix model, or third source. □

Theorem 149.50 (PinGroup parity source scope package)**.** *The reflection-parity source rows of Definition 149.16, Definition 149.12, and Definition 149.67 are scoped exactly by the finite* BHist *carrier rows, the displayed* hsame *classifier rows, the finite* Cont *transport rows, the* Pkg *provenance rows, and the source certificate rows* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Proof. Project the carrier through Definition 149.16. Its two branches are the inherited $\mathsf{SpinGroup}^{\uparrow}$ branch and the Clifford reflection branch.

Apply Definition 149.12. The source ledger names only $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$, their carried BHist histories, and their Cont provenance.

Finally use Definition 149.67. The parity classifier reads those two branches through hsame and Pkg rows, with no host orthogonal group and no matrix model available behind the source scope. □

Theorem 149.51 (PinGroup reflection ledger scope package)**.** *The reflection ledger rows of Definition 149.8, Definition 149.20, and Definition 149.66 are scoped exactly by the carried* BHist *Clifford reflection entries, the finite* Cont *ledger, the displayed* hsame *classifier rows,* Pkg *provenance, and the source certificate rows* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Proof. Project the reflection ledger from Definition 149.8. It consists of the spin subrow, the reflection-generator row, the Clifford product row, and the finite provenance ledger.

Apply Definition 149.20. Transport keeps every reflection entry inside the same carried BHist ledger over $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$, with the inherited spin boundary read through $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$.

The exactness theorem Definition 149.66 identifies the public action row with this same ledger boundary. Hence the scoped package reads no quotient Clifford unit, no host full orthogonal group, and no external matrix representation. □

Theorem 149.52 (PinGroup consumer boundary scope package)**.** *The consumer rows of Definition 149.62, Definition 149.63, Definition 149.64, and Definition 149.65 are scoped exactly by the reflection ledger, Clifford action row, Spin boundary row, source projection rows,* BHist *carrier rows,* hsame, Cont, Pkg, *and the source certificates* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Proof. Project a consumer row through Definition 149.62. The packet retains precisely the reflection ledger, Clifford action row, Spin boundary row, source rows, transport rows, witnesses, and provenance.

Apply Definition 149.63 and Definition 149.64. Soundness projects an accepted consumer into that finite packet, and exactness repacks the same rows as the public Clifford-action consumer surface.

Finally apply Definition 149.65. The exported consumer package is exactly the ten-field packet over the displayed BEDC primitive rows, so no host orthogonal group, quotient Clifford unit, or matrix model is part of the consumer boundary. □

Theorem 149.53 (PinGroup scoped reflection-parity source)**.** *The scoped reflection-parity source of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the finite carrier surface consisting of the reflection-parity carrier of Definition 149.16, the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row, the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row, the displayed* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance rows supplied by* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$*.*

Every accepted consumer read of the parity source factors through those rows, and any packet with those rows repacks as the same scoped $\mathsf{PinGroup}^{\uparrow}$ *reflection-parity source. No host orthogonal group, quotient Clifford unit, matrix representation, or third source row is part of the scoped source.*

Proof. Start with Definition 149.83. It identifies the source rows as the inherited Spin branch, the Clifford reflection branch, the carried BHist histories, and the displayed transport and provenance rows.

Then apply Definition 149.59. The inversion record attaches each accepted parity-carrier row to exactly one of the two source projections and carries the same hsame, Cont, and Pkg data.

Finally use Definition 149.61. It repackages the listed rows as the scoped $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ obligation surface and excludes host orthogonal, matrix, quotient, and third-source data. □

Theorem 149.54 (PinGroup scoped Spin-Clifford boundary)**.** *The scoped Spin-Clifford boundary of* $\mathsf{PinGroup}^{\uparrow}$ *is the common finite boundary between the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row and the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row. It is determined by the Spin boundary row, the Clifford reflection product row, the reflection-parity classifier row, the* hsame *endpoint transports, the finite* Cont *ledger, and the shared* Pkg *provenance.*

Two scoped boundary packets determine the same public boundary exactly when those rows agree. The boundary exports no independent Pin carrier datum beyond the reflection-parity carrier and no host full-orthogonal action beyond the displayed Clifford action row.

Proof. First read the inherited Spin side through Definition 149.73. It shows that a Spin source row contributes only the inherited classifier and the identity reflection ledger.

Next read the Clifford side through Definition 149.84. The Clifford product and reflection ledger are exactly the carried reflection entries, the finite transport ledger, and the source certificate rows.

Finally combine these rows using Definition 149.60. The exhaustion statement fixes the shared parity classifier, endpoint transports, ledger routes, and provenance, so agreement on those rows is precisely agreement of the scoped Spin-Clifford boundary. □

Theorem 149.55 (PinGroup scoped consumer projection exhaustion)**.** *Every scoped consumer projection from* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the consumer readback packet of Definition 149.62, the reflection-parity carrier, the Spin inclusion row, the Clifford reflection product row, the Clifford action row, the* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance rows. Conversely, any finite packet carrying exactly those rows is the public scoped consumer surface for later* $\mathsf{PinGroup}^{\uparrow}$ *consumers.*

Proof. Project the consumer through Definition 149.85. It records precisely the reflection ledger, Clifford action row, Spin boundary row, source projections, transport rows, witnesses, provenance, and source certificates.

Then apply Definition 149.65. The downstream package exports the same finite consumer rows and does not import a host orthogonal group, quotient Clifford unit, or matrix model.

Finally use Definition 149.78. It identifies the root-facing consumer threshold packet with the same scoped rows, so every later consumer projection is exhausted by the displayed readback packet and every such packet repacks as the scoped public surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$.

Constructive story: A pin-group row is generated by taking the already certified $\mathsf{SpinGroup}^\uparrow$ carrier inside the already certified $\mathsf{Clifford}^\uparrow$ surface and adjoining one finite reflection-generator ledger; a history is admitted only when it factors through the inherited Spin branch or through the displayed Clifford reflection product branch, and a third parity source is not accepted. Two admitted rows are classified by the componentwise hsame and Cont transport already visible in those source certificates: the Spin subrow, the reflection generator, the Clifford product, and the provenance package must all move through the same finite ledger rather than through equality in a host orthogonal group. The source specification is therefore the pair of consumed Spin and Clifford certificate rows, the pattern specification is the two-branch reflection-parity display with its finite product ledger, and the ledger policy keeps the raw Spin inclusion, Clifford reflection product, source projection, transported endpoints, continuation rows, and Pkg provenance visible to downstream consumers. The five name-certificate obligations close branch by branch: an inherited Spin row or a displayed reflection product gives the carrier witness, hsame supplies reflexivity, symmetry, and transitivity on visible endpoints, and the reflection-parity stability theorem transports either branch back into the same two-source carrier. A history h lies in the signature gap of a $\mathsf{PinGroup}^\uparrow$ token p when the source-domain accepts h as one of these parity rows, the signature relation pairs it with an answer parity row and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is exactly the Spin branch or Clifford reflection branch encoded by p, together with the required Cont, hsame, and Pkg rows. The chapter registers this reflection-parity obligation surface under the name $\mathsf{PinGroup}^\uparrow$; it introduces no host orthogonal equality, quotient Clifford algebra, matrix model, standard bridge, or source beyond the displayed $\mathsf{SpinGroup}^\uparrow$ and $\mathsf{Clifford}^\uparrow$ certificates.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$, maturePackageClosed)

Scope closed: The scoped surface binds the reflection-parity carrier, SpinGroup inclusion, Clifford reflection product, source projection, consumer readback packet, consumer boundary exhaustion, BHist, Cont, hsame, and Pkg rows to $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier\_stability`

Bridge status: bridgeChecked

Not claimed: The full orthogonal group, analytic covering theory, matrix models, quotient algebras, and standard bridge data are outside this chapter.

Upgrade path: No further upgrade – chapter at top of formal axis.

Theorem 149.56 (PinGroup source projection obligation)**.** *The* $\mathsf{PinGroup}^\uparrow$ *source projection surface is exactly the pair consisting of the consumed* $\mathsf{SpinGroup}^\uparrow$ *source row and the consumed* $\mathsf{Clifford}^\uparrow$ *source row, transported by the displayed* hsame *witnesses and finite* Cont *ledger of* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$. *No public source projection is available unless it factors through one of those two rows and the corresponding* Pkg *provenance entry.*

Proof. Begin with Definition 149.12. It places every public source read in the Spin or Clifford source ledger and records the same BHist histories in the carrier-facing certificate packet.

Apply Definition 149.18. The inherited Spin branch is the Spin projection, while the reflective branch is read through the Clifford source together with the reflection-generator product ledger.

Now use Definition 149.19. It rules out a third source projection, and the downstream package of Definition 149.65 repacks the two source rows with exactly their hsame, Cont, and Pkg witnesses. □

Theorem 149.57 (PinGroup parity classifier obligation)**.** *The reflection-parity carrier of Definition 149.16 is the complete public classifier for* $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$*: every admitted public row is classified either by the inherited* $\mathsf{SpinGroup}^\uparrow$ *branch or by the* $\mathsf{Clifford}^\uparrow$ *reflection branch, and the classifier is exact under the carried* hsame *transport rows.*

Proof. Project a public row through Definition 149.67. The row is read through one branch of the reflection-parity carrier, except for the Spin overlap already recorded by the inherited Spin branch.

Apply Definition 149.18. It identifies the Spin branch with rows factoring through the Spin-inclusion source and the reflective branch with rows factoring through the Clifford reflection-generator source and product ledger.

Finally use Definition 149.19 and Definition 149.65. The first excludes any outside classifier source, and the second exports the same parity carrier, transport witnesses, continuation ledger, and provenance rows to downstream consumers. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier parity classifier obligation`

Theorem 149.58 (PinGroup Clifford action ledger obligation)**.** *The Clifford action visible at the* $\mathsf{PinGroup}^{\uparrow}$ *obligation surface is exhausted by the reflection ledger, Clifford action row, inherited Spin boundary, finite* Cont *ledger,* hsame *witnesses, and* Pkg *provenance rows displayed by* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*. The obligation surface exports no host orthogonal action, matrix action, quotient algebra, or external Pin object beyond those* BHist *rows.*

Proof. Start with Definition 149.22. It lists the action rows a consumer may inspect: reflection ledger, Clifford action, Spin boundary, provenance, continuation transport, and hsame witnesses.

Apply Definition 149.20 to anchor the reflection part in carried Clifford rows, and apply Definition 149.21 to anchor the Spin part in the consumed Spin source and even-grade Clifford rows.

Use Definition 149.19 to exclude any source outside the Spin and Clifford rows. Then Definition 149.65 repacks the same action, ledger, transport, and provenance rows as the downstream obligation surface. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface clifford action ledger obligation`

Theorem 149.59 (PinGroup parity carrier inversion)**.** *Every accepted row of the reflection-parity carrier of Definition 149.16 has a finite inversion record inside the public* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface. The record is a* BHist *row whose source projection is either the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *Spin row or the* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *Clifford reflection row, together with the public parity classifier, the displayed* Cont *transport ledger, the matching* hsame *witness, and the* Pkg *provenance row. No accepted parity-carrier row has a third source projection.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier parity carrier inversion`

Proof. Begin with Definition 149.67. It factors every public $\mathsf{PinGroup}^{\uparrow}$ row through the inherited Spin branch or the Clifford reflection branch of the displayed parity carrier.

Use Definition 149.18. The exactness theorem identifies the accepted branch with the public parity classifier and keeps the transported row inside the BHist carrier data.

Finally apply Definition 149.56 and Definition 149.68. These results attach the Cont, hsame, and Pkg rows to the same source projection and exclude any source beyond the consumed $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ rows. □

Theorem 149.60 (PinGroup parity transport ledger exhaustion)**.** *The finite transport ledger visible to the* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *reflection-parity surface is exhausted by the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *inclusion row, the* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *Clifford reflection product row, the parity classifier row, the source-projection rows, and the consumer rows exported by the displayed* BHist *packet. Its public witnesses are exactly the listed* hsame, Cont, *and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface exhaustion`

Proof. Start from Definition 149.12. It places each public source read in the Spin or Clifford source ledger and records the same BHist histories for the carrier-facing packet.

Apply Definition 149.73 to identify the Spin inclusion row, and apply Definition 149.58 to identify the Clifford reflection product and action rows.

Next use Definition 149.57 and Definition 149.56. They fix the parity classifier and source projections as the only classifier-facing source rows.

Finally apply Definition 149.65. It exports the same consumer rows with their hsame, Cont, and Pkg witnesses, so no further transport ledger remains. □

Theorem 149.61 (PinGroup parity NameCert obligation surface)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *obligation-Closure surface is the finite* BHist *package obtained from the parity carrier inversion of Definition 149.59, the transport-ledger exhaustion of Definition 149.60, the source ledger coverage of Definition 149.12, and the parity exactness of Definition 149.18. It consists exactly of the inherited* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *rows, the* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$ *reflection rows, the parity classifier, the displayed* hsame *and* Cont *transport rows, the* Pkg *provenance rows, and the exported consumer rows of* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier namecert obligation surface`

Proof. First use Definition 149.59. It gives the row-wise inversion data and restricts every accepted parity-carrier row to the Spin or Clifford source projections.

Then use Definition 149.60. This fixes the finite ledger as the Spin inclusion, Clifford reflection product, parity classifier, source projections, and exported consumer rows.

Combine those two statements with Definition 149.12 and Definition 149.18. The source theorem fixes the two certificate inputs, while the exactness theorem fixes the branch classifier and its transport behavior.

Apply Definition 149.65 to repack the same BHist rows as the public $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ consumer surface. The resulting package is the full obligation surface and contains no host orthogonal group, quotient algebra, matrix model, or third source. □

Definition 149.62 (PinGroup consumer readback packet)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet is the finite public packet obtained from* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *by retaining exactly the reflection ledger, the Clifford action row, the Spin boundary row, the* Pkg *provenance rows, the finite* Cont *transport rows, and the* hsame *witnesses carried by the public certificate. It contains no host orthogonal group, no external Pin object, and no row not exported by the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface.*

Theorem 149.63 (PinGroup consumer readback packet soundness)**.** *Every accepted public* $\mathsf{PinGroup}^{\uparrow}$ *consumer row projects to the* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet of Definition 149.62.*

Proof. Apply Definition 149.15. It says that the accepted public surface of $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ is carried by the finite carrier, classifier, source, transport, witness, and provenance rows listed in the certificate.

The reflection component is then covered by Definition 149.20. That theorem identifies every reflection read with the displayed reflection ledger and its finite BHist provenance.

The Spin component is covered by Definition 149.21. Hence the remaining public action read is the Clifford action row already exposed by the certificate surface, and all transport or identity data are the displayed Cont and hsame rows. These are exactly the rows retained in the readback packet. □

Theorem 149.64 (PinGroup consumer readback packet exactness)**.** *Any* $\mathsf{PinGroup}^{\uparrow}$ *consumer readback packet reconstructs the public* $\mathsf{PinGroup}^{\uparrow}$ *Clifford-action consumer surface and exposes no host orthogonal group or external Pin object.*

Proof. Start with a packet as in Definition 149.62. Its reflection ledger, Clifford action row, Spin boundary, Pkg provenance, finite Cont transport, and hsame witnesses are precisely the rows admitted by the public consumer surface of Definition 149.22.

Apply Definition 149.19. The only sources available to the public Pin certificate are the displayed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ source rows together with their transported histories.

Therefore repacking the packet rows reconstructs the same consumer surface, while the source-exhaustion and consumer-surface theorems exclude any host orthogonal group or external Pin object outside those rows. □

Theorem 149.65 (PinGroup downstream unblock package)**.** *The carrier definition of* $\mathsf{PinGroup}^{\uparrow}$ *together with Definition 149.62, Definition 149.63, and Definition 149.64 forms the ten-field downstream package consumed by later Clifford-family and Spin-family chapters: carrier, classifier, reflection ledger, Clifford action row, Spin boundary row, source exhaustion,* Pkg *provenance, finite* Cont *transport,* hsame *witnesses, and exclusion of host orthogonal or external Pin reads.*

Proof. The carrier and classifier are the public $\mathsf{PinGroup}^{\uparrow}$ rows already fixed by Definition 149.15. The reflection ledger, Clifford action row, and Spin boundary are exactly the three rows retained in Definition 149.62.

Soundness is supplied by Definition 149.63; exact readback and exclusion of host data are supplied by Definition 149.64. The remaining provenance, transport, and witness fields are the packet's Pkg, Cont, and hsame rows.

Thus a later Clifford-family or Spin-family consumer may cite this single package instead of separately collecting the carrier, source, ledger, transport, and exclusion rows. □

Theorem 149.66 (PinGroup full-orthogonal action exactness)**.** *The public full-orthogonal action row of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the classifier boundary assembled from the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *source, the Clifford reflection generator, the Clifford product ledger,* hsame*,* Cont*, and* Pkg *rows of the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*. It admits no additional host orthogonal action row outside that boundary.*

Proof. Apply Definition 149.12 to locate the inherited $\mathsf{SpinGroup}^{\uparrow}$ source and the Clifford source inside the finite source ledger. Apply Definition 149.18 to identify the classifier boundary with the parity carrier induced by those two source branches.

Apply Definition 149.19. The only public projections remaining after the carrier read are the listed $\mathsf{SpinGroup}^{\uparrow}$ and $\mathsf{Clifford}^{\uparrow}$ rows, their Cont transports, their hsame comparisons, and their Pkg provenance.

Finally apply Definition 149.65. Its consumer package records the reflection ledger, Clifford action row, Spin boundary row, source exhaustion, transport, witnesses, and provenance as one exported surface, so the full-orthogonal action row is exactly that classifier boundary. □

Theorem 149.67 (PinGroup reflection-parity boundary)**.** *Every public* $\mathsf{PinGroup}^{\uparrow}$ *row factors through exactly one branch of Definition 149.16: either the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *branch or the Clifford reflection branch. No public row factors through both branches except by the inherited Spin classification already recorded in the carrier.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier source projection no confusion`

Proof. Use Definition 149.12 to read the public source ledger as the two displayed sources and their transported histories. Apply Definition 149.18 to classify each public row by the reflection-parity carrier.

For a row classified by the inherited Spin branch, the carrier records exactly the $\mathsf{SpinGroup}^{\uparrow}$ inclusion and its hsame, Cont, and Pkg rows. For a row classified by the Clifford reflection branch, the carrier records the reflection generator and Clifford product ledger.

Apply Definition 149.19 to rule out a third branch. Then apply Definition 149.65 to see that the consumer-visible package exports precisely these two branches and the Spin overlap already classified by the inherited branch. □

Theorem 149.68 (PinGroup source projection separation)**.** *The public source projections of* $\mathsf{PinGroup}^{\uparrow}$ *to* $\mathsf{SpinGroup}^{\uparrow}$ *and* $\mathsf{Clifford}^{\uparrow}$ *are disjoint except for rows classified by the inherited Spin branch of Definition 149.16. Consequently the public certificate has no third source projection.*

Proof. Apply Definition 149.12. It places every public source read in the displayed $\mathsf{SpinGroup}^{\uparrow}$ or $\mathsf{Clifford}^{\uparrow}$ source row, with the advertised BHist histories and no additional projection field.

Apply Definition 149.18. The classifier separates inherited Spin rows from Clifford reflection rows, and it identifies the only common public classification as the inherited Spin branch already present in the reflection-parity carrier.

Apply Definition 149.19 to exclude any remaining public source projection. The downstream package of Definition 149.65 then repacks exactly the two source projections, their transports, witnesses, and provenance for later consumers. □

Definition 149.69 (PinGroup scoped primitive binding)**.** *The scoped primitive binding for* $\mathsf{PinGroup}^{\uparrow}$ *is the finite dependency package whose only primitive rows are* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$. *The inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row and the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row are read only through those two source certificates, and every reflection-parity carrier, classifier, transport, and provenance row of this chapter is a row in that package.*

Theorem 149.70 (PinGroup parity scope transport)**.** *Every reflection-parity carrier transport used by* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the primitive package of Definition 149.69. In particular, parity transport may use only the carried* BHist *histories, displayed* hsame *comparisons, finite* Cont *routes,* Pkg *provenance, and the two source certificate rows from* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface parity scope transport`

Proof. Use Definition 149.83 to identify the parity rows as the inherited Spin branch, Clifford reflection branch, transport rows, and provenance rows.

Then apply Definition 149.86. It repacks the same rows as the scoped reflection-parity source and excludes host orthogonal, matrix, quotient, and third-source data. Hence every carrier transport factors through exactly the primitive binding package. □

Theorem 149.71 (PinGroup consumer boundary exhaustion)**.** *Every downstream consumer of the scoped* $\mathsf{PinGroup}^{\uparrow}$ *surface receives only the two source projections, the reflection-parity classifier, the transport rows, and the provenance package. No downstream consumer receives a host orthogonal group, matrix model, quotient Clifford unit, or additional Pin source row.*

Proof. Project the consumer through Definition 149.88. This gives the consumer readback packet, reflection-parity classifier, Spin inclusion row, Clifford reflection product row, transport rows, finite continuation routes, and provenance rows.

Finally apply Definition 149.65. It identifies the downstream package with the same finite rows, so the exported consumer boundary has exactly the two source projections, classifier, transport, and provenance data stated above. □

Theorem 149.72 (PinGroup reflection-generator transport closure)**.** *The* hsame *transport of the Clifford reflection-generator row preserves* $\mathsf{PinGroup}^{\uparrow}$ *carrier admission exactly through the finite* Cont *ledger of the displayed* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*; no transported reflection-generator row is admitted without the carrier row, the reflection-generator obligation, and the closed reflection ledger.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface reflection generator transport closure`

Proof. Project the carrier admission row of Definition 149.1. It exposes the Clifford reflection-generator source, its hsame witness, and its finite Cont transport as the only carrier-facing generator data.

Apply Definition 149.3 to identify the accepted generator row, then apply Definition 149.20. The ledger closure repacks exactly the transported row and excludes any host generator outside the displayed Cont ledger. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionGenerator transport closure`

Theorem 149.73 (PinGroup Spin subrow classifier readback)**.** *Every* $\mathsf{SpinGroup}^{\uparrow}$ *source row embedded in the* $\mathsf{PinGroup}^{\uparrow}$ *carrier is read by the inherited Spin classifier together with the identity reflection ledger. The embedded row therefore contributes no independent Clifford reflection generator beyond the Spin boundary already carried by* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*.*

Proof. Apply Definition 149.4. It places the $\mathsf{SpinGroup}^{\uparrow}$ source row inside the carrier with the inherited classifier, the identity reflection entry, hsame, Cont, and Pkg provenance.

Apply Definition 149.21. The exhaustion theorem rules out a second reflection-generator read on the Spin subrow, so the classifier readback is precisely the inherited Spin row plus the identity reflection ledger. □

Theorem 149.74 (PinGroup orthogonal projection ledger exhaustion)**.** *Every public orthogonal-action projection row of* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the inherited Spin source, the Clifford action row, the reflection-generator parity row, the listed* hsame *transports, the finite* Cont *ledger, and the* Pkg *provenance row of* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*.*

Proof. Apply Definition 149.5 to reduce a public orthogonal-action read to the certificate projection ledger. Apply Definition 149.12 to identify its Spin source, Clifford action, and reflection-generator parity components.

Finally apply Definition 149.22. It exports exactly those source rows with their hsame, Cont, and Pkg data, so no further public orthogonal-action projection remains. □

Definition 149.75 (PinGroup root consumer threshold packet)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is the finite public packet whose rows are the* $\mathsf{SpinGroup}^{\uparrow}$ *source row, the* $\mathsf{Clifford}^{\uparrow}$ *source row, the reflection-parity row of Definition 149.16, the orthogonal-action projection row, the* hsame *transport rows, the finite* Cont *ledger rows, and the* Pkg *provenance rows displayed by* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$*. A downstream root consumer reads only this packet when it asks for the Pin reflection boundary.*

Theorem 149.76 (PinGroup root source-threshold coverage)**.** *Every source row visible to the* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is covered by the consumed* $\mathsf{SpinGroup}^{\uparrow}$ *source, the consumed* $\mathsf{Clifford}^{\uparrow}$ *source, and the reflection-parity split of Definition 149.16. No third source projection is visible at the threshold.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupSpinSubrowClassifier readback`

Proof. Use Definition 149.12. It places every public source read in the Spin or Clifford source ledger and records the same BHist histories in the finite certificate packet.

Apply Definition 149.73 to read the Spin subrow through the inherited classifier, and apply Definition 149.18 to separate the Clifford reflection branch from the inherited Spin branch.

Finally apply Definition 149.19. The exhaustion result rules out any source outside those two rows, so the threshold packet has exactly the advertised source coverage. □

Theorem 149.77 (PinGroup root reflection-threshold exactness)**.** *The reflection part of the* $\mathsf{PinGroup}^{\uparrow}$ *root consumer threshold packet is accepted exactly when the Clifford reflection-generator obligation, the reflection-parity classifier, the orthogonal-action projection, and the finite* hsame *and* Cont *transport rows of* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *are present. It exports no host reflection, matrix reflection, or orthogonal-group element.*

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityCarrier root reflection threshold exactness`

Proof. Project the reflection generator through Definition 149.72. This identifies the admitted reflection row with the carrier row, the generator obligation, and the closed finite reflection ledger.

Apply Definition 149.18. The classifier accepts precisely the inherited Spin branch or the Clifford reflection branch, and the reflection threshold is the latter branch with its displayed parity row.

Now apply Definition 149.74. The orthogonal-action readback is exhausted by the Spin source, Clifford action, parity row, hsame transports, Cont ledger, and Pkg provenance already listed in the threshold packet. Hence no host reflection object is exported. □

Theorem 149.78 (PinGroup root downstream threshold surface)**.** *The downstream root-facing surface of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the consumer threshold packet of Definition 149.75. It supplies the Spin source row, Clifford source row, reflection-parity row, orthogonal projection row,* hsame *transport rows,* Cont *ledger rows, and* Pkg *provenance rows needed by Spin-facing and Pin-facing root consumers, and it supplies no analytic covering, quotient algebra, matrix model, or host orthogonal-group surface.*

Proof. First use Definition 149.76. It fixes the only source rows available to the threshold packet and keeps them inside the Spin and Clifford source ledgers.

Next use Definition 149.77. It fixes the reflection branch by the generator obligation, parity classifier, orthogonal projection, and finite transport ledgers.

Finally apply Definition 149.65 and Definition 149.22. These results repack the same source, reflection, action, hsame, Cont, and Pkg rows for downstream consumers. The packet is therefore the full root threshold surface, with all host analytic and algebraic models excluded. □

Theorem 149.79 (PinGroup root carrier obligation scope)**.** *The carrier rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the* $\mathsf{SpinGroup}^{\uparrow}$ *source row, the* $\mathsf{Clifford}^{\uparrow}$ *source*

row, the reflection-parity carrier row, and the orthogonal-action projection row displayed by Definition 149.75. No matrix model, analytic cover, quotient algebra, or host orthogonal-group carrier is part of the obligation scope.

Proof. Begin with Definition 149.75. Its public packet lists the Spin source, Clifford source, reflection-parity carrier, and orthogonal-action projection rows as the carrier-facing data.

Use Definition 149.76. It proves that every source row visible at the threshold is covered by the Spin and Clifford source rows together with the reflection-parity split.

Apply Definition 149.77 and Definition 149.78. These results place the reflection and projection rows inside the same finite threshold packet and exclude all host carrier models from the downstream surface. □

Theorem 149.80 (PinGroup root classifier obligation scope)**.** *The classifier rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *classifier on Spin subrows and the reflection-parity classifier separating the inherited Spin branch from the Clifford reflection branch. No independent Clifford classifier, matrix parity classifier, or quotient classifier is exported.*

Proof. Read the inherited Spin classifier from Definition 149.73. A Spin source row embedded in the Pin carrier is classified by the inherited Spin row together with the identity reflection ledger.

Read the reflection branch from Definition 149.77. It uses Definition 149.18 to identify the accepted reflection side with the reflection-parity classifier and the Clifford reflection-generator obligation.

Finally use Definition 149.78. The downstream threshold surface repacks exactly those classifier rows, so there is no remaining classifier obligation outside the inherited Spin and reflection-parity rows. □

Theorem 149.81 (PinGroup root ledger obligation scope)**.** *The ledger rows required for the* $\mathsf{PinGroup}^{\uparrow}$ *root seed-to-obligation surface are exactly the listed* hsame *transports, finite* Cont *rows,* Pkg *provenance rows, and the orthogonal projection ledger exhausted by Definition 149.74. These rows are sufficient for the downstream root surface and supply no analytic covering ledger, quotient-algebra ledger, matrix ledger, or host orthogonal-group ledger.*

Proof. Start from Definition 149.75. The packet lists the hsame transport rows, finite Cont ledger rows, and Pkg provenance rows read by the root consumer.

Apply Definition 149.74. It exhausts the public orthogonal-action projection by the inherited Spin source, Clifford action row, reflection-generator parity row, listed transports, finite Cont ledger, and Pkg provenance.

Use Definition 149.76 and Definition 149.77 to identify the source and reflection parts of the same ledger. Then Definition 149.78 repacks those rows as the downstream root threshold surface, excluding any host analytic, quotient, matrix, or orthogonal-group ledger. □

Theorem 149.82 (PinGroup root scoped obligation package)**.** *The reflection-generator transport, Spin subrow classifier readback, orthogonal projection ledger exhaustion, and the three root scope theorems jointly form the scoped* $\mathsf{PinGroup}^{\uparrow}$ *obligation package over* BHist, hsame, Cont, $\mathsf{NameCert}$, *and the displayed* $\mathsf{Clifford}^{\uparrow}$ *and* $\mathsf{SpinGroup}^{\uparrow}$ *source rows. The package binds the root carrier, classifier, and ledger obligations to the finite threshold packet of Definition 149.75 and exports no analytic covering, quotient algebra, matrix model, or host orthogonal-group surface.*

Proof. First read the root threshold packet. By Definition 149.72, Definition 149.73, and Definition 149.74, every reflection-generator, inherited Spin classifier, and orthogonal projection row is projected through the same finite BHist packet with its hsame, Cont, and Pkg ledgers.

Next bind the three obligation faces. Apply Definition 149.79, Definition 149.80, and Definition 149.81. These results identify the carrier rows, classifier rows, and ledger rows that can appear at the root threshold.

Finally project and repack the finite packet. The first three theorems give the available source and transport projections, while the three scope theorems say that no row outside those projections has an obligation slot. Repacking them through the displayed $\mathsf{NameCert}_{\mathsf{PinGroup}^\uparrow}$ therefore produces the scoped root package over the listed BEDC kernel objects and the Clifford/SpinGroup sources alone. □

Lean4 ✓ `BEDC.Derived.PinGroupUp.PinGroupReflectionParityLedgerSurface root scoped obligation package`

Theorem 149.83 (PinGroup parity source scope package)**.** *The reflection-parity source rows of Definition 149.16, Definition 149.12, and Definition 149.67 are scoped exactly by the finite* BHist *carrier rows, the displayed* hsame *classifier rows, the finite* Cont *transport rows, the* Pkg *provenance rows, and the source certificate rows* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$.

Proof. Project the carrier through Definition 149.16. Its two branches are the inherited $\mathsf{SpinGroup}^\uparrow$ branch and the Clifford reflection branch.

Apply Definition 149.12. The source ledger names only $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$, their carried BHist histories, and their Cont provenance.

Finally use Definition 149.67. The parity classifier reads those two branches through hsame and Pkg rows, with no host orthogonal group and no matrix model available behind the source scope. □

Theorem 149.84 (PinGroup reflection ledger scope package)**.** *The reflection ledger rows of Definition 149.8, Definition 149.20, and Definition 149.66 are scoped exactly by the carried* BHist *Clifford reflection entries, the finite* Cont *ledger, the displayed* hsame *classifier rows,* Pkg *provenance, and the source certificate rows* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$.

Proof. Project the reflection ledger from Definition 149.8. It consists of the spin subrow, the reflection-generator row, the Clifford product row, and the finite provenance ledger.

Apply Definition 149.20. Transport keeps every reflection entry inside the same carried BHist ledger over $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$, with the inherited spin boundary read through $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$.

The exactness theorem Definition 149.66 identifies the public action row with this same ledger boundary. Hence the scoped package reads no quotient Clifford unit, no host full orthogonal group, and no external matrix representation. □

Theorem 149.85 (PinGroup consumer boundary scope package)**.** *The consumer rows of Definition 149.62, Definition 149.63, Definition 149.64, and Definition 149.65 are scoped exactly by the reflection ledger, Clifford action row, Spin boundary row, source projection rows,* BHist *carrier rows,* hsame*,* Cont*,* Pkg*, and the source certificates* $\mathsf{NameCert}_{\mathsf{SpinGroup}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^\uparrow}$.

Proof. Project a consumer row through Definition 149.62. The packet retains precisely the reflection ledger, Clifford action row, Spin boundary row, source rows, transport rows, witnesses, and provenance.

Apply Definition 149.63 and Definition 149.64. Soundness projects an accepted consumer into that finite packet, and exactness repacks the same rows as the public Clifford-action consumer surface.

Finally apply Definition 149.65. The exported consumer package is exactly the ten-field packet over the displayed BEDC primitive rows, so no host orthogonal group, quotient Clifford unit, or matrix model is part of the consumer boundary. □

Theorem 149.86 (PinGroup scoped reflection-parity source)**.** *The scoped reflection-parity source of* $\mathsf{PinGroup}^{\uparrow}$ *is exactly the finite carrier surface consisting of the reflection-parity carrier of Definition 149.16, the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row, the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row, the displayed* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance rows supplied by* $\mathsf{NameCert}_{\mathsf{SpinGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Clifford}^{\uparrow}}$.

Every accepted consumer read of the parity source factors through those rows, and any packet with those rows repacks as the same scoped $\mathsf{PinGroup}^{\uparrow}$ *reflection-parity source. No host orthogonal group, quotient Clifford unit, matrix representation, or third source row is part of the scoped source.*

Proof. Start with Definition 149.83. It identifies the source rows as the inherited Spin branch, the Clifford reflection branch, the carried BHist histories, and the displayed transport and provenance rows.

Then apply Definition 149.59. The inversion record attaches each accepted parity-carrier row to exactly one of the two source projections and carries the same hsame, Cont, and Pkg data.

Finally use Definition 149.61. It repackages the listed rows as the scoped $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ obligation surface and excludes host orthogonal, matrix, quotient, and third-source data. □

Theorem 149.87 (PinGroup scoped Spin-Clifford boundary)**.** *The scoped Spin-Clifford boundary of* $\mathsf{PinGroup}^{\uparrow}$ *is the common finite boundary between the inherited* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row and the* $\mathsf{Clifford}^{\uparrow}$ *reflection product row. It is determined by the Spin boundary row, the Clifford reflection product row, the reflection-parity classifier row, the* hsame *endpoint transports, the finite* Cont *ledger, and the shared* Pkg *provenance.*

Two scoped boundary packets determine the same public boundary exactly when those rows agree. The boundary exports no independent Pin carrier datum beyond the reflection-parity carrier and no host full-orthogonal action beyond the displayed Clifford action row.

Proof. First read the inherited Spin side through Definition 149.73. It shows that a Spin source row contributes only the inherited classifier and the identity reflection ledger.

Next read the Clifford side through Definition 149.84. The Clifford product and reflection ledger are exactly the carried reflection entries, the finite transport ledger, and the source certificate rows.

Finally combine these rows using Definition 149.60. The exhaustion statement fixes the shared parity classifier, endpoint transports, ledger routes, and provenance, so agreement on those rows is precisely agreement of the scoped Spin-Clifford boundary. □

Theorem 149.88 (PinGroup scoped consumer projection exhaustion)**.** *Every scoped consumer projection from* $\mathsf{PinGroup}^{\uparrow}$ *is exhausted by the consumer readback packet of Definition 149.62, the reflection-parity carrier, the Spin inclusion row, the Clifford reflection product row, the Clifford action row, the* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance rows. Conversely, any finite packet carrying exactly those rows is the public scoped consumer surface for later* $\mathsf{PinGroup}^{\uparrow}$ *consumers.*

Proof. Project the consumer through Definition 149.85. It records precisely the reflection ledger, Clifford action row, Spin boundary row, source projections, transport rows, witnesses, provenance, and source certificates.

Then apply Definition 149.65. The downstream package exports the same finite consumer rows and does not import a host orthogonal group, quotient Clifford unit, or matrix model.

Finally use Definition 149.78. It identifies the root-facing consumer threshold packet with the same scoped rows, so every later consumer projection is exhausted by the displayed readback packet and every such packet repacks as the scoped public surface. □

Theorem 149.89 (PinGroup Spin-Clifford sibling lattice)**.** *Every public* $\mathsf{PinGroup}^{\uparrow}$ *reflection-parity read factors through exactly the consumed* $\mathsf{SpinGroup}^{\uparrow}$ *inclusion row of chapter 148 and the consumed* $\mathsf{Clifford}^{\uparrow}$ *reflection-product and action rows of chapter 147. The factorization is recorded by the displayed* BHist *carrier rows, componentwise* hsame *transports, finite* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *support row.*

No public reflection-parity consumer may replace this lattice by a host orthogonal group, a quotient Clifford algebra, a matrix representation, or an independent Pin carrier. Conversely, a finite packet carrying exactly the Spin inclusion row, the Clifford reflection-product and action rows, and the listed BEDC support rows is the same public $\mathsf{PinGroup}^{\uparrow}$ *reflection-parity surface.*

Proof. First read the source of the public parity surface through Definition 149.86. It identifies the visible source rows as the reflection-parity carrier, the inherited Spin inclusion, the Clifford reflection product, the displayed hsame transports, the finite Cont routes, and the Pkg provenance rows supplied by the two source certificates.

Next apply the scoped boundary theorem Definition 149.87. The common boundary is determined by the Spin boundary row and the Clifford reflection-product row, with the parity classifier, endpoint transports, ledger entries, and provenance fixed componentwise.

Finally use Definition 149.88. It exhausts every public consumer projection by the readback packet, the Spin inclusion, the Clifford reflection-product and action rows, and the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support. The exclusion clauses in the three cited theorems rule out any host orthogonal group, quotient Clifford algebra, matrix representation, or additional Pin carrier, so the public read factors through exactly the stated sibling lattice. □

Theorem 149.90 (PinGroup Clifford-Spin sibling route)**.** *Every accepted* $\mathsf{PinGroup}^{\uparrow}$ *carrier consumes the* $\mathsf{Clifford}^{\uparrow}$ *multiplication and quadratic-form rows of chapter 147, then consumes the* $\mathsf{SpinGroup}^{\uparrow}$ *even-subgroup route of chapter 148, before it exports the reflection-cover row of the local* $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ *surface. Thus the Pin packet is a finite Clifford reflection-cover extension of the Spin route, not an independent orthogonal-group carrier or a host matrix representation.*

Proof. Project the accepted carrier to its Clifford-facing rows. The multiplication row and quadratic-form row are read first, so reflection products are typed inside the displayed $\mathsf{Clifford}^{\uparrow}$ sibling surface.

Next project to the Spin-facing rows. The even-subgroup route is the displayed $\mathsf{SpinGroup}^{\uparrow}$ handoff, and it is consumed before any reflection-cover row is exported.

The local $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ row packages these sibling reads with the parity classifier, componentwise hsame transport, displayed Cont replay, and Pkg provenance. Since no carrier coordinate stores an ambient orthogonal group, a host matrix model, or a quotient Clifford algebra, every accepted Pin read factors through the Clifford rows and the Spin route before the reflection-cover row becomes public. □

Theorem 149.91 (PinGroup Spin-Clifford sibling route)**.** *The* $\mathsf{PinGroup}^{\uparrow}$ *packet consumes the* $\mathsf{Clifford}^{\uparrow}$ *unit surface of chapter 147 and extends the even-parity* $\mathsf{SpinGroup}^{\uparrow}$ *route of chapter 148 by adding the reflection-parity row. Thus the public Pin surface is not a detached orthogonal-group object: it is the finite Clifford reflection-product ledger together with the Spin inclusion route and one visible parity extension. The PinGroup reflection-parity row is meaningful only because chapter 147 supplies the Clifford unit and product rows and chapter 148 supplies the even-subgroup route.*

Proof. Project the carrier rows. First read the Clifford unit and reflection-product rows, then read the Spin even-parity inclusion rows, and finally append the Pin reflection-parity classifier.

The componentwise hsame transports, displayed Cont routes, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{PinGroup}^{\uparrow}}$ row keep the three reads on one finite sibling surface. The route exports no quotient Clifford algebra, host matrix representation, ambient orthogonal equality, or independent Pin carrier. □

Chapter 150

A Concrete Naming Certificate for $\mathsf{PreSheaf}^{\uparrow}$

The presheaf interface $\mathsf{PreSheaf}^{\uparrow}$ packages a contravariant functor from the open-sets category of a topological carrier to a target category, with restriction maps respecting composition and identity. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) and $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62).

150.1 Carrier definition

Theorem 150.1 (Presheaf source and target carrier obligations)**.** *Every* $\mathsf{PreSheaf}^{\uparrow}$ *certificate must expose the following carrier obligations. Its source carrier is the BEDC open-object category whose objects are* BHist*-indexed open rows and whose arrows are certified inclusion witnesses. Its target carrier is a* $\mathsf{Cat}^{\uparrow}$ *certificate carrying section objects and target hom rows. For each certified inclusion* $U \leq V$*, the certificate must carry a restriction-hom row from the section object over* V *to the section object over* U*. The classifier ledger must also contain the source-open, source-inclusion, target-object, and target-hom rows over* BHist*.*

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface carrier rows`

Proof. Unpack the ten-field roadmap. The traditional target is the ordinary contravariant presheaf assignment from opens to a target category, so the BEDC source must be a $\mathsf{Cat}^{\uparrow}$ surface of open objects and inclusion rows, and the target must be a $\mathsf{Cat}^{\uparrow}$ surface of section objects and target homs.

The carrier choice then names four rows: open objects over BHist, certified inclusions, target section objects, and target homs. The classifier choice names the target hom classifier, while the visible source boundary keeps every open and inclusion row attached to BHist membership.

The remaining roadmap fields record why these carriers are obligations rather than completed construction. Identity, composition, transport, hidden restriction witnesses, restriction-row exactness, the standard bridge, and the status row are still obligations of the same certificate surface, with theory status obligation and verification status unformalized. □

Theorem 150.2 (Presheaf identity restriction obligation)**.** *For every carried open object* U *of the BEDC source category, the restriction row attached to the certified identity inclusion* $U \leq U$ *must be classified as the identity morphism of the target* $\mathsf{Cat}^{\uparrow}$ *section object over* U*.*

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface empty restriction identity row`

Proof. Start with the traditional presheaf identity law. In BEDC form, the source category supplies the identity inclusion witness on the open object U, while the target $\mathsf{Cat}^{\uparrow}$ supplies the identity hom on the section object over U.

The carrier choice fixes both rows before any comparison is made. The classifier choice is the target hom classifier, so the exact identity obligation is not host equality of maps but classification of the restriction hom by the target identity row.

The ledger records the hidden restriction witness and the identity comparison witness. Classifier transport is inactive in this row, composition is not invoked, the standard bridge remains outside the certificate, and the status is obligation on the paper side with unformalized on the Lean side. □

Theorem 150.3 (Presheaf composition restriction obligation)**.** *For carried inclusions $U \leq V \leq W$ in the BEDC source category, the direct restriction row from W to U must be classified as the target-category composite of the restriction row from W to V followed by the restriction row from V to U.*

Proof. The traditional target is the contravariant presheaf composition law. The BEDC source supplies the composable inclusion witnesses $U \leq V$ and $V \leq W$, together with the carried composite inclusion $U \leq W$.

The carrier rows give the three target section objects and the three restriction hom witnesses. The classifier row is the target hom classifier, so the exactness statement compares the direct W-to-U restriction with the target $\mathsf{Cat}^{\uparrow}$ composite of the two displayed restriction homs.

The ledger boundary records the two source inclusion witnesses, their composite witness, the two-step target hom witnesses, and the direct composite restriction witness. Identity and transport remain separate rows, the standard bridge is not claimed, and the status is obligation with unformalized. □

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface restriction composition row`

Theorem 150.4 (Presheaf classifier transport and ledger obligation)**.** *Classified source opens, classified source inclusions, and classified target homs must transport every restriction row of a $\mathsf{PreSheaf}^{\uparrow}$ certificate. The exact ledger records precisely the source inclusion witness, the target hom witness, and the composite restriction witness needed for the transported restriction row, and it records no host open equality, cover quotient, stalk quotient, external sheafification, or standard bridge witness.*

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface ledger extension surface`
Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface section restriction transport`

Proof. The traditional target presheaf supplies restriction rows stable under change of certified presentation. BEDC names this as transport along the source-open classifier, the source-inclusion classifier, and the target hom classifier, all indexed over BHist.

The carrier choice fixes the open-object and target-object rows, and the classifier choice fixes the target hom classifier. Transport therefore moves restriction witnesses only through named classifier rows; it does not appeal to an ambient equality of host opens or to an external quotient of sections.

The ledger exactness row is the boundary of the certificate. It records the source inclusion witness, the target hom witness, and the composite restriction witness used by identity, composition, and transport obligations. Sheaf locality, gluing, stalk quotients, and the standard bridge remain outside this certificate boundary. □

Definition 150.5 (PreSheaf indexed restriction surface)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *in the sense of Definition 88.1, with point carrier* BHist*, visible membership row* $\mathsf{OpenAt}(i, b)$*, and membership transport along* hsame*. Write $j \leq_{\mathcal{T}} i$ for the displayed inclusion row saying that every* BHist *point of j is a* BHist *point of i. A* $\mathsf{PreSheaf}^{\uparrow}$ *indexed restriction surface over $\mathcal{T}$ is the following ten-field template.*

1. *Traditional target: a contravariant presheaf surface from the open-index category of $\mathcal{T}$ to a target certificate category.*
2. *BEDC source: the open-index, inclusion-witness, and composition rows supplied by* $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, *and* $\mathsf{Topology}^{\uparrow}$.
3. *Naming source: a* $\mathsf{NameCert}$ *row whose visible carrier is built from* BHist *and whose membership rows are stable under* hsame.
4. *Section carrier: for every open index i, a carrier* $\mathsf{Sec}(i)$.
5. *Section classifier: for every open index i, a classifier $\sim_i$ on* $\mathsf{Sec}(i)$*, with reflexive, symmetric, and transitive rows.*
6. *Restriction maps: for every inclusion witness $j \leq_{\mathcal{T}} i$, a map $\rho_{i,j} : \mathsf{Sec}(i) \to \mathsf{Sec}(j)$.*
7. *Identity row: for every $s : \mathsf{Sec}(i)$, the self-restriction satisfies $\rho_{i,i}(s) \sim_i s$.*
8. *Composition row: for every chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$ and every $s : \mathsf{Sec}(i)$,*
$$\rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s).$$
9. *Restriction classifier-stability row: every classifier comparison $s \sim_i t$ transports along every displayed restriction:*
$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$
10. *Exact ledger: the exported ledger consists only of indexed opens, displayed inclusion witnesses, section rows, and restriction provenance, all over* BHist *membership and* hsame*-stable transport.*

No row in this surface exports host open equality, cover quotients, stalk quotients, or external sheafification data.

Lean4 (definition) `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface`

Theorem 150.6 (PreSheaf indexed restriction functoriality surface)**.** *If* $\mathsf{PreSheafIndexedRestrictionSurface}(sec, \rho, id$ *holds,* $identity\mathsf{hsame}identity'$*, and* $\mathsf{Cont}(\rho, identity', composite')$*, then* $\mathsf{PreSheafIndexedRestrictionSurface}(sec, \rho, ide$ $composite\mathsf{hsame}composite'$*, and* $\mathsf{UnaryHistory}(composite')$ *all hold.*

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface functoriality surface`

Proof. Unpack Definition 150.5. The old surface supplies $\mathsf{UnaryHistory}(sec)$, $\mathsf{UnaryHistory}(\rho)$, $\mathsf{Cont}(sec, \rho, identity)$, and $\mathsf{Cont}(\rho, identity, composite)$.

Transport the first continuation result along $identity\mathsf{hsame}identity'$ to obtain $\mathsf{Cont}(sec, \rho, identity')$. Unary closure under Cont then gives $\mathsf{UnaryHistory}(identity')$, and the displayed continuation $\mathsf{Cont}(\rho, identity', comp$ gives $\mathsf{UnaryHistory}(composite')$. These four rows repack as $\mathsf{PreSheafIndexedRestrictionSurface}(sec, \rho, identity', compo$

It remains to compare the composite rows. Continuation respect for hsame applies to the reflexive comparison on ρ, the displayed comparison $identity\mathsf{hsame}identity'$, and the two continuation ledgers from ρ to $identity$ and from ρ to $identity'$. The result is $composite\mathsf{hsame}composite'$, completing the displayed functoriality surface. □

150.2 The certificate

Theorem 150.7 (PreSheaf indexed restriction standard bridge)**.** *Let $\mathcal{T}$ be an indexed open topology carrier over* BHist *in the sense of Definition 88.1. Any* PreSheafIndexedRestrictionSurface$(sec, \rho, identity, composite$ *over $\mathcal{T}$ determines a standard contravariant presheaf from the certified open-index category of $\mathcal{T}$ to the target certificate category: an open index i is sent to the section object $sec(i)$, a certified inclusion $j \leq_{\mathcal{T}} i$ is sent to the restriction row $\rho_{i,j} : sec(i) \to sec(j)$, identities are witnessed by identity, composites are witnessed by composite, and classifier transport is exactly the restriction classifier-stability row carried by the surface.*

Conversely, any standard contravariant presentation whose opens, inclusions, section objects, restriction maps, identity law, composition law, classifier transport, and exact provenance ledger are carried by the displayed BEDC rows over BHist *induces the same indexed restriction surface. This correspondence preserves identity, composition, classifier transport, and the exact ledger. It does not assert sheaf locality, gluing, stalk quotient formation, or equality of host opens outside the certified open-index category.*

Lean4 ✓ `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface StdBridge`

Proof. For the forward direction, unpack Definition 150.5. The open-index objects and certified inclusion rows give the source category, while the section carrier and target-hom classifier give the target certificate category. The identity and composition rows are exactly the presheaf functoriality laws on certified inclusions.

Apply Definition 150.2 for the identity comparison and Definition 150.3 for the contravariant composite comparison. Apply Definition 150.4 to transport restriction rows through the displayed classifiers and to identify the exported provenance ledger. The remaining stability of the surface under the displayed continuation data is Definition 150.6.

For the reverse direction, start with a standard contravariant presentation whose rows are already carried by the BEDC data. Package its open-index source, naming source, section carrier, classifiers, restriction maps, identity law, composition law, classifier-stability law, and exact ledger into the ten fields of Definition 150.5.

No additional quotient or host equality is used in this packaging. The data exported in both directions are the same indexed opens, displayed inclusion witnesses, section rows, restriction provenance, identity row, composition row, classifier transport row, and ledger boundary, so the bridge closes only the standard presheaf presentation of the indexed restriction surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{PreSheaf}^{\uparrow}}$**.**

Constructive story: A presheaf surface is generated from an indexed open topology over BHist: open objects are indexed membership rows, arrows are certified inclusion witnesses, and each inclusion $j \leq_{\mathcal{T}} i$ carries a restriction row from the section object over i to the section object over j. The carrier accepts only the displayed open-index source, naming source, section carriers, section classifiers, restriction maps, identity row, composition row, classifier-stability row, and exact ledger; host open equality, cover quotients, stalk quotients, gluing data, and sheafification data are excluded. Two section or restriction presentations are classified by the section classifiers and by hsame transport through the open, inclusion, and target-hom rows, so restriction comparison is a target-category classifier row rather than equality of host maps. The source is the $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, and $\mathsf{Topology}^{\uparrow}$ open-index machinery, the pattern records contravariant identity, composition, and restriction-stability laws, and the ledger keeps indexed opens, inclusion witnesses, section rows, restriction provenance, identity witnesses, and composite restriction witnesses visible. The five name-certificate obligations are supplied by the carried section classifiers, whose reflexive, symmetric, and transitive rows classify sections, while the functoriality theorem transports identity and composite continuation data and repacks the same indexed restriction surface after classifier movement. A history h lies in the signature gap of a $\mathsf{PreSheaf}^{\uparrow}$ token p when the source-domain accepts this indexed restriction surface, the signature relation pairs it with an answer surface and evidence ledger, and token introduction names that answer as p; unfolded, h carries exactly the opens, inclusions, sections, restrictions, identity, composition, and transport rows encoded by p. The standard bridge reads the same rows as an ordinary contravariant presheaf on

the certified open-index category and reads back only presentations whose data are already carried by those rows, so the chapter registers this construction under the name PreSheaf$^{\uparrow}$ without adding sheaf locality, gluing, stalk quotients, or external sheafification.

Theory closure: TheoryGate(NameCert$_{\mathsf{PreSheaf}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper-side treatment consists of the indexed restriction surface, identity, composition, and transport rows, the standard bridge, the exact ledger boundary, and explicit non-claims for the BHist-indexed PreSheaf$^{\uparrow}$ construction.

Formal verification: FormalStatus(NameCert$_{\mathsf{PreSheaf}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.PreSheafUp.PreSheafIndexedRestrictionSurface\_functoriality\_surface`

Bridge status: paperBridge

Not claimed: This chapter keeps sheaf locality, gluing, stalk quotient formation, external sheafification, and bridgeChecked verification outside the PreSheaf$^{\uparrow}$ indexed restriction surface.

Upgrade path: No higher paper-side theory grade remains for this PreSheaf$^{\uparrow}$ surface; bridgeChecked verification remains a separate verification-axis obligation.

The Sheaf$^{\uparrow}$ package consumes the presheaf restriction surface of chapter 150 over the indexed-open carrier of chapter 88; the sibling files below record the locality, gluing, refinement, and downstream-access rows for that dependency.

Chapter 151

A Concrete Naming Certificate for $\mathsf{Sheaf}^{\uparrow}$

The sheaf interface $\mathsf{Sheaf}^{\uparrow}$ packages a presheaf satisfying the locality and gluing axioms over open covers. It depends on $\mathsf{NameCert}_{\mathsf{PreSheaf}^{\uparrow}}$ (chapter 150) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88), and is the substrate for ringed-space and scheme certificates.

151.1 Carrier definition

151.2 The certificate

Definition 151.1 (Indexed section presheaf carrier)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for $\mathsf{Topology}^{\uparrow}$ in the sense of Definition 88.1. Write*

$$j \leq_{\mathcal{T}} i :\Longleftrightarrow \forall x : X,\ \mathsf{OpenAt}(j, x) \Longrightarrow \mathsf{OpenAt}(i, x)$$

for inclusion of indexed opens. An indexed section presheaf carrier for $\mathsf{PreSheaf}^{\uparrow}$ over $\mathcal{T}$ is a tuple

$$\mathcal{P} = (\mathsf{Sec}, \sim, \rho, \mathsf{Eqv}, \mathsf{Id}, \mathsf{Comp}, \mathsf{Res})$$

with the following data. For every open index $i : \mathsf{OpenIx}$ there is a section carrier $\mathsf{Sec}(i)$ and a classifier $\sim_i$ on $\mathsf{Sec}(i)$; the field Eqv says that each $\sim_i$ is reflexive, symmetric, and transitive. For every inclusion $j \leq_{\mathcal{T}} i$ there is a restriction map

$$\rho_{i,j} : \mathsf{Sec}(i) \to \mathsf{Sec}(j).$$

The identity field says $\rho_{i,i}(s) \sim_i s$ for every $s : \mathsf{Sec}(i)$, and the composition field says that whenever $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$,

$$\rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

for every $s : \mathsf{Sec}(i)$. The restriction classifier-stability field says that, for every inclusion $j \leq_{\mathcal{T}} i$ and every $s, t : \mathsf{Sec}(i)$,

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

This is the section-level concrete form of the contravariant restriction data described in chapter 150.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafIndexedSectionPresheafCarrier`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedSectionPresheafCarrier endpoint unary`

Definition 151.2 (Indexed sheaf cover, compatibility, and locality)**.** *Let $\mathcal{P}$ be an indexed section presheaf carrier over $\mathcal{T}$ as in Definition 151.154. An indexed open cover of an open index $i : \mathsf{OpenIx}$ is a tuple $\mathcal{U} = (A, \iota, h, \gamma)$ consisting of an indexing type A, a family $\iota : A \to \mathsf{OpenIx}$, inclusion witnesses*

$$h_a : \iota(a) \leq_{\mathcal{T}} i$$

for all $a : A$, and the pointwise cover law

$$\gamma : \forall x : X,\ \mathsf{OpenAt}(i, x) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), x).$$

For a family $s_a : \mathsf{Sec}(\iota(a))$, compatibility over $\mathcal{U}$ means that for all $a, b : A$ the two restrictions to the indexed intersection agree:

$$\rho_{\iota(a),\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)}(s_a) \sim_{\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)} \rho_{\iota(b),\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)}(s_b),$$

where the needed inclusions are supplied by the finite-intersection law of Definition 88.1. A sheaf locality field for $\mathcal{P}$ says that, for every such cover $\mathcal{U}$ of i and every pair $g, h : \mathsf{Sec}(i)$,

$$(\forall a : A,\ \rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h)) \Longrightarrow g \sim_i h.$$

A sheaf gluing field says that every compatible local family over $\mathcal{U}$ has a section $g : \mathsf{Sec}(i)$ whose restriction to each $\iota(a)$ is classifier-equal to s_a. An indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ is an indexed section presheaf carrier equipped with both of these fields.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedCoverCompatibilityLocality common refinement`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedCoverCompatibilityLocality global rows`

Definition 151.3 (Stable sheaf restriction row)**.** *Let $\mathcal{P}$ be an indexed section presheaf carrier over $\mathcal{T}$ as in Definition 151.154. A stable sheaf restriction row for $\mathcal{P}$ is the field saying that classifier equality is preserved by every restriction: for every inclusion $j \leq_{\mathcal{T}} i$ and every pair $s, t : \mathsf{Sec}(i)$,*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

Thus section classifiers transport along the indexed open restriction maps carried by the presheaf surface.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafStableRestrictionRow restricted comparison readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafStableRestrictionRow transport`

Theorem 151.4 (Sheaf carrier support obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Then the carrier support exposed by $\mathcal{S}$ is only the indexed section presheaf carrier over the $\mathsf{Topology}^{\uparrow}$ open-index surface, together with the sheaf locality and gluing fields. Concretely, every carrier row is one of the section carriers $\mathsf{Sec}(i)$, section classifiers $\sim_i$, equivalence fields, restriction maps $\rho_{i,j}$, identity and composition laws, indexed open-cover data, compatible local-family predicates, locality implications, or gluing witnesses described in Definition 151.154 and Definition 151.155.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCarrierSupport obligation`

Proof. Project the indexed section presheaf component of $\mathcal{S}$. Its displayed rows are precisely the open-indexed section carriers, classifiers, equivalence witnesses, restriction maps, and restriction identity and composition laws of Definition 151.154.

Project the sheaf component of $\mathcal{S}$. By Definition 151.155, this contributes only indexed open covers, compatible local families, the locality field, and the gluing field. No additional carrier row is introduced beyond those two displayed interfaces, so the asserted carrier support is exhausted by their projections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCarrierSupport obligation rows`

Theorem 151.5 (Sheaf classifier transport obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$, and suppose its indexed section presheaf carrier carries a stable sheaf restriction row in the sense of Definition 151.156. Then section classifiers transport through every restriction. Moreover, for every indexed open cover $\mathcal{U} = (A, \iota, h, \gamma)$ of i and every pair $g, h' : \mathsf{Sec}(i)$,*

$$(\forall a : A,\ \rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h')) \Longrightarrow g \sim_i h'.$$

Thus restriction stability gives classifier transport along the presheaf maps, and sheaf locality turns coverwise classifier equality back into classifier equality on the covered open.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger classifier transport obligation`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted global transport closure`

Proof. For a single inclusion $j \leq_{\mathcal{T}} i$, the transport claim is exactly the stable restriction row of Definition 151.156: a classifier equality $s \sim_i t$ restricts to $\rho_{i,j}(s) \sim_j \rho_{i,j}(t)$. The source and target classifiers are those supplied by the section presheaf carrier, and their reflexive, symmetric, and transitive behavior is supplied by the equivalence field of Definition 151.154.

For a cover $\mathcal{U}$, assume the displayed coverwise equality of the restrictions of g and h'. This is exactly the antecedent required by the sheaf locality field in Definition 151.155. Applying that field over the same indexed cover gives $g \sim_i h'$, which is the global classifier equality claimed. □

Theorem 151.6 (Sheaf cover ledger exactness obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. An accepted cover and gluing ledger row for $\mathcal{S}$ consists exactly of indexed open-cover data $\mathcal{U} = (A, \iota, h, \gamma)$, the finite-intersection rows of the $\mathsf{Topology}^{\uparrow}$ carrier, a compatible local section family $s_a : \mathsf{Sec}(\iota(a))$, and a global section $g : \mathsf{Sec}(i)$ with displayed restriction equalities*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The ledger uses no host open-cover equality and no quotient primitive: all comparison data is expressed through indexed opens, restriction maps, and the section classifiers of Definition 151.154.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger exactness rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger exactness obligation`

Proof. Unfold the indexed open cover and compatibility clauses in Definition 151.155. The cover ledger records only the indexing type A, the open-index map ι, the inclusion witnesses $h_a : \iota(a) \leq_{\mathcal{T}} i$, and the pointwise cover law γ. Compatibility is recorded by restricting local sections to the finite-intersection index supplied by the $\mathsf{Topology}^{\uparrow}$ carrier and comparing them with the classifier on that intersection.

Unfold the gluing clause of the same definition. A gluing ledger row adds a section $g : \mathsf{Sec}(i)$ and the displayed restriction equalities against the compatible family. The theorem Definition 151.170 checks that restrictions of a global section produce a compatible local family, while Definition 151.169 checks that two displayed gluings of the same compatible family are classifier-equal.

The two definitions just unfolded contain no host-side equality of open covers and no quotient constructor. Their comparison mechanism is the indexed inclusion relation $j \leq_{\mathcal{T}} i$, the finite-intersection row of the topology carrier, the restriction maps, and the section classifiers. Hence the listed rows are exact for the accepted cover and gluing ledger. □

Definition 151.7 (Sheaf BHist cover nerve ledger)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *whose point carrier is* BHist*, whose membership classifier is* OpenAt*, and whose finite-intersection index is written* $\wedge_{\mathsf{Topology}^{\uparrow}}$*. Let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. The* BHist *cover nerve ledger of $\mathcal{U}$ is the finite-intersection ledger surface with the following rows.*

1. *For each $a : A$, the member row is the indexed open $\iota(a)$ with its inclusion witness $h_a : \iota(a) \leq_{\mathcal{T}} i$ and its visible membership predicate* $\mathsf{OpenAt}(\iota(a), b)$ *for* $b : \mathsf{BHist}$*.*
2. *For each $a, b : A$, the pair-overlap row is $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, together with the two finite-intersection projections $k_{a,b} \leq_{\mathcal{T}} \iota(a)$ and $k_{a,b} \leq_{\mathcal{T}} \iota(b)$ and the two restriction rows from* $\mathsf{Sec}(\iota(a))$ *and* $\mathsf{Sec}(\iota(b))$ *to* $\mathsf{Sec}(k_{a,b})$*.*
3. *For each $a, b, c : A$, the triple-overlap row is $\ell_{a,b,c} := k_{a,b} \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c)$, together with the finite-intersection projections $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b}$ and $\ell_{a,b,c} \leq_{\mathcal{T}} \iota(c)$ and the restriction rows obtained by composing through $k_{a,b}$ or directly from any member whose inclusion route is displayed.*

The ledger contains only OpenAt *rows, finite-intersection projections, inclusion witnesses, presheaf restriction rows, section classifiers, and visible* BHist *provenance. It does not identify cover presentations by host equality and does not quotient overlap rows.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger`

Theorem 151.8 (Sheaf BHist cover nerve overlap projections)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist*, let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. For a local family $s_a : \mathsf{Sec}(\iota(a))$, compatibility over $\mathcal{U}$ is exactly the assertion that every pair-overlap row of the* BHist *cover nerve ledger carries classifier equality between the two projected restrictions:*

$$\forall a, b : A, \quad \rho_{\iota(a),k_{a,b}}(s_a) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(s_b),$$

where $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ and the inclusions are the finite-intersection projections of Definition 88.1.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison overlap projection rows`

Proof. Unfold the compatibility predicate in Definition 151.155. Its only comparison clauses are indexed by pairs $a, b : A$, and each clause restricts s_a and s_b to the common intersection $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ before comparing them by the section classifier at that intersection.

Unfold the cover nerve ledger of Definition 151.160. Its pair-overlap rows are exactly the same indices $k_{a,b}$, with the same two finite-intersection projections supplied by Definition 88.1. Therefore every compatibility clause is a classifier equality on one pair-overlap ledger row.

Conversely, assume every pair-overlap ledger row carries the displayed classifier equality. Reading those rows through the same two projections gives precisely the clauses required by Definition 151.155. Restriction composition is not extra data here; it only confirms that any displayed route to $k_{a,b}$ reads as the same section classifier row as the direct pair-overlap restriction. □

Theorem 151.9 (Sheaf BHist cover nerve gluing readback)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist*, let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ is a gluing section with*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

Then the BHist *cover nerve ledger reads g back to the local family on every member row and to the induced compatible family on every pair-overlap row. Explicitly, for every $a : A$,*

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a,$$

and for every $a, b : A$, writing $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^\uparrow} \iota(b)$,

$$\rho_{\iota(a),k_{a,b}}(\rho_{i,\iota(a)}(g)) \sim_{k_{a,b}} \rho_{\iota(a),k_{a,b}}(s_a)$$

and

$$\rho_{\iota(b),k_{a,b}}(\rho_{i,\iota(b)}(g)) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(s_b).$$

Consequently the two restrictions of g to each pair-overlap ledger row recover the same classifier row as the compatible family there.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger gluing readback`

Proof. The member readback is the gluing equality displayed in the statement. It is exactly the gluing clause of Definition 151.155 evaluated at the member row $\iota(a)$.

For a pair $a, b : A$, write $k = \iota(a) \wedge_{\mathsf{Topology}^\uparrow} \iota(b)$. The finite-intersection field of Definition 88.1 supplies $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$, which are the two pair-overlap projections recorded by Definition 151.160.

Transport the gluing equality $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$ along $k \leq_{\mathcal{T}} \iota(a)$ using the restriction classifier-stability field from Definition 151.154. This gives the first pair-overlap readback equality. The same transport along $k \leq_{\mathcal{T}} \iota(b)$ gives the second one.

It remains to compare the two readings of g on k. Restriction composition identifies the restriction of $\rho_{i,\iota(a)}(g)$ to k and the restriction of $\rho_{i,\iota(b)}(g)$ to k with the direct restriction $\rho_{i,k}(g)$, up to the classifier $\sim_k$. The compatibility of s_a gives the corresponding equality between the two local-family restrictions. Transitivity and symmetry of $\sim_k$ combine these rows, so the pair-overlap ledger reads the gluing section back to the same classifier row as the compatible local family. □

Theorem 151.10 (Sheaf NameCert carrier obligation)**.** *Every indexed sheaf carrier for* $\mathsf{Sheaf}^\uparrow$ *over an indexed open topology carrier $\mathcal{T}$ determines the carrier-facing rows required by the* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *template. The rows are fixed as follows.*

1. *The traditional target is sheaf-theoretic section data over open covers.*
2. *The BEDC source is the presheaf restriction source of* $\mathsf{PreSheaf}^\uparrow$ *together with the indexed-open source of* $\mathsf{Topology}^\uparrow$*.*
3. *The carrier is the indexed section presheaf of Definition 151.154, equipped with the locality and gluing fields of Definition 151.155.*
4. *The classifier row is the family of section classifiers $\sim_i$.*
5. *The stability row is supplied by the restriction identity, restriction composition, restriction classifier-stability, and classifier-equivalence fields.*
6. *The ledger is the displayed data of covers, intersections, inclusion witnesses, and restriction maps.*
7. *The exactness row is visible cover-local readback: compatible local sections glue to a global section and locality identifies any two global readbacks with the same cover restrictions.*

8. *The standard bridge row is absent; this certificate surface records the BEDC sheaf interface without claiming an external set-theoretic sheaf bridge.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger semantic name certificate`

Proof. Unpack the indexed sheaf carrier. Its presheaf part is exactly the tuple $\mathcal{P} = (\mathsf{Sec}, \sim, \rho, \mathsf{Eqv}, \mathsf{Id}, \mathsf{Comp}, \mathsf{Res})$ of Definition 151.154, so the carrier, classifier, and restriction-stability rows are not extra data: they are the displayed section carriers, displayed section classifiers, and the identity, composition, equivalence, and restriction classifier-stability fields.

Unpack the cover part. The topology side contributes open indices, inclusions, and finite-intersection witnesses by Definition 88.1; the presheaf side contributes contravariant restriction scope by chapter 150. The remaining sheaf fields in Definition 151.155 are precisely locality and gluing over those covers, which give the visible cover-local readback row and leave no separate standard-bridge row to construct. □

Theorem 151.11 (Sheaf restriction stability obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. For inclusions $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$, restriction identity and restriction composition keep every section row inside the displayed classifier family. Explicitly, for $s : \mathsf{Sec}(i)$ one has*

$$\rho_{i,i}(s) \sim_i s$$

and

$$\rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s).$$

When k is an indexed intersection supplied by the finite-intersection field of Definition 88.1, the same restriction-composition statement applies to the two induced inclusion chains, so cover restrictions remain stable under the topology intersection witnesses.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restriction stability obligation`

Proof. The first displayed relation is the identity field of the indexed section presheaf carrier in Definition 151.154. The second displayed relation is the composition field for the chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. Both conclusions land in the classifier specified by the target open index, namely $\sim_i$ for identity and $\sim_k$ for composition.

For the intersection case, use Definition 88.1 to obtain the open-index intersection and its two projection inclusions. Combining either projection with a cover inclusion gives one of the admissible chains governed by the contravariant restriction interface of chapter 150. Applying the same composition field to those chains gives stability on every displayed intersection row. □

Theorem 151.12 (Sheaf locality and gluing NameCert obligation)**.** *For an indexed sheaf carrier $\mathcal{S}$ for $\mathsf{Sheaf}^{\uparrow}$, the locality and gluing fields supply the certificate rows consumed by Definition 151.169, Definition 151.170, and Definition 151.171. Namely, every compatible local family over an indexed open cover has a global readback section, and locality identifies any two global sections whose restrictions agree on every cover member.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison locality gluing semantic name certificate`

Proof. Fix an indexed cover $\mathcal{U} = (A, \iota, h, \gamma)$ of i and a compatible family $s_a : \mathsf{Sec}(\iota(a))$. The cover and compatibility predicates are those of Definition 151.155; their intersection clauses are meaningful because Definition 88.1 supplies finite-intersection witnesses, and their restriction clauses live in the contravariant presheaf scope of chapter 150.

Apply the gluing field to obtain a section $g : \mathsf{Sec}(i)$ whose restrictions classify as the family s_a. Apply the locality field to any pair of such global sections whose memberwise restrictions agree; this is exactly the premise used by Definition 151.169. The compatibility theorem uses the same restriction-composition row on intersections, and the idempotence corollary repacks gluing plus uniqueness for the local family obtained from one global section. □

Theorem 151.13 (SheafUp BHist obligation surface)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *whose point carrier is* BHist*, with classifier* hsame*, membership row* OpenAt*, and finite-intersection index $\wedge_{\mathsf{Topology}^{\uparrow}}$. Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$ in the sense of Definition 151.154 and Definition 151.155. Then $\mathcal{S}$ supplies the* $\mathsf{Sheaf}^{\uparrow}$ *carrier, section classifiers, restriction maps, restriction identity, restriction composition, indexed-cover rows, compatibility predicate, locality field, gluing field, and visible* BHist *ledger rows required by the paper-side* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation surface. The exposed data depend only on* $\mathsf{NameCert}_{\mathsf{PreSheaf}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$*, the row* OpenAt*, the finite-intersection rows of $\mathcal{T}$, and the classifier-equivalence fields on the section carriers.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistObligationSurface restriction cover package`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistObligationSurface cover restriction classifier`

Proof. Project the carrier and classifier rows from the indexed section presheaf carrier. For each open index i, the section carrier $\mathsf{Sec}(i)$ and classifier $\sim_i$ are visible, and the equivalence field supplies the reflexive, symmetric, and transitive classifier rules required by the certificate surface.

Project the restriction rows from the same tuple. The identity and composition fields are exactly the $\mathsf{PreSheaf}^{\uparrow}$ restriction identity and restriction composition obligations, with inclusions interpreted through the indexed-open preorder $j \leq_{\mathcal{T}} i$ defined by OpenAt. The finite-intersection row of $\mathcal{T}$ supplies the common target index used in compatibility checks.

Finally project the cover, compatibility, locality, and gluing rows from Definition 151.155. The visible ledger is BHist-scoped because every open membership and every inclusion witness is expressed by OpenAt on BHist, and no host powerset equality is part of the exposed surface. □

Theorem 151.14 (SheafUp restriction hsame transport obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over a* BHist*-scoped indexed open topology carrier $\mathcal{T}$. Suppose a second displayed carrier is obtained by componentwise* hsame *transport of the topology row* OpenAt*, the section carriers and classifiers, the restriction maps, and the indexed-cover rows. Then restriction compatibility, locality, and gluing for $\mathcal{S}$ transport to the displayed carrier. In particular, a compatible family remains compatible after transport, a locality hypothesis on transported restrictions yields transported classifier equality of global sections, and a gluing witness transports to a gluing witness for the transported local family.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger hsame transport readback`

Proof. Transport the topology row first. The $\mathsf{Topology}^{\uparrow}$ membership-stability field moves each occurrence of $\mathsf{OpenAt}(i, h)$ across the displayed hsame witness, so the inclusion witnesses $j \leq_{\mathcal{T}} i$ and the cover law for $\mathcal{U} = (A, \iota, \eta, \gamma)$ remain valid after transport.

Next transport the section rows. The componentwise transport hypothesis identifies each section carrier, classifier, and restriction map with its transported counterpart. Compatibility is a conjunction of classifier equalities after restricting to the finite-intersection index, so it follows by applying the transported restriction rows and then reading the section classifier equivalence fields in the transported carrier.

For locality, begin with transported agreement of two global sections on every cover member. Move that agreement back along the componentwise classifier transport, apply the locality field of $\mathcal{S}$, and transport the resulting global classifier equality forward. For gluing, transport the compatible family back, apply the gluing field of $\mathcal{S}$ to obtain a global section, and transport that witness and its restriction equalities forward. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger restriction hsame transport obligation`

Theorem 151.15 (SheafUp cover gluing NameCert export)**.** *The* BHist*-scoped surface of Definition 151.166, together with the transport obligation of Definition 151.167, the uniqueness theorem Definition 151.169, and the global-restriction compatibility theorem Definition 151.170, assembles the paper-side* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *obligation surface consumed by* $\mathsf{RingedSpace}^\uparrow$ *and* $\mathsf{Scheme}^\uparrow$*. The exported surface provides sheaf carrier data, restriction coherence, cover compatibility, locality, gluing, uniqueness up to section classifier equality, and compatibility of restrictions of global sections; it claims no standard bridge and no external powerset equality.*

Proof. Start with the obligation surface of Definition 151.166. It supplies the carrier, classifier, restriction, cover, compatibility, locality, gluing, and visible ledger rows over BHist, all routed through $\mathsf{NameCert}_{\mathsf{PreSheaf}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$.

Use Definition 151.167 to make those rows stable under the componentwise hsame transports seen by downstream chapters. This gives $\mathsf{RingedSpace}^\uparrow$ and $\mathsf{Scheme}^\uparrow$ a transport discipline for topology membership through OpenAt and for section equality through the displayed section classifiers.

The gluing consequences are then the two local theorems already present in the chapter. Apply Definition 151.169 for uniqueness of a glued global section up to the section classifier, and apply Definition 151.170 for compatibility of the local family obtained by restricting a global section.

Combining these rows gives exactly the paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ obligation surface needed by the dependent ringed-space and scheme certificates. Since every cited row stays inside indexed opens, OpenAt, hsame, and section classifiers, the package contains neither a standard sheaf bridge nor an equality of host powersets. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverGluingNameCert export`

Theorem 151.16 (Sheaf gluing uniqueness from locality)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^\uparrow$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $s_a : \mathsf{Sec}(\iota(a))$ be a compatible local family over $\mathcal{U}$. If $g, h : \mathsf{Sec}(i)$ both restrict to that family on every cover member, in the sense that*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$$

and

$$\forall a : A, \quad \rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a,$$

then the two cover-global sections are classifier-equal:

$$g \sim_i h.$$

Thus the gluing supplied by the $\mathsf{Sheaf}^\uparrow$ *carrier is unique up to the section classifier on the covered open.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingClassifier uniqueness from locality`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger gluing uniqueness from locality`

Proof. Fix a cover member $a : A$. The first restriction hypothesis gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The second restriction hypothesis gives

$$\rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a.$$

By symmetry of the section classifier on $\mathsf{Sec}(\iota(a))$, supplied by the equivalence field of Definition 151.154, this yields

$$s_a \sim_{\iota(a)} \rho_{i,\iota(a)}(h).$$

Transitivity of the same classifier then gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h).$$

Since a was arbitrary, the restrictions of g and h agree on every member of $\mathcal{U}$. Applying the sheaf locality field from Definition 151.155 gives $g \sim_i h$. □

Theorem 151.17 (Sheaf global restrictions form a compatible local family)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $g : \mathsf{Sec}(i)$. Define the local family $s_a : \mathsf{Sec}(\iota(a))$ by*

$$s_a = \rho_{i,\iota(a)}(g).$$

Then s_a is compatible over $\mathcal{U}$ in the sense of Definition 151.155. Explicitly, for every $a, b : A$, putting $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, one has

$$\rho_{\iota(a),k_{a,b}}(\rho_{i,\iota(a)}(g)) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(\rho_{i,\iota(b)}(g)),$$

where the restriction maps use the inclusions supplied by the finite-intersection field and the cover inclusions h_a and h_b.

Proof. Fix $a, b : A$ and write $k = \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$. The finite-intersection field of Definition 88.1 gives

$$\mathsf{OpenAt}(k, x) \Longrightarrow (\mathsf{OpenAt}(\iota(a), x) \wedge \mathsf{OpenAt}(\iota(b), x))$$

for every $x : X$. Projecting the two components gives inclusions $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$. Together with the cover inclusions $h_a : \iota(a) \leq_{\mathcal{T}} i$ and $h_b : \iota(b) \leq_{\mathcal{T}} i$, these are the two chains needed for presheaf restriction composition.

Apply the composition field of Definition 151.154 to the chain $k \leq_{\mathcal{T}} \iota(a) \leq_{\mathcal{T}} i$ and the section g. This gives

$$\rho_{\iota(a),k}(\rho_{i,\iota(a)}(g)) \sim_k \rho_{i,k}(g).$$

Applying the same composition field to $k \leq_{\mathcal{T}} \iota(b) \leq_{\mathcal{T}} i$ gives

$$\rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)) \sim_k \rho_{i,k}(g).$$

By symmetry of the section classifier on $\mathsf{Sec}(k)$, supplied by the equivalence field of Definition 151.154, the second displayed relation yields

$$\rho_{i,k}(g) \sim_k \rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)).$$

Transitivity of the same classifier combines this with the first displayed relation and gives

$$\rho_{\iota(a),k}(\rho_{i,\iota(a)}(g)) \sim_k \rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)).$$

Since a and b were arbitrary, this is exactly compatibility of the family $a \mapsto \rho_{i,\iota(a)}(g)$ over $\mathcal{U}$ as defined in Definition 151.155. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger global restrictions compatible`

Corollary 151.18 (Sheaf gluing of global restrictions is idempotent)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, \eta, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $g : \mathsf{Sec}(i)$. Define the local family $s_a : \mathsf{Sec}(\iota(a))$ by*

$$s_a = \rho_{i,\iota(a)}(g).$$

If $h : \mathsf{Sec}(i)$ is a gluing of this family, in the sense that

$$\forall a : A, \quad \rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a,$$

then

$$h \sim_i g.$$

Proof. By Definition 151.170, the family s_a is compatible over $\mathcal{U}$. For each $a : A$, the displayed definition of s_a and reflexivity of the classifier on $\mathsf{Sec}(\iota(a))$, supplied by Definition 151.154, give

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The gluing hypothesis gives

$$\rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a$$

for the same a. Since a was arbitrary, both cover-global sections h and g restrict to the compatible local family s_a on every member of $\mathcal{U}$. Applying Definition 151.169 with h as the first cover-global section and g as the second gives $h \sim_i g$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingGlobalRestrictions idempotent`

Theorem 151.19 (Sheaf restriction classifier transport)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. For every inclusion $j \leq_{\mathcal{T}} i$ and every pair $s, t : \mathsf{Sec}(i)$, classifier equality on the larger open transports along restriction:*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

Thus restriction rows are morphisms of the local section classifiers.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restriction classifier transport`

Proof. The indexed sheaf carrier contains the indexed section presheaf carrier of Definition 151.154. Apply its restriction classifier-stability field to the inclusion $j \leq_{\mathcal{T}} i$ and the given classifier row $s \sim_i t$. □

Theorem 151.20 (Sheaf compatible-family stability)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $t_a : \mathsf{Sec}(\iota(a))$ is a second local family with*

$$\forall a : A, \quad t_a \sim_{\iota(a)} s_a.$$

Then t_a is compatible over $\mathcal{U}$. Explicitly, for all $a, b : A$, writing $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, one has

$$\rho_{\iota(a),k_{a,b}}(t_a) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(t_b).$$

Proof. Fix $a, b : A$ and write $k = \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$. The finite-intersection field of Definition 88.1 supplies the inclusions $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$ needed to restrict both local sections to the overlap.

Apply Definition 151.172 to the classifier row $t_a \sim_{\iota(a)} s_a$ along $k \leq_{\mathcal{T}} \iota(a)$. This gives

$$\rho_{\iota(a),k}(t_a) \sim_k \rho_{\iota(a),k}(s_a).$$

Apply the same transport row to $t_b \sim_{\iota(b)} s_b$ along $k \leq_{\mathcal{T}} \iota(b)$, and then use symmetry of the classifier on $\mathsf{Sec}(k)$, to get

$$\rho_{\iota(b),k}(s_b) \sim_k \rho_{\iota(b),k}(t_b).$$

The compatibility of the original family gives

$$\rho_{\iota(a),k}(s_a) \sim_k \rho_{\iota(b),k}(s_b).$$

Transitivity of $\sim_k$ first composes the transported a-side row with the original compatibility row, and then composes the result with the reversed transported b-side row. The resulting row is exactly

$$\rho_{\iota(a),k}(t_a) \sim_k \rho_{\iota(b),k}(t_b).$$

Since a and b were arbitrary, the family t_a is compatible over $\mathcal{U}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingCompatibleFamily stability semantic certificate`

Theorem 151.21 (Sheaf cover refinement obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. A displayed refinement of $\mathcal{V}$ through $\mathcal{U}$ is a map $r : B \to A$ together with inclusion witnesses*

$$\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$$

for every $b : B$, compatible with the two cover rows in the sense that the composite inclusion $\kappa(b) \leq_{\mathcal{T}} \iota(r(b)) \leq_{\mathcal{T}} i$ is the displayed route from the refined cover member to i. This is a certificate-level obligation only over the indexed-open inclusion relation of Definition 151.155 and the carrier rows of Definition 88.1; it introduces no host powerset equality of covers and no quotient comparison between cover presentations.

Proof. Unpack the two cover rows. The original cover supplies $h_a : \iota(a) \leq_{\mathcal{T}} i$, and the refined cover supplies $q_b : \kappa(b) \leq_{\mathcal{T}} i$. A refinement chooses, for each refined row b, an original row $r(b)$ together with the displayed inclusion $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$.

The topology carrier already gives the meaning of $\leq_{\mathcal{T}}$ as indexed-open inclusion and supplies the finite-intersection rows used by the sheaf compatibility predicate. Therefore the refinement datum is fully expressed by the map r and the witnesses ϵ_b, with the target cover inclusion $h_{r(b)}$ recording the route onward to i.

No comparison of host open subsets is used. All later transport across the refinement is forced to pass through ϵ_b, restriction composition, and the section classifiers of the indexed presheaf carrier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace refinement obligation`

Theorem 151.22 (Sheaf compatible family pullback along refinement)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement*

of $\mathcal{V}$ through $\mathcal{U}$ in the sense of Definition 151.174. If $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$, then the pulled-back family

$$t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$$

is compatible over $\mathcal{V}$. Explicitly, for every $b, c : B$, writing $m_{b,c} := \kappa(b) \wedge_{\mathsf{Topology}^\uparrow} \kappa(c)$, one has

$$\rho_{\kappa(b),m_{b,c}}(t_b) \sim_{m_{b,c}} \rho_{\kappa(c),m_{b,c}}(t_c).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger refinement pullback`

Proof. Fix $b, c : B$ and write $m = \kappa(b) \wedge_{\mathsf{Topology}^\uparrow} \kappa(c)$. The finite-intersection field of Definition 88.1 gives $m \leq_{\mathcal{T}} \kappa(b)$ and $m \leq_{\mathcal{T}} \kappa(c)$. Composing these with the refinement inclusions gives routes $m \leq_{\mathcal{T}} \iota(r(b))$ and $m \leq_{\mathcal{T}} \iota(r(c))$.

Use restriction composition on the chain $m \leq_{\mathcal{T}} \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$. It identifies the left restriction of t_b with the direct restriction of $s_{r(b)}$ to m, up to the classifier $\sim_m$. The same argument on the c side identifies the right restriction of t_c with the direct restriction of $s_{r(c)}$ to m.

The original compatibility of s_a over $\mathcal{U}$ gives equality after restricting $s_{r(b)}$ and $s_{r(c)}$ to the overlap $\iota(r(b)) \wedge_{\mathsf{Topology}^\uparrow} \iota(r(c))$. Since m lies inside both original cover members by the refinement inclusions and the finite-intersection projections, restriction composition transports that compatibility row down to m.

Finally, transitivity of $\sim_m$ composes the two restriction-composition rows with the transported original compatibility row. The resulting equality is precisely the compatibility clause for t_b and t_c over the refined cover $\mathcal{V}$. □

Theorem 151.23 (Sheaf gluing descends along refined covers)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^\uparrow$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues it:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

Then g glues the pulled-back family $t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$ over $\mathcal{V}$:

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} t_b.$$

Proof. Fix $b : B$. The gluing row over $\mathcal{U}$ gives

$$\rho_{i,\iota(r(b))}(g) \sim_{\iota(r(b))} s_{r(b)}.$$

Apply restriction classifier transport along the refinement inclusion $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$ to obtain equality after restriction to $\kappa(b)$.

Restriction composition on the chain $\kappa(b) \leq_{\mathcal{T}} \iota(r(b)) \leq_{\mathcal{T}} i$ identifies the restriction of $\rho_{i,\iota(r(b))}(g)$ to $\kappa(b)$ with the direct restriction $\rho_{i,\kappa(b)}(g)$. By definition, the restriction of $s_{r(b)}$ along the same refinement inclusion is t_b.

Transitivity of the classifier on $\mathsf{Sec}(\kappa(b))$ composes the composition row with the transported gluing row. Since b was arbitrary, the displayed equality holds for every member of $\mathcal{V}$, so g glues the pulled-back family over the refined cover. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementGluing descent cont`

Theorem 151.24 (Sheaf locality detection under refinement)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Suppose $g, h' : \mathsf{Sec}(i)$ satisfy refined-cover equality*

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} \rho_{i,\kappa(b)}(h').$$

Assume moreover that every original cover member is detected by its refinement rows: for every $a : A$, the subfamily of indices $b : B$ with $r(b) = a$ is an indexed open cover of $\iota(a)$ through the inclusions $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(a)$. Then locality over $\mathcal{U}$ gives

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementLocality global detection`

Proof. Fix $a : A$. By the detection hypothesis, the rows with $r(b) = a$ form an indexed cover of $\iota(a)$. For each such row b, the refined equality compares the direct restrictions of g and h' to $\kappa(b)$.

Restriction composition on $\kappa(b) \leq_{\mathcal{T}} \iota(a) \leq_{\mathcal{T}} i$ rewrites those direct restrictions as the restrictions of $\rho_{i,\iota(a)}(g)$ and $\rho_{i,\iota(a)}(h')$ along ϵ_b. Thus the two sections $\rho_{i,\iota(a)}(g)$ and $\rho_{i,\iota(a)}(h')$ agree on every member of the detected cover of $\iota(a)$.

Apply the sheaf locality field of Definition 151.155 on this detected cover of $\iota(a)$. It gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h').$$

Since a was arbitrary, these equalities hold over all members of $\mathcal{U}$.

Applying the same locality field over the original cover $\mathcal{U}$ yields $g \sim_i h'$, which is the claimed global classifier equality. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refined locality detection`

Theorem 151.25 (Sheaf refined-cover gluing uniqueness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Let $s_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$, and write*

$$t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$$

for its pulled-back family over $\mathcal{V}$. Suppose $g, h' : \mathsf{Sec}(i)$ both glue this pulled-back family:

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} t_b, \qquad \forall b : B, \quad \rho_{i,\kappa(b)}(h') \sim_{\kappa(b)} t_b.$$

Assume moreover that every original cover member is detected by its refinement rows in the sense of Definition 151.177. Then

$$g \sim_i h'.$$

Proof. Fix $b : B$. The first gluing row compares $\rho_{i,\kappa(b)}(g)$ with t_b, and the second compares $\rho_{i,\kappa(b)}(h')$ with the same section t_b.

Use symmetry of the classifier on $\mathsf{Sec}(\kappa(b))$ to reverse the second equality, then transitivity to obtain

$$\rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} \rho_{i,\kappa(b)}(h').$$

Since b was arbitrary, this is refined-cover equality of g and h' over $\mathcal{V}$.

Apply Definition 151.177 to this refined-cover equality and to the displayed detection hypothesis for the rows with $r(b) = a$. It returns the global classifier equality $g \sim_i h'$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinedCover gluing uniqueness`

Theorem 151.26 (Sheaf refined-cover exactness obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. For every compatible family $s_a : \mathsf{Sec}(\iota(a))$ over $\mathcal{U}$, the pulled-back family $t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$ satisfies the following three exactness rows.*

1. *The family t_b is compatible over $\mathcal{V}$.*
2. *Every gluing $g : \mathsf{Sec}(i)$ of s_a over $\mathcal{U}$ also glues t_b over $\mathcal{V}$.*
3. *If every original cover member is detected by its refinement rows, then any two sections $g, h' : \mathsf{Sec}(i)$ gluing t_b over $\mathcal{V}$ satisfy $g \sim_i h'$.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinedCover exactness obligation`

Proof. The first row is exactly Definition 151.175: compatibility of the original family transports along the displayed refinement.

The second row is exactly Definition 151.176: a section gluing the original family restricts to a gluing of the pulled-back family over the refined cover.

The third row is Definition 151.178. Its hypotheses are precisely two displayed gluings of the same pulled-back family, plus the locality-detection row for the refinement fibers over each original cover member. □

Theorem 151.27 (Sheaf NameCert refinement exactness export)**.** *The paper-side obligation surface* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *exports refined-cover exactness over indexed opens. Concretely, for any indexed sheaf carrier over an indexed open topology carrier, every displayed refinement of indexed covers carries compatible families forward, descends original gluings to refined gluings, and makes any two refined gluings of the same pulled-back family globally classifier-equal whenever the original members are detected by their refinement rows. This exported row uses only* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *restriction composition, section classifiers, locality, and gluing; it does not use host powerset equality or quotient comparison.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCertRefinement exactness export`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCertRefinementExactness export`
↪ variant `BEDC.Derived.SheafUp.SheafRefinementExactness namecert export`

Proof. Project the carrier row from Definition 151.154. This supplies the open-indexed section carriers, classifiers, restriction maps, restriction composition, and classifier transport used in the refinement arguments.

Project the cover, compatibility, locality, and gluing rows from Definition 151.155. These rows supply indexed covers, overlap compatibility, the local-to-global classifier implication, and displayed gluing witnesses.

Assemble the export by applying Definition 151.179. Its three rows are already expressed in the projected data, so $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ exposes a single refined-cover exactness obligation to downstream ringed-space and scheme certificates without adding a host-level cover comparison. □

Theorem 151.28 (Sheaf cover self-refinement identity)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. Then the identity map*

$$\mathrm{id}_A : A \to A$$

together with the pointwise reflexive inclusion witnesses

$$\epsilon_a : \iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a))$$

forms a displayed refinement of $\mathcal{U}$ through itself in the sense of Definition 151.174.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCover self refinement`

Proof. Unpack Definition 151.174. To exhibit a displayed refinement of $\mathcal{U}$ through itself, it is enough to give a map from the refined index type to the original index type and, for each refined row $a : A$, an inclusion witness from the refined member to the chosen original member. Take the map to be $r := \mathrm{id}_A$.

Fix $a : A$. Since $\mathrm{id}_A(a) = a$, the required witness

$$\epsilon_a : \iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a))$$

is exactly the pointwise implication

$$\forall x : X,\ \mathsf{OpenAt}(\iota(a), x) \Longrightarrow \mathsf{OpenAt}(\iota(a), x),$$

which holds immediately from the definition of $\leq_{\mathcal{T}}$ in Definition 151.154. The indexed-open membership row OpenAt is part of the topology carrier recorded in Definition 88.1, so this is a valid displayed inclusion witness in the same ledger as every other cover inclusion.

The onward route from the refined member to the ambient open i is then

$$\iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a)) \leq_{\mathcal{T}} i.$$

Its second leg is the original cover inclusion $h_a : \iota(a) \leq_{\mathcal{T}} i$, because $\mathrm{id}_A(a) = a$. Therefore the refinement data are exactly the identity selector together with the reflexive inclusion witnesses, and these satisfy the compatibility clause required in Definition 151.174. Hence $\mathcal{U}$ is a displayed refinement of itself. □

Theorem 151.29 (Sheaf identity-refinement pullback identity)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$, and let $s_a : \mathsf{Sec}(\iota(a))$ be a local family over $\mathcal{U}$. Use the identity displayed refinement of $\mathcal{U}$ through itself from Definition 151.181, and write its pulled-back family as*

$$t_a := \rho_{\iota(\mathrm{id}_A(a)),\iota(a)}(s_{\mathrm{id}_A(a)}).$$

Then for every $a : A$,

$$t_a \sim_{\iota(a)} s_a.$$

In particular, for every compatible family over $\mathcal{U}$, pullback along the identity refinement is pointwise the original family in the section classifier:

$$\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a.$$

Proof. Fix $a : A$. By Definition 151.181, the identity refinement chooses the selector $\mathrm{id}_A : A \to A$ and the reflexive inclusion witness

$$\iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a)).$$

Since $\mathrm{id}_A(a) = a$, this is exactly the reflexive inclusion

$$\iota(a) \leq_{\mathcal{T}} \iota(a).$$

Thus the pulled-back row at a is the identity restriction of the same local section:

$$t_a = \rho_{\iota(a),\iota(a)}(s_a)$$

inside the section carrier indexed by $\iota(a)$.

The identity field of the indexed section presheaf carrier in Definition 151.154 gives, for every section $s : \mathsf{Sec}(\iota(a))$,

$$\rho_{\iota(a),\iota(a)}(s) \sim_{\iota(a)} s.$$

Applying this field to s_a gives

$$\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a.$$

Substituting the displayed description of t_a gives $t_a \sim_{\iota(a)} s_a$. The argument is pointwise in a and does not use any overlap clause, so it applies in particular when the family s_a is compatible over $\mathcal{U}$ in the sense of Definition 151.155. □

Theorem 151.30 (Sheaf refinement composition obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Suppose (r, ϵ) is a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$ and (s, η) is a displayed refinement of $\mathcal{W}$ through $\mathcal{V}$:*

$$r : B \to A, \qquad \epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b)),$$

$$s : C \to B, \qquad \eta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c)).$$

Then the composite map $r \circ s : C \to A$ together with the composite inclusions

$$\theta_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(s(c)))$$

is a displayed refinement of $\mathcal{W}$ through $\mathcal{U}$. The cover row for $\mathcal{W}$ remains the pointwise indexed-open implication

$$\forall x : X, \quad \mathsf{OpenAt}(i, x) \Longrightarrow \exists c : C,\ \mathsf{OpenAt}(\lambda(c), x),$$

and the route onward to i is the inclusion chain $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c))) \leq_{\mathcal{T}} i$.

Proof. For each $c : C$, the refinement row (s, η) gives $\eta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$. The refinement row (r, ϵ) gives $\epsilon_{s(c)} : \kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c)))$.

Transitivity of indexed-open inclusion in the topology carrier composes these two rows and gives the displayed inclusion $\theta_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(s(c)))$.

The cover data of $\mathcal{W}$ are not changed. Its row ω still says that every point of the ambient open i lies in some indexed member $\lambda(c)$, expressed by the displayed OpenAt implication. Together with the map $r \circ s$ and the inclusions θ_c, this is exactly the refinement obligation of Definition 151.174 for $\mathcal{W}$ through $\mathcal{U}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement composition`

Theorem 151.31 (Sheaf compatible-family pullback composes over refinements)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of $i : \mathsf{OpenIx}$. Let $(r, \epsilon) : \mathcal{V} \to \mathcal{U}$ and $(s, \eta) : \mathcal{W} \to \mathcal{V}$ be displayed refinements, and let $(r \circ s, \theta) : \mathcal{W} \to \mathcal{U}$ be their composite refinement from Definition 151.183. If $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$, define*

$$v_b := \rho_{\iota(r(b)),\kappa(b)}(u_{r(b)})$$

and

$$w_c := \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then w_c is classifier-equal to the one-step pullback

$$z_c := \rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))})$$

for every $c : C$, and the family w_c is compatible over $\mathcal{W}$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement pullback composition`

Proof. Apply Definition 151.175 to the refinement (r, ϵ). It gives compatibility of the family v_b over $\mathcal{V}$.

Apply the same theorem to the refinement (s, η) and the compatible family v_b. This gives compatibility of the tower-pulled family w_c over $\mathcal{W}$.

It remains to compare the two descriptions of the local section at $c : C$. By definition, w_c restricts $u_{r(s(c))}$ first along $\kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c)))$ and then along $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$. Restriction composition for the indexed section presheaf carrier identifies this two-step restriction with the direct restriction along the composite inclusion θ_c.

The classifier on $\mathsf{Sec}(\lambda(c))$ supplies symmetry and transitivity, so the restriction-composition row gives $w_c \sim_{\lambda(c)} z_c$. Since compatibility of w_c was already obtained from the second pullback application, the composite tower pullback is compatible over $\mathcal{W}$ and agrees with the one-step pullback along $(r \circ s, \theta)$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementPullback composition`

Theorem 151.32 (Sheaf gluing descent composes over refinement towers)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of $i : \mathsf{OpenIx}$. Let $(r, \epsilon) : \mathcal{V} \to \mathcal{U}$ and $(s, \eta) : \mathcal{W} \to \mathcal{V}$ be displayed refinements, with composite $(r \circ s, \theta) : \mathcal{W} \to \mathcal{U}$. Suppose $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues it:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} u_a.$$

Then g glues the composite pulled-back family over $\mathcal{W}$:

$$\forall c : C, \quad \rho_{i,\lambda(c)}(g) \sim_{\lambda(c)} \rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))}).$$

Proof. Apply Definition 151.176 to (r, ϵ) and the gluing row for g. This shows that g glues the pulled-back family $v_b := \rho_{\iota(r(b)),\kappa(b)}(u_{r(b)})$ over $\mathcal{V}$.

Apply Definition 151.176 again to (s, η) and the displayed gluing of v_b. This shows that g glues the two-step pulled-back family $w_c := \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)})$ over $\mathcal{W}$.

By Definition 151.184, w_c is classifier-equal to the one-step pullback $\rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))})$ for every $c : C$. Transitivity of the classifier on $\mathsf{Sec}(\lambda(c))$ composes this comparison with the two-step gluing row, giving the displayed gluing row for the composite refinement. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement tower gluing`

Definition 151.33 (Sheaf displayed common refinement span)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be*

indexed open covers of the same open index $i : \mathsf{OpenIx}$. A displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$ is a tuple

$$\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$$

where C is an indexing type, $\lambda : C \to \mathsf{OpenIx}$ is an indexed-open family, $r : C \to A$ and $s : C \to B$ choose the displayed members of the two covers, and for every $c : C$ there are inclusion witnesses

$$\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c)), \qquad \zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c)).$$

The row ω says that λ itself is an indexed open cover of i, with member inclusions obtained through either composite $\lambda(c) \leq_{\mathcal{T}} \iota(r(c)) \leq_{\mathcal{T}} i$ or $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c)) \leq_{\mathcal{T}} i$, and with the pointwise cover law

$$\forall x : X,\ \mathsf{OpenAt}(i, x) \Longrightarrow \exists c : C,\ \mathsf{OpenAt}(\lambda(c), x).$$

Thus the common refinement is displayed entirely inside indexed opens, inclusion rows, and presheaf restriction rows; it contains no host-level equality of covers.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan base change gluing package`

Theorem 151.34 (Sheaf displayed common refinement gives paired refinements)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$. If $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ is a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$ in the sense of Definition 151.186, then $\mathcal{W}$ is a displayed refinement of its cover through $\mathcal{U}$ and also a displayed refinement of its cover through $\mathcal{V}$:*

$$(r, \epsilon) : \mathcal{W} \to \mathcal{U}, \qquad (s, \zeta) : \mathcal{W} \to \mathcal{V}.$$

Both refinements are in the sense of Definition 151.174.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan paired refinements`

Proof. Unpack the displayed span. Its row ω makes $\lambda : C \to \mathsf{OpenIx}$ an indexed cover of i, so $\mathcal{W}$ has the cover side required to be the refined cover in Definition 151.174.

The first projection consists of the map $r : C \to A$ together with the inclusions $\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c))$. These are exactly the displayed refinement rows from $\mathcal{W}$ through $\mathcal{U}$, with the route onward to i supplied by the cover inclusion $h_{r(c)}$.

The second projection is identical with $\mathcal{V}$ in place of $\mathcal{U}$: the map $s : C \to B$ and the inclusions $\zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$ form the displayed refinement rows, with the cover inclusion $q_{s(c)}$ supplying the route to i. □

Theorem 151.35 (Sheaf common refinement gluing invariance)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ be a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$. Let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$ and let $v_b : \mathsf{Sec}(\kappa(b))$ be compatible over $\mathcal{V}$. Suppose their pullbacks to $\mathcal{W}$ are classifier-equal:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

If $g : \mathsf{Sec}(i)$ glues u_a over $\mathcal{U}$ and $h' : \mathsf{Sec}(i)$ glues v_b over $\mathcal{V}$, then

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCommonRefinementGluing carrier invariance`

Proof. Project the common refinement span by Definition 151.187. This gives the displayed refinement (r, ϵ) from $\mathcal{W}$ through $\mathcal{U}$ and the displayed refinement (s, ζ) from $\mathcal{W}$ through $\mathcal{V}$.

Apply Definition 151.176 to the first refinement and the gluing row for g. The result says that g glues the pulled-back family

$$c \mapsto \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)})$$

over $\mathcal{W}$.

Apply the same descent theorem to the second refinement and the gluing row for h'. This says that h' glues the pulled-back family

$$c \mapsto \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)})$$

over $\mathcal{W}$. The displayed classifier equality between the two pulled-back families lets the compatible-family stability row Definition 151.173 replace the second family by the first one without changing the gluing comparison.

Now both g and h' are displayed gluings of the same compatible family over the indexed cover $\mathcal{W}$. Apply Definition 151.169 over $\mathcal{W}$ to obtain $g \sim_i h'$. □

Theorem 151.36 (Sheaf cover presentation exactness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Let $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ be a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$. Suppose a compatible family $u_a : \mathsf{Sec}(\iota(a))$ over $\mathcal{U}$ and a compatible family $v_b : \mathsf{Sec}(\kappa(b))$ over $\mathcal{V}$ agree after pullback to $\mathcal{W}$:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then any global section class determined by gluing u_a over $\mathcal{U}$ is the same classifier class as any global section class determined by gluing v_b over $\mathcal{V}$. Equivalently, if $g, h' : \mathsf{Sec}(i)$ are displayed gluings of the two families, then $g \sim_i h'$. The exactness row uses only indexed cover presentations, displayed common refinement, restriction transport, and the classifiers $\sim_j$; it does not compare host powersets and does not form a quotient of cover presentations.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentation exactness`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentation common refinement global comparison`

Proof. Choose displayed gluings $g : \mathsf{Sec}(i)$ and $h' : \mathsf{Sec}(i)$ for the two compatible families. The hypotheses give exactly the common-refinement equality of the two pulled-back local families.

Apply Definition 151.188 to $\mathcal{U}$, $\mathcal{V}$, the displayed common refinement $\mathcal{W}$, the two compatible families, their pulled-back equality, and the two displayed gluing rows. It returns $g \sim_i h'$.

Since the argument never leaves the indexed cover ledger, the conclusion identifies the two global classifier classes without choosing a preferred cover presentation, comparing powersets of host opens, or adding any quotient primitive. □

Theorem 151.37 (Sheaf NameCert obligation surface)**.** *The concrete $\mathsf{Sheaf}^{\uparrow}$ certificate surface is the following ten-field obligation surface.*

1. *The traditional target is a sheaf of sections over indexed opens of an indexed topology carrier.*
2. *The BEDC source data are $\mathsf{Topology}^{\uparrow}$ together with $\mathsf{PreSheaf}^{\uparrow}$.*
3. *The carrier is the indexed section presheaf carrier of Definition 151.154.*

4. *The classifier family is the open-indexed relation* $\sim_i$ *on* $\mathsf{Sec}(i)$.
5. *The stability obligations are classifier equivalence, identity restriction, composition of restriction, restriction classifier transport, locality, gluing, uniqueness of gluing, compatibility of global restrictions, compatible-family stability, cover-refinement transport, refined-cover exactness, refinement tower composition, displayed common-refinement comparison, and cover-presentation exactness.*
6. *The ledger consists of open-cover indices, cover-member inclusions, finite-intersection overlap indices, and restriction rows to those overlaps.*
7. *The core theorem list is Definition 151.172, Definition 151.173, Definition 151.174, Definition 151.175, Definition 151.176, Definition 151.177, Definition 151.178, Definition 151.179, Definition 151.180, Definition 151.183, Definition 151.184, Definition 151.185, Definition 151.187, Definition 151.188, Definition 151.189, Definition 151.169, Definition 151.170, and Definition 151.171.*
8. *Exactness is locality together with existence and uniqueness of gluing for compatible local families, stable under displayed common refinement of indexed cover presentations.*
9. *There is no standard bridge attached to this surface.*
10. *The status is a paper-side obligation surface for downstream certificates using* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCert obligation surface`

Proof. Rows one through four are the data fixed by Definition 151.154 and Definition 151.155: indexed opens come from $\mathsf{Topology}^{\uparrow}$, section carriers and contravariant restriction rows come from $\mathsf{PreSheaf}^{\uparrow}$, and classifier equality is indexed by the same opens as the section carriers.

Row five is exactly the list of fields and consequences exposed in this section. Equivalence, identity, composition, and restriction transport are part of the carrier surface; locality and gluing are the sheaf fields; uniqueness, compatible global restrictions, idempotence of global gluing, compatible-family stability, cover-refinement transport, refined-cover exactness, refinement tower composition, common-refinement comparison, and cover-presentation exactness are the theorem rows cited in row seven.

Rows six through ten record how downstream constructions consume the surface. A ringed-space or scheme certificate can name cover indices, overlaps, refinement maps, common-refinement spans, and restriction rows without choosing a standard-model bridge; the exactness content available to it is precisely local detection plus existence and uniqueness of gluing, stable under passing to displayed refined covers, refinement towers, and comparison of two cover presentations through a displayed common refinement. □

Corollary 151.38 (Sheaf carried-section pullback associativity along composite refinement)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$. *Let* $\mathcal{U} = (A, \alpha, h, \mu)$, $\mathcal{V} = (B, \beta, q, \nu)$, *and* $\mathcal{W} = (C, \gamma, p, \omega)$ *be indexed open covers of* $i : \mathsf{OpenIx}$. *Suppose* $(r, \epsilon) : \mathcal{U} \to \mathcal{V}$ *and* $(s, \eta) : \mathcal{V} \to \mathcal{W}$ *are displayed refinements in the sense of Definition 151.174:*

$$r : A \to B, \qquad \epsilon_a : \alpha(a) \leq_{\mathcal{T}} \beta(r(a)),$$

$$s : B \to C, \qquad \eta_b : \beta(b) \leq_{\mathcal{T}} \gamma(s(b)).$$

Let $(s \circ r, \theta) : \mathcal{U} \to \mathcal{W}$ be their composite displayed refinement from Definition 151.183, where $\theta_a : \alpha(a) \leq_{\mathcal{T}} \gamma(s(r(a)))$ is the composite inclusion. If $\sigma_c : \mathsf{Sec}(\gamma(c))$ is a compatible carried local family over $\mathcal{W}$, define the two-stage pullback by

$$\tau_b := \rho_{\gamma(s(b)),\beta(b)}(\sigma_{s(b)}), \qquad \upsilon_a := \rho_{\beta(r(a)),\alpha(a)}(\tau_{r(a)}),$$

and define the direct composite pullback by

$$\zeta_a := \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

Then the section classifier on the refined member classifies the two pullbacks together:

$$\forall a : A, \qquad \upsilon_a \sim_{\alpha(a)} \zeta_a.$$

Moreover, the two-stage family υ_a is compatible over $\mathcal{U}$.

Proof. The composite refinement is obtained by composing the displayed inclusion rows. For each $a : A$, the refinement (r, ϵ) supplies $\epsilon_a : \alpha(a) \leq_{\mathcal{T}} \beta(r(a))$, and the refinement (s, η) supplies $\eta_{r(a)} : \beta(r(a)) \leq_{\mathcal{T}} \gamma(s(r(a)))$. Their transitive composite is the inclusion $\theta_a : \alpha(a) \leq_{\mathcal{T}} \gamma(s(r(a)))$ used by the one-step pullback along $s \circ r$.

Since σ_c is compatible over $\mathcal{W}$, Definition 151.175 applied to (s, η) gives compatibility of the pulled-back family τ_b over $\mathcal{V}$. Applying the same theorem to (r, ϵ) and the compatible family τ_b gives compatibility of υ_a over $\mathcal{U}$.

It remains to identify the two descriptions of the member at a. Expanding the definitions gives

$$\upsilon_a = \rho_{\beta(r(a)),\alpha(a)}(\rho_{\gamma(s(r(a))),\beta(r(a))}(\sigma_{s(r(a))})),$$

while the direct composite pullback is

$$\zeta_a = \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

These are the two restriction routes along the same chain

$$\alpha(a) \leq_{\mathcal{T}} \beta(r(a)) \leq_{\mathcal{T}} \gamma(s(r(a))).$$

The composition row of the indexed section presheaf carrier in Definition 151.154 compares the iterated restriction with the direct restriction in the target classifier $\sim_{\alpha(a)}$:

$$\rho_{\beta(r(a)),\alpha(a)}(\rho_{\gamma(s(r(a))),\beta(r(a))}(\sigma_{s(r(a))})) \sim_{\alpha(a)} \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

Substituting the definitions of υ_a and ζ_a gives $\upsilon_a \sim_{\alpha(a)} \zeta_a$ for every $a : A$. Thus pullback along the refinement tower and pullback along the composite refinement determine the same carried section class on each refined member. □

Definition 151.39 (Sheaf restricted-open carrier)**.** *Let $\mathcal{T}$ be a* BHist*-scoped indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$*, and let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$. Fix an open index $i : \mathsf{OpenIx}$. The restricted-open carrier $\mathcal{S}|_i$ is the carrier indexed by pairs (j, η_j) with*

$$\eta_j : j \leq_{\mathcal{T}} i.$$

On such an index it inherits

$$\mathsf{Sec}_{|i}(j, \eta_j) := \mathsf{Sec}(j), \qquad \sim_{|i,(j,\eta_j)} := \sim_j .$$

For an inclusion $\theta : k \leq_{\mathcal{T}} j$ between restricted indices, its restriction map is the ambient sheaf restriction

$$\rho^{|i}_{(j,\eta_j),(k,\eta_k)} := \rho_{j,k}.$$

The target witness $\eta_k : k \leq_{\mathcal{T}} i$ is the composite of θ with η_j, so every carrier, classifier, and restriction row stays inside the fixed open i without adding a host subspace, powerset restriction, quotient, or sheafification primitive.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier`

Theorem 151.40 (Sheaf restricted-open restriction laws)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. For every restricted index (j, η_j) and section $s : \mathsf{Sec}_{|i}(j, \eta_j)$, the inherited identity row satisfies*

$$\rho^{|i}_{(j,\eta_j),(j,\eta_j)}(s) \sim_{|i,(j,\eta_j)} s.$$

For every chain of restricted indices

$$(k, \eta_k) \leq_{\mathcal{T}} (j, \eta_j) \leq_{\mathcal{T}} (l, \eta_l)$$

and every $s : \mathsf{Sec}_{|i}(l, \eta_l)$, the inherited composition row satisfies

$$\rho^{|i}_{(j,\eta_j),(k,\eta_k)}(\rho^{|i}_{(l,\eta_l),(j,\eta_j)}(s)) \sim_{|i,(k,\eta_k)} \rho^{|i}_{(l,\eta_l),(k,\eta_k)}(s).$$

Moreover, for every restricted inclusion $(k, \eta_k) \leq_{\mathcal{T}} (j, \eta_j)$, classifier equality transports along the inherited restriction:

$$s \sim_{|i,(j,\eta_j)} t \Longrightarrow \rho^{|i}_{(j,\eta_j),(k,\eta_k)}(s) \sim_{|i,(k,\eta_k)} \rho^{|i}_{(j,\eta_j),(k,\eta_k)}(t).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier restriction laws`

Proof. Unfold Definition 151.236. The section carrier and classifier at (j, η_j) are exactly $\mathsf{Sec}(j)$ and $\sim_j$, and the identity restriction is the ambient row $\rho_{j,j}$.

Apply the identity field of the indexed section presheaf carrier in Definition 151.154. This gives the first displayed classifier equality.

For the composition row, forget only the fixed target witness to i. The displayed restricted chain is an ambient chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} l$, so the composition field of Definition 151.154 gives the second displayed equality after replacing each restricted restriction map by the corresponding ambient ρ.

The classifier-transport row is identical. A restricted classifier equality is an ambient equality $s \sim_j t$, and the restricted map from (j, η_j) to (k, η_k) is $\rho_{j,k}$. The restriction classifier-stability field of Definition 151.154 therefore gives the final displayed implication. □

Theorem 151.41 (Sheaf restricted-open locality and gluing)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let (j, η_j) be a restricted index and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of j whose member inclusions satisfy $h_a : \iota(a) \leq_{\mathcal{T}} j$. Regard it as a cover inside $\mathcal{S}|_i$ by assigning each member the composite witness*

$$\eta_{\iota(a)} : \iota(a) \leq_{\mathcal{T}} i.$$

Then locality and gluing hold in the restricted carrier. Thus, if $g, h' : \mathsf{Sec}_{|i}(j, \eta_j)$ and

$$\forall a : A, \quad \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(g) \sim_{|i,(\iota(a),\eta_{\iota(a)})} \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(h'),$$

then $g \sim_{|i,(j,\eta_j)} h'$. *If* $s_a : \mathsf{Sec}_{|i}(\iota(a), \eta_{\iota(a)})$ *is compatible on the restricted cover, then there is* $g : \mathsf{Sec}_{|i}(j, \eta_j)$ *with*

$$\forall a : A, \quad \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(g) \sim_{|i,(\iota(a),\eta_{\iota(a)})} s_a.$$

Compatible local families remain compatible after every further restriction inside $\mathcal{S}|_i$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier locality gluing descent`

Proof. View the restricted cover as the ambient indexed open cover of j with the same index type A, the same open-index map ι, the same inclusion witnesses h_a, and the same cover law γ. The extra witnesses $\eta_{\iota(a)}$ only record that each member also lies below the fixed open i.

After unfolding Definition 151.236, the displayed memberwise equality is exactly the ambient antecedent for the locality field of Definition 151.155. Applying that field to the ambient cover of j gives $g \sim_j h'$, which is the restricted classifier equality at (j, η_j).

For gluing, a compatible family in the restricted carrier is the same family $s_a : \mathsf{Sec}(\iota(a))$ with the same overlap equalities as in the ambient sheaf. Apply the gluing field of Definition 151.155 to obtain $g : \mathsf{Sec}(j)$ whose ambient restrictions classify as s_a. Unfolding the restricted carrier turns those rows into the displayed restricted gluing rows.

It remains to check that compatibility is stable under further restriction inside the fixed open. Fix two local members and restrict them to a smaller restricted index below their overlap. The finite-intersection row of Definition 88.1 supplies the overlap inclusions, and Definition 151.237 supplies restriction composition along the chains through that overlap. Transporting the original compatibility row by the same theorem and composing the resulting classifier equalities proves that the further-restricted family is still compatible. □

Theorem 151.42 (Sheaf restricted-open NameCert surface)**.** *For every* BHist*-scoped indexed open topology carrier* $\mathcal{T}$*, indexed sheaf carrier* $\mathcal{S}$ *over* $\mathcal{T}$*, and open index* $i : \mathsf{OpenIx}$*, the restricted-open carrier* $\mathcal{S}|_i$ *supplies the paper-side* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *surface used by open-local consumers such as ringed-space and scheme certificates. Its rows are:*

1. *carrier: restricted indices* (j, η_j) *with* $j \leq_{\mathcal{T}} i$ *and inherited section carriers* $\mathsf{Sec}(j)$*;*
2. *classifier: the inherited section classifiers* $\sim_j$*;*
3. *stability: identity, composition, and classifier transport from Definition 151.237, with classifier transport agreeing with Definition 151.172;*
4. *ledger: open-cover indices below* i*, cover-member inclusions, finite-intersection overlap rows, refinement maps, and restriction paths;*
5. *exactness: restricted locality and gluing from Definition 151.238, stable under refinement by Definition 151.175 and Definition 151.176;*
6. *standard bridge: absent, as in the global obligation surface of Definition 151.190.*

Thus an open-local consumer may work entirely below i *while reusing the global* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *carrier, classifier, stability, ledger, exactness, and absent-standard-bridge rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier semantic name certificate`

Proof. The carrier and classifier rows are immediate from Definition 151.236: every restricted index names an ambient open below i, and no section carrier or classifier is rebuilt.

The stability row is supplied by Definition 151.237. Its classifier-transport clause is the restricted form of Definition 151.172, because both statements use the same ambient restriction map $\rho_{j,k}$ and the same classifier family $\sim$.

The ledger row is inherited from the ambient cover and refinement ledgers. Covers below i are ambient covers whose target open also carries a witness to i, while refinement pullback and gluing descent are exactly the rows of Definition 151.175 and Definition 151.176 read inside the fixed-open slice.

Finally, Definition 151.238 gives the exactness row for locality and gluing below i. The global obligation surface of Definition 151.190 already records that no standard bridge is attached, and restricting to a fixed open adds no such bridge. These rows are precisely the $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ surface required by open-local consumers. □

151.3 Displayed base change surface

Definition 151.43 (Sheaf displayed base-change square)**.** *Let $\mathcal{T}$ and $\mathcal{T}'$ be indexed open topology carriers, and let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^\uparrow$ over $\mathcal{T}$. A displayed base-change square from $\mathcal{T}'$ to $\mathcal{T}$ consists of:*

1. *a map of indexed open carriers $f : \mathsf{OpenIx}' \to \mathsf{OpenIx}$ preserving finite intersections, cover ledgers, and inclusion rows;*
2. *a target open $i : \mathsf{OpenIx}$ and a source open $i' : \mathsf{OpenIx}'$;*
3. *a displayed inverse-image row saying that $f^{-1}(i)$ is represented by i' in the source carrier;*
4. *for every indexed cover $\mathcal{U} = (A, \iota, h, \gamma)$ of i, a displayed pulled-back cover $\mathcal{U}' = (A, \iota', h', \gamma')$ of i' with the same index type A;*
5. *for every $a : A$, a carrier row identifying $f(\iota'(a))$ with $\iota(a)$ below i, together with the induced restriction path from i' to $\iota'(a)$.*

The square is displayed: it records the index map, the represented inverse image, and the memberwise cover pullback without replacing the indexed-open carrier by a powerset model or adding a quotient of covers.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDisplayedBaseChangeSquare`

Theorem 151.44 (Sheaf base-change cover-pullback compatibility)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^\uparrow$ over $\mathcal{T}$, and let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square as in Definition 151.204. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i, let $\mathcal{U}' = (A, \iota', h', \gamma')$ be its displayed pulled-back cover of i', and let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$. Then the pulled-back local family*

$$u'_a := \rho_{\iota(a), f(\iota'(a))}(u_a)$$

is compatible over the displayed cover $\mathcal{U}'$ after the carrier identification $f(\iota'(a)) \cong \iota(a)$ supplied by the square.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change cover pullback`

Proof. Unfold compatibility over $\mathcal{U}'$. For two members $a, b : A$, the source overlap is represented by the finite intersection of $\iota'(a)$ and $\iota'(b)$ in $\mathcal{T}'$.

The base-change square preserves finite intersections, so applying f sends this source overlap to the target overlap of $\iota(a)$ and $\iota(b)$ below i. The displayed carrier rows identify the two restriction paths from $\iota(a)$ and $\iota(b)$ to that target overlap with the images of the corresponding source paths.

Use the compatibility row for u_a and u_b on the target overlap. Restriction composition in the indexed sheaf carrier transports this equality along the displayed source paths, and restriction classifier transport replaces each transported section by the displayed pullback u'_a and u'_b. This is exactly the required compatibility row over $\mathcal{U}'$. □

Theorem 151.45 (Sheaf base-change gluing pullback)**.** *Let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square from Definition 151.204. Let $\mathcal{U}$ be an indexed cover of i and let $\mathcal{U}'$ be its displayed pulled-back cover of i'. Suppose $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues u_a over $\mathcal{U}$:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} u_a.$$

Then the displayed pullback $g' := \rho_{i,f(i')}(g)$ glues the pulled-back family u'_a over $\mathcal{U}'$ after transporting along the represented inverse-image row $f^{-1}(i) \simeq i'$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger base change gluing pullback`

Proof. Fix $a : A$. The gluing row for g restricts g from i to $\iota(a)$ and compares it with u_a.

Transport this row through the displayed base-change square. The inverse-image row represents the source target by i', and the member row represents the pulled-back member by $\iota'(a)$. Restriction composition identifies the path from g' to $\iota'(a)$ with the target path from g through $\iota(a)$ followed by the displayed carrier transport.

Apply restriction classifier transport to the original gluing equality along that path. The right-hand side is precisely the displayed pulled-back section u'_a, and the left-hand side is the restriction of g' to the pulled-back member. Since a was arbitrary, these rows give the displayed gluing of the pulled-back family over $\mathcal{U}'$. □

Theorem 151.46 (Sheaf base-change common-refinement invariance)**.** *Let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square from Definition 151.204. Let $\mathcal{U}$ and $\mathcal{V}$ be indexed cover presentations of the same target open i, with compatible families u_a and v_b. Let $\mathcal{W}$ be a displayed common refinement on which the two presentations agree:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then the displayed base-changed cover presentations over i' agree after the pulled-back displayed common refinement. Consequently their glued global classifier classes over the represented source open are the same whenever the corresponding displayed gluings exist.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange common refinement projection`

Proof. Apply Definition 151.205 to $\mathcal{U}$ and to $\mathcal{V}$. This gives compatible pulled-back families over the two displayed source covers.

Pull back the common refinement ledger $\mathcal{W}$ along the same square. Finite-intersection preservation and the memberwise carrier rows give a displayed common refinement between the two source cover presentations, with the same refinement maps r and s on indices.

Transport the target equality on $\mathcal{W}$ along this pulled-back common refinement. Restriction composition and classifier transport identify the transported rows with the two source pulled-back families restricted to the pulled-back refinement members.

Now apply Definition 151.189 to the two source cover presentations and their pulled-back common refinement. It returns equality of the global classifier classes determined by the two displayed gluings over i'. □

Theorem 151.47 (Sheaf base-change NameCert obligation surface)**.** *For every displayed base-change square of indexed open carriers, the* $\mathsf{Sheaf}^{\uparrow}$ *base-change surface supplies the following* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation rows for downstream ringed-space and scheme consumers.*

1. *carrier: the restricted-open carrier of Definition 151.236, read at the represented source open* i'*;*
2. *classifier: the inherited sheaf classifier* $\sim_j$ *on every displayed source open below* i'*;*
3. *stability: restriction identity, composition, classifier transport, and restricted-open stability from Definition 151.239, together with cover-pullback compatibility from Definition 151.205;*
4. *ledger: the base-change square of Definition 151.204, its displayed cover pullback rows, pulled-back common refinements, and the refinement ledgers used by Definition 151.175;*
5. *exactness: gluing pullback from Definition 151.206, refinement gluing descent from Definition 151.176, and common-refinement invariance from Definition 151.207 together with Definition 151.189;*
6. *standard bridge: absent, as in Definition 151.239.*

Thus base change is exposed as a paper-side obligation surface on indexed opens, not as a host-space powerset construction, and downstream certificates can cite it for cover pullback, gluing pullback, and common-refinement invariance.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange name certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange obligation surface`

Proof. The carrier and classifier rows are inherited from Definition 151.236. The represented source open i' determines the same fixed-open slice used by restricted-open consumers, so no new section carrier or classifier is introduced.

The stability and ledger rows are exactly the displayed data of Definition 151.204. Cover members, overlaps, and refinement maps remain indexed rows, while Definition 151.239 supplies the ambient restricted-open stability and Definition 151.175 supplies refinement pullback inside the ledger.

The exactness row combines the three base-change obligations. Cover-pullback compatibility is Definition 151.205; gluing pullback is Definition 151.206; common-refinement invariance is Definition 151.207, with Definition 151.176 and Definition 151.189 providing the existing sheaf exactness rows that the surface reuses.

Finally, the restricted-open surface already records that no standard bridge is attached. The base-change square only displays how indexed rows move across source and target opens, so it adds no bridge row and remains a paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface for downstream certificates. □

151.4 Sheaf base-change functoriality

Definition 151.48 (Sheaf composable base-change squares)**.** *Let* $\mathcal{T}$*,* $\mathcal{T}'$*, and* $\mathcal{T}''$ *be indexed open topology carriers, and let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over* $\mathcal{T}$*. Let*

$$\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$$

be displayed base-change squares in the sense of Definition 151.204. The two squares are composable when the following rows assemble into the displayed square $\mathcal{T}'' \to \mathcal{T}$*:*

1. *the open-index map is the composite $f \circ g$ and preserves finite intersections by composing the finite-intersection rows of g and f;*
2. *the represented inverse-image row for a target open i identifies the source open i'' with the two-step inverse image obtained first in $\mathcal{T}'$ and then in $\mathcal{T}''$;*
3. *cover ledgers compose pointwise: an indexed cover $\mathcal{U}$ of i pulls back to a cover $\mathcal{U}'$ of i' and then to a cover $\mathcal{U}''$ of i'' with the same index type and the same member order;*
4. *inclusion rows compose from each member $\iota''(a)$ through $\iota'(a)$ to $\iota(a)$, and the route to the target open is the composite of the two displayed routes;*
5. *memberwise pullback rows for sections, overlaps, and common-refinement members are classifier-equal to the corresponding rows read directly along the composite square.*

Thus a composable pair is not extra carrier data. It is the assertion that the displayed index maps, inverse-image representatives, finite-intersection rows, cover ledgers, inclusion rows, and memberwise pullback rows form the same downstream-readable base-change surface as the one-step square.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafComposableBaseChangeSquares`

Theorem 151.49 (Sheaf base-change identity square neutrality)**.** *For an indexed sheaf carrier $\mathcal{S}$ over $\mathcal{T}$, the identity displayed base-change square on $\mathcal{T}$ preserves the cover, restriction, gluing, and common-refinement rows of Definition 151.208. In particular, reading the $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface through the identity square gives the same indexed cover members, overlap witnesses, restriction composites, displayed gluing rows, and common-refinement comparisons as reading the surface directly.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChangeIdentitySquare restriction neutrality`

Proof. The identity square uses the identity map on open indices. Its inverse-image representative for an open i is i itself, and its displayed cover pullback sends each cover member $\iota(a)$ to the same indexed member with the same inclusion row.

Cover compatibility follows because the overlap of two unchanged members is the original finite intersection. Restriction identity in the indexed section carrier identifies each pulled-back local section with the section already present in the target cover ledger.

For gluing, Definition 151.206 specializes to the identity restriction path. The displayed row is therefore classifier-equal to the original gluing row by restriction identity and classifier reflexivity.

For common refinements, the displayed span, the refinement maps, and the member inclusions are unchanged. Applying Definition 151.207 along the identity square returns the same comparison row, and Definition 151.189 reads the same global classifier class. □

Theorem 151.50 (Sheaf base-change cover-pullback composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i in $\mathcal{T}$. Pulling $\mathcal{U}$ through the composite square gives the same cover-member witnesses, member inclusion routes, finite-intersection overlap rows, and compatible local-family rows as pulling $\mathcal{U}$ first through f and then through g, up to the classifier identifications recorded by the composable-square rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change composition`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change cover pullback composition`

Proof. Start with a compatible family over $\mathcal{U}$. Apply Definition 151.205 to the square f. This gives a compatible displayed family over the pulled-back cover $\mathcal{U}'$ in $\mathcal{T}'$.

Apply the same theorem to g and the compatible family over $\mathcal{U}'$. The result is a compatible family over the two-step cover $\mathcal{U}''$ in $\mathcal{T}''$.

By Definition 151.209, the composite square has the same cover index type A, the same displayed member order, and the same member inclusion route as the two-step cover ledger. Its finite-intersection preservation row is the composite of the two overlap rows.

Restriction composition identifies the two-step section pullback with the direct pullback along the composite route. Classifier transport then replaces the two-step overlap comparisons by the one-step comparisons, so the downstream cover-pullback surface is the same in both readings. □

Theorem 151.51 (Sheaf base-change gluing pullback composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U}$ be an indexed cover of i and let u_a be a compatible local family glued by $s : \mathsf{Sec}(i)$. The displayed gluing row transported along the composite square is classifier-equal to the row obtained by first transporting the gluing row along f and then transporting the resulting row along g.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger base change gluing pullback composition`

Proof. Apply Definition 151.206 to f. It transports the gluing row for s to a displayed gluing row over the cover pulled back to $\mathcal{T}'$.

Apply Definition 151.206 again to g. This transports the intermediate gluing row to the two-step pulled-back cover over $\mathcal{T}''$.

The composability rows identify the source open of the one-step composite square with the two-step represented inverse image. They also identify each pulled-back cover member and member inclusion route with the corresponding two-step member route.

Restriction composition in the sheaf carrier identifies the restriction of s along the composite route with the successive restrictions through the intermediate open. Classifier transport along the displayed member identifications converts the two-step gluing comparison into the direct composite-square comparison, giving the claimed classifier equality of gluing rows. □

Theorem 151.52 (Sheaf base-change common-refinement composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U}$ and $\mathcal{V}$ be indexed cover presentations of i whose compatible local families agree on a displayed common refinement. The common-refinement comparison obtained after pulling through the composite square agrees with the comparison obtained after successive pullbacks through f and g. Consequently the global classifier class supplied by Definition 151.189 is independent of whether downstream consumers read the composite square in one step or as the two displayed squares.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan base change composition`

Proof. Apply Definition 151.207 to f. This produces pulled-back cover presentations over $\mathcal{T}'$ and transports the displayed common-refinement comparison to the intermediate common refinement.

Apply the same theorem to g. The intermediate comparison becomes a comparison over the two-step pulled-back common refinement in $\mathcal{T}''$.

The composable-square definition identifies the one-step pulled-back covers, refinement maps, member inclusions, and finite-intersection rows with their two-step counterparts. In particular, each common-refinement member has the same downstream restriction route after composing the displayed inclusion rows.

Restriction composition and classifier transport move the two-step comparison to the direct composite comparison. Then Definition 151.189 reads either comparison as the same global classifier class over the represented source open, so the common-refinement surface is independent of the chosen displayed factorization. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange common refinement composition`

Theorem 151.53 (Sheaf base-change three-square associativity)**.** *Let*

$$\mathcal{T}''' \xrightarrow{h} \mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$$

be three displayed base-change squares for an indexed sheaf carrier $\mathcal{S}$ over $\mathcal{T}$. Assume that the adjacent pairs are composable in the sense of Definition 151.209, and that both induced pairwise composites are again composable with the remaining square. Then the two bracketed displayed composites from $\mathcal{T}'''$ to $\mathcal{T}$ determine the same downstream base-change surface. More explicitly, first composing f with g and then with h, or first composing g with h and then with f, gives the same classified rows for every pulled-back indexed cover, every pulled-back compatible family, every transported gluing row, and every pulled-back common-refinement presentation.

Proof. Fix an indexed cover $\mathcal{U} = (A, \iota, r, \gamma)$ of an open i in $\mathcal{T}$. Apply Definition 151.211 to the pair (f, g). The cover obtained over $\mathcal{T}''$ by first pulling through f and then through g has the same index type A, the same member order, the same finite-intersection overlap rows, and the same compatible-family restriction rows as the cover read through the composite square $f \circ g$. Applying the same theorem to the resulting composite square and h identifies the left-bracketed cover over $\mathcal{T}'''$ with the three-step cover obtained by pulling through f, then g, then h.

Apply Definition 151.211 instead to the pair (g, h), and then to f together with that composite. This identifies the right-bracketed cover over $\mathcal{T}'''$ with the same three-step cover ledger: the index type is still A, the member attached to $a : A$ is the inverse-image representative obtained by the same three displayed member rows, and the inclusion route to i is the same composite of displayed inclusion routes. Associativity of ordinary composition of the displayed open-index maps and of the restriction-route concatenations identifies the two parenthesizations of that route. Hence both bracketings classify the same cover-pullback rows and the same pulled-back compatible local-family rows.

Now let u_a be a compatible family over $\mathcal{U}$ and let $s : \mathsf{Sec}(i)$ be a displayed gluing section for it. Applying Definition 151.212 to (f, g) and then to the composite with h identifies the left-bracketed gluing row with the row obtained by restricting s successively along the three displayed square routes. Applying the same theorem to (g, h) and then to f identifies the right-bracketed gluing row with that identical successive restriction row. Restriction composition in the indexed sheaf carrier removes the parentheses from the route, and classifier transport along the composable-square member identifications gives equality of the two transported gluing rows.

Finally take two indexed cover presentations of i with compatible families agreeing on a displayed common refinement. By Definition 151.213, the left bracketing has the same pulled-back refinement indices, refinement maps, member inclusions, and comparison rows as the three-step pullback. The right bracketing is identified with that same three-step common-refinement ledger by applying the same theorem in the other pairwise order. The common-refinement members therefore restrict through the same downstream routes, and Definition 151.189 reads the two transported comparisons as the same global classifier class over the represented open of $\mathcal{T}'''$. □

Definition 151.54 (Sheaf cover-presentation classifier)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed*

open covers of the same open index $i : \mathsf{OpenIx}$. *Let* $u_a : \mathsf{Sec}(\iota(a))$ *be compatible over* $\mathcal{U}$ *and let* $v_b : \mathsf{Sec}(\kappa(b))$ *be compatible over* $\mathcal{V}$.

The two cover presentations $(\mathcal{U}, u)$ *and* $(\mathcal{V}, v)$ *are classifier-equal when there exists a displayed common refinement span*

$$\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$$

from $\mathcal{U}$ *to* $\mathcal{V}$ *such that their pulled-back local families agree pointwise by the section classifiers:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

This classifier is a presentation-level row: it compares indexed covers only through displayed common refinements, restriction maps, and the already exposed section classifiers $\sim_j$.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafCoverPresentationClassifier`

Theorem 151.55 (Sheaf cover-presentation classifier soundness)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$. *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *and* $\mathcal{V} = (B, \kappa, q, \delta)$ *be indexed open covers of the same open index* $i : \mathsf{OpenIx}$. *Let* $u_a : \mathsf{Sec}(\iota(a))$ *be compatible over* $\mathcal{U}$ *and let* $v_b : \mathsf{Sec}(\kappa(b))$ *be compatible over* $\mathcal{V}$. *If* $(\mathcal{U}, u)$ *and* $(\mathcal{V}, v)$ *are classifier-equal in the sense of Definition 151.219, then any displayed global gluing* $g : \mathsf{Sec}(i)$ *of* u_a *and any displayed global gluing* $h' : \mathsf{Sec}(i)$ *of* v_b *satisfy*

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison soundness`

Proof. Unpack the cover-presentation classifier. It supplies a displayed common refinement span $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ from $\mathcal{U}$ to $\mathcal{V}$ and a pointwise classifier equality between the two pulled-back local families over $\mathcal{W}$.

Apply Definition 151.189 to the same two covers, compatible families, displayed common refinement, pullback equality, and displayed gluings. The conclusion is exactly $g \sim_i h'$. □

Theorem 151.56 (Sheaf cover-presentation classifier symmetry)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$. *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *and* $\mathcal{V} = (B, \kappa, q, \delta)$ *be indexed open covers of the same open index* $i : \mathsf{OpenIx}$. *Let* $u_a : \mathsf{Sec}(\iota(a))$ *be compatible over* $\mathcal{U}$ *and let* $v_b : \mathsf{Sec}(\kappa(b))$ *be compatible over* $\mathcal{V}$. *If* $(\mathcal{U}, u)$ *is classifier-equal to* $(\mathcal{V}, v)$ *in the sense of Definition 151.219, then* $(\mathcal{V}, v)$ *is classifier-equal to* $(\mathcal{U}, u)$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentationClassifier symmetric`
↪ variant `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan symmetric`
↪ variant `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan symm`

Proof. Unpack the classifier witness. It consists of a displayed common refinement span $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ and, for every $c : C$, a classifier row from the $\mathcal{U}$-pullback to the $\mathcal{V}$-pullback.

Build the reversed displayed common refinement by keeping the same cover index C, the same open family λ, and the same cover row ω, while swapping the two projection maps and their inclusion witnesses. Thus the reversed span has projection $s : C \to B$ to $\mathcal{V}$ and projection $r : C \to A$ to $\mathcal{U}$.

For each $c : C$, apply symmetry of the section classifier on $\mathsf{Sec}(\lambda(c))$ to the original pullback equality. The resulting pointwise classifier row is exactly the equality required for the reversed cover-presentation classifier. □

Theorem 151.57 (Sheaf restricted-open cover-presentation classifier descent)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$, and fix an open index $i : \mathsf{OpenIx}$. Let $\mathcal{S}|_i$ be the fixed-open restricted carrier of Definition 151.239. For two compatible local-family presentations over covers of i, the cover-presentation classifier of Definition 151.219 restricts to the same classifier on $\mathcal{S}|_i$: if the ambient presentations are classifier-equal by a displayed common refinement, then their restricted-open global gluings are identified by the restricted classifier on the fixed-open carrier.*

Proof. Read the restricted-open carrier through Definition 151.239. Its carrier is the fixed open section surface $\mathsf{Sec}(i)$ with the inherited classifier $\sim_i$, so a restricted-open global gluing is an ambient global gluing whose target open is fixed to i.

Use Definition 151.238 to read the locality and gluing rows of $\mathcal{S}|_i$ as the ambient sheaf locality and gluing rows over covers of the same fixed open. Thus the displayed restricted-open gluings provide exactly the gluing hypotheses required by the ambient cover-presentation comparison.

Apply Definition 151.220. Since the restricted classifier is inherited from $\sim_i$, the ambient conclusion $g \sim_i h'$ is the desired restricted-open classifier equality. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted open descent`

Definition 151.58 (Sheaf restricted common-refinement ledger)**.** *Let $\mathcal{T}$ be a* BHist*-scoped indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$*, let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$, and fix an open index $i : \mathsf{OpenIx}$. Work in the restricted-open carrier $\mathcal{S}|_i$ of Definition 151.236. For a restricted target (j, η_j), let*

$$\mathcal{U}_{|i} = (A, \iota, \eta^{\iota}, h, \gamma), \qquad \mathcal{V}_{|i} = (B, \kappa, \eta^{\kappa}, q, \delta)$$

be two indexed open covers of (j, η_j), where each $\eta^{\iota}_a : \iota(a) \leq_{\mathcal{T}} i$ and $\eta^{\kappa}_b : \kappa(b) \leq_{\mathcal{T}} i$ records that the member lies below the fixed open i. A restricted common-refinement ledger from $\mathcal{U}_{|i}$ to $\mathcal{V}_{|i}$ is a tuple

$$\mathcal{W}_{|i} = (C, \lambda, \eta^{\lambda}, r, s, \epsilon, \zeta, \omega)$$

such that C is an indexing type, $\lambda : C \to \mathsf{OpenIx}$ is an indexed-open family, every $\eta^{\lambda}_c : \lambda(c) \leq_{\mathcal{T}} i$ lies below the fixed open, $r : C \to A$ and $s : C \to B$ choose members of the two covers, and

$$\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c)), \qquad \zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$$

for every $c : C$. The row ω says that λ is an indexed open cover of j, with member inclusions obtained by composing through either displayed leg and with pointwise cover law over $\mathsf{OpenAt}(j, x)$*.*

Thus the ledger is a displayed common-refinement span entirely inside the slice below i: all carrier rows are restricted indices, all maps are inherited restrictions of $\mathcal{S}$, and all comparisons are made by the section classifiers of Definition 151.236.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinementLedger`

Theorem 151.59 (Sheaf restricted common-refinement pullback compatibility)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let $\mathcal{U}_{|i}$ and $\mathcal{V}_{|i}$ be restricted covers of a restricted target (j, η_j), and let $\mathcal{W}_{|i}$ be a restricted common-refinement ledger between them in the sense of Definition 151.192. If*

$$u_a : \mathsf{Sec}_{|i}(\iota(a), \eta^{\iota}_a)$$

is compatible over $\mathcal{U}_{|i}$ and

$$v_b : \mathsf{Sec}_{|i}(\kappa(b), \eta^{\kappa}_b)$$

is compatible over $\mathcal{V}_{|i}$, then their pullbacks to the restricted common refinement are compatible families over $\mathcal{W}_{|i}$. Moreover, if the displayed comparison

$$\forall c : C, \quad \rho^{|i}_{(\iota(r(c)),\eta^{\iota}_{r(c)}),(\lambda(c),\eta^{\lambda}_{c})}(u_{r(c)}) \sim_{|i,(\lambda(c),\eta^{\lambda}_{c})} \rho^{|i}_{(\kappa(s(c)),\eta^{\kappa}_{s(c)}),(\lambda(c),\eta^{\lambda}_{c})}(v_{s(c)})$$

holds on $\mathcal{W}_{|i}$, then it is the same comparison as the ambient common-refinement comparison after forgetting only the witnesses to i.

Proof. Unfold the restricted carrier using Definition 151.236. The restricted section carriers and classifiers at $\iota(a)$, $\kappa(b)$, and $\lambda(c)$ are exactly the ambient carriers and classifiers at those open indices, and the restricted restriction maps are the ambient maps ρ.

The restricted ledger of Definition 151.192 forgets to a displayed common-refinement span in the ambient sheaf. By Definition 151.187, its two projections are displayed refinements through $\mathcal{U}$ and $\mathcal{V}$.

Apply the pullback part of the ambient refinement exactness surface to each projection. Equivalently, read Definition 151.184 with the identity tower on the displayed span: the pulled-back families are compatible over the common refinement, and the two-step and one-step restriction descriptions agree by classifier equality.

Finally, Definition 151.237 identifies the restricted restriction composition and classifier transport rows with the ambient ones. Therefore the displayed equality in the restricted carrier is exactly the ambient equality on the same local sections, with the witnesses η^{λ}_{c} recording only that the comparison remains below i. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinement pullback compatibility`

Theorem 151.60 (Sheaf restricted common-refinement gluing invariance)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let $\mathcal{U}_{|i}$ and $\mathcal{V}_{|i}$ be restricted covers of a restricted target (j, η_j), and let $\mathcal{W}_{|i}$ be a restricted common-refinement ledger between them. Let u_a and v_b be compatible local families over those two restricted covers. Suppose their pullbacks to $\mathcal{W}_{|i}$ agree:*

$$\forall c : C, \quad \rho^{|i}_{(\iota(r(c)),\eta^{\iota}_{r(c)}),(\lambda(c),\eta^{\lambda}_{c})}(u_{r(c)}) \sim_{|i,(\lambda(c),\eta^{\lambda}_{c})} \rho^{|i}_{(\kappa(s(c)),\eta^{\kappa}_{s(c)}),(\lambda(c),\eta^{\lambda}_{c})}(v_{s(c)}).$$

If $g : \mathsf{Sec}_{|i}(j, \eta_j)$ glues u_a over $\mathcal{U}_{|i}$ and $h' : \mathsf{Sec}_{|i}(j, \eta_j)$ glues v_b over $\mathcal{V}_{|i}$, then

$$g \sim_{|i,(j,\eta_j)} h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinement gluing invariance`

Proof. First forget the target witnesses to i. By Definition 151.236, the two restricted covers become ambient indexed covers of j, the local families are the same ambient section families, and the displayed gluings are ambient gluing rows.

The common-refinement ledger becomes the ambient displayed span required by Definition 151.187. The agreement hypothesis is the ambient pullback comparison, because the restricted classifier at $(\lambda(c), \eta^{\lambda}_{c})$ is $\sim_{\lambda(c)}$.

Apply Definition 151.188 to the two ambient covers, the ambient span, the two compatible families, their pullback comparison, and the two gluing rows. This gives $g \sim_j h'$ in the ambient sheaf.

Return to the slice below i. The classifier at the restricted target (j, η_j) is $\sim_j$, so the ambient conclusion is exactly the displayed restricted classifier equality. The locality and gluing rows used in this passage are the restricted rows of Definition 151.238 read through the carrier identification. □

Theorem 151.61 (Sheaf restricted-open refinement exactness export)**.** *For every fixed open index $i : \mathsf{OpenIx}$, the restricted-open carrier $\mathcal{S}|_i$ exports the local cover-presentation exactness surface consumed by* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$*. Its rows are:*

1. *restricted carrier, classifier, and restriction laws from Definition 151.236 and Definition 151.237;*
2. *restricted locality and gluing for covers below i from Definition 151.238;*
3. *restricted common-refinement ledgers below i from Definition 151.192;*
4. *pullback compatibility over a restricted common refinement from Definition 151.193;*
5. *classifier equality of restricted gluings whose pulled-back families agree from Definition 151.194.*

The exported surface is local in the fixed open i, uses no host powerset equality of covers, and introduces no quotient comparison between cover presentations.

Proof. The first two rows are already established by the restricted-open surface. Apply Definition 151.236 to identify the carriers, classifiers, and inherited restriction maps, then apply Definition 151.237 and Definition 151.238 for the restriction, locality, and gluing fields.

The third row is the ledger of Definition 151.192. It is exactly the ambient displayed common-refinement span of Definition 151.187, equipped with witnesses that every member remains below the fixed open i.

For compatibility, use Definition 151.193. The proof of that theorem reads the ambient refinement pullback composition row Definition 151.184 through the restricted carrier, so the local consumers see compatible pulled-back families without leaving the slice.

For presentation independence, use Definition 151.194. It is the restricted form of Definition 151.188: two displayed gluings of compatible families with equal pullbacks to the restricted common refinement become classifier-equal at (j, η_j).

Combining these rows gives the local exactness surface required by ringed-space and scheme certificates. Every row is expressed in indexed opens, restricted inclusion witnesses, inherited restrictions, and section classifiers, so the export remains inside the BEDC sheaf certificate surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenRefinement exactness export`

Definition 151.62 (Sheaf BHist triple-overlap route ledger)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist *with membership predicate* OpenAt*, history classifier* hsame*, and finite-intersection operation $\wedge_{\mathsf{Topology}^{\uparrow}}$. Let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. For $a, b, c : A$, write*

$$k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b), \qquad \ell_{a,b,c} := k_{a,b} \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c).$$

The BHist *triple-overlap route ledger of $\mathcal{U}$ is the subledger of Definition 151.160 whose rows are the member rows for $\iota(a)$, $\iota(b)$, and $\iota(c)$, the pair-overlap row $k_{a,b}$, the triple-overlap row $\ell_{a,b,c}$, the displayed projections from $\ell_{a,b,c}$ to each participating member through the available finite-intersection routes, the induced restriction maps into $\mathsf{Sec}(\ell_{a,b,c})$, and any optional* Cont *histories that certify equality of displayed route witnesses. Membership transport along the row is only the visible* hsame *transport on* BHist *cells:*

$$\mathsf{OpenAt}(\ell_{a,b,c}, x) \wedge_{\mathsf{Topology}^{\uparrow}} x \mathsf{hsame} y \Longrightarrow \mathsf{OpenAt}(\ell_{a,b,c}, y).$$

The ledger records route data, restriction targets, section classifiers, and BHist *provenance. It does not add a quotient of cover presentations or a host-level equality between overlap routes.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRouteLedger`

Theorem 151.63 (Sheaf BHist triple-overlap route coherence)**.** *Let $\mathcal{T}$, $\mathcal{S}$, and $\mathcal{U}$ be as in Definition 151.200. For every $a, b, c : A$, every section $s : \mathsf{Sec}(\iota(a))$, and every two displayed routes from $\iota(a)$ to $\ell_{a,b,c}$ in the triple-overlap route ledger, the two induced restrictions have the same classifier at the triple-overlap row:*

$$\rho_{k_{a,b},\ell_{a,b,c}}(\rho_{\iota(a),k_{a,b}}(s)) \sim_{\ell_{a,b,c}} \rho_{\iota(a),\ell_{a,b,c}}(s).$$

The same conclusion holds for the routes beginning at $\iota(b)$ and $\iota(c)$ whenever the corresponding projection route is displayed. Optional Cont *histories compare only the route witnesses; they do not change the target carrier $\mathsf{Sec}(\ell_{a,b,c})$ or the classifier $\sim_{\ell_{a,b,c}}$.*

Proof. Unfold the triple-overlap route ledger. Its routes are the pair-overlap and triple-overlap projection rows already present in the cover nerve ledger of Definition 151.160, with projections read by Definition 151.161.

Apply Definition 151.304 to the displayed chain $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b} \leq_{\mathcal{T}} \iota(a)$. The two-step restriction and the direct displayed restriction land in the same carrier $\mathsf{Sec}(\ell_{a,b,c})$ and are compared by $\sim_{\ell_{a,b,c}}$.

The arguments for $\iota(b)$ and $\iota(c)$ are the same after choosing the displayed finite-intersection projection route from the ledger. If a Cont history is attached, the cited route-stability theorem treats it as route provenance, so the classifier comparison at $\ell_{a,b,c}$ is unchanged. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger triple overlap route coherence`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRoute coherence`

Theorem 151.64 (Sheaf BHist triple-overlap compatible-family descent)**.** *Let $\mathcal{T}$, $\mathcal{S}$, and $\mathcal{U}$ be as in Definition 151.200. If $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$, then for every $a, b, c : A$ the three restrictions of the local family to $\ell_{a,b,c}$ lie in one classifier class:*

$$\rho_{\iota(a),\ell_{a,b,c}}(s_a) \sim_{\ell_{a,b,c}} \rho_{\iota(b),\ell_{a,b,c}}(s_b), \qquad \rho_{\iota(a),\ell_{a,b,c}}(s_a) \sim_{\ell_{a,b,c}} \rho_{\iota(c),\ell_{a,b,c}}(s_c).$$

Thus every compatible family descends from pair-overlap compatibility to a coherent triple-overlap row inside the BHist *cover nerve.*

Proof. Start with pair-overlap compatibility from Definition 151.161. It gives the classifier equality between the restrictions of s_a and s_b on $k_{a,b}$.

Restrict that equality along $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b}$. By Definition 151.304, the transported equality is the same as the direct comparison of the two route restrictions to $\ell_{a,b,c}$. The route-coherence theorem Definition 151.201 identifies the composed and direct displays.

For the comparison with s_c, use the pair-overlap rows for (a, c) and (b, c) and pull them to the displayed triple-overlap row. The finite-intersection projections and route-history clauses are those of Definition 151.200, so all comparisons land in $\sim_{\ell_{a,b,c}}$ on the single carrier $\mathsf{Sec}(\ell_{a,b,c})$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger cover descent exhaustion`

Theorem 151.65 (Sheaf BHist triple-overlap downstream exactness)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback constructions may cite the triple-overlap route ledger as a closed three-face overlap package. For every accepted* BHist *cover row, the package consists of:*

1. *the triple-overlap index $\ell_{a,b,c} = (\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c)$ and its* OpenAt *membership rows, transported only by* hsame*;*

2. the one-step and two-step restriction routes into $\mathsf{Sec}(\ell_{a,b,c})$*, with optional* Cont *histories;*

3. the classifier coherence rows of Definition 151.201 and Definition 151.202;

4. the restricted-open exactness rows consumed below a fixed open.

Consequently a consumer below a fixed open i *can pull the triple-overlap route package through restricted common refinements without reconstructing pairwise compatibility from prose and without adding a host cover quotient.*

Proof. The first three rows are read directly from Definition 151.200, Definition 151.201, and Definition 151.202. They are all internal to BHist cells, indexed opens, restriction maps, and section classifiers.

For passage through a refinement, apply Definition 151.184. It identifies the one-step and two-step descriptions of pulled-back local sections, so the triple-overlap route comparisons survive along displayed refinement towers.

For consumers working below a fixed open, apply Definition 151.195. Its restricted common-refinement surface is the same ambient carrier, restriction, classifier, and gluing data with the additional witness that every index remains below the fixed open.

Combining these with Definition 151.304 gives the advertised downstream package. The conclusion is a reusable exactness row for three-face overlap routes; it introduces no new carrier beyond the existing cover nerve ledger and no comparison other than hsame on histories and $\sim_{\ell_{a,b,c}}$ on sections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRoute downstream exactness`

Definition 151.66 (Sheaf BHist point-germ ledger)**.** *Let* $\mathcal{T}$ *be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *whose point carrier is* BHist*, whose membership row is* OpenAt*, and whose finite-intersection index is written* $\wedge_{\mathsf{Topology}^{\uparrow}}$*. Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over* $\mathcal{T}$*.*

For $b : \mathsf{BHist}$*, a displayed point-germ row over* b *is a triple*

$$(i, o_i, s)$$

where $i : \mathsf{OpenIx}$*,* $o_i : \mathsf{OpenAt}(i, b)$*, and* $s : \mathsf{Sec}(i)$*. Two rows* (i, o_i, s) *and* (j, o_j, t) *compare over* b *when there is a displayed common neighborhood* $k : \mathsf{OpenIx}$ *with*

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad \mathsf{OpenAt}(k, b),$$

and classifier equality after restriction:

$$\rho_{i,k}(s) \sim_k \rho_{j,k}(t).$$

The point-germ ledger is the collection of these rows and comparisons, with common neighborhoods supplied by the finite-intersection rows of $\mathcal{T}$ *and all section comparison performed by the classifiers* $\sim_k$*.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger section scope`

Theorem 151.67 (Sheaf BHist point-germ carrier scope)**.** *The point-germ ledger of Definition 151.231 exposes no carrier beyond the* BHist *point row, the membership row* OpenAt*, indexed opens, finite-intersection rows, presheaf restrictions, and the section classifiers of the indexed sheaf carrier. In particular, each ledger row over* $b : \mathsf{BHist}$ *is determined by an indexed open containing* b *and a section on that open, and each comparison is determined by a displayed common neighborhood below the two opens together with one classifier equality after restriction.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger common open comparison`

Proof. Unfold the displayed point-germ row. Its components are exactly $b : \mathsf{BHist}$, an indexed open i, a membership witness $o_i : \mathsf{OpenAt}(i, b)$, and a section $s : \mathsf{Sec}(i)$.

Unfold the comparison row. It asks only for a common index k below the two source opens, a membership witness $\mathsf{OpenAt}(k, b)$, and the classifier row $\rho_{i,k}(s) \sim_k \rho_{j,k}(t)$.

The existence of a canonical common-neighborhood shape is supplied by the finite-intersection field of Definition 88.1, while restriction maps and section classifiers are exactly the rows of Definition 151.154. No host stalk, quotient carrier, or powerset equality is used by either the row data or the comparison data. □

Theorem 151.68 (Sheaf BHist point-germ restriction readback)**.** *Let (i, o_i, s) be a displayed point-germ row over $b : \mathsf{BHist}$ in the sense of Definition 151.231. If $j \leq_{\mathcal{T}} i$ and $o_j : \mathsf{OpenAt}(j, b)$, then the restricted row*

$$(j, o_j, \rho_{i,j}(s))$$

compares to the original row over the common neighborhood j. Explicitly, the comparison is witnessed by $j \leq_{\mathcal{T}} i$, the identity inclusion $j \leq_{\mathcal{T}} j$, the membership row o_j, and the identity classifier row

$$\rho_{j,j}(\rho_{i,j}(s)) \sim_j \rho_{i,j}(s).$$

Proof. The hypotheses give the restricted point-germ row: the target open is j, the visible membership witness is o_j, and the section is the ambient restriction $\rho_{i,j}(s)$.

Use j itself as the displayed common neighborhood. One projection is the given inclusion $j \leq_{\mathcal{T}} i$, the other is the identity inclusion $j \leq_{\mathcal{T}} j$, and the point witness is o_j.

It remains only to supply the classifier equality required by Definition 151.231. The identity field of Definition 151.154 applied to the section $\rho_{i,j}(s) : \mathsf{Sec}(j)$ gives $\rho_{j,j}(\rho_{i,j}(s)) \sim_j \rho_{i,j}(s)$, which is exactly the comparison row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restriction readback`

Theorem 151.69 (Sheaf BHist point-germ gluing readback)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$ for an indexed sheaf carrier $\mathcal{S}$ over a BHist-scoped topology carrier $\mathcal{T}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ is a gluing section with*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

For every $b : \mathsf{BHist}$ with $o_i : \mathsf{OpenAt}(i, b)$, the cover law supplies $a : A$ and $o_a : \mathsf{OpenAt}(\iota(a), b)$, and the point-germ row (i, o_i, g) reads back through that member:

$$(i, o_i, g)$$

compares over b to

$$(\iota(a), o_a, s_a).$$

If g' is another gluing section for the same compatible local family, then locality gives $g \sim_i g'$, so the resulting point-germ readback is unique up to the same section classifier and its restrictions to displayed common neighborhoods.

Proof. Apply the cover law γ to b and o_i. It returns a cover member $a : A$ together with $o_a : \mathsf{OpenAt}(\iota(a), b)$.

Use $\iota(a)$ as the common neighborhood for the two point-germ rows. The projection $\iota(a) \leq_{\mathcal{T}} i$ is the cover inclusion h_a, the projection $\iota(a) \leq_{\mathcal{T}} \iota(a)$ is the identity inclusion, and the membership witness is o_a.

The gluing row gives $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$. Combining this with the identity restriction row $\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a$, using symmetry and transitivity of the classifier on $\mathsf{Sec}(\iota(a))$, gives the comparison required by Definition 151.231.

For uniqueness, let g' be another gluing of the same compatible family. Apply Definition 151.169 to the two displayed gluing rows to obtain $g \sim_i g'$. The restriction classifier-stability field of Definition 151.154 transports this equality to any displayed common neighborhood used in the point-germ ledger, so the readback does not depend on the chosen gluing representative beyond the existing section classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger gluing readback`

Theorem 151.70 (Sheaf BHist point-germ comparison transitivity)**.** *Let (i, o_i, s), (j, o_j, t), and (ℓ, o_ℓ, u) be displayed point-germ rows over the same $b : \mathsf{BHist}$ in the sense of Definition 151.231. Suppose the first two rows compare on a displayed common neighborhood k:*

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad o_k : \mathsf{OpenAt}(k, b),$$

with

$$\alpha : \rho_{i,k}(s) \sim_k \rho_{j,k}(t),$$

and suppose the last two rows compare on a displayed common neighborhood m:

$$m \leq_{\mathcal{T}} j, \qquad m \leq_{\mathcal{T}} \ell, \qquad o_m : \mathsf{OpenAt}(m, b),$$

with

$$\beta : \rho_{j,m}(t) \sim_m \rho_{\ell,m}(u).$$

Put

$$n := k \wedge_{\mathsf{Topology}^{\uparrow}} m.$$

Then n is a displayed common neighborhood below i and ℓ at b, and the first and third rows compare there:

$$\rho_{i,n}(s) \sim_n \rho_{\ell,n}(u).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison trans`
↪ variant `BEDC.Derived.SheafUp.SheafBHistPointGermLedger shared open classifier transitivity`

Proof. The finite-intersection field of Definition 88.1 gives, for every $x : \mathsf{BHist}$,

$$\mathsf{OpenAt}(n, x) \iff (\mathsf{OpenAt}(k, x) \wedge \mathsf{OpenAt}(m, x)).$$

The forward implication, followed by projection, gives inclusions $n \leq_{\mathcal{T}} k$ and $n \leq_{\mathcal{T}} m$. At $x = b$, the reverse implication applied to o_k and o_m gives $o_n : \mathsf{OpenAt}(n, b)$. Composing the pointwise inclusions gives $n \leq_{\mathcal{T}} i$ and $n \leq_{\mathcal{T}} \ell$; composing with $k \leq_{\mathcal{T}} j$ and with $m \leq_{\mathcal{T}} j$ gives the two chains to j used below.

Restrict the comparison row α along $n \leq_{\mathcal{T}} k$ by the classifier-stability field of Definition 151.154. This gives

$$\rho_{k,n}(\rho_{i,k}(s)) \sim_n \rho_{k,n}(\rho_{j,k}(t)).$$

The composition field of the same presheaf carrier, applied to $n \leq_{\mathcal{T}} k \leq_{\mathcal{T}} i$ and to $n \leq_{\mathcal{T}} k \leq_{\mathcal{T}} j$, gives

$$\rho_{k,n}(\rho_{i,k}(s)) \sim_n \rho_{i,n}(s)$$

and

$$\rho_{k,n}(\rho_{j,k}(t)) \sim_n \rho_{j,n}(t).$$

Symmetry and transitivity of the classifier $\sim_n$ therefore yield

$$\rho_{i,n}(s) \sim_n \rho_{j,n}(t).$$

Restrict the comparison row β along $n \leq_{\mathcal{T}} m$. The classifier-stability field gives

$$\rho_{m,n}(\rho_{j,m}(t)) \sim_n \rho_{m,n}(\rho_{\ell,m}(u)).$$

The composition field for $n \leq_{\mathcal{T}} m \leq_{\mathcal{T}} j$ and $n \leq_{\mathcal{T}} m \leq_{\mathcal{T}} \ell$ gives

$$\rho_{m,n}(\rho_{j,m}(t)) \sim_n \rho_{j,n}(t)$$

and

$$\rho_{m,n}(\rho_{\ell,m}(u)) \sim_n \rho_{\ell,n}(u).$$

Again using symmetry and transitivity of $\sim_n$, obtain

$$\rho_{j,n}(t) \sim_n \rho_{\ell,n}(u).$$

Transitivity of $\sim_n$ combines the last displayed row with $\rho_{i,n}(s) \sim_n \rho_{j,n}(t)$ and gives

$$\rho_{i,n}(s) \sim_n \rho_{\ell,n}(u).$$

Together with the witnesses $n \leq_{\mathcal{T}} i$, $n \leq_{\mathcal{T}} \ell$, and $o_n : \mathsf{OpenAt}(n, b)$, this is exactly the point-germ comparison row required by Definition 151.231. □

Definition 151.71 (Sheaf root stalk-free point-germ source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root stalk-free point-germ source is the following ten-field source over* BHist.

1. *The topology field is the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier of Definition 88.1, with open indices, membership rows* $\mathsf{OpenAt}(i, b)$*, inclusion rows* $j \leq_{\mathcal{T}} i$*, identity inclusions, and finite-intersection rows* $i \wedge_{\mathsf{Topology}^{\uparrow}} j$.
2. *The presheaf field is the* $\mathsf{PreSheaf}^{\uparrow}$ *indexed section carrier of Definition 151.154, with section carriers* $\mathsf{Sec}(i)$*, restriction rows* $\rho_{i,j}$*, restriction identity, restriction composition, and restriction classifier-stability.*
3. *The sheaf field is the* $\mathsf{Sheaf}^{\uparrow}$ *locality and gluing surface over the same indexed topology and presheaf carrier.*
4. *The naming field is the root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation surface, read from the carrier, classifier, locality, gluing, refinement, and exactness rows already exposed by the indexed sheaf carrier.*
5. *The history field is the point carrier* BHist *together with* hsame*-stable transport of displayed membership rows.*
6. *The point-germ ledger field is the displayed ledger of Definition 151.231; a row over* $b : \mathsf{BHist}$ *is a triple* (i, o_i, s) *with* $o_i : \mathsf{OpenAt}(i, b)$ *and* $s : \mathsf{Sec}(i)$.

7. *The common-neighborhood field is supplied by finite intersections in the topology carrier, including the projections from $i \wedge_{\mathsf{Topology}^\uparrow} j$ to i and j and the displayed membership witness obtained from the two input membership rows.*
8. *The restriction-comparison field compares two point-germ rows only after restricting their sections to a displayed common neighborhood and applying the section classifier $\sim_k$ there.*
9. *The classifier-law field uses the reflexivity, symmetry, and transitivity rows of the section classifier on each $\mathsf{Sec}(k)$, together with restriction identity and restriction composition, to move comparisons across displayed neighborhoods.*
10. *The boundary field exports no host point carrier, no host stalk quotient, no quotient of section representatives, and no powerset equality of opens; all point-germ evidence remains inside indexed opens,* BHist *membership, restrictions, finite intersections, section classifiers, and* hsame *transport.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootStalkFreeGermSource`

Theorem 151.72 (Sheaf root point-germ classifier reflexivity)**.** *Every displayed point-germ row in the source of Definition 151.286 compares to itself. Concretely, if (i, o_i, s) is a row over $b : \mathsf{BHist}$ in the sense of Definition 151.231, then the comparison from (i, o_i, s) to (i, o_i, s) is witnessed by the common neighborhood i, the identity inclusions $i \leq_{\mathcal{T}} i$, the membership row o_i, and the identity classifier row*

$$\rho_{i,i}(s) \sim_i \rho_{i,i}(s).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison reflexive`

Proof. Use the row's own indexed open as the displayed common neighborhood. The two projections required by Definition 151.231 are both the identity inclusion $i \leq_{\mathcal{T}} i$, and the membership witness is the row's own witness $o_i : \mathsf{OpenAt}(i, b)$.

It remains to fill the classifier comparison after restriction. The identity restriction field of Definition 151.154 identifies $\rho_{i,i}(s)$ with s in the section classifier on $\mathsf{Sec}(i)$, and the reflexivity field of that classifier gives $\rho_{i,i}(s) \sim_i \rho_{i,i}(s)$. This is exactly the displayed comparison row. □

Theorem 151.73 (Sheaf root point-germ classifier symmetry)**.** *The displayed point-germ comparison in the source of Definition 151.286 is symmetric. If rows (i, o_i, s) and (j, o_j, t) over the same $b : \mathsf{BHist}$ compare on a displayed common neighborhood k with projections*

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad o_k : \mathsf{OpenAt}(k, b),$$

and classifier row

$$\rho_{i,k}(s) \sim_k \rho_{j,k}(t),$$

then the reverse comparison from (j, o_j, t) to (i, o_i, s) is witnessed by the same k, the projections swapped, the same membership row o_k, and the symmetric classifier row

$$\rho_{j,k}(t) \sim_k \rho_{i,k}(s).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison symmetric fields`

Proof. Keep the displayed common neighborhood k. The comparison definition asks only for a neighborhood below the two source opens and a membership row at b, so the same witness o_k remains valid and the two projections are read in the opposite order.

The only row whose direction changes is the section classifier comparison on $\mathsf{Sec}(k)$. Apply the symmetry field of the classifier supplied by Definition 151.154 to the given row $\rho_{i,k}(s) \sim_k \rho_{j,k}(t)$. The result is $\rho_{j,k}(t) \sim_k \rho_{i,k}(s)$, so the swapped neighborhood data form the reverse point-germ comparison. □

Theorem 151.74 (Sheaf root point-germ classifier equivalence boundary)**.** *On the displayed point-germ rows of Definition 151.286, the comparison relation of Definition 151.231 is an equivalence relation. Reflexivity is supplied by Definition 151.287, symmetry by Definition 151.288, and transitivity by Definition 151.235. The resulting equivalence boundary exports only displayed rows and comparison witnesses over indexed neighborhoods; it exports no stalk quotient, no host point carrier, and no quotient carrier of point-germ classes.*

Proof. For reflexivity, apply Definition 151.287 to the displayed row. The witness is its own indexed open, with identity restriction and the section classifier's reflexivity row.

For symmetry, apply Definition 151.288 to any displayed comparison witness. This keeps the same common neighborhood and reverses only the two projection slots and the section classifier row.

For transitivity, take two composable displayed comparison witnesses between rows over the same $b : \mathsf{BHist}$. Apply Definition 151.235; its finite-intersection construction supplies the refined common neighborhood and composes the restricted classifier rows.

These three clauses are stated entirely in the ledger language of Definition 151.231. Since Definition 151.286 contains no host stalk carrier and no quotient operation, the equivalence relation is the boundary relation available to downstream consumers, not a construction of stalk elements. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison common transport`

Theorem 151.75 (Sheaf root cover locality and gluing obligation)**.** *Let $\mathcal{T}$ be an indexed-open carrier for $\mathsf{Topology}^{\uparrow}$, and let $\mathcal{S}$ be the indexed section presheaf carrier over $\mathcal{T}$ supplied by the $\mathsf{PreSheaf}^{\uparrow}$ restriction surface. Then the indexed sheaf carrier of Definition 151.154, with classifier family $\sim_i$ and indexed covers as in Definition 151.155, supplies the carrier, classifier, locality, and gluing rows required by the root $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ ten-field template of Definition 151.190.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverLocalityGluing obligation surface`

Proof. Unfold the indexed section presheaf carrier. Its carrier row is the family $\mathsf{Sec}(i)$ over open indices $i : \mathsf{OpenIx}$, and its restriction row is the stable transport $\rho_{i,j}$ along displayed inclusions $j \leq_{\mathcal{T}} i$.

Unfold the indexed cover compatibility and locality surface. An indexed cover records member opens, cover inclusions, and finite-intersection overlap rows, so a compatible family is already expressed entirely in the $\mathsf{Topology}^{\uparrow}$ and $\mathsf{PreSheaf}^{\uparrow}$ ledgers.

The sheaf fields then provide exactly the two root rows needed by the certificate: locality detects equality of global sections from equality after restriction to every cover member, and gluing supplies a global section for every compatible local family. These are the carrier, classifier, locality, and gluing entries named in the root template row of Definition 151.190. □

Theorem 151.76 (Sheaf root restriction refinement obligation)**.** *For an indexed sheaf carrier over $\mathcal{T}$, every displayed refinement of indexed covers preserves compatible families and transports gluing rows through restriction. Hence the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root surface may replace a cover by any displayed refinement without changing the local-family compatibility ledger or the global gluing classifier row.*

Proof. Start with a displayed refinement of indexed covers. The refinement obligation of Definition 151.174 records the member map and the inclusion rows that route each refined open into the original cover member.

Apply Definition 151.175. A compatible family on the original indexed cover pulls back along the displayed refinement to a compatible family on the refined cover, because every overlap comparison is transported by the restriction composition and classifier-transport rows.

Apply Definition 151.176. If a global section glues the original compatible family, then the same global section glues the pulled-back family after the restriction transport supplied by the refinement. Thus the root certificate can consume either cover presentation with the same global classifier class. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRestrictionRefinement obligation`

Theorem 151.77 (Sheaf root common-refinement exactness obligation)**.** *Let two indexed cover presentations of the same open carry compatible local families. If the families agree after pullback to a displayed common refinement span, then their displayed gluings determine the same global section classifier class. This exactness uses only indexed cover data, displayed common refinement, and restriction transport; it does not quotient cover presentations.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCommonRefinement exactness obligation`
↪ variant `BEDC.Derived.SheafUp.SheafRootCommonRefinement obligation carrier exactness`

Proof. Unfold the displayed common-refinement span of Definition 151.186. The span consists of one indexed cover together with two displayed refinement projections into the two cover presentations being compared.

By Definition 151.187, the span yields the two refinement maps needed to pull both local families to the common cover. The hypothesis says that these two pulled-back families are classifier-equal at every member of that common cover.

Apply Definition 151.188. The two global sections, each viewed as a gluing after descent along its refinement projection, are equal in the classifier $\sim_i$ of the base open.

Finally apply Definition 151.189. The conclusion is an equality of global section classifier classes for the two cover presentations themselves, with no host open-cover equality and no quotient of cover presentations introduced into the root surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCommonRefinement route exactness`

Definition 151.78 (Sheaf root NameCert field inventory)**.** *The root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *field inventory is the following ten-field surface.*

1. *The traditional target is a sheaf of sections over indexed opens, read over accepted indexed covers rather than host open-cover equality.*
2. *The BEDC source is* $\mathsf{Topology}^{\uparrow}$ *together with the* $\mathsf{PreSheaf}^{\uparrow}$ *restriction surface.*
3. *The carrier row is the indexed section family* $\mathsf{Sec}(i)$ *of Definition 151.154.*
4. *The classifier row is the open-indexed section classifier family* $\sim_i$*.*

5. *The carrier-transport stability row keeps section carriers and classifiers aligned under the displayed indexed-open and* BHist *transport rows.*
6. *The restriction-stability row consists of restriction identity, restriction composition, and classifier preservation by restriction.*
7. *The locality row detects global classifier equality from memberwise classifier equality on an indexed cover.*
8. *The gluing row supplies a global section readback for every compatible local family.*
9. *The refinement-exactness row transports compatible families and gluing witnesses through displayed refinements and common refinements.*
10. *The ledger and presentation row consists of indexed covers, common-refinement spans, and cover-presentation invariance; it carries no standard bridge.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootNameCertFieldInventory`

Theorem 151.79 (Sheaf root NameCert carrier and classifier fields)**.** *Let $\mathcal{T}$ be an indexed-open carrier for* $\mathsf{Topology}^{\uparrow}$*, and let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$. Then the carrier, classifier, carrier-transport, and restriction-stability fields of Definition 151.279 are supplied by Definition 151.154, Definition 151.155, Definition 151.157, Definition 151.158, and Definition 151.164.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertCarrierClassifier fields`

Proof. Project the indexed section carrier from $\mathcal{S}$. By Definition 151.154, the visible carrier rows are the section families $\mathsf{Sec}(i)$, and the classifier rows are the relations $\sim_i$ with their equivalence fields.

Apply Definition 151.157. It exhausts the carrier support by indexed sections, section classifiers, restriction maps, restriction identity and composition rows, indexed covers, compatibility predicates, locality, and gluing. Thus the root inventory has no additional carrier primitive to construct.

Apply Definition 151.158 and Definition 151.164. These provide classifier transport along restrictions, identity restriction, composition of two displayed restriction routes, and stability on finite-intersection rows supplied by $\mathsf{Topology}^{\uparrow}$.

Finally read the cover-facing source through Definition 151.155. It contributes only indexed covers and compatible local-family predicates, so the projected carrier and classifier fields repack exactly as the carrier, classifier, carrier-transport, and restriction-stability fields of the root inventory. □

Theorem 151.80 (Sheaf root NameCert locality and gluing fields)**.** *For an indexed sheaf carrier over $\mathcal{T}$, the locality and gluing fields of Definition 151.279 are supplied by Definition 151.283, Definition 151.169, and Definition 151.170.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertLocalityGluing fields`

Proof. Begin with an indexed cover $\mathcal{U} = (A, \iota, h, \gamma)$ of an open index i and a compatible local family $s_a : \mathsf{Sec}(\iota(a))$. The cover, overlap, and compatibility rows are exactly the rows of Definition 151.155.

Apply Definition 151.283. It identifies locality and gluing as root $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ rows over the same indexed cover and the same classifier family $\sim_i$.

The uniqueness side is then the projection of Definition 151.169. Two global sections that display the same compatible local family are equal in the global classifier because locality detects equality from all cover members.

The readback side is supplied by Definition 151.170. Restricting a global section to the members of an indexed cover produces a compatible local family, so the gluing row and the locality row are closed under the named cover ledger. □

Theorem 151.81 (Sheaf root NameCert refinement exactness fields)**.** *For an indexed sheaf carrier over $\mathcal{T}$, the refinement, common-refinement, and cover-presentation exactness fields of Definition 151.279 are supplied by Definition 151.284, Definition 151.285, Definition 151.189, and Definition 151.293.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertRefinementExactness fields`

Proof. Start with a displayed refinement of indexed covers. Apply Definition 151.284; it transports compatible local families and gluing rows along the refinement map using only displayed inclusion routes and restriction stability.

For two cover presentations, pass to a displayed common-refinement span. Apply Definition 151.285; agreement after pullback to the common cover identifies the two global gluing classifier classes.

Apply Definition 151.189. This repacks the common-refinement comparison as invariance of the cover presentation itself, without adding host cover equality or a quotient of cover presentations.

Finally apply Definition 151.293. The route-exactness row records the same inclusion and restriction-route comparisons as NameCert-consumable ledger data, so the refinement and presentation fields close inside the root inventory of Definition 151.279. □

151.5 Root obligations for downstream certificates

Definition 151.82 (SheafUp root-unblock BEDC source)**.** *The root-unblock source for* $\mathsf{Sheaf}^{\uparrow}$ *is the ten-field certificate surface consumed by ringed-space, scheme, and restricted-open sheaf constructions.*

1. *The traditional target is sheaves of sections over indexed opens.*
2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* NameCert.
3. *The history ledger is the* BHist *cover-nerve ledger of Definition 151.160.*
4. *The carrier is the indexed section presheaf carrier of Definition 151.154, equipped with the locality and gluing fields of Definition 151.155.*
5. *The classifier family is the open-indexed relation* $\sim_i$ *on* $\mathsf{Sec}(i)$.
6. *The cover ledger records cover indices* A, *cover-member maps* $\iota : A \to \mathsf{OpenIx}$, *and pointwise cover rows over* BHist.
7. *The overlap ledger records finite intersections* $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(a')$ *and their projection rows.*
8. *The restriction ledger records routes from a target open to cover members and overlaps, with identity, composition, and classifier-stability rows.*
9. *Optional route histories are recorded by* Cont *rows, and history-cell membership is transported only by* hsame.

10. *The surface contains no quotient of cover presentations and no equality of host powersets of opens.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource member point germ`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource cover membership`

Theorem 151.83 (Sheaf root-unblock cover membership obligation)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an accepted cover row of an open index i over a* BHist *topology ledger. Then every displayed history membership in the covered open has a displayed cover-member witness:*

$$\forall b : \mathsf{BHist},\ \mathsf{OpenAt}(i, b) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), b).$$

All overlap information used downstream is recorded only through finite-intersection rows and hsame*-stable* BHist *membership, not through host powerset equality.*

Proof. Unfold the accepted cover row. Its pointwise cover component is exactly the displayed implication from $\mathsf{OpenAt}(i, b)$ to a cover index $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$.

For overlap rows, use the finite-intersection field of the indexed topology carrier as in Definition 151.161. It supplies the overlap index and the two projection rows back to the participating cover members.

History transport is then read from the BHist cover-nerve ledger of Definition 151.160. That ledger admits only hsame-stable membership transport, so the exported cover-membership row stays internal to indexed opens and history cells. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockCoverMembership obligation`

Theorem 151.84 (Sheaf root-unblock restriction stability obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Restriction identity, restriction composition, stable restriction rows, and* Cont *associativity for route histories preserve the target section classifier along one-step and two-step restriction routes. Concretely, for $j \leq_{\mathcal{T}} i$ and $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$, the rows*

$$\rho_{i,i}(s) \sim_i s, \qquad s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t), \qquad \rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

are the classifier-preserving route rows exposed to downstream certificates.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockRestrictionStability semantic name certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock restriction stability rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route history target classifier stability`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock restriction stability surface`

Proof. The identity and composition rows are fields of the indexed section presheaf carrier in Definition 151.154. The one-step classifier preservation row is the stable restriction row of Definition 151.156, also cited as Definition 151.172.

For a two-step route, first use restriction classifier transport along $j \leq_{\mathcal{T}} i$, then compose with the route from j to k. The displayed composition row identifies this two-step restriction with the direct restriction from i to k in the classifier $\sim_k$.

If the ledger also carries Cont histories for the same routes, their associativity only compares displayed route histories. It does not alter the open index k or the classifier $\sim_k$, so it preserves the same target section classifier consumed by the certificate. □

Theorem 151.85 (Sheaf root-unblock locality and gluing obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i. Compatible local families with displayed gluings have a* NameCert*-consumable exactness row: locality gives global classifier equality for any two global readbacks whose restrictions agree on the cover, and gluing supplies existence of a global readback without quotienting cover presentations.*

Proof. The existence half is the gluing field in Definition 151.155. Given a compatible local family, it supplies a section $g : \mathsf{Sec}(i)$ together with displayed restriction rows to each $\iota(a)$.

The uniqueness half is locality. If two global readbacks restrict to classifier-equal sections on every cover member, the locality field returns equality in the global classifier $\sim_i$; Definition 151.169 packages the same argument for two displayed gluings of one compatible family.

Refinement and presentation changes are handled by the existing refinement rows Definition 151.176, Definition 151.179, Definition 151.188, and Definition 151.189. Each row uses displayed cover maps, common refinements, restriction stability, Cont route histories when present, and hsame-stable membership; none introduces a quotient of cover presentations. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock locality gluing faces`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead locality gluing refinement inversion`

Definition 151.86 (Sheaf root cover-nerve export surface)**.** *The root cover-nerve export surface for* $\mathsf{Sheaf}^{\uparrow}$ *is the three-row* BHist*-scoped certificate surface consumed by downstream chapters.*

1. *The traditional target is sheaves over indexed opens, read through section carriers on a cover nerve rather than through host open covers.*
2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* NameCert.
3. *The carrier is the family of indexed sections over* BHist *opens, using* $\mathsf{Sec}(i)$ *from Definition 151.154 for each open index i.*
4. *The classifier family is the displayed section relation $\sim_i$ on* $\mathsf{Sec}(i)$.
5. *The stability rows are restriction identity, restriction composition, classifier transport, and optional* Cont *route-history transport.*
6. *The ledger rows are cover-member cells, pair-overlap cells, and route-history cells in the* BHist *cover nerve of Definition 151.160.*
7. *The exactness rows are cover membership, restriction route stability, and locality/gluing.*
8. *The cover-membership row sends every accepted* $\mathsf{OpenAt}(i, b)$ *cell to a displayed cover member and its pair-overlap ledger context.*
9. *The downstream export is exactly the rows listed here:* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers receive no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*
10. *There is no standard bridge in this surface.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootCoverNerveExportSurface`

Theorem 151.87 (Sheaf root cover-nerve membership exhaustion)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an accepted cover row of an indexed open i over the* BHist *topology ledger. Every displayed cell* $\mathsf{OpenAt}(i, b)$ *in this accepted cover has a cover-member witness and a pair-overlap row inside the* BHist *cover nerve:*

$$\forall b : \mathsf{BHist},\ \mathsf{OpenAt}(i, b) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), b)$$

and for every second member $a' : A$ the ledger also contains the finite-intersection row for $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(a')$ with its two projections to the participating members.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve membership exhaustion`

Proof. Apply the cover-membership obligation of Definition 151.299. It reads the accepted cover row as a BHist-indexed implication from an ambient displayed cell to a cover-member witness, so every $\mathsf{OpenAt}(i, b)$ cell is exhausted by a displayed member $\iota(a)$.

The pair-overlap row is then the overlap projection surface of Definition 151.161, unpacked inside the cover-nerve ledger of Definition 151.160. For each pair $a, a' : A$, the finite-intersection row supplies the overlap index and the two projections back to $\iota(a)$ and $\iota(a')$.

Because the ledger transports membership only by hsame, this exhaustion stays scoped to BHist cells and indexed opens. No host cover equality or quotient of cover presentations is introduced. □

Theorem 151.88 (Sheaf root cover-nerve restriction route stability)**.** *Let $\mathcal{S}$ be the indexed section carrier of Definition 151.154 over an indexed open topology carrier. One-step and two-step restrictions preserve section classifiers:*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t), \qquad \rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

for every displayed chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. Optional Cont *route histories compare route witnesses only and do not alter the target classifier $\sim_j$ or $\sim_k$.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger route hsame transport`

Proof. The first displayed row is the restriction classifier-transport field of Definition 151.154. It is also the one-step stability clause isolated by Definition 151.300.

For the two-step row, apply the composition field of the same carrier to the chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. The comparison lands in $\sim_k$, so the direct restriction and the composed restriction have the same target classifier.

If a Cont history is present, use the route-history part of Definition 151.300. Those histories record associativity of displayed routes; they do not change the open index of the restricted section, hence cannot change the classifier family consumed downstream. □

Theorem 151.89 (Sheaf root cover-nerve downstream coverage)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback constructions receive exactly the rows of Definition 151.302: cover-member cells, pair-overlap cells, one-step and two-step restriction stability rows, optional* Cont *route histories, and locality/gluing exactness rows. They receive no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Proof. The carrier part is fixed by Definition 151.154: downstream chapters can read only indexed section carriers, section classifiers, restrictions, and the identity, composition, and classifier-transport rows attached to them.

The cover part is fixed by Definition 151.160 and Definition 151.303. These provide cover-member cells and pair-overlap cells over BHist, with overlap projections supplied by Definition 151.161.

The exactness part is the union of the three root obligations. Cover membership comes from Definition 151.299; restriction route stability comes from Definition 151.300; locality and gluing come from Definition 151.301.

Those cited rows are precisely the rows listed in Definition 151.302. Since none of them introduces host cover equality, a cover quotient, a stalk quotient, or an external sheafification operation, no downstream consumer obtains such a row from this export surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve downstream coverage`

Theorem 151.90 (Sheaf root cover-nerve exact globalization package)**.** *The root cover-nerve export surface of Definition 151.302 forms an* ExactGlobalizeBase*-style package over the indexed-open* BHist *cover nerve. Its coverage face is Definition 151.303; its base soundness face is Definition 151.304; its base completeness and exactness face is the locality-gluing row of Definition 151.301. Hence* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$ *may consume one classifier-exact cover-nerve package, with no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve exact globalize package`

Proof. Unpack Definition 151.302. The carrier is the indexed family $\mathsf{Sec}(i)$ over BHist opens, the classifier is the displayed relation $\sim_i$, and the ledger is the cover nerve of Definition 151.160.

The coverage face is exactly Definition 151.303. It sends each displayed $\mathsf{OpenAt}(i, b)$ cell to a cover member and records the pair-overlap rows needed by downstream restriction routes.

The base soundness face is Definition 151.304. One-step restriction, two-step restriction, classifier transport, and optional Cont route histories preserve the section classifier on the target indexed open.

The base completeness and exactness face is Definition 151.301. Gluing constructs the global readback from compatible local rows, and locality identifies any two global readbacks whose restrictions agree on the accepted cover.

These are precisely the coverage, soundness, and completeness fields required by the exact-globalization constructor of Definition 9199.16, with the relation field constrained as in Definition 9199.11. Repacking the three displayed faces therefore gives the single classifier-exact cover-nerve package consumed by the downstream chapters, and Definition 151.305 fixes that no quotient or external sheafification row is exported. □

151.6 Identity-cover root package

Definition 151.91 (Sheaf identity-cover root package)**.** *For an indexed open i in the* $\mathsf{Sheaf}^{\uparrow}$ *root-obligation surface, the identity-cover root package is the accepted one-member cover of i with cover index type* Unit *and member map $\iota : \mathsf{Unit} \to \mathsf{OpenIx}$ constantly equal to i. Its membership row is the identity row on $\mathsf{OpenAt}(i, b)$ for each $b : \mathsf{BHist}$, its only overlap row is the finite-intersection cell $i \wedge_{\mathsf{Topology}^{\uparrow}} i$, and its exposed restriction route is the identity restriction $\rho_{i,i}$.*

The package ledger is restricted to BHist *membership cells,* hsame *transport of those cells, the self-overlap projections for $i \wedge_{\mathsf{Topology}^{\uparrow}} i$, and the presheaf identity row identifying $\rho_{i,i}(s)$ with s in the classifier $\sim_i$. It carries no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafIdentityCoverRootPackage`

Theorem 151.92 (Sheaf identity-cover membership exactness)**.** *Let i be an indexed open and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of Definition 151.227. For every $b : \mathsf{BHist}$, the displayed membership row is exact:*

$$\mathsf{OpenAt}(i, b) \iff \exists a : \mathsf{Unit},\ \mathsf{OpenAt}(\iota(a), b).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger identity open membership cont exactness`

Proof. For the forward direction, use the unique member of Unit. Since ι is constantly i, the required displayed cover-member cell is the original cell $\mathsf{OpenAt}(i, b)$ read through the identity membership row.

For the reverse direction, destruct the displayed witness $a : \mathsf{Unit}$. The member map again reads as i, so the cover-member cell is exactly a cell of $\mathsf{OpenAt}(i, b)$.

Both directions stay inside the BHist ledger and use only hsame transport when a history cell is reindexed. No equality of ambient host covers is used. □

Theorem 151.93 (Sheaf identity-cover restriction readback)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier, and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of an indexed open i. For every section $s : \mathsf{Sec}(i)$, the restriction route exposed by $\mathcal{U}_{\mathrm{id}}$ is classifier-equal to $\rho_{i,i}(s)$ and hence classifier-equal to s by the presheaf identity row:*

$$\rho^{\mathcal{U}_{\mathrm{id}}}(s) \sim_i \rho_{i,i}(s), \qquad \rho_{i,i}(s) \sim_i s.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIdentityCover restriction readback`

Proof. Unpack the identity-cover root package. Its only cover member is i, and the route from the ambient open to that member is the identity route, so the exposed restriction readback is the displayed route $\rho_{i,i}(s)$.

Apply the identity row of the indexed section presheaf carrier from Definition 151.154. That row identifies $\rho_{i,i}(s)$ with s in the classifier $\sim_i$.

The self-overlap cell $i \wedge_{\mathsf{Topology}^{\uparrow}} i$ supplies no additional restriction target; it only records the overlap ledger row already attached to the identity route. □

Theorem 151.94 (Sheaf identity-cover gluing collapse)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier, and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of an indexed open i. A compatible local family on $\mathcal{U}_{\mathrm{id}}$ is classifier-equivalent to exactly one global section over i: gluing supplies a global readback, and locality identifies any two global readbacks whose identity-cover restrictions agree.*

Proof. First apply the gluing part of Definition 151.301 to the compatible local family over $\mathcal{U}_{\mathrm{id}}$. This produces a global section $g : \mathsf{Sec}(i)$ whose restriction to the unique cover member agrees with the displayed local section.

The agreement row is read back through Definition 151.229. Because the only exposed route is $\rho_{i,i}$ and the presheaf identity row identifies $\rho_{i,i}(g)$ with g, the local family has no separate cover presentation beyond its single global readback.

For uniqueness, take two global readbacks whose restrictions agree on the identity cover. The membership exactness row of Definition 151.228 reduces coverwise agreement to agreement on the lone Unit member, and Definition 151.229 turns that agreement into agreement of the two global sections over i.

Apply the locality part of Definition 151.301. It returns classifier equality in $\sim_i$, so the compatible local family collapses to one global section up to the section classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIdentityCover gluing collapse`

Definition 151.95 (Sheaf downstream root source)**.** *The downstream root source for $\mathsf{Sheaf}^{\uparrow}$ is the displayed certificate surface obtained by taking the indexed-open carrier of $\mathsf{Topology}^{\uparrow}$, the restriction carrier of $\mathsf{PreSheaf}^{\uparrow}$, the locality and gluing surface of $\mathsf{Sheaf}^{\uparrow}$, the cover-nerve ledger of*

Definition 151.160, the point-germ ledger of Definition 151.231, and the refinement exactness rows of Definition 151.179 and Definition 151.189.

This source exposes only indexed opens, BHist *membership rows, restriction maps, section classifiers, compatible local-family predicates, point-germ comparisons, displayed refinements, and cover-presentation exactness. It contains no host powerset equality and no quotient of cover presentations.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDownstreamRootSource`

Theorem 151.96 (Sheaf RingedSpace local ring row)**.** *Let $\mathcal{S}$ be an indexed* $\mathsf{Sheaf}^{\uparrow}$ *carrier over an indexed-open* $\mathsf{Topology}^{\uparrow}$ *carrier $\mathcal{T}$. Suppose each section carrier* $\mathsf{Sec}(i)$ *carries the* $\mathsf{CommRing}^{\uparrow}$ *operation rows required for a local-ring row, and suppose every restriction map $\rho_{i,j}$ preserves addition, multiplication, zero, one, unit detection, maximal-ideal detection, and the section classifier. Then the source of Definition 151.223 exposes the structure-sheaf rows consumed by* $\mathsf{RingedSpace}^{\uparrow}$*: open-indexed commutative ring sections, classifier-stable restrictions, pointwise local-ring readbacks through the point-germ ledger, and local compatibility of the section classifier.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRingedSpaceLocalRing row`

Proof. Project the downstream source of Definition 151.223. Its carrier rows are the indexed sections, classifiers, restrictions, locality and gluing fields, cover ledger, point-germ ledger, and refinement exactness rows already supplied by $\mathsf{Sheaf}^{\uparrow}$.

Use Definition 151.300 for restriction stability. The assumed operation preservation rows ride on the same restriction routes, so the ring operations and the section classifier are transported together along every inclusion $j \leq_{\mathcal{T}} i$.

For local-ring readback, use the point-germ ledger of Definition 151.231. A row (i, o_i, s) records an indexed open containing a history cell and a section over that open; comparison is performed on a displayed common neighborhood by restriction and the section classifier. Thus unit and maximal-ideal rows are repacked as point-germ rows without forming a stalk quotient.

The resulting package has exactly the rows requested by the $\mathsf{RingedSpace}^{\uparrow}$ consumer: a structure sheaf indexed by opens, ring-preserving restrictions, classifier-stable pointwise readback, and local-ring data visible through the existing ledger rows. □

Theorem 151.97 (Sheaf Scheme gluing cover row)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be a displayed affine cover presentation of an indexed open i for an indexed* $\mathsf{Sheaf}^{\uparrow}$ *carrier $\mathcal{S}$. Suppose each member $\iota(a)$ carries a local ringed chart row, and suppose the chart rows are compatible on the finite-intersection overlap rows $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ after restriction of sections, local-ring operations, and section classifiers. Then the downstream root source exposes a global section classifier row consumed by* $\mathsf{Scheme}^{\uparrow}$*: displayed local chart sections glue to a global section over i, and any two displayed gluings determine the same global classifier class after common-refinement comparison.*

Proof. First read cover membership from Definition 151.299. Every displayed history cell of the ambient open has a cover member witness, and pairwise overlap rows are supplied by finite intersections in the $\mathsf{Topology}^{\uparrow}$ carrier.

The assumed overlap compatibility is exactly the compatible local-family predicate of Definition 151.155, with the local ringed chart rows transported by restriction. Applying Definition 151.301 gives a displayed global section and identifies any two global readbacks that agree on the cover.

Refinement descent then supplies invariance under a different displayed affine cover. Use Definition 151.176 to pass gluing along refinements, Definition 151.179 for the refined exactness row, and Definition 151.189 for common-refinement comparison.

Thus $\mathsf{Scheme}^{\uparrow}$ receives a global section classifier row assembled from cover membership, finite-intersection overlaps, locality, gluing, refinement descent, and cover-presentation exactness, with no quotient of cover presentations. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeGluingCoverRow chart trace cons readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace cons readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace result deterministic`

Theorem 151.98 (Sheaf topology pullback cover row)**.** *Let $f : Y \to X$ be a classifier-respecting* BHist *map, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover row for a* $\mathsf{Sheaf}^{\uparrow}$ *carrier over X. Pull the cover back through the* $\mathsf{Topology}^{\uparrow}$ *pullback-open rows of Definition 88.60. Then the pulled-back cover preserves cover membership, restriction stability, and compatible local-family predicates: each source history cell covered by the pulled-back ambient open has a pulled-back cover-member witness, restriction maps commute with classifier transport along the pulled-back inclusion rows, and compatible local sections remain compatible after pullback to finite-intersection overlap rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafTopologyPullbackCover membership restriction compatibility`

Proof. Start with the topology pullback-open rows. The map row for f transports source classifier witnesses to target classifier witnesses, while Definition 88.62 preserves finite intersections and Definition 88.64 preserves displayed cover unions.

Apply Definition 151.299 to the target cover row and then precompose the resulting membership witnesses with f. The pulled-back cover-member witness is the same index $a : A$, read through the pulled-back predicate of Definition 88.60.

For restrictions, use Definition 151.300. The source inclusion rows are obtained by pulling back the target inclusions, and the classifier-respecting row for f supplies the transport needed to compare the source-side section classifiers.

Finally, compatibility of local families is checked on pairwise finite-intersection overlap rows. Since finite meets commute with the displayed pullback row and restriction classifier transport is stable along the same routes, every target overlap equality pulls back to the corresponding source overlap equality. This is the compatible local-family predicate required by the downstream topology pullback consumer. □

Definition 151.99 (Sheaf root export BHist closure surface)**.** *The root export surface for* $\mathsf{Sheaf}^{\uparrow}$ *is the following ten-field* BHist*-closed package carried by* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*.*

1. *The traditional target is sheaves of sections over indexed opens.*
2. *The BEDC source is the joint* $\mathsf{Topology}^{\uparrow}$ *and* $\mathsf{PreSheaf}^{\uparrow}$ *surface over* BHist*, read through* $\mathsf{NameCert}$*.*
3. *The history ledger is the cover-nerve ledger of Definition 151.160, with membership transport only through* hsame*.*
4. *The carrier is the indexed section presheaf of Definition 151.154.*
5. *The classifier is the open-indexed section classifier family $\sim_i$.*
6. *The stability rows are identity, composition, restriction classifier transport, and route-history associativity when* Cont *rows are present.*

7. *The cover ledger consists of indexed cover members, finite-intersection overlap rows, displayed refinement maps, and common-refinement spans.*
8. *The exactness rows are locality, gluing, refinement pullback, refinement gluing descent, and common-refinement gluing invariance.*
9. *The downstream threshold exports only these indexed-open, section, restriction, locality, gluing, and refinement rows.*
10. *The standard bridge row is absent; no host powerset equality, cover quotient, stalk quotient, or external sheafification primitive is exported.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootExportSurface`
Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootExportBHistClosureSurface`

Theorem 151.100 (Sheaf root export carrier scope)**.** *Let $\mathcal{T}$ be the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier and let $\mathcal{S}$ be the* $\mathsf{PreSheaf}^{\uparrow}$ *indexed section carrier equipped with the sheaf locality and gluing rows. The root export surface of Definition 151.267 exposes exactly the following carrier data: open indices and inclusion rows from $\mathcal{T}$, indexed section carriers* $\mathsf{Sec}(i)$*, section classifiers $\sim_i$, restriction maps $\rho_{i,j}$,* hsame*-stable* BHist *membership, and the cover-nerve ledger of Definition 151.160. It exports no carrier whose elements are host opens, quotiented covers, or external stalk representatives.*

Proof. Project the topology part first. The indexed-open carrier supplies open indices, inclusion rows, finite intersections, and the OpenAt membership predicate; Definition 151.160 records those rows over BHist and allows membership transport only through hsame.

Project the presheaf part next. By Definition 151.154, the only section-level carrier rows are $\mathsf{Sec}(i)$, $\sim_i$, the restriction maps, and their identity, composition, equivalence, and classifier-transport fields.

Finally use Definition 151.157 and Definition 151.299. These identify the carrier support and cover membership obligations as indexed-open and BHist-ledger data, so no host open carrier, cover quotient, or stalk representative is part of the export. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport carrier scope`

Theorem 151.101 (Sheaf root export stability and exactness package)**.** *For every indexed sheaf carrier $\mathcal{S}$ over an indexed-open carrier $\mathcal{T}$, the root export surface of Definition 151.267 packages the complete stability and exactness rows needed by downstream certificates:*

1. *cover-member witnesses and overlap projections from the* BHist *cover ledger;*
2. *identity, composition, and restriction classifier-stability for section restrictions;*
3. *locality and gluing exactness over indexed covers;*
4. *refinement pullback and refined-cover gluing descent;*
5. *common-refinement presentation exactness, including the restricted-open common-refinement rows below a fixed open.*

Every row is expressed in indexed opens, restriction maps, section classifiers, displayed refinements, common-refinement spans, Cont *route histories when present, and* hsame*-stable history membership.*

Proof. The cover-member and overlap rows are those of Definition 151.299, together with the pair-overlap projections of Definition 151.161. They keep the cover ledger internal to indexed opens and BHist cells.

The restriction rows are exactly Definition 151.300. Its identity, composition, classifier-stability, and optional Cont route-history clauses are the stability rows exported by the root package.

The locality and gluing rows are supplied by Definition 151.301. Refinement contributes Definition 151.175, Definition 151.176, and Definition 151.179.

Common-refinement exactness is read from Definition 151.188 and Definition 151.189; below a fixed open it is read from Definition 151.195. These rows assemble the displayed package without adding any host-level cover equality or quotient comparison. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport stability exactness package`

Theorem 151.102 (Sheaf root export downstream threshold)**.** *The root export surface of Definition 151.267 is the carried* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *threshold available to* $\mathsf{RingedSpace}^\uparrow$, $\mathsf{Scheme}^\uparrow$, *and restricted-open consumers. Such consumers receive only the indexed-open carrier, the section classifier family, restriction identity and composition rows, restriction classifier-stability rows, locality and gluing rows, the refinement ledger, common-refinement exactness, and the absent-standard-bridge row. In particular, they do not receive a standard bridge, host powerset cover equality, cover quotient, stalk quotient, or external sheafification operation from* $\mathsf{Sheaf}^\uparrow$.

Proof. For the global sheaf surface, apply Definition 151.190, Definition 151.283, and Definition 151.284. These rows expose the carrier, classifier, restriction, locality, gluing, and refinement obligations already present in $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$.

For the local consumers, apply Definition 151.239 and Definition 151.195. They show that working below a fixed open reuses the same ambient section carriers, classifiers, restrictions, cover ledgers, and exactness rows.

The negative part is part of the same export boundary. The root-unblock source of Definition 151.298 and the global obligation surface both state that no standard bridge or host-level cover comparison is exported, so ringed-space, scheme, and restricted-open chapters must cite the indexed threshold rather than reconstructing a larger classical sheaf interface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport downstream threshold`

Definition 151.103 (Sheaf root threshold certificate source)**.** *The* $\mathsf{Sheaf}^\uparrow$ *root threshold certificate source is the* BHist*-indexed package consisting of the* $\mathsf{Topology}^\uparrow$ *topology carrier, the* $\mathsf{PreSheaf}^\uparrow$ *presheaf restriction carrier, the open-indexed section classifier family, the cover-nerve ledger, the point-germ ledger, the restricted-open ledger, the displayed base-change rows, and the refinement and common-refinement exactness rows. It is a source of threshold certificates only through indexed opens,* BHist *membership, section classifiers, restriction maps, displayed refinements, displayed base-change squares, restricted-open slices, and* hsame*-stable transport.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootThresholdCertificateSource`

Theorem 151.104 (Sheaf root threshold carrier and classifier obligation)**.** *The certificate source of Definition 151.294 supplies the carrier and classifier obligations of the* $\mathsf{Sheaf}^\uparrow$ *root solely through indexed opens,* BHist *membership, the section classifier family, restriction maps, and* hsame*-stable transport. In particular, the carrier side is exhausted by open indices, section carriers* $\mathsf{Sec}(i)$*, classifier rows* $\sim_i$*, restriction rows* $\rho_{i,j}$*, cover membership over* BHist*, and point-germ rows read on displayed neighborhoods.*

Proof. Read the carrier row from Definition 151.154. It supplies the open-indexed section carriers, the section classifiers, the restriction maps, and the identity, composition, equivalence, and classifier-transport rows attached to them.

Read the history side from Definition 151.160. Its cover-member rows are indexed by open carriers and BHist cells, and transport across history witnesses is only the displayed hsame transport already recorded in the ledger.

For pointwise readback, use Definition 151.231. A point-germ row chooses an indexed neighborhood containing the history cell and compares sections by restricting to displayed common neighborhoods, so it adds no host point, stalk quotient, or external carrier beyond the classifier and restriction rows already named. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold carrier classifier semantic certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold semantic name certificate`

Theorem 151.105 (Sheaf root threshold gluing and refinement obligation)**.** *The certificate source of Definition 151.294 assembles the exactness obligation of the* $\mathsf{Sheaf}^{\uparrow}$ *root from locality, gluing, refinement pullback, refinement gluing descent, restricted common-refinement exactness, and base-change gluing pullback. Each exactness row is expressed through indexed covers, compatible local families, displayed refinements, restricted-open slices, displayed base-change squares, section classifiers, and restriction transport.*

Proof. Begin with the root export exactness package of Definition 151.269. It already groups locality, gluing, refinement pullback, refinement gluing descent, and common-refinement presentation exactness as the stability and exactness rows exported by $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

The restricted-open part is read in the same package from the restricted common-refinement rows below a fixed indexed open. These rows keep the ambient section classifiers and restriction maps, and only narrow the cover ledger to the displayed slice.

For movement across a displayed source and target, apply Definition 151.208. Its cover-pullback, gluing-pullback, and common-refinement rows reuse the same exactness package after the displayed base-change square identifies the relevant source opens and pulled-back cover members. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold gluing refinement obligation`

Theorem 151.106 (Sheaf root threshold downstream coverage obligation)**.** *Every* $\mathsf{Sheaf}^{\uparrow}$ *row consumed by* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers is covered by the threshold source of Definition 151.294. Thus downstream chapters receive their sheaf-side data from the topology carrier, restriction carrier, section classifiers, cover-nerve ledger, point-germ ledger, restricted-open ledger, displayed base-change rows, and refinement or common-refinement exactness rows of that single source.*

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, apply Definition 151.197. Its sheaf-side requests are precisely the indexed section carriers, classifiers, restriction stability, cover-gluing exactness, restricted-open surface, and displayed base-change surface listed in the threshold source.

For $\mathsf{Scheme}^{\uparrow}$, apply Definition 151.198. Each affine or ringed-space chart first consumes the ringed-space sheaf boundary, and overlap compatibility is discharged by the cover-presentation and common-refinement exactness rows already included in the source.

For topology pullback consumers, apply Definition 151.226. The pulled-back cover rows are displayed base-change rows over the same indexed-open and BHist ledgers, so they are covered by the threshold source without adding a host powerset cover comparison or external sheaf model. □

Lean4 ✓ BEDC.Derived.SheafUp.SheafRootThreshold downstream coverage obligation

Definition 151.107 (Sheaf root consumer-threshold projection source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root consumer-threshold projection source is the* BHist*-indexed package obtained from Definition 151.294 by exposing three consumer faces: the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing face, and the topology pullback face. It is recorded by the following ten fields.*

1. *The traditional target is the sheaf-side data of a structure sheaf that can be read by ringed spaces, schemes, and pullback-open consumers.*
2. *The BEDC source is the single threshold source of Definition 151.294, not a separate host sheaf object.*
3. *The carrier row is the indexed-open section carrier* $\mathsf{Sec}(i)$*, with restricted-open carriers and displayed source carriers obtained only by slicing or pulling back indexed opens.*
4. *The classifier row is the section classifier family* $\sim_i$*, together with its restricted-open and displayed base-change readbacks.*
5. *The restriction row is restriction identity, restriction composition, and classifier transport for every displayed inclusion used by the three consumers.*
6. *The RingedSpaceUp projection row is the local-ring consumer surface: section carriers, section classifiers, ring-preserving restriction routes, point-germ local-ring readback, restricted-open rows, and base-change rows.*
7. *The SchemeUp projection row is the affine-chart gluing surface: chart-wise ringed-space projections, displayed affine cover membership, overlap compatibility, and common-refinement comparison.*
8. *The topology pullback projection row is the displayed base-change surface: cover pullback, gluing pullback, pulled-back common refinement, and classifier transport along the displayed square.*
9. *The ledger and exactness row is the cover-nerve ledger, point-germ ledger, restricted-open ledger, refinement ledger, cover-presentation exactness, and base-change exactness already present in the threshold source.*
10. *The standard-bridge field is absent: the projection source exports no host powerset cover equality, no cover quotient, no stalk quotient, no external sheafification operation, and no* $\mathsf{StandardBridge}$*.*

Thus the same BHist*-indexed source is projected separately to the three consumer families without duplicating the sheaf root obligations.*

Lean4 (definition) BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjectionSource
Lean4 ✓ BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjectionSource projection faces
Lean4 (definition) BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjection source

Theorem 151.108 (Sheaf root RingedSpace consumer projection)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring consumer receives exactly the indexed sections, section classifiers, restriction identity, restriction composition, restriction transport, point-germ local-ring readback, restricted-open rows, and base-change rows of Definition 151.256. No additional sheaf carrier, cover comparison, stalk quotient, or standard bridge is available through this projection.*

Lean4 ✓ BEDC.Derived.SheafUp.SheafRootConsumerRingedSpaceProjection semantic name certificate
Lean4 ✓ BEDC.Derived.SheafUp.SheafRootRingedSpaceConsumerProjection scope

Proof. Start from Definition 151.197. Its sheaf-side list asks for section carriers, classifiers, restriction stability, cover-gluing exactness, restricted-open rows, and base-change rows, together with non-sheaf commutative-ring data supplied outside $\mathsf{Sheaf}^{\uparrow}$.

The carrier and classifier entries are supplied by Definition 151.295. This gives the open-indexed section carrier, the classifier family, restriction identity and composition, classifier transport, BHist cover membership, and point-germ rows read on displayed neighborhoods.

The exactness and transport entries are supplied by Definition 151.296. Locality, gluing, refinement pullback, restricted-open exactness, and displayed base-change exactness are already fields of the root threshold source, so the ringed-space projection is precisely the listed face of Definition 151.256. □

Theorem 151.109 (Sheaf root Scheme consumer projection)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing consumer receives the same threshold source by chart-wise* $\mathsf{RingedSpace}^{\uparrow}$ *projection, followed by cover-presentation exactness and common-refinement exactness on chart overlaps. Thus affine-chart sections, overlap classifiers, glued section classes, and comparison across common refinements are all read from Definition 151.256.*

Proof. Apply Definition 151.198. Each affine or ringed-space chart first reads the sheaf boundary through the ringed-space consumer, so the chart-wise carrier, classifier, restriction, restricted-open, point-germ, and base-change rows are the rows identified in Definition 151.257.

The coverage claim is Definition 151.297: every sheaf row consumed by $\mathsf{Scheme}^{\uparrow}$ is already covered by the threshold source. This keeps the chart gluing surface inside the same BHist-indexed package.

For independence of the chosen affine cover presentation, use Definition 151.189. The displayed common refinement compares the pulled-back local families and identifies the resulting global classifier class, so no quotient of cover presentations or external sheaf model is introduced. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace unary result`

Theorem 151.110 (Sheaf root topology pullback consumer projection)**.** *Topology pullback consumers receive only the displayed base-change, cover-pullback, gluing-pullback, and common-refinement rows of Definition 151.256. These rows preserve pulled-back cover membership, compatible local-family predicates, glued section classifiers, and common-refinement comparison, without exporting the ringed-space local-ring face or the scheme affine-chart face.*

Proof. Begin with Definition 151.226. It identifies the consumer request as a displayed pullback of indexed cover rows: cover membership, restriction stability, and compatible local-family predicates are transported along the topology pullback-open rows.

The complete base-change surface is Definition 151.208. Its displayed square supplies cover pullback, gluing pullback, and common-refinement invariance using the same indexed-open carrier, classifier family, cover ledger, and refinement exactness fields recorded in Definition 151.256.

Since this consumer reads only displayed source and target rows, the projection discards the ringed-space local-ring field and the scheme affine-chart field. What remains is exactly the base-change and common-refinement face of the root threshold source, with no host powerset cover comparison or standard bridge. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootConsumerPullbackProjection base change face`

Definition 151.111 (Sheaf root face exactness source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root face exactness source is the four-face package obtained from the* BHist *root-unblock source, the cover-nerve export surface,*

and the consumer-threshold projection source. It is read over BHist *histories,* hsame *transport, optional* Cont *route histories, the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier, the* $\mathsf{PreSheaf}^{\uparrow}$ *restriction carrier, and the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation rows.*

1. *The cover-membership face consists of accepted cover rows, member witnesses* $\mathsf{OpenAt}(\iota(a), b)$*, finite-intersection overlap rows, and* hsame*-stable history transport from Definition 151.160.*
2. *The restriction-route face consists of the section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, restrictions* $\rho_{i,j}$*, identity rows, composition rows, classifier transport, and optional* Cont *route-history associativity rows.*
3. *The locality, gluing, and refinement exactness face consists of compatible local-family predicates, gluing witnesses, locality comparison, displayed cover refinement, refinement pullback, refinement gluing descent, displayed common-refinement comparison, and cover-presentation exactness.*
4. *The downstream projection face consists only of the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring projection, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing projection, and the topology pullback projection named in Definition 151.256.*

The package contains no host powerset equality of open covers, no cover quotient, no stalk quotient, no external sheafification operation, and no StandardBridge *field.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootFaceExactnessSource`

Theorem 151.112 (Sheaf root face classifier coverage)**.** *Every row of the root-unblock source of Definition 151.298 and every row of the cover-nerve export surface of Definition 151.302 lands in exactly one of the first three faces of Definition 151.271. The downstream projection face receives only projections of those faces and adds no root carrier, root classifier, or root exactness row.*

Proof. For the cover rows, read the cover ledger in Definition 151.160. The accepted cover, cover-member witness, finite-intersection overlap, pair-overlap projection, and hsame membership transport rows are precisely the cover-membership face. The exhaustion and projection theorems Definition 151.303 and Definition 151.161 show that no additional cover row is required.

For the restriction rows, use Definition 151.300 and Definition 151.304. Their identity, composition, classifier-preservation, two-step route, and optional Cont history clauses are exactly the restriction-route face.

For the exactness rows, use Definition 151.301, Definition 151.175, Definition 151.176, Definition 151.179, and Definition 151.189. These rows cover locality, gluing, displayed refinement, common-refinement comparison, and cover-presentation exactness, so they land in the locality, gluing, and refinement exactness face.

Finally compare with the consumer-threshold source of Definition 151.256. Its ringed-space, scheme, and topology pullback rows cite the same carrier, classifier, cover, restriction, and exactness rows through projection, so they occupy the downstream projection face rather than adding root data. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead coverage`

Theorem 151.113 (Sheaf root face gluing exactness)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over a* BHist*-scoped indexed open topology carrier* $\mathcal{T}$*, and let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an accepted indexed cover of* $i : \mathsf{OpenIx}$*. For every compatible local family* $s_a : \mathsf{Sec}(\iota(a))$*, locality plus gluing plus refinement exactness gives a* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*-consumable exactness row:*

1. *a global section* $g : \mathsf{Sec}(i)$ *restricts to the local family;*
2. *any two global readbacks whose cover restrictions agree are classifier-equal in* $\sim_i$*;*
3. *after any displayed refinement or displayed common refinement, the pulled-back local families determine the same global classifier class.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted global soundness`

Proof. Begin with the compatible local family over $\mathcal{U}$. The gluing field in Definition 151.155 supplies a global section $g : \mathsf{Sec}(i)$ and the displayed member equalities $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$.

Use locality from the same definition for uniqueness. If two global readbacks agree on every member row, locality returns classifier equality in $\sim_i$; the same argument is packaged by Definition 151.169.

Now pass to a displayed refinement. The compatibility row is transported by Definition 151.175, and the gluing row descends by Definition 151.176. The combined refined-cover statement is Definition 151.179.

For comparison of two cover presentations, use the displayed common-refinement surface of Definition 151.186. The invariance theorem Definition 151.188, together with Definition 151.189, identifies the two resulting global classifier classes.

All cited steps use indexed covers, BHist membership, hsame transport, section classifiers, restriction composition, and optional Cont route histories. Therefore the exactness row is consumable by $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ without adding a host cover comparison or quotient row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restricted global soundness`

Theorem 151.114 (Sheaf root face downstream separation)**.** *The* $\mathsf{RingedSpace}^\uparrow$*,* $\mathsf{Scheme}^\uparrow$*, and topology pullback consumers receive only projections of the four faces of Definition 151.271. Consumer-specific rows such as local-ring structure, affine-chart spectra data, and displayed pullback-open choices do not feed back into the root* $\mathsf{Sheaf}^\uparrow$ *carrier, root classifier, cover ledger, restriction-route face, or locality and gluing exactness face.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead downstream separation`

Proof. For $\mathsf{RingedSpace}^\uparrow$, apply Definition 151.257. Its sheaf-side input is the indexed section carrier, section classifier, restriction stability, point-germ readback, restricted-open rows, and base-change rows projected from the root source. The commutative-ring and local-ring rows are supplied outside the sheaf root.

For $\mathsf{Scheme}^\uparrow$, apply Definition 151.258. Each chart first reads the ringed-space projection, while affine-chart and spectra data remain chart-side data. The sheaf contribution is only cover-presentation exactness and common-refinement comparison already present in the root exactness face.

For topology pullback consumers, apply Definition 151.259 and Definition 151.226. The pullback row transports cover membership, compatible families, gluing, and common refinements through the displayed base-change surface, but it does not introduce a ringed-space local-ring row or a scheme affine-chart row.

The downstream consumption boundary of Definition 151.196 and the exhaustion theorem Definition 151.199 close the separation. They state that consumers can only read the listed sheaf-side projections, so consumer-specific structure cannot be returned as a new root $\mathsf{Sheaf}^\uparrow$ obligation. □

Lean4 ✓ BEDC.Derived.SheafUp.SheafRootFaceRead downstream projection separation

Definition 151.115 (SheafUp root consumer projection seal)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root consumer projection seal is the three-consumer package assembled from the consumer-threshold projection source of Definition 151.256, the root face exactness source of Definition 151.271, and the downstream consumption boundary of Definition 151.196. Its three public projections are the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring projection, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart projection, and the topology pullback projection. Each projection is a read-only face of the same* BHist*-indexed sheaf root package, and none of the projections exports host powerset equality, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Lean4 (definition) BEDC.Derived.SheafUp.SheafRootConsumerProjectionSeal

Theorem 151.116 (SheafUp RingedSpace local-ring projection seal)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face of Definition 151.252 may read only the* $\mathsf{Sheaf}^{\uparrow}$ *section carriers, section classifiers, restriction stability rows, cover-gluing exactness rows, restricted-open rows, and displayed base-change rows. The commutative-ring and local-ring data used by the consumer are supplied from* $\mathsf{CommRing}^{\uparrow}$ *outside* $\mathsf{Sheaf}^{\uparrow}$*. Through this sealed projection, the consumer cannot read host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Proof. The consumer-threshold source of Definition 151.256 names the ringed-space projection row as a face of the root threshold package. Its existing projection theorem Definition 151.257 identifies exactly the section carrier, classifier, restriction, point-germ readback, restricted-open, and base-change rows available to $\mathsf{RingedSpace}^{\uparrow}$.

The root face coverage and exactness results Definition 151.272, Definition 151.273, and Definition 151.274 show that these rows are projections of the root cover-membership, restriction-route, and locality-gluing-refinement faces. They add no root carrier and no consumer-specific exactness row.

Finally, Definition 151.199 exhausts the downstream sheaf-side reads. The local-ring and commutative-ring structure therefore enters only from $\mathsf{CommRing}^{\uparrow}$, while host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure remain outside the sealed projection. □

Lean4 ✓ BEDC.Derived.SheafUp.SheafRootRingedSpaceLocalRingProjection seal

Theorem 151.117 (SheafUp Scheme affine-chart projection seal)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face of Definition 151.252 may read affine-chart gluing only through cover-presentation rows, displayed common-refinement rows, and the* $\mathsf{RingedSpace}^{\uparrow}$ *projection rows sealed in Definition 151.253. Spectra data and chart-ring data are supplied outside* $\mathsf{Sheaf}^{\uparrow}$*. Through this sealed projection, the consumer cannot read host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Lean4 ✓ BEDC.Derived.SheafUp.SheafRootSchemeAffineChartProjection seal

Proof. The consumer-threshold source of Definition 151.256 names the scheme projection row as chart-wise access through ringed-space projections, cover-presentation exactness, and common-refinement comparison. The existing projection theorem Definition 151.258 supplies this chart-wise reading of the same threshold source.

The root face exactness package then separates the sheaf rows from chart data. By Definition 151.272 and Definition 151.273, cover-presentation comparison and common-refinement invariance are already part of the locality, gluing, and refinement exactness face; by Definition 151.274, chart-local spectra and ring rows do not feed back into the root sheaf package.

Apply Definition 151.199 to the scheme consumption boundary. Every sheaf row consumed by $\mathsf{Scheme}^{\uparrow}$ is already listed there, so spectra data, chart-ring data, host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure are not supplied by $\mathsf{Sheaf}^{\uparrow}$. □

Theorem 151.118 (SheafUp topology pullback projection seal)**.** *The topology pullback face of Definition 151.252 may read only pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and common-refinement transport along the displayed base-change surface. It does not read the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face or the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and it exports no host powerset equality, cover quotient, stalk quotient, external sheafification, or standard bridge closure.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootTopologyPullbackProjection seal`

Proof. The consumer-threshold source of Definition 151.256 names the topology pullback projection as the displayed base-change face. The existing projection theorem Definition 151.259 identifies the available rows as cover pullback, gluing pullback, pulled-back common refinement, and classifier transport along the displayed square.

The root face coverage and exactness rows control those reads. Use Definition 151.272 for cover membership and restriction-route stability, and use Definition 151.273 for compatible-family transport, gluing pullback, and common-refinement comparison.

The separation theorem Definition 151.274, together with Definition 151.199, removes the other two consumer faces from the topology pullback projection. Thus the pullback consumer receives only the displayed base-change rows and no host powerset equality, cover quotient, stalk quotient, external sheafification, or standard bridge closure. □

Definition 151.119 (Sheaf consumer access trace source)**.** *A finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access trace is the freely generated finite list syntax whose constructors are the following read events:*

1. *carrier and classifier reads of the indexed section carriers* $\mathsf{Sec}(i)$ *and classifiers* $\sim_i$*;*
2. *restriction-route reads of identity, composition, classifier transport, and optional* Cont *route-history rows;*
3. *cover-membership reads of accepted covers, member witnesses, finite-intersection overlaps, and* hsame *membership transport;*
4. *locality and gluing reads of compatible-family predicates, local agreement, global witnesses, and uniqueness rows;*
5. *refinement and common-refinement reads of displayed refinements, refinement pullbacks, gluing descent, and common-refinement comparison rows;*
6. *point-germ reads of named pointwise readback rows without forming stalk quotients;*
7. *base-change reads of displayed base-change squares, pulled-back cover membership, pulled-back compatible families, and gluing transport;*
8. *the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring consumer projection;*
9. *the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart consumer projection;*
10. *the topology pullback consumer projection.*

Every constructor is formed over BHist *histories,* hsame *transport, optional* Cont *route histories, the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier, the* $\mathsf{PreSheaf}^{\uparrow}$ *section carrier, and the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *rows. The trace source has no constructor for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerAccessTraceSource`

Theorem 151.120 (Sheaf consumer access trace face coverage)**.** *Every constructor of Definition 151.244 lands in exactly one face: either one of the root faces of Definition 151.271 or one of the three consumer projections sealed in Definition 151.252.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead restriction route readback`

Proof. Proceed by cases on the freely generated trace constructor.

The carrier, classifier, restriction-route, cover-membership, locality, gluing, refinement, common-refinement, point-germ, and base-change cases are root-facing reads. The carrier and classifier rows land in the restriction-route face, the accepted-cover and overlap rows land in the cover-membership face, and the compatibility, locality, gluing, refinement, common-refinement, point-germ, and base-change rows land in the locality, gluing, and refinement exactness face. This placement is the coverage statement of Definition 151.272, with exactness supplied by Definition 151.273.

The remaining cases are the three downstream consumer constructors. The $\mathsf{RingedSpace}^{\uparrow}$ constructor lands in Definition 151.253, the $\mathsf{Scheme}^{\uparrow}$ constructor lands in Definition 151.254, and the topology pullback constructor lands in Definition 151.255.

These targets are disjoint by construction of Definition 151.271: the first three faces contain root sheaf rows, while the downstream face contains only projections. Thus each constructor has exactly one landing face. □

Theorem 151.121 (Sheaf consumer access trace no-feedback)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback constructors of Definition 151.244 do not create further* $\mathsf{Sheaf}^{\uparrow}$ *carrier rows, classifier rows, exactness rows, or bridge rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace no feedback`

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, the local-ring constructor reads the sheaf-side carrier, classifier, restriction, point-germ, restricted-open, and base-change rows only through the sealed projection. By Definition 151.274, the commutative-ring and local-ring data are outside the sheaf root and cannot return as root carrier, classifier, or exactness rows.

For $\mathsf{Scheme}^{\uparrow}$, the affine-chart constructor first passes through the ringed-space projection and then reads cover-presentation and common-refinement rows. The same separation theorem keeps spectra data and chart-ring data outside the sheaf root, so the chart constructor contributes no root row.

For topology pullback, the constructor reads displayed base-change transport, cover pullback, compatible-family transport, gluing pullback, and common-refinement transport. The pullback-open choices are consumer-side data by Definition 151.274, not root sheaf obligations.

Finally apply Definition 151.199. The downstream boundary exhausts all sheaf-side reads and excludes host powerset equality, cover quotients, external sheaf models, and bridge closure, so no consumer constructor can manufacture a further $\mathsf{Sheaf}^{\uparrow}$ root row. □

Theorem 151.122 (Sheaf consumer access trace exhaustion)**.** *Every allowed downstream* $\mathsf{Sheaf}^{\uparrow}$ *access by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors through a finite access trace of Definition 151.244.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append exhaustion`

Proof. Inspect the downstream row lists in Definition 151.196. Carrier and classifier access is represented by the carrier-classifier constructor; restriction stability is represented by the restriction-route constructor; cover ledgers are represented by the cover-membership constructor; locality, gluing, refinement, common-refinement, restricted-open, point-germ, and base-change access are represented by their corresponding trace constructors.

Now inspect the consumer projections in Definition 151.252. The $\mathsf{RingedSpace}^{\uparrow}$ local-ring projection is represented by the ringed-space consumer constructor, the $\mathsf{Scheme}^{\uparrow}$ affine-chart projection by the scheme consumer constructor, and the displayed pullback projection by the topology pullback constructor.

By Definition 151.245, each selected constructor lands in the correct root face or sealed consumer projection. By Definition 151.246, selecting a consumer constructor does not add any further sheaf row that would require another constructor outside the trace grammar.

The relevant downstream proof uses only finitely many rows from the displayed boundary and projection lists. Listing those rows in their order of use gives the required finite trace, and every allowed access is therefore factored through Definition 151.244. □

Definition 151.123 (Sheaf root access normal form)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root access normal form is the finite classification of downstream-visible root reads generated by Definition 151.244. Its classes are:*

1. *carrier, classifier, and restriction-route rows for the indexed section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, restrictions* $\rho_{i,j}$*, identity rows, composition rows, classifier transport, and optional* Cont *route histories;*
2. *cover-member and overlap rows for accepted covers, member witnesses, finite-intersection overlaps, pair-overlap projections, and* hsame *membership transport;*
3. *locality, gluing, refinement, common-refinement, and base-change rows for compatible-family predicates, global witnesses, uniqueness rows, displayed refinements, refinement pullbacks, gluing descent, cover-presentation exactness, displayed common refinements, displayed base-change squares, cover pullback, compatible-family transport, and gluing pullback;*
4. *point-germ comparison rows that expose named pointwise readbacks without forming stalk quotients;*
5. *the three downstream projection faces: the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring projection, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart projection, and the topology pullback projection.*

These classes are read-only faces of the same BHist*-indexed sheaf root package. They contain no class for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, standard bridges, or consumer-private algebraic, chart, or pullback data.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootAccessNormalFormSourceCase`

Theorem 151.124 (Sheaf root access normal-form coverage)**.** *Every admitted* $\mathsf{Sheaf}^{\uparrow}$ *root access trace of Definition 151.244 lands in one class of Definition 151.240.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead locality gluing readback`

Proof. Proceed by cases on the trace constructor of Definition 151.244.

Carrier, classifier, and restriction-route reads land in the first normal-form class. The root face source of Definition 151.271 places section carriers, section classifiers, restrictions, identity rows,

composition rows, classifier transport, and optional route histories in the restriction-route face, and Definition 151.272 gives the corresponding coverage.

Cover-membership and overlap reads land in the second class. The accepted-cover row, member witness, finite-intersection overlap, pair-overlap projection, and hsame transport are exactly the cover-membership rows isolated by Definition 151.245.

Locality, gluing, refinement, common-refinement, and base-change reads land in the third class. Their exactness rows are the locality, gluing, and refinement face of Definition 151.271, with gluing exactness supplied by Definition 151.273; the downstream boundary of Definition 151.196 records the same restricted-open, base-change, refinement, and exactness rows.

Point-germ reads land in the fourth class because Definition 151.244 admits named pointwise readbacks only as point-germ comparison rows. The same definition excludes stalk quotient formation, so the point-germ case does not branch into an additional quotient class.

The remaining constructors are the three downstream consumer projections. They land in the fifth class by the projection seal of Definition 151.252, and the face coverage theorem Definition 151.245 identifies no further trace constructor. Thus every admitted access has a normal-form landing class. □

Theorem 151.125 (Sheaf root access normal-form consumer factorization)**.** *Every downstream* $\mathsf{Sheaf}^{\uparrow}$ *access used by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors first through Definition 151.240 and then through the existing projection seals.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace consumer access trace`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootAccessNormalForm consumer factorization`

Proof. Begin with an allowed downstream access. By Definition 151.247, it is represented by a finite trace of Definition 151.244. Apply Definition 151.241 to send each trace constructor to its normal-form class.

For $\mathsf{RingedSpace}^{\uparrow}$, the relevant classes are carrier, classifier, restriction, cover-gluing, restricted-open, base-change, and point-germ comparison rows. The local-ring projection seal Definition 151.253 reads exactly those sheaf-side classes and supplies no commutative-ring or local-ring row from the sheaf root.

For $\mathsf{Scheme}^{\uparrow}$, first pass through the ringed-space projection and then use the cover-presentation and displayed common-refinement classes. The affine-chart projection seal Definition 151.254 identifies spectra and chart-ring rows as consumer-side data, while Definition 151.276 lists the remaining sheaf rows visible to the joint face.

For topology pullback, use the base-change class together with cover-membership, restriction-route, compatible-family, gluing, and common-refinement rows. The pullback projection seal Definition 151.255 is exactly this factor, and Definition 151.277 prevents the other two consumer faces from entering it.

The factorization therefore has two stages: access traces land in the finite normal form, and the three downstream consumers read their respective normal-form classes only through the sealed projections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace root access factorization`

Theorem 151.126 (Sheaf root access normal form exports no extra rows)**.** *The normal form of Definition 151.240 exports no host powerset equality, no cover quotient, no stalk quotient, no external sheafification row, no standard bridge row, and no consumer-private algebraic, chart, or pullback data.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootAccessNormalForm no extra rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead normal form readback`

Proof. For host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridges, inspect the source grammar. The trace source of Definition 151.244 has no constructor for those rows, and the root face exactness source of Definition 151.271 explicitly keeps them outside the four root faces.

For consumer-private algebraic rows, apply Definition 151.253. It says the commutative-ring and local-ring data used by $\mathsf{RingedSpace}^{\uparrow}$ are supplied outside $\mathsf{Sheaf}^{\uparrow}$, so the normal form cannot export them as sheaf root rows.

For affine-chart and spectra rows, apply Definition 151.254. The scheme face reads sheaf rows through ringed-space projections, cover-presentation exactness, and common-refinement comparison, while spectra data and chart-ring data remain outside the sheaf root.

For pullback-private choices, apply Definition 151.255. The topology pullback face reads displayed base-change transport, pulled-back cover membership, compatible-family transport, gluing pullback, and common-refinement transport; it does not export consumer-specific pullback-open choices as root data.

Finally combine the joint face and downstream boundary. The joint consumer face noninterference theorem Definition 151.277 prevents private consumer data from feeding back into the root, and Definition 151.199 exhausts the sheaf-side rows consumed downstream. Thus the normal form exports only the listed finite classes and no extra row. □

Definition 151.127 (Sheaf consumer trace composition source)**.** *Let T_1 and T_2 be finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces of Definition 151.244. Their consumer trace composition $T_1 \star T_2$ is the finite trace obtained by listing every constructor of T_1 in its given order and then listing every constructor of T_2 in its given order. The empty trace is a two-sided unit for this operation.*

The source of this operation is restricted to the same objects as the access trace grammar: BHist *histories,* hsame *transport, optional* Cont *route histories,* $\mathsf{Topology}^{\uparrow}$ *indexed opens,* $\mathsf{PreSheaf}^{\uparrow}$ *section carriers, and* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *rows. No constructor of $T_1 \star T_2$ may mention host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows except through the sealed consumer projections already present in Definition 151.244.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerAccessTraceCompositionSource`
Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerTraceCompositionSource`

Theorem 151.128 (Sheaf consumer trace concatenation coverage)**.** *For any finite traces T_1 and T_2 of Definition 151.244, every constructor in the composed trace $T_1 \star T_2$ of Definition 151.215 lands in the same root face or sealed consumer projection that it occupied before composition.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append membership coverage`

Proof. Proceed by the ordered list presentation of $T_1 \star T_2$.

For a constructor appearing in the first segment, apply Definition 151.245 to its occurrence in T_1. Its landing face is one of the root faces of Definition 151.271 or one of the sealed consumer projections of Definition 151.252; the concatenation operation only preserves the occurrence and its order inside the first segment.

For a constructor appearing in the second segment, apply the same coverage theorem to its occurrence in T_2. The first segment supplies no wrapper and no coercion around the second segment, so the second occurrence keeps the landing face it had before composition.

Thus every constructor in the concatenated trace has exactly the face assigned to it by the original access trace coverage theorem. □

Theorem 151.129 (Sheaf consumer trace composition no-feedback)**.** *Composing finite* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback consumer traces by Definition 151.215 creates no additional* $\mathsf{Sheaf}^{\uparrow}$ *carrier row, classifier row, exactness row, or bridge row.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append no zero extension`

Proof. First apply Definition 151.246 to the consumer constructors in T_1. Each $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, and topology pullback event reads through the sealed projection and contributes no root carrier, classifier, exactness, or bridge row.

Apply the same theorem to the consumer constructors in T_2. The composition source merely places the second trace after the first, so no event in the second segment obtains a new sheaf row from the preceding segment.

It remains to rule out feedback across the boundary between the two segments. By Definition 151.274, consumer-specific algebraic, chart, and pullback data are outside the root sheaf faces. By Definition 151.199, all allowed downstream sheaf reads have already been exhausted by the listed root rows and sealed projections.

Therefore the concatenation boundary carries only the finite order of reads. It supplies no constructor capable of manufacturing a further $\mathsf{Sheaf}^{\uparrow}$ carrier, classifier, exactness, or bridge row. □

Theorem 151.130 (Sheaf consumer trace factorization composes)**.** *Suppose two allowed downstream* $\mathsf{Sheaf}^{\uparrow}$ *accesses by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factor through finite traces* T_1 *and* T_2 *of Definition 151.244. Their sequential use factors through the composed trace* $T_1 \star T_2$ *of Definition 151.215.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger trace factorization composes`

Proof. Choose the trace $T_1 \star T_2$ by listing the constructors witnessing the first downstream access and then listing the constructors witnessing the second downstream access. This is a finite trace because both inputs are finite and the composition source is ordinary finite concatenation.

The first access factors through the first segment by the assumed factorization of T_1. The second access factors through the second segment by the assumed factorization of T_2, and the preceding segment changes only the position of the second segment in the list.

By Definition 151.216, every constructor in both segments still lands in its original root face or sealed projection. By Definition 151.217, the boundary between the two segments creates no additional sheaf row that would require another access constructor.

The sequential downstream use is therefore represented by first reading along T_1 and then reading along T_2, which is exactly the composed finite trace. □

Definition 151.131 (Sheaf consumer access trace composition source)**.** *Let* P *be the fixed* BHist*-indexed* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root package used by Definition 151.244. If* T_1 *and* T_2 *are finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces over* P*, their composite* $T_1 \mathbin{++} T_2$ *is the finite list concatenation obtained by reading all constructors of* T_1 *followed by all constructors of* T_2*. The source constructors of* $T_1 \mathbin{++} T_2$ *are still exactly the constructors of Definition 151.244: carrier and classifier reads, restriction-route reads, cover-membership reads, locality and gluing reads, refinement and common-refinement reads, point-germ reads, base-change reads, and the three sealed consumer projection reads for* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback.*

The composite carries no additional constructor for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows. Its only extra operation is finite list concatenation inside the same BHist*-scoped root package P.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTraceCompositionSource membership split`

Theorem 151.132 (Sheaf consumer access trace concatenation closure)**.** *Accepted finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces over one* BHist*-indexed* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root package are closed under the composition operation of Definition 151.248. In particular, if T_1 and T_2 are generated by Definition 151.244, then $T_1 \mathbin{++} T_2$ is generated by the same grammar and contains no constructor for host powerset equality, cover quotients, stalk quotients, external sheafification, or standard bridge rows.*

Proof. Induct on the second trace T_2 as a finite list of constructors. In the empty case, $T_1 \mathbin{++} T_2$ is just T_1, so acceptance is the given acceptance of the first trace.

In the cons case, write T_2 as a shorter trace followed by one final constructor c. By the induction hypothesis, concatenating T_1 with the shorter trace remains an accepted trace over the same root package.

It remains to append c. The constructor cases are exactly the cases listed in Definition 151.244: carrier and classifier, restriction route, cover membership, locality and gluing, refinement and common refinement, point germ, base change, and the three downstream consumer projections. Each case appends one already admitted constructor, so the resulting list is still accepted by the same grammar.

The excluded host-level operations are not constructor cases. Since finite concatenation only appends constructors already present in the grammar, it cannot create a host powerset equality row, a cover quotient, a stalk quotient, an external sheafification step, or a standard bridge row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append closed`

Theorem 151.133 (Sheaf consumer access trace face-map stability)**.** *For finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces T_1 and T_2 over the same* BHist*-indexed root package, the landing-face assignment of Definition 151.245 sends $T_1 \mathbin{++} T_2$ to the finite concatenation of the landing-face reads of T_1 and the landing-face reads of T_2. The same assignment preserves the no-feedback separation of Definition 151.246 across the composite trace.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace face map stability`

Proof. Proceed by constructor cases on the appended segment T_2. The empty appended segment contributes no landing-face read, so the landing-face list of the composite is the landing-face list of T_1.

For a root-facing constructor, Definition 151.245 gives its unique root face. Appending the constructor appends exactly that face read after the face reads already assigned to the previous part of the composite.

For a downstream consumer constructor, Definition 151.245 sends the constructor to its sealed consumer projection. By Definition 151.246, that projection does not return a new $\mathsf{Sheaf}^{\uparrow}$ carrier row, classifier row, exactness row, or bridge row.

Thus the landing-face assignment commutes with finite list concatenation, and the downstream no-feedback separation remains valid after the two traces are read sequentially. □

Theorem 151.134 (Sheaf composite consumer access exhaustion)**.** *Every sequential downstream* $\mathsf{Sheaf}^{\uparrow}$ *access by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors through one finite* BHist*-scoped trace obtained by concatenating the finite traces for the individual accesses.*

Proof. Apply Definition 151.247 to the first downstream access. This gives a finite trace over the displayed BHist-indexed $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ root package whose constructors are those of Definition 151.244.

Apply Definition 151.247 again to the next downstream access, or to each member of the finite sequential access list. Each application gives another finite trace over the same root package, because the downstream consumers read the sealed $\mathsf{Sheaf}^{\uparrow}$ root package rather than creating a replacement root.

Concatenate the resulting finite traces in their order of downstream use. By Definition 151.249, the concatenation is still an accepted finite trace in the same grammar.

Finally use Definition 151.250. The composite trace preserves the landing-face assignment and the no-feedback separation, so the sequential access never leaves the finite BHist-scoped trace surface and never imports host-level sheaf machinery. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace composite exhaustion`

Theorem 151.135 (Sheaf root downstream consumer carrier scope)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback receive their* $\mathsf{Sheaf}^{\uparrow}$ *carrier rows only from the indexed section carrier over* BHist *opens in Definition 151.154, together with the cover-nerve ledger of Definition 151.160. Their sheaf-side carrier scope is exactly the indexed open carrier, the section carriers* $\mathsf{Sec}(i)$*, the section classifiers* $\sim_i$*, the restriction maps* $\rho_{i,j}$*, cover-member cells, pair-overlap cells, and* hsame*-stable ledger transport. No host powerset equality, cover quotient, stalk quotient, or external sheafification row is exported to these consumers.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer carrier scope`

Proof. Read the carrier source from Definition 151.298. Its carrier clause points to Definition 151.154, so every section-level carrier read by a downstream consumer is one of the open-indexed section carriers, classifiers, restrictions, and identity or composition rows already listed there.

Read the history side from Definition 151.160 and the cover-nerve export surface of Definition 151.302. The only additional cells are cover-member cells, finite-intersection pair-overlap cells, route-history cells when present, and membership transport through hsame.

Finally apply the downstream coverage theorem Definition 151.305 and the projection seal Definition 151.252. These rows are projected read-only to $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, and topology pullback, so none of the three consumers obtains host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row from the root package. □

Theorem 151.136 (Sheaf root downstream consumer classifier stability)**.** *Every restriction route exposed from the* $\mathsf{Sheaf}^{\uparrow}$ *root to* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback preserves the relevant section classifier. One-step and two-step routes preserve classifiers by Definition 151.304; membership reindexing is transported only through* hsame*; optional* Cont *route histories compare displayed route witnesses without changing the target open or the target classifier. Hence consumer restriction routes do not add any host powerset equality, cover quotient, stalk quotient, or external sheafification row.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer classifier stability`

Proof. For section restrictions, apply Definition 151.304. It states that the one-step restriction of classifier-equal sections lands in the target classifier and that the composed two-step route agrees with the direct route in the classifier of the final open.

For membership movement, use the cover-nerve ledger of Definition 151.160. Its transport row is hsame-stable membership transport over BHist cells, so route changes do not replace the indexed open carrier by a host open or a quotient carrier.

If optional Cont histories are present, use the route-history clause cited in Definition 151.300. Those histories compare the witnesses for displayed routes; they do not alter the open index on which $\sim_j$ or $\sim_k$ is read.

The three projection seals Definition 151.253, Definition 151.254, and Definition 151.255 then pass the same classifier-stable routes to the downstream consumers without exporting host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row. □

Theorem 151.137 (Sheaf root downstream consumer exactness coverage)**.** *The* Sheaf$^{\uparrow}$ *exactness surface consumed by* RingedSpace$^{\uparrow}$*,* Scheme$^{\uparrow}$*, and topology pullback is exhausted by cover membership, locality and gluing, refinement descent, common-refinement exactness, and the downstream projection seals. Concretely, cover membership is supplied by Definition 151.299 and Definition 151.303; locality and gluing are supplied by Definition 151.301; refinement descent and refined exactness are supplied by Definition 151.176 and Definition 151.179; common-refinement exactness is supplied by Definition 151.188 and Definition 151.189; and consumer access is sealed by the three projection theorems. No host powerset equality, cover quotient, stalk quotient, or external sheafification row is exported.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer exactness coverage`

Proof. Start with cover membership. The accepted-cover cell is unpacked by Definition 151.299, and Definition 151.303 records the corresponding cover-member and pair-overlap cells inside the BHist cover nerve.

For local exactness, use Definition 151.301. It gives existence of a global readback from a compatible local family and classifier uniqueness for global readbacks whose restrictions agree on the cover.

For refinement, apply Definition 151.176 and the package theorem Definition 151.179. These rows keep the same global classifier class after passing to displayed refinements. For comparison of cover presentations, use Definition 151.188 and Definition 151.189.

Finally pass to consumers through Definition 151.253, Definition 151.254, and Definition 151.255. Each consumer receives a projection of the listed cover, restriction, locality, gluing, refinement, and common-refinement rows; none receives host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row. □

Definition 151.138 (Sheaf root joint consumer face)**.** *The* Sheaf$^{\uparrow}$ *root joint consumer face is the shared* BHist*-indexed projection package assembled from the projection seal of Definition 151.252, the consumer-threshold projection source of Definition 151.256, the root face exactness source of Definition 151.271, and the downstream consumption boundary of Definition 151.196. It has one root package and three read-only consumer faces: the* RingedSpace$^{\uparrow}$ *local-ring face, the* Scheme$^{\uparrow}$ *affine-chart face, and the topology pullback face. Each face reads the same* BHist*-scoped sheaf root rows for section carriers, section classifiers, restriction transport, cover-gluing exactness, restricted opens, displayed base change, cover presentations, and displayed common refinements.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace chart trace e0 endpoint absurd`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace normal form boundary`

Theorem 151.139 (Sheaf root joint consumer face exhaustion)**.** *Every sheaf-side row visible through the joint consumer face of Definition 151.275 to* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *or topology pullback consumers is one of the following rows: indexed section carrier, section classifier, restriction identity, restriction composition, restriction classifier transport, cover-locality and cover-gluing exactness, restricted-open carrier and inherited sheaf rows, displayed base-change transport, cover-presentation exactness, or displayed common-refinement comparison. No other sheaf-side row is exported by the joint face.*

Proof. Split over the three projections named in Definition 151.252.

For the $\mathsf{RingedSpace}^{\uparrow}$ projection, apply Definition 151.253. Its sheaf-side reads are the section carrier, classifier, restriction-stability, cover-gluing, restricted-open, and base-change rows. The root face coverage theorem Definition 151.272 places the carrier, classifier, and restriction rows inside the first three faces of the root exactness source.

For the $\mathsf{Scheme}^{\uparrow}$ projection, apply Definition 151.254. Chart-wise reads factor through the ringed-space projection, and the only additional sheaf-side comparisons are cover-presentation exactness and displayed common-refinement comparison. These are exactly the locality, gluing, and refinement rows supplied by Definition 151.273.

For the topology pullback projection, apply Definition 151.255. The available rows are pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and displayed common-refinement transport along the base-change surface.

Finally use Definition 151.199. It exhausts downstream sheaf reads by the carrier, classifier, restriction, cover-gluing, restricted-open, base-change, refinement, and exactness rows already listed in the statement, so the joint consumer face exports no further sheaf-side row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace exhaustion`

Theorem 151.140 (Sheaf root joint consumer face noninterference)**.** *None of the three consumer projections of Definition 151.275 exports another consumer's private data back into the* $\mathsf{Sheaf}^{\uparrow}$ *root face. The* $\mathsf{RingedSpace}^{\uparrow}$ *projection does not return private algebraic or local-ring rows to the root face; the* $\mathsf{Scheme}^{\uparrow}$ *projection does not return private affine-chart, spectra, or chart-ring rows; and the topology pullback projection does not return private pullback-open choices or consumer-specific pullback witnesses to the root face.*

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, the projection seal Definition 151.253 says that commutative-ring and local-ring data are supplied outside $\mathsf{Sheaf}^{\uparrow}$. Thus those algebraic rows are read by the consumer only after the sheaf-side projection has been fixed.

For $\mathsf{Scheme}^{\uparrow}$, the projection seal Definition 151.254 keeps spectra data and chart-ring data outside $\mathsf{Sheaf}^{\uparrow}$. The scheme face reads sheaf rows through chart-wise ringed-space projections and common-refinement comparisons, but it does not add a chart carrier, chart classifier, or spectra row to the root package.

For topology pullback, the projection seal Definition 151.255 restricts the face to displayed base-change, cover pullback, gluing pullback, and common-refinement transport. It explicitly does not read the ringed-space local-ring face or the scheme affine-chart face.

The separation theorem Definition 151.274 identifies all three consumers as projections of the same four root faces. Together with Definition 151.199, this prevents consumer-specific algebraic, chart, or pullback data from re-entering the $\mathsf{Sheaf}^{\uparrow}$ carrier, classifier, cover ledger, restriction-route face, or locality and gluing exactness face. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace noninterference`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace no feedback unary boundary`

Theorem 151.141 (Sheaf root joint consumer face NameCert boundary)**.** *The joint consumer face of Definition 151.275 exposes the following ten-field* $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ *boundary.*

1. *The traditional target is the sheaf-side consumer projection package read by ringed spaces, schemes, and topology pullback consumers.*
2. *The BEDC sources are* $\mathsf{Topology}^\uparrow$, $\mathsf{PreSheaf}^\uparrow$, *and* $\mathsf{NameCert}$.
3. *The carrier field is the indexed section presheaf carrier* $\mathsf{Sec}(i)$ *and its restricted-open or displayed base-change readbacks.*
4. *The classifier field is the section classifier relation* $\sim_i$ *and its restricted-open or displayed base-change transports.*
5. *The stability field consists of restriction identity, restriction composition, classifier transport, locality, gluing, refinement transport, and base-change transport.*
6. *The ledger field consists of the* BHist *cover nerve, cover-member rows, overlap rows,* hsame *transport, and optional route histories.*
7. *The exactness field consists of the joint exhaustion row of Definition 151.276 and the joint noninterference row of Definition 151.277.*
8. *The downstream-use field consists exactly of the* $\mathsf{RingedSpace}^\uparrow$ *local-ring face, the* $\mathsf{Scheme}^\uparrow$ *affine-chart face, and the topology pullback face.*
9. *The boundary exports no host powerset equality, cover quotient, stalk quotient, external sheafification operation, or consumer-private root data.*
10. *No standard bridge is attached to this boundary.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace semantic name certificate`

Proof. Begin with the root consumer-threshold projection source of Definition 151.256. It already names the traditional consumer target, the single threshold source, the carrier and classifier rows, the restriction row, the three consumer projection rows, the ledger and exactness row, and the absent standard-bridge field.

The root face exactness source of Definition 151.271 refines these fields into cover-membership, restriction-route, locality-gluing-refinement, and downstream projection faces. Use Definition 151.272 for carrier, classifier, cover ledger, and restriction-route coverage, and use Definition 151.273 for locality, gluing, refinement, cover-presentation, and base-change exactness.

The projection seals identify the downstream-use field. Apply Definition 151.253, Definition 151.254, and Definition 151.255 to split the boundary into the three consumer faces.

It remains to justify exactness and exclusion. The joint exhaustion theorem Definition 151.276 supplies the listed public sheaf rows, while the joint noninterference theorem Definition 151.277 and the downstream separation theorem Definition 151.274 remove consumer-private algebraic, chart, and pullback rows from the root face. The downstream consumption exhaustion theorem Definition 151.199 then leaves no standard bridge, host powerset equality, cover quotient, stalk quotient, or external sheafification operation in the boundary. □

Definition 151.142 (Sheaf root route exactness packet)**.** *The* $\mathsf{Sheaf}^\uparrow$ *root route exactness packet is the following ten-field* BHist*-scoped surface.*

1. *The traditional target is the sheaf route from an accepted indexed cover cell to the section row consumed by downstream certificates.*

2. *The BEDC source is the joint* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* $\mathsf{NameCert}$ *surface, read over* BHist *histories and optional* Cont *route histories.*
3. *The carrier is the indexed-open carrier of* $\mathsf{Topology}^{\uparrow}$ *together with the section carrier* $\mathsf{Sec}(i)$ *of Definition 151.154.*
4. *The classifier is the open-indexed section relation* $\sim_i$ *on* $\mathsf{Sec}(i)$*, transported only along displayed restriction routes.*
5. *The stability rows are restriction identity, restriction composition, one-step classifier transport, two-step classifier transport, and route-history associativity when* Cont *rows are present.*
6. *The ledger rows are cover-member cells, pair-overlap cells, route witnesses, and* hsame *membership transport in the* BHist *cover nerve.*
7. *The exactness rows are cover-cell membership exhaustion, restriction-route classifier transport, locality and gluing, displayed refinement descent, and common-refinement comparison.*
8. *The downstream consumers are exactly the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and topology pullback constructions.*
9. *The packet contains no host powerset equality of open covers, no quotient of cover presentations, no stalk quotient, and no external sheafification operation.*
10. *The status is a root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *route-exactness surface: it records the rows available for downstream use and does not assert standard bridge closure.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootRouteExactnessPacket`

Theorem 151.143 (Sheaf route exactness membership transport)**.** *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an accepted indexed cover of* i *over the* BHist *topology ledger. For every displayed cell* $\mathsf{OpenAt}(i, b)$ *and every displayed restriction route from* i *to a cover member or pair-overlap row, the packet of Definition 151.290 transports the cover-member witness through the route and preserves the target section classifier on the reached open.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRouteExactness membership transport`

Proof. First build the cover witness. Apply Definition 151.303 to the accepted cover row. It sends the displayed cell $\mathsf{OpenAt}(i, b)$ to a member $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$ and supplies the finite-intersection row needed for comparison with any second member.

Next transport along the restriction route. Apply Definition 151.304. Its one-step and two-step clauses keep the section comparison inside the classifier of the reached member or overlap open.

The transported member witness and the transported classifier row use the same indexed open route. Since both cited rows are recorded over BHist and use hsame for membership transport, the result stays inside the cover nerve and introduces no host cover equality or cover quotient. □

Theorem 151.144 (Sheaf route exactness Cont composition)**.** *When optional* Cont *histories are present in the* $\mathsf{Sheaf}^{\uparrow}$ *route ledger, their composition rows compose displayed route witnesses only. They preserve the target open index and therefore preserve the target section classifier* $\sim_j$ *or* $\sim_k$ *already transported by restriction stability.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route history stability`

Proof. Start with the one-step route. The restriction stability obligation of Definition 151.300 gives classifier transport from $\sim_i$ to $\sim_j$ along $j \leq_{\mathcal{T}} i$.

For a composite route $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$, use the composition clause of Definition 151.300. The direct restriction from i to k and the route through j are compared in the same target classifier $\sim_k$.

Now read the optional Cont row. By Definition 151.304, such a history compares route witnesses and does not change the reached open. Hence route-history composition can only rebracket the displayed path; the classifier already attached to the reached open is unchanged. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route cont composition`

Theorem 151.145 (Sheaf route exactness NameCert consumption)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers receive exactly the route-exactness packet of Definition 151.290: cover-member cells, restriction classifier transport, optional* Cont *route-history composition, and the downstream projection rows sealed for those consumers. No consumer receives a larger sheaf interface from this packet.*

Proof. First identify the common downstream surface. Apply Definition 151.305. It lists the cover-member cells, pair-overlap cells, one-step and two-step restriction stability rows, optional Cont histories, and locality and gluing exactness rows available to downstream consumers.

For the ringed-space consumer, apply Definition 151.253. The local-ring face may read the sheaf section carrier, classifier, restriction stability, cover-gluing exactness, restricted-open rows, and displayed base-change rows, while local-ring structure itself is supplied outside $\mathsf{Sheaf}^{\uparrow}$.

For the scheme consumer, apply Definition 151.254. Its affine-chart read is routed through cover-presentation rows, displayed common-refinement rows, and the sealed ringed-space projection, so it receives the same route-exactness packet rather than a separate sheaf surface.

For topology pullback consumers, apply Definition 151.255. The pullback face reads pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and common-refinement transport along displayed base change.

The three projections exhaust the consumers named in Definition 151.290. Since each cited seal excludes host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure, downstream NameCert use is exactly the route-exactness packet and nothing larger. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRouteExactness namecert consumption`

Definition 151.146 (Sheaf root cover-descent source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root cover-descent source is the following* BHist*-scoped source tuple. It is read over a* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier with point carrier* BHist*, membership row* OpenAt*, inclusion relation* $\leq_{\mathcal{T}}$*, and finite-intersection rows; an indexed* $\mathsf{Sheaf}^{\uparrow}$ *carrier with section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, and restriction maps* $\rho_{i,j}$*; an indexed cover* $\mathcal{U} = (A, \iota, h, \gamma)$ *of an ambient open* i*; member inclusions* $h_a : \iota(a) \leq_{\mathcal{T}} i$*; displayed restriction routes to members and finite-intersection overlaps; a compatible local family* $s_a : \mathsf{Sec}(\iota(a))$*; and the section classifier rows used to compare restrictions on members, overlaps, and glued readbacks.*

The source admits only these displayed data: BHist *histories, indexed open membership, cover-member witnesses, member and overlap inclusions, restriction-route witnesses, compatible-family overlap equalities, locality, gluing, and section classifiers. It excludes stalks, quotient carriers, host powerset equality of covers, and external sheafification.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootCoverDescentSource`

Theorem 151.147 (Sheaf root cover-descent carrier exactness)**.** *The source of Definition 151.260 exposes exactly* BHist, OpenAt, *cover membership, restriction maps, finite-intersection overlap rows, and section classifiers. In particular, every carrier or classifier row visible to cover descent is one of the indexed-open carrier rows of* $\mathsf{Topology}^{\uparrow}$*, the indexed section rows of* $\mathsf{Sheaf}^{\uparrow}$*, or the compatible-family and locality rows of the sheaf cover surface.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent carrier exactness`

Proof. Unfold Definition 151.260. The topology component contributes only BHist, indexed opens, OpenAt, inclusion witnesses, and finite-intersection rows. These are exactly the displayed carrier and membership rows of Definition 88.1.

Unfold the indexed sheaf component. By Definition 151.154, the section-level rows are the carriers $\mathsf{Sec}(i)$, classifiers $\sim_i$, restriction maps $\rho_{i,j}$, and restriction stability fields attached to displayed inclusion routes.

Finally unfold the cover and local-family component through Definition 151.155. It adds cover membership, member inclusions, finite-intersection overlap comparisons, locality, and gluing. None of the three unfolded sources contains a stalk carrier, a quotient carrier, host powerset equality, or external sheafification, so the displayed list is exact. □

Theorem 151.148 (Sheaf root cover-descent gluing exhaustion)**.** *Every root cover-descent comparison route for the source of Definition 151.260 factors through a cover member or a displayed common refinement, then through restriction-route exactness, and finally through the locality or gluing classifier row. Thus the cover-descent route surface is exhausted by cover membership, finite-intersection overlap rows, restriction transport, point-germ readback, and gluing uniqueness.*

↪variant `BEDC.Derived.SheafUp.SheafBHistPointGermLedger cover descent exhaustion`

Proof. First apply the cover law γ in the indexed cover $\mathcal{U}$. Each history cell $b : \mathsf{BHist}$ lying in the ambient open is sent to a member $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$, and the finite-intersection rows of Definition 88.1 supply the displayed overlaps used for pairwise comparison.

Next route the comparison through the sheaf restriction surface. Apply Definition 151.291 to transport the member witness through the displayed route, and apply Definition 151.292 when the comparison is represented by a composed route history. Both steps keep the target section classifier attached to the reached open.

It remains to read the local family through gluing. Apply Definition 151.234 for the memberwise readback of a glued section, and apply Definition 151.169 to identify any two global readbacks that agree on all displayed members. The route therefore ends at the existing locality or gluing classifier row and introduces no further carrier or classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent common refinement germ exactness`

Theorem 151.149 (Sheaf root cover-descent downstream interface)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers may consume only the cover-descent source of Definition 151.260, the carrier exactness row of Definition 151.261, the gluing exhaustion row of Definition 151.262, and the downstream exactness coverage row of Definition 151.266. They receive no additional sheaf carrier and no additional sheaf classifier.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent downstream interface`

Proof. For the ringed-space consumer, apply Definition 151.224. Its sheaf-side data are section carriers, classifiers, restriction stability, point-germ readback, and local compatibility rows, all already present in the cover-descent source and its carrier exactness row.

For the scheme consumer, apply Definition 151.225. The chart gluing request is routed through cover membership, finite-intersection overlaps, compatible local families, gluing, and common-refinement comparison, which are precisely the rows exhausted by Definition 151.262.

For topology pullback, apply Definition 151.226. Pullback cover membership and compatible-family transport are displayed over the same indexed-open and restriction-route rows, so they add no carrier beyond Definition 151.260.

Finally apply Definition 151.266. It seals the three consumer projections to cover membership, locality and gluing, refinement descent, common-refinement exactness, and projection rows. Hence downstream access is exactly the cover-descent interface named in the statement. □

151.7 Downstream consumption boundary

Definition 151.150 (Sheaf downstream consumption boundary)**.** *The downstream consumption boundary exported by* $\mathsf{Sheaf}^{\uparrow}$ *to* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$ *is the following ten-field boundary.*

1. *The traditional target is an open-indexed sheaf of sections over an indexed open topology carrier.*
2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* $\mathsf{NameCert}$.
3. *The carrier row is the indexed section presheaf carrier of Definition 151.154.*
4. *The classifier row is the section classifier family* $\sim_i$ *on* $\mathsf{Sec}(i)$ *from the same carrier.*
5. *The locality and gluing rows are the indexed-cover compatibility, locality, and gluing fields of Definition 151.155.*
6. *The cover ledger is the indexed cover row: cover indices, cover-member maps, inclusion witnesses, pointwise cover membership, and finite-intersection overlap rows.*
7. *The refinement ledger is the displayed refinement, refinement-tower, and common-refinement surface used by Definition 151.189.*
8. *The restricted-open ledger is the slice carrier and its inherited restriction, locality, and gluing rows from Definition 151.239.*
9. *The base-change ledger is the displayed base-change square and its cover-pullback, gluing-pullback, and common-refinement rows from Definition 151.208.*
10. *The exactness row is cover presentation exactness together with restricted common-refinement invariance, and no standard bridge is attached to this boundary.*

This boundary is the only sheaf-side interface available to downstream chapters: it names indexed sections, section classifiers, displayed cover rows, displayed refinements, restricted opens, and displayed base change, but it does not import a host-space model of sheaves.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDownstreamConsumptionBoundary`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafUp StdBridge`

Theorem 151.151 (Ringed-space consumption obligation)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *certificate consumes exactly the* $\mathsf{Sheaf}^{\uparrow}$ *carrier, section classifier, restriction stability, cover-gluing exactness, restricted-open surface, and base-change surface listed in Definition 151.196, together with the*

$\mathsf{CommRing}^{\uparrow}$ *rows asserting that the section carriers and stalk rows carry commutative-ring structure. On the sheaf side, every row required by* $\mathsf{RingedSpace}^{\uparrow}$ *is one of:*

1. *the indexed section carriers* $\mathsf{Sec}(i)$ *and classifiers* $\sim_i$*;*
2. *restriction identity, restriction composition, and restriction classifier transport;*
3. *locality, gluing, and cover-presentation exactness for indexed covers;*
4. *the restricted-open surface below a named open;*
5. *the displayed base-change surface for inverse-image and cover-pullback rows.*

No further sheaf row is needed to state the paper-side ringed-space certificate boundary.

Proof. The carrier and classifier rows are the first projections of the $\mathsf{Sheaf}^{\uparrow}$ boundary. They are the section carriers and section classifiers of Definition 151.154, while restriction identity, restriction composition, and classifier transport are the stability rows already exported in Definition 151.168.

For local ringed-space data, restrict the sheaf to each displayed open. The required open-local carrier, classifier, restriction, locality, gluing, and no-bridge rows are exactly the restricted-open surface of Definition 151.239.

For inverse-image or change-of-base comparisons, use the displayed base-change surface of Definition 151.208. The remaining rows mentioned in the statement are the commutative-ring and stalk rows supplied on the $\mathsf{CommRing}^{\uparrow}$ side; they do not ask $\mathsf{Sheaf}^{\uparrow}$ for any host powerset equality, cover quotient, external sheaf model, or standard bridge. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRingedSpaceConsumption obligation`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer chart endpoint classifier`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer RingedSpace boundary rows`

Theorem 151.152 (Scheme consumption obligation)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *certificate consumes the same* $\mathsf{Sheaf}^{\uparrow}$ *downstream boundary only through a cover by affine or ringed-space charts and the* $\mathsf{CommRing}^{\uparrow}$ *spectra rows attached to those charts. Concretely, each chart reads the sheaf rows through Definition 151.197; compatibility across chart overlaps uses the cover-presentation exactness and common-refinement gluing invariance rows of* $\mathsf{Sheaf}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeConsumption obligation`

Proof. On each affine or ringed-space chart, apply Definition 151.197. This identifies the sheaf-side data available to the chart as the carrier, classifier, restriction stability, cover-gluing exactness, restricted-open surface, and base-change surface in Definition 151.196.

On overlaps between charts, compare the two displayed cover presentations through a displayed common refinement. The equality of glued section classes is supplied by Definition 151.189, and the comparison of two gluings after passing to a common refinement is supplied by Definition 151.188.

The affine and spectra content is therefore external to the sheaf boundary: it comes from the ringed-space chart and $\mathsf{CommRing}^{\uparrow}$ spectra rows. The sheaf chapter contributes only the displayed indexed-cover, restricted-open, and base-change rows already enumerated in the boundary. □

Theorem 151.153 (Sheaf downstream consumption exhaustion)**.** *Every* $\mathsf{Sheaf}^{\uparrow}$ *row used by* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$ *in the two downstream consumption obligations is one of the rows in Definition 151.196. Consequently, the downstream chapters import no host powerset equality of opens, no quotient of cover presentations, no external sheaf model, and no bridge closure from* $\mathsf{Sheaf}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumption joint exhaustion`

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, inspect Definition 151.197. Its sheaf-side rows are precisely the carrier, classifier, restriction-stability, cover-gluing, restricted-open, and base-change entries of Definition 151.196. The commutative-ring and stalk rows named there are not sheaf rows.

For $\mathsf{Scheme}^{\uparrow}$, inspect Definition 151.198. Each chart first passes through the ringed-space consumption obligation, and every overlap comparison is discharged by cover-presentation exactness or common-refinement gluing invariance, both already included in the boundary's refinement and exactness rows.

Thus the union of sheaf rows consumed by the two downstream chapters is exhausted by the ten-field boundary. Since the boundary itself excludes host powerset equality, cover quotients, external sheaf models, and standard bridges, none of those structures is imported downstream through $\mathsf{Sheaf}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumption boundary joint exhaustion`

Closure status for $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

Constructive story: A sheaf row starts with a $\mathsf{Topology}^{\uparrow}$ indexed-open carrier and a $\mathsf{PreSheaf}^{\uparrow}$ restriction surface, then attaches section carriers over each open index, section classifiers, restriction maps, indexed cover rows, overlap intersections, and the locality and gluing fields. The carrier admits exactly those indexed presheaf packets whose cover data is displayed by the topology ledger and whose local families satisfy the overlap compatibility rows; a cover presentation with missing inclusions, missing overlap comparisons, or no gluing/locality witness is outside the sheaf surface. Two sheaf presentations are classified together when the section classifiers identify the relevant global or restricted sections after transport through restrictions, refinements, common refinements, restricted opens, and base-change squares, not when host open covers or stalk quotients are identified. The source specification is the topology-plus-presheaf cover surface, the pattern specification records restriction identity and composition, restriction classifier stability, locality, gluing, refinement invariance, common-refinement exactness, point-germ rows, and downstream access traces, and the ledger keeps cover indices, member maps, inclusion proofs, overlap restrictions, base-change routes, and consumer projections visible. The five name-certificate obligations are supplied by the indexed section carrier and its classifier family: an admitted section surface inhabits the carrier, each local classifier is reflexive, symmetric, and transitive, and restriction/refinement transport keeps classified representatives inside the same displayed cover-gluing interface. A sheaf packet h lies in the signature gap of a $\mathsf{Sheaf}^{\uparrow}$ token p when the source-domain accepts its indexed cover and section data, the signature relation pairs it with an answer sheaf packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, the compatible local family, its gluing, and all refinement or restricted-open rows must be the ones encoded by p. The checked bridge here reads the same indexed section, restriction, locality, and gluing rows as the standard sheaf interface for downstream ringed-space and scheme consumers, while still refusing host powerset equality, cover quotients, stalk quotients, and external sheafification.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper-side package is the indexed sheaf downstream boundary of section 151.10, bound by Definition 151.247, Definition 151.251, Definition 151.276, and Definition 151.263.

151.8 Carrier definition

151.9 The certificate

Definition 151.154 (Indexed section presheaf carrier)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *in the sense of Definition 88.1. Write*

$$j \leq_{\mathcal{T}} i :\Longleftrightarrow \forall x : X,\ \mathsf{OpenAt}(j, x) \Longrightarrow \mathsf{OpenAt}(i, x)$$

for inclusion of indexed opens. An indexed section presheaf carrier for $\mathsf{PreSheaf}^{\uparrow}$ *over* $\mathcal{T}$ *is a tuple*

$$\mathcal{P} = (\mathsf{Sec}, \sim, \rho, \mathsf{Eqv}, \mathsf{Id}, \mathsf{Comp}, \mathsf{Res})$$

with the following data. For every open index $i : \mathsf{OpenIx}$ *there is a section carrier* $\mathsf{Sec}(i)$ *and a classifier* $\sim_i$ *on* $\mathsf{Sec}(i)$*; the field* Eqv *says that each* $\sim_i$ *is reflexive, symmetric, and transitive. For every inclusion* $j \leq_{\mathcal{T}} i$ *there is a restriction map*

$$\rho_{i,j} : \mathsf{Sec}(i) \to \mathsf{Sec}(j).$$

The identity field says $\rho_{i,i}(s) \sim_i s$ *for every* $s : \mathsf{Sec}(i)$*, and the composition field says that whenever* $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$*,*

$$\rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

for every $s : \mathsf{Sec}(i)$*. The restriction classifier-stability field says that, for every inclusion* $j \leq_{\mathcal{T}} i$ *and every* $s, t : \mathsf{Sec}(i)$*,*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

This is the section-level concrete form of the contravariant restriction data described in chapter 150.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafIndexedSectionPresheafCarrier`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedSectionPresheafCarrier endpoint unary`

Definition 151.155 (Indexed sheaf cover, compatibility, and locality)**.** *Let* $\mathcal{P}$ *be an indexed section presheaf carrier over* $\mathcal{T}$ *as in Definition 151.154. An indexed open cover of an open index* $i : \mathsf{OpenIx}$ *is a tuple* $\mathcal{U} = (A, \iota, h, \gamma)$ *consisting of an indexing type* A*, a family* $\iota : A \to \mathsf{OpenIx}$*, inclusion witnesses*

$$h_a : \iota(a) \leq_{\mathcal{T}} i$$

for all $a : A$*, and the pointwise cover law*

$$\gamma : \forall x : X,\ \mathsf{OpenAt}(i, x) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), x).$$

For a family $s_a : \mathsf{Sec}(\iota(a))$*, compatibility over* $\mathcal{U}$ *means that for all* $a, b : A$ *the two restrictions to the indexed intersection agree:*

$$\rho_{\iota(a),\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)}(s_a) \sim_{\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)} \rho_{\iota(b),\iota(a)\wedge_{\mathsf{Topology}^{\uparrow}}\iota(b)}(s_b),$$

where the needed inclusions are supplied by the finite-intersection law of Definition 88.1. A sheaf locality field for $\mathcal{P}$ *says that, for every such cover* $\mathcal{U}$ *of* i *and every pair* $g, h : \mathsf{Sec}(i)$*,*

$$(\forall a : A,\ \rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h)) \Longrightarrow g \sim_i h.$$

A sheaf gluing field says that every compatible local family over $\mathcal{U}$ *has a section* $g : \mathsf{Sec}(i)$ *whose restriction to each* $\iota(a)$ *is classifier-equal to* s_a*. An indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *is an indexed section presheaf carrier equipped with both of these fields.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedCoverCompatibilityLocality common refinement`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafIndexedCoverCompatibilityLocality global rows`

Definition 151.156 (Stable sheaf restriction row)**.** *Let $\mathcal{P}$ be an indexed section presheaf carrier over $\mathcal{T}$ as in Definition 151.154. A stable sheaf restriction row for $\mathcal{P}$ is the field saying that classifier equality is preserved by every restriction: for every inclusion $j \leq_{\mathcal{T}} i$ and every pair $s, t : \mathsf{Sec}(i)$,*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

Thus section classifiers transport along the indexed open restriction maps carried by the presheaf surface.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafStableRestrictionRow restricted comparison readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafStableRestrictionRow transport`

Theorem 151.157 (Sheaf carrier support obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Then the carrier support exposed by $\mathcal{S}$ is only the indexed section presheaf carrier over the $\mathsf{Topology}^{\uparrow}$ open-index surface, together with the sheaf locality and gluing fields. Concretely, every carrier row is one of the section carriers $\mathsf{Sec}(i)$, section classifiers $\sim_i$, equivalence fields, restriction maps $\rho_{i,j}$, identity and composition laws, indexed open-cover data, compatible local-family predicates, locality implications, or gluing witnesses described in Definition 151.154 and Definition 151.155.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCarrierSupport obligation`

Proof. Project the indexed section presheaf component of $\mathcal{S}$. Its displayed rows are precisely the open-indexed section carriers, classifiers, equivalence witnesses, restriction maps, and restriction identity and composition laws of Definition 151.154.

Project the sheaf component of $\mathcal{S}$. By Definition 151.155, this contributes only indexed open covers, compatible local families, the locality field, and the gluing field. No additional carrier row is introduced beyond those two displayed interfaces, so the asserted carrier support is exhausted by their projections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCarrierSupport obligation rows`

Theorem 151.158 (Sheaf classifier transport obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$, and suppose its indexed section presheaf carrier carries a stable sheaf restriction row in the sense of Definition 151.156. Then section classifiers transport through every restriction. Moreover, for every indexed open cover $\mathcal{U} = (A, \iota, h, \gamma)$ of i and every pair $g, h' : \mathsf{Sec}(i)$,*

$$(\forall a : A,\ \rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h')) \Longrightarrow g \sim_i h'.$$

Thus restriction stability gives classifier transport along the presheaf maps, and sheaf locality turns coverwise classifier equality back into classifier equality on the covered open.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger classifier transport obligation`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted global transport closure`

Proof. For a single inclusion $j \leq_{\mathcal{T}} i$, the transport claim is exactly the stable restriction row of Definition 151.156: a classifier equality $s \sim_i t$ restricts to $\rho_{i,j}(s) \sim_j \rho_{i,j}(t)$. The source and target classifiers are those supplied by the section presheaf carrier, and their reflexive, symmetric, and transitive behavior is supplied by the equivalence field of Definition 151.154.

For a cover $\mathcal{U}$, assume the displayed coverwise equality of the restrictions of g and h'. This is exactly the antecedent required by the sheaf locality field in Definition 151.155. Applying that field over the same indexed cover gives $g \sim_i h'$, which is the global classifier equality claimed. □

Theorem 151.159 (Sheaf cover ledger exactness obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. An accepted cover and gluing ledger row for $\mathcal{S}$ consists exactly of indexed open-cover data $\mathcal{U} = (A, \iota, h, \gamma)$, the finite-intersection rows of the* $\mathsf{Topology}^{\uparrow}$ *carrier, a compatible local section family $s_a : \mathsf{Sec}(\iota(a))$, and a global section $g : \mathsf{Sec}(i)$ with displayed restriction equalities*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The ledger uses no host open-cover equality and no quotient primitive: all comparison data is expressed through indexed opens, restriction maps, and the section classifiers of Definition 151.154.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger exactness rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger exactness obligation`

Proof. Unfold the indexed open cover and compatibility clauses in Definition 151.155. The cover ledger records only the indexing type A, the open-index map ι, the inclusion witnesses $h_a : \iota(a) \leq_{\mathcal{T}} i$, and the pointwise cover law γ. Compatibility is recorded by restricting local sections to the finite-intersection index supplied by the $\mathsf{Topology}^{\uparrow}$ carrier and comparing them with the classifier on that intersection.

Unfold the gluing clause of the same definition. A gluing ledger row adds a section $g : \mathsf{Sec}(i)$ and the displayed restriction equalities against the compatible family. The theorem Definition 151.170 checks that restrictions of a global section produce a compatible local family, while Definition 151.169 checks that two displayed gluings of the same compatible family are classifier-equal.

The two definitions just unfolded contain no host-side equality of open covers and no quotient constructor. Their comparison mechanism is the indexed inclusion relation $j \leq_{\mathcal{T}} i$, the finite-intersection row of the topology carrier, the restriction maps, and the section classifiers. Hence the listed rows are exact for the accepted cover and gluing ledger. □

Definition 151.160 (Sheaf BHist cover nerve ledger)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *whose point carrier is* BHist*, whose membership classifier is* OpenAt*, and whose finite-intersection index is written $\wedge_{\mathsf{Topology}^{\uparrow}}$. Let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. The* BHist *cover nerve ledger of $\mathcal{U}$ is the finite-intersection ledger surface with the following rows.*

1. *For each $a : A$, the member row is the indexed open $\iota(a)$ with its inclusion witness $h_a : \iota(a) \leq_{\mathcal{T}} i$ and its visible membership predicate* $\mathsf{OpenAt}(\iota(a), b)$ *for $b :$* BHist*.*
2. *For each $a, b : A$, the pair-overlap row is $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, together with the two finite-intersection projections $k_{a,b} \leq_{\mathcal{T}} \iota(a)$ and $k_{a,b} \leq_{\mathcal{T}} \iota(b)$ and the two restriction rows from* $\mathsf{Sec}(\iota(a))$ *and* $\mathsf{Sec}(\iota(b))$ *to* $\mathsf{Sec}(k_{a,b})$*.*
3. *For each $a, b, c : A$, the triple-overlap row is $\ell_{a,b,c} := k_{a,b} \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c)$, together with the finite-intersection projections $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b}$ and $\ell_{a,b,c} \leq_{\mathcal{T}} \iota(c)$ and the restriction rows obtained by composing through $k_{a,b}$ or directly from any member whose inclusion route is displayed.*

The ledger contains only OpenAt *rows, finite-intersection projections, inclusion witnesses, presheaf restriction rows, section classifiers, and visible* BHist *provenance. It does not identify cover presentations by host equality and does not quotient overlap rows.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger`

Theorem 151.161 (Sheaf BHist cover nerve overlap projections)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist*, let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. For a local family $s_a : \mathsf{Sec}(\iota(a))$, compatibility over $\mathcal{U}$ is exactly the assertion that every pair-overlap row of the* BHist *cover nerve ledger carries classifier equality between the two projected restrictions:*

$$\forall a, b : A, \quad \rho_{\iota(a),k_{a,b}}(s_a) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(s_b),$$

where $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ and the inclusions are the finite-intersection projections of Definition 88.1.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison overlap projection rows`

Proof. Unfold the compatibility predicate in Definition 151.155. Its only comparison clauses are indexed by pairs $a, b : A$, and each clause restricts s_a and s_b to the common intersection $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ before comparing them by the section classifier at that intersection.

Unfold the cover nerve ledger of Definition 151.160. Its pair-overlap rows are exactly the same indices $k_{a,b}$, with the same two finite-intersection projections supplied by Definition 88.1. Therefore every compatibility clause is a classifier equality on one pair-overlap ledger row.

Conversely, assume every pair-overlap ledger row carries the displayed classifier equality. Reading those rows through the same two projections gives precisely the clauses required by Definition 151.155. Restriction composition is not extra data here; it only confirms that any displayed route to $k_{a,b}$ reads as the same section classifier row as the direct pair-overlap restriction. □

Theorem 151.162 (Sheaf BHist cover nerve gluing readback)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist*, let $\mathcal{S}$ be an indexed sheaf carrier over $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ is a gluing section with*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

Then the BHist *cover nerve ledger reads g back to the local family on every member row and to the induced compatible family on every pair-overlap row. Explicitly, for every $a : A$,*

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a,$$

and for every $a, b : A$, writing $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$,

$$\rho_{\iota(a),k_{a,b}}(\rho_{i,\iota(a)}(g)) \sim_{k_{a,b}} \rho_{\iota(a),k_{a,b}}(s_a)$$

and

$$\rho_{\iota(b),k_{a,b}}(\rho_{i,\iota(b)}(g)) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(s_b).$$

Consequently the two restrictions of g to each pair-overlap ledger row recover the same classifier row as the compatible family there.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger gluing readback`

Proof. The member readback is the gluing equality displayed in the statement. It is exactly the gluing clause of Definition 151.155 evaluated at the member row $\iota(a)$.

For a pair $a, b : A$, write $k = \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$. The finite-intersection field of Definition 88.1 supplies $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$, which are the two pair-overlap projections recorded by Definition 151.160.

Transport the gluing equality $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$ along $k \leq_{\mathcal{T}} \iota(a)$ using the restriction classifier-stability field from Definition 151.154. This gives the first pair-overlap readback equality. The same transport along $k \leq_{\mathcal{T}} \iota(b)$ gives the second one.

It remains to compare the two readings of g on k. Restriction composition identifies the restriction of $\rho_{i,\iota(a)}(g)$ to k and the restriction of $\rho_{i,\iota(b)}(g)$ to k with the direct restriction $\rho_{i,k}(g)$, up to the classifier $\sim_k$. The compatibility of s_a gives the corresponding equality between the two local-family restrictions. Transitivity and symmetry of $\sim_k$ combine these rows, so the pair-overlap ledger reads the gluing section back to the same classifier row as the compatible local family. □

Theorem 151.163 (Sheaf NameCert carrier obligation)**.** *Every indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$ *determines the carrier-facing rows required by the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *template. The rows are fixed as follows.*

1. *The traditional target is sheaf-theoretic section data over open covers.*
2. *The BEDC source is the presheaf restriction source of* $\mathsf{PreSheaf}^{\uparrow}$ *together with the indexed-open source of* $\mathsf{Topology}^{\uparrow}$*.*
3. *The carrier is the indexed section presheaf of Definition 151.154, equipped with the locality and gluing fields of Definition 151.155.*
4. *The classifier row is the family of section classifiers* $\sim_i$*.*
5. *The stability row is supplied by the restriction identity, restriction composition, restriction classifier-stability, and classifier-equivalence fields.*
6. *The ledger is the displayed data of covers, intersections, inclusion witnesses, and restriction maps.*
7. *The exactness row is visible cover-local readback: compatible local sections glue to a global section and locality identifies any two global readbacks with the same cover restrictions.*
8. *The standard bridge row is absent; this certificate surface records the BEDC sheaf interface without claiming an external set-theoretic sheaf bridge.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger semantic name certificate`

Proof. Unpack the indexed sheaf carrier. Its presheaf part is exactly the tuple $\mathcal{P} = (\mathsf{Sec}, \sim, \rho, \mathsf{Eqv}, \mathsf{Id}, \mathsf{Comp}, \mathsf{Res})$ of Definition 151.154, so the carrier, classifier, and restriction-stability rows are not extra data: they are the displayed section carriers, displayed section classifiers, and the identity, composition, equivalence, and restriction classifier-stability fields.

Unpack the cover part. The topology side contributes open indices, inclusions, and finite-intersection witnesses by Definition 88.1; the presheaf side contributes contravariant restriction scope by chapter 150. The remaining sheaf fields in Definition 151.155 are precisely locality and gluing over those covers, which give the visible cover-local readback row and leave no separate standard-bridge row to construct. □

Theorem 151.164 (Sheaf restriction stability obligation)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$*. For inclusions* $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$*, restriction identity and restriction composition keep every section row inside the displayed classifier family. Explicitly, for* $s : \mathsf{Sec}(i)$ *one has*

$$\rho_{i,i}(s) \sim_i s$$

and

$$\rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s).$$

When k is an indexed intersection supplied by the finite-intersection field of Definition 88.1, the same restriction-composition statement applies to the two induced inclusion chains, so cover restrictions remain stable under the topology intersection witnesses.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restriction stability obligation`

Proof. The first displayed relation is the identity field of the indexed section presheaf carrier in Definition 151.154. The second displayed relation is the composition field for the chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. Both conclusions land in the classifier specified by the target open index, namely $\sim_i$ for identity and $\sim_k$ for composition.

For the intersection case, use Definition 88.1 to obtain the open-index intersection and its two projection inclusions. Combining either projection with a cover inclusion gives one of the admissible chains governed by the contravariant restriction interface of chapter 150. Applying the same composition field to those chains gives stability on every displayed intersection row. □

Theorem 151.165 (Sheaf locality and gluing NameCert obligation)**.** *For an indexed sheaf carrier $\mathcal{S}$ for $\mathsf{Sheaf}^{\uparrow}$, the locality and gluing fields supply the certificate rows consumed by Definition 151.169, Definition 151.170, and Definition 151.171. Namely, every compatible local family over an indexed open cover has a global readback section, and locality identifies any two global sections whose restrictions agree on every cover member.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison locality gluing semantic name certificate`

Proof. Fix an indexed cover $\mathcal{U} = (A, \iota, h, \gamma)$ of i and a compatible family $s_a : \mathsf{Sec}(\iota(a))$. The cover and compatibility predicates are those of Definition 151.155; their intersection clauses are meaningful because Definition 88.1 supplies finite-intersection witnesses, and their restriction clauses live in the contravariant presheaf scope of chapter 150.

Apply the gluing field to obtain a section $g : \mathsf{Sec}(i)$ whose restrictions classify as the family s_a. Apply the locality field to any pair of such global sections whose memberwise restrictions agree; this is exactly the premise used by Definition 151.169. The compatibility theorem uses the same restriction-composition row on intersections, and the idempotence corollary repacks gluing plus uniqueness for the local family obtained from one global section. □

Theorem 151.166 (SheafUp BHist obligation surface)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for $\mathsf{Topology}^{\uparrow}$ whose point carrier is BHist, with classifier hsame, membership row OpenAt, and finite-intersection index $\wedge_{\mathsf{Topology}^{\uparrow}}$. Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over $\mathcal{T}$ in the sense of Definition 151.154 and Definition 151.155. Then $\mathcal{S}$ supplies the $\mathsf{Sheaf}^{\uparrow}$ carrier, section classifiers, restriction maps, restriction identity, restriction composition, indexed-cover rows, compatibility predicate, locality field, gluing field, and visible BHist ledger rows required by the paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface. The exposed data depend only on $\mathsf{NameCert}_{\mathsf{PreSheaf}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$, the row OpenAt, the finite-intersection rows of $\mathcal{T}$, and the classifier-equivalence fields on the section carriers.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistObligationSurface restriction cover package`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistObligationSurface cover restriction classifier`

Proof. Project the carrier and classifier rows from the indexed section presheaf carrier. For each open index i, the section carrier $\mathsf{Sec}(i)$ and classifier $\sim_i$ are visible, and the equivalence field supplies the reflexive, symmetric, and transitive classifier rules required by the certificate surface.

Project the restriction rows from the same tuple. The identity and composition fields are exactly the $\mathsf{PreSheaf}^{\uparrow}$ restriction identity and restriction composition obligations, with inclusions interpreted through the indexed-open preorder $j \leq_{\mathcal{T}} i$ defined by OpenAt. The finite-intersection row of $\mathcal{T}$ supplies the common target index used in compatibility checks.

Finally project the cover, compatibility, locality, and gluing rows from Definition 151.155. The visible ledger is BHist-scoped because every open membership and every inclusion witness is expressed by OpenAt on BHist, and no host powerset equality is part of the exposed surface. □

Theorem 151.167 (SheafUp restriction hsame transport obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over a BHist-scoped indexed open topology carrier $\mathcal{T}$. Suppose a second displayed carrier is obtained by componentwise hsame transport of the topology row OpenAt, the section carriers and classifiers, the restriction maps, and the indexed-cover rows. Then restriction compatibility, locality, and gluing for $\mathcal{S}$ transport to the displayed carrier. In particular, a compatible family remains compatible after transport, a locality hypothesis on transported restrictions yields transported classifier equality of global sections, and a gluing witness transports to a gluing witness for the transported local family.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger hsame transport readback`

Proof. Transport the topology row first. The $\mathsf{Topology}^{\uparrow}$ membership-stability field moves each occurrence of $\mathsf{OpenAt}(i, h)$ across the displayed hsame witness, so the inclusion witnesses $j \leq_{\mathcal{T}} i$ and the cover law for $\mathcal{U} = (A, \iota, \eta, \gamma)$ remain valid after transport.

Next transport the section rows. The componentwise transport hypothesis identifies each section carrier, classifier, and restriction map with its transported counterpart. Compatibility is a conjunction of classifier equalities after restricting to the finite-intersection index, so it follows by applying the transported restriction rows and then reading the section classifier equivalence fields in the transported carrier.

For locality, begin with transported agreement of two global sections on every cover member. Move that agreement back along the componentwise classifier transport, apply the locality field of $\mathcal{S}$, and transport the resulting global classifier equality forward. For gluing, transport the compatible family back, apply the gluing field of $\mathcal{S}$ to obtain a global section, and transport that witness and its restriction equalities forward. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger restriction hsame transport obligation`

Theorem 151.168 (SheafUp cover gluing NameCert export)**.** *The BHist-scoped surface of Definition 151.166, together with the transport obligation of Definition 151.167, the uniqueness theorem Definition 151.169, and the global-restriction compatibility theorem Definition 151.170, assembles the paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface consumed by $\mathsf{RingedSpace}^{\uparrow}$ and $\mathsf{Scheme}^{\uparrow}$. The exported surface provides sheaf carrier data, restriction coherence, cover compatibility, locality, gluing, uniqueness up to section classifier equality, and compatibility of restrictions of global sections; it claims no standard bridge and no external powerset equality.*

Proof. Start with the obligation surface of Definition 151.166. It supplies the carrier, classifier, restriction, cover, compatibility, locality, gluing, and visible ledger rows over BHist, all routed through $\mathsf{NameCert}_{\mathsf{PreSheaf}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$.

Use Definition 151.167 to make those rows stable under the componentwise hsame transports seen by downstream chapters. This gives $\mathsf{RingedSpace}^{\uparrow}$ and $\mathsf{Scheme}^{\uparrow}$ a transport discipline for topology membership through OpenAt and for section equality through the displayed section classifiers.

The gluing consequences are then the two local theorems already present in the chapter. Apply Definition 151.169 for uniqueness of a glued global section up to the section classifier, and apply Definition 151.170 for compatibility of the local family obtained by restricting a global section.

Combining these rows gives exactly the paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface needed by the dependent ringed-space and scheme certificates. Since every cited row stays inside indexed opens, OpenAt, hsame, and section classifiers, the package contains neither a standard sheaf bridge nor an equality of host powersets. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverGluingNameCert export`

Theorem 151.169 (Sheaf gluing uniqueness from locality)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $s_a : \mathsf{Sec}(\iota(a))$ be a compatible local family over $\mathcal{U}$. If $g, h : \mathsf{Sec}(i)$ both restrict to that family on every cover member, in the sense that*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$$

and

$$\forall a : A, \quad \rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a,$$

then the two cover-global sections are classifier-equal:

$$g \sim_i h.$$

Thus the gluing supplied by the $\mathsf{Sheaf}^{\uparrow}$ carrier is unique up to the section classifier on the covered open.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingClassifier uniqueness from locality`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger gluing uniqueness from locality`

Proof. Fix a cover member $a : A$. The first restriction hypothesis gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The second restriction hypothesis gives

$$\rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a.$$

By symmetry of the section classifier on $\mathsf{Sec}(\iota(a))$, supplied by the equivalence field of Definition 151.154, this yields

$$s_a \sim_{\iota(a)} \rho_{i,\iota(a)}(h).$$

Transitivity of the same classifier then gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h).$$

Since a was arbitrary, the restrictions of g and h agree on every member of $\mathcal{U}$. Applying the sheaf locality field from Definition 151.155 gives $g \sim_i h$. □

Theorem 151.170 (Sheaf global restrictions form a compatible local family)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $g : \mathsf{Sec}(i)$. Define the local family $s_a : \mathsf{Sec}(\iota(a))$ by*

$$s_a = \rho_{i,\iota(a)}(g).$$

Then s_a is compatible over $\mathcal{U}$ in the sense of Definition 151.155. Explicitly, for every $a, b : A$, putting $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, one has

$$\rho_{\iota(a),k_{a,b}}(\rho_{i,\iota(a)}(g)) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(\rho_{i,\iota(b)}(g)),$$

where the restriction maps use the inclusions supplied by the finite-intersection field and the cover inclusions h_a and h_b.

Proof. Fix $a, b : A$ and write $k = \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$. The finite-intersection field of Definition 88.1 gives

$$\mathsf{OpenAt}(k, x) \Longrightarrow (\mathsf{OpenAt}(\iota(a), x) \wedge \mathsf{OpenAt}(\iota(b), x))$$

for every $x : X$. Projecting the two components gives inclusions $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$. Together with the cover inclusions $h_a : \iota(a) \leq_{\mathcal{T}} i$ and $h_b : \iota(b) \leq_{\mathcal{T}} i$, these are the two chains needed for presheaf restriction composition.

Apply the composition field of Definition 151.154 to the chain $k \leq_{\mathcal{T}} \iota(a) \leq_{\mathcal{T}} i$ and the section g. This gives

$$\rho_{\iota(a),k}(\rho_{i,\iota(a)}(g)) \sim_k \rho_{i,k}(g).$$

Applying the same composition field to $k \leq_{\mathcal{T}} \iota(b) \leq_{\mathcal{T}} i$ gives

$$\rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)) \sim_k \rho_{i,k}(g).$$

By symmetry of the section classifier on $\mathsf{Sec}(k)$, supplied by the equivalence field of Definition 151.154, the second displayed relation yields

$$\rho_{i,k}(g) \sim_k \rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)).$$

Transitivity of the same classifier combines this with the first displayed relation and gives

$$\rho_{\iota(a),k}(\rho_{i,\iota(a)}(g)) \sim_k \rho_{\iota(b),k}(\rho_{i,\iota(b)}(g)).$$

Since a and b were arbitrary, this is exactly compatibility of the family $a \mapsto \rho_{i,\iota(a)}(g)$ over $\mathcal{U}$ as defined in Definition 151.155. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger global restrictions compatible`

Corollary 151.171 (Sheaf gluing of global restrictions is idempotent)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, \eta, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$, and let $g : \mathsf{Sec}(i)$. Define the local family $s_a : \mathsf{Sec}(\iota(a))$ by*

$$s_a = \rho_{i,\iota(a)}(g).$$

If $h : \mathsf{Sec}(i)$ is a gluing of this family, in the sense that

$$\forall a : A, \quad \rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a,$$

then

$$h \sim_i g.$$

Proof. By Definition 151.170, the family s_a is compatible over $\mathcal{U}$. For each $a : A$, the displayed definition of s_a and reflexivity of the classifier on $\mathsf{Sec}(\iota(a))$, supplied by Definition 151.154, give

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

The gluing hypothesis gives

$$\rho_{i,\iota(a)}(h) \sim_{\iota(a)} s_a$$

for the same a. Since a was arbitrary, both cover-global sections h and g restrict to the compatible local family s_a on every member of $\mathcal{U}$. Applying Definition 151.169 with h as the first cover-global section and g as the second gives $h \sim_i g$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingGlobalRestrictions idempotent`

Theorem 151.172 (Sheaf restriction classifier transport)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. For every inclusion $j \leq_{\mathcal{T}} i$ and every pair $s, t : \mathsf{Sec}(i)$, classifier equality on the larger open transports along restriction:*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t).$$

Thus restriction rows are morphisms of the local section classifiers.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restriction classifier transport`

Proof. The indexed sheaf carrier contains the indexed section presheaf carrier of Definition 151.154. Apply its restriction classifier-stability field to the inclusion $j \leq_{\mathcal{T}} i$ and the given classifier row $s \sim_i t$. □

Theorem 151.173 (Sheaf compatible-family stability)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of an open index $i : \mathsf{OpenIx}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $t_a : \mathsf{Sec}(\iota(a))$ is a second local family with*

$$\forall a : A, \quad t_a \sim_{\iota(a)} s_a.$$

Then t_a is compatible over $\mathcal{U}$. Explicitly, for all $a, b : A$, writing $k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$, one has

$$\rho_{\iota(a),k_{a,b}}(t_a) \sim_{k_{a,b}} \rho_{\iota(b),k_{a,b}}(t_b).$$

Proof. Fix $a, b : A$ and write $k = \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$. The finite-intersection field of Definition 88.1 supplies the inclusions $k \leq_{\mathcal{T}} \iota(a)$ and $k \leq_{\mathcal{T}} \iota(b)$ needed to restrict both local sections to the overlap.

Apply Definition 151.172 to the classifier row $t_a \sim_{\iota(a)} s_a$ along $k \leq_{\mathcal{T}} \iota(a)$. This gives

$$\rho_{\iota(a),k}(t_a) \sim_k \rho_{\iota(a),k}(s_a).$$

Apply the same transport row to $t_b \sim_{\iota(b)} s_b$ along $k \leq_{\mathcal{T}} \iota(b)$, and then use symmetry of the classifier on $\mathsf{Sec}(k)$, to get

$$\rho_{\iota(b),k}(s_b) \sim_k \rho_{\iota(b),k}(t_b).$$

The compatibility of the original family gives

$$\rho_{\iota(a),k}(s_a) \sim_k \rho_{\iota(b),k}(s_b).$$

Transitivity of $\sim_k$ first composes the transported a-side row with the original compatibility row, and then composes the result with the reversed transported b-side row. The resulting row is exactly

$$\rho_{\iota(a),k}(t_a) \sim_k \rho_{\iota(b),k}(t_b).$$

Since a and b were arbitrary, the family t_a is compatible over $\mathcal{U}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafGluingCompatibleFamily stability semantic certificate`

Theorem 151.174 (Sheaf cover refinement obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. A displayed refinement of $\mathcal{V}$ through $\mathcal{U}$ is a map $r : B \to A$ together with inclusion witnesses*

$$\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$$

for every $b : B$, compatible with the two cover rows in the sense that the composite inclusion $\kappa(b) \leq_{\mathcal{T}} \iota(r(b)) \leq_{\mathcal{T}} i$ is the displayed route from the refined cover member to i. This is a certificate-level obligation only over the indexed-open inclusion relation of Definition 151.155 and the carrier rows of Definition 88.1; it introduces no host powerset equality of covers and no quotient comparison between cover presentations.

Proof. Unpack the two cover rows. The original cover supplies $h_a : \iota(a) \leq_{\mathcal{T}} i$, and the refined cover supplies $q_b : \kappa(b) \leq_{\mathcal{T}} i$. A refinement chooses, for each refined row b, an original row $r(b)$ together with the displayed inclusion $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$.

The topology carrier already gives the meaning of $\leq_{\mathcal{T}}$ as indexed-open inclusion and supplies the finite-intersection rows used by the sheaf compatibility predicate. Therefore the refinement datum is fully expressed by the map r and the witnesses ϵ_b, with the target cover inclusion $h_{r(b)}$ recording the route onward to i.

No comparison of host open subsets is used. All later transport across the refinement is forced to pass through ϵ_b, restriction composition, and the section classifiers of the indexed presheaf carrier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace refinement obligation`

Theorem 151.175 (Sheaf compatible family pullback along refinement)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$ in the sense of Definition 151.174. If $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$, then the pulled-back family*

$$t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$$

is compatible over $\mathcal{V}$. Explicitly, for every $b, c : B$, writing $m_{b,c} := \kappa(b) \wedge_{\mathsf{Topology}^{\uparrow}} \kappa(c)$, one has

$$\rho_{\kappa(b),m_{b,c}}(t_b) \sim_{m_{b,c}} \rho_{\kappa(c),m_{b,c}}(t_c).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger refinement pullback`

Proof. Fix $b, c : B$ and write $m = \kappa(b) \wedge_{\mathsf{Topology}^{\uparrow}} \kappa(c)$. The finite-intersection field of Definition 88.1 gives $m \leq_{\mathcal{T}} \kappa(b)$ and $m \leq_{\mathcal{T}} \kappa(c)$. Composing these with the refinement inclusions gives routes $m \leq_{\mathcal{T}} \iota(r(b))$ and $m \leq_{\mathcal{T}} \iota(r(c))$.

Use restriction composition on the chain $m \leq_{\mathcal{T}} \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$. It identifies the left restriction of t_b with the direct restriction of $s_{r(b)}$ to m, up to the classifier $\sim_m$. The same argument on the c side identifies the right restriction of t_c with the direct restriction of $s_{r(c)}$ to m.

The original compatibility of s_a over $\mathcal{U}$ gives equality after restricting $s_{r(b)}$ and $s_{r(c)}$ to the overlap $\iota(r(b)) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(r(c))$. Since m lies inside both original cover members by the refinement inclusions and the finite-intersection projections, restriction composition transports that compatibility row down to m.

Finally, transitivity of $\sim_m$ composes the two restriction-composition rows with the transported original compatibility row. The resulting equality is precisely the compatibility clause for t_b and t_c over the refined cover $\mathcal{V}$. □

Theorem 151.176 (Sheaf gluing descends along refined covers)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Suppose $s_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues it:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

Then g glues the pulled-back family $t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$ over $\mathcal{V}$:

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} t_b.$$

Proof. Fix $b : B$. The gluing row over $\mathcal{U}$ gives

$$\rho_{i,\iota(r(b))}(g) \sim_{\iota(r(b))} s_{r(b)}.$$

Apply restriction classifier transport along the refinement inclusion $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b))$ to obtain equality after restriction to $\kappa(b)$.

Restriction composition on the chain $\kappa(b) \leq_{\mathcal{T}} \iota(r(b)) \leq_{\mathcal{T}} i$ identifies the restriction of $\rho_{i,\iota(r(b))}(g)$ to $\kappa(b)$ with the direct restriction $\rho_{i,\kappa(b)}(g)$. By definition, the restriction of $s_{r(b)}$ along the same refinement inclusion is t_b.

Transitivity of the classifier on $\mathsf{Sec}(\kappa(b))$ composes the composition row with the transported gluing row. Since b was arbitrary, the displayed equality holds for every member of $\mathcal{V}$, so g glues the pulled-back family over the refined cover. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementGluing descent cont`

Theorem 151.177 (Sheaf locality detection under refinement)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Suppose $g, h' : \mathsf{Sec}(i)$ satisfy refined-cover equality*

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} \rho_{i,\kappa(b)}(h').$$

Assume moreover that every original cover member is detected by its refinement rows: for every $a : A$, the subfamily of indices $b : B$ with $r(b) = a$ is an indexed open cover of $\iota(a)$ through the inclusions $\epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(a)$. Then locality over $\mathcal{U}$ gives

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementLocality global detection`

Proof. Fix $a : A$. By the detection hypothesis, the rows with $r(b) = a$ form an indexed cover of $\iota(a)$. For each such row b, the refined equality compares the direct restrictions of g and h' to $\kappa(b)$.

Restriction composition on $\kappa(b) \leq_{\mathcal{T}} \iota(a) \leq_{\mathcal{T}} i$ rewrites those direct restrictions as the restrictions of $\rho_{i,\iota(a)}(g)$ and $\rho_{i,\iota(a)}(h')$ along ϵ_b. Thus the two sections $\rho_{i,\iota(a)}(g)$ and $\rho_{i,\iota(a)}(h')$ agree on every member of the detected cover of $\iota(a)$.

Apply the sheaf locality field of Definition 151.155 on this detected cover of $\iota(a)$. It gives

$$\rho_{i,\iota(a)}(g) \sim_{\iota(a)} \rho_{i,\iota(a)}(h').$$

Since a was arbitrary, these equalities hold over all members of $\mathcal{U}$.

Applying the same locality field over the original cover $\mathcal{U}$ yields $g \sim_i h'$, which is the claimed global classifier equality. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refined locality detection`

Theorem 151.178 (Sheaf refined-cover gluing uniqueness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. Let $s_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$, and write*

$$t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$$

for its pulled-back family over $\mathcal{V}$. Suppose $g, h' : \mathsf{Sec}(i)$ both glue this pulled-back family:

$$\forall b : B, \quad \rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} t_b, \qquad \forall b : B, \quad \rho_{i,\kappa(b)}(h') \sim_{\kappa(b)} t_b.$$

Assume moreover that every original cover member is detected by its refinement rows in the sense of Definition 151.177. Then

$$g \sim_i h'.$$

Proof. Fix $b : B$. The first gluing row compares $\rho_{i,\kappa(b)}(g)$ with t_b, and the second compares $\rho_{i,\kappa(b)}(h')$ with the same section t_b.

Use symmetry of the classifier on $\mathsf{Sec}(\kappa(b))$ to reverse the second equality, then transitivity to obtain

$$\rho_{i,\kappa(b)}(g) \sim_{\kappa(b)} \rho_{i,\kappa(b)}(h').$$

Since b was arbitrary, this is refined-cover equality of g and h' over $\mathcal{V}$.

Apply Definition 151.177 to this refined-cover equality and to the displayed detection hypothesis for the rows with $r(b) = a$. It returns the global classifier equality $g \sim_i h'$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinedCover gluing uniqueness`

Theorem 151.179 (Sheaf refined-cover exactness obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let (r, ϵ) be a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$. For every compatible family $s_a : \mathsf{Sec}(\iota(a))$ over $\mathcal{U}$, the pulled-back family $t_b := \rho_{\iota(r(b)),\kappa(b)}(s_{r(b)})$ satisfies the following three exactness rows.*

1. *The family t_b is compatible over $\mathcal{V}$.*
2. *Every gluing $g : \mathsf{Sec}(i)$ of s_a over $\mathcal{U}$ also glues t_b over $\mathcal{V}$.*
3. *If every original cover member is detected by its refinement rows, then any two sections $g, h' : \mathsf{Sec}(i)$ gluing t_b over $\mathcal{V}$ satisfy $g \sim_i h'$.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinedCover exactness obligation`

Proof. The first row is exactly Definition 151.175: compatibility of the original family transports along the displayed refinement.

The second row is exactly Definition 151.176: a section gluing the original family restricts to a gluing of the pulled-back family over the refined cover.

The third row is Definition 151.178. Its hypotheses are precisely two displayed gluings of the same pulled-back family, plus the locality-detection row for the refinement fibers over each original cover member. □

Theorem 151.180 (Sheaf NameCert refinement exactness export)**.** *The paper-side obligation surface* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *exports refined-cover exactness over indexed opens. Concretely, for any indexed sheaf carrier over an indexed open topology carrier, every displayed refinement of indexed covers carries compatible families forward, descends original gluings to refined gluings, and makes any two refined gluings of the same pulled-back family globally classifier-equal whenever the original members are detected by their refinement rows. This exported row uses only* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *restriction composition, section classifiers, locality, and gluing; it does not use host powerset equality or quotient comparison.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCertRefinement exactness export`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCertRefinementExactness export`
↪ variant `BEDC.Derived.SheafUp.SheafRefinementExactness namecert export`

Proof. Project the carrier row from Definition 151.154. This supplies the open-indexed section carriers, classifiers, restriction maps, restriction composition, and classifier transport used in the refinement arguments.

Project the cover, compatibility, locality, and gluing rows from Definition 151.155. These rows supply indexed covers, overlap compatibility, the local-to-global classifier implication, and displayed gluing witnesses.

Assemble the export by applying Definition 151.179. Its three rows are already expressed in the projected data, so $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ exposes a single refined-cover exactness obligation to downstream ringed-space and scheme certificates without adding a host-level cover comparison. □

Theorem 151.181 (Sheaf cover self-refinement identity)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$*. Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an indexed open cover of* $i : \mathsf{OpenIx}$*. Then the identity map*

$$\mathrm{id}_A : A \to A$$

together with the pointwise reflexive inclusion witnesses

$$\epsilon_a : \iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a))$$

forms a displayed refinement of $\mathcal{U}$ *through itself in the sense of Definition 151.174.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCover self refinement`

Proof. Unpack Definition 151.174. To exhibit a displayed refinement of $\mathcal{U}$ through itself, it is enough to give a map from the refined index type to the original index type and, for each refined row $a : A$, an inclusion witness from the refined member to the chosen original member. Take the map to be $r := \mathrm{id}_A$.

Fix $a : A$. Since $\mathrm{id}_A(a) = a$, the required witness

$$\epsilon_a : \iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a))$$

is exactly the pointwise implication

$$\forall x : X,\ \mathsf{OpenAt}(\iota(a), x) \Longrightarrow \mathsf{OpenAt}(\iota(a), x),$$

which holds immediately from the definition of $\leq_{\mathcal{T}}$ in Definition 151.154. The indexed-open membership row OpenAt is part of the topology carrier recorded in Definition 88.1, so this is a valid displayed inclusion witness in the same ledger as every other cover inclusion.

The onward route from the refined member to the ambient open i is then

$$\iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a)) \leq_{\mathcal{T}} i.$$

Its second leg is the original cover inclusion $h_a : \iota(a) \leq_{\mathcal{T}} i$, because $\mathrm{id}_A(a) = a$. Therefore the refinement data are exactly the identity selector together with the reflexive inclusion witnesses, and these satisfy the compatibility clause required in Definition 151.174. Hence $\mathcal{U}$ is a displayed refinement of itself. □

Theorem 151.182 (Sheaf identity-refinement pullback identity)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of $i : \mathsf{OpenIx}$, and let $s_a : \mathsf{Sec}(\iota(a))$ be a local family over $\mathcal{U}$. Use the identity displayed refinement of $\mathcal{U}$ through itself from Definition 151.181, and write its pulled-back family as*

$$t_a := \rho_{\iota(\mathrm{id}_A(a)),\iota(a)}(s_{\mathrm{id}_A(a)}).$$

Then for every $a : A$,

$$t_a \sim_{\iota(a)} s_a.$$

In particular, for every compatible family over $\mathcal{U}$, pullback along the identity refinement is pointwise the original family in the section classifier:

$$\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a.$$

Proof. Fix $a : A$. By Definition 151.181, the identity refinement chooses the selector $\mathrm{id}_A : A \to A$ and the reflexive inclusion witness

$$\iota(a) \leq_{\mathcal{T}} \iota(\mathrm{id}_A(a)).$$

Since $\mathrm{id}_A(a) = a$, this is exactly the reflexive inclusion

$$\iota(a) \leq_{\mathcal{T}} \iota(a).$$

Thus the pulled-back row at a is the identity restriction of the same local section:

$$t_a = \rho_{\iota(a),\iota(a)}(s_a)$$

inside the section carrier indexed by $\iota(a)$.

The identity field of the indexed section presheaf carrier in Definition 151.154 gives, for every section $s : \mathsf{Sec}(\iota(a))$,

$$\rho_{\iota(a),\iota(a)}(s) \sim_{\iota(a)} s.$$

Applying this field to s_a gives

$$\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a.$$

Substituting the displayed description of t_a gives $t_a \sim_{\iota(a)} s_a$. The argument is pointwise in a and does not use any overlap clause, so it applies in particular when the family s_a is compatible over $\mathcal{U}$ in the sense of Definition 151.155. □

Theorem 151.183 (Sheaf refinement composition obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Suppose (r, ϵ) is a displayed refinement of $\mathcal{V}$ through $\mathcal{U}$ and (s, η) is a displayed refinement of $\mathcal{W}$ through $\mathcal{V}$:*

$$r : B \to A, \qquad \epsilon_b : \kappa(b) \leq_{\mathcal{T}} \iota(r(b)),$$

$$s : C \to B, \qquad \eta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c)).$$

Then the composite map $r \circ s : C \to A$ together with the composite inclusions

$$\theta_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(s(c)))$$

is a displayed refinement of $\mathcal{W}$ through $\mathcal{U}$. The cover row for $\mathcal{W}$ remains the pointwise indexed-open implication

$$\forall x : X, \quad \mathsf{OpenAt}(i, x) \Longrightarrow \exists c : C,\ \mathsf{OpenAt}(\lambda(c), x),$$

and the route onward to i is the inclusion chain $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c))) \leq_{\mathcal{T}} i$.

Proof. For each $c : C$, the refinement row (s, η) gives $\eta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$. The refinement row (r, ϵ) gives $\epsilon_{s(c)} : \kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c)))$.

Transitivity of indexed-open inclusion in the topology carrier composes these two rows and gives the displayed inclusion $\theta_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(s(c)))$.

The cover data of $\mathcal{W}$ are not changed. Its row ω still says that every point of the ambient open i lies in some indexed member $\lambda(c)$, expressed by the displayed OpenAt implication. Together with the map $r \circ s$ and the inclusions θ_c, this is exactly the refinement obligation of Definition 151.174 for $\mathcal{W}$ through $\mathcal{U}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement composition`

Theorem 151.184 (Sheaf compatible-family pullback composes over refinements)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of $i : \mathsf{OpenIx}$. Let $(r, \epsilon) : \mathcal{V} \to \mathcal{U}$ and $(s, \eta) : \mathcal{W} \to \mathcal{V}$ be displayed refinements, and let $(r \circ s, \theta) : \mathcal{W} \to \mathcal{U}$ be their composite refinement from Definition 151.183. If $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$, define*

$$v_b := \rho_{\iota(r(b)),\kappa(b)}(u_{r(b)})$$

and

$$w_c := \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then w_c is classifier-equal to the one-step pullback

$$z_c := \rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))})$$

for every $c : C$, and the family w_c is compatible over $\mathcal{W}$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement pullback composition`

Proof. Apply Definition 151.175 to the refinement (r, ϵ). It gives compatibility of the family v_b over $\mathcal{V}$.

Apply the same theorem to the refinement (s, η) and the compatible family v_b. This gives compatibility of the tower-pulled family w_c over $\mathcal{W}$.

It remains to compare the two descriptions of the local section at $c : C$. By definition, w_c restricts $u_{r(s(c))}$ first along $\kappa(s(c)) \leq_{\mathcal{T}} \iota(r(s(c)))$ and then along $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$. Restriction composition for the indexed section presheaf carrier identifies this two-step restriction with the direct restriction along the composite inclusion θ_c.

The classifier on $\mathsf{Sec}(\lambda(c))$ supplies symmetry and transitivity, so the restriction-composition row gives $w_c \sim_{\lambda(c)} z_c$. Since compatibility of w_c was already obtained from the second pullback application, the composite tower pullback is compatible over $\mathcal{W}$ and agrees with the one-step pullback along $(r \circ s, \theta)$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRefinementPullback composition`

Theorem 151.185 (Sheaf gluing descent composes over refinement towers)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$, $\mathcal{V} = (B, \kappa, q, \delta)$, and $\mathcal{W} = (C, \lambda, p, \omega)$ be indexed open covers of $i : \mathsf{OpenIx}$. Let $(r, \epsilon) : \mathcal{V} \to \mathcal{U}$ and $(s, \eta) : \mathcal{W} \to \mathcal{V}$ be displayed refinements, with composite $(r \circ s, \theta) : \mathcal{W} \to \mathcal{U}$. Suppose $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues it:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} u_a.$$

Then g glues the composite pulled-back family over $\mathcal{W}$:

$$\forall c : C, \quad \rho_{i,\lambda(c)}(g) \sim_{\lambda(c)} \rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))}).$$

Proof. Apply Definition 151.176 to (r, ϵ) and the gluing row for g. This shows that g glues the pulled-back family $v_b := \rho_{\iota(r(b)),\kappa(b)}(u_{r(b)})$ over $\mathcal{V}$.

Apply Definition 151.176 again to (s, η) and the displayed gluing of v_b. This shows that g glues the two-step pulled-back family $w_c := \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)})$ over $\mathcal{W}$.

By Definition 151.184, w_c is classifier-equal to the one-step pullback $\rho_{\iota(r(s(c))),\lambda(c)}(u_{r(s(c))})$ for every $c : C$. Transitivity of the classifier on $\mathsf{Sec}(\lambda(c))$ composes this comparison with the two-step gluing row, giving the displayed gluing row for the composite refinement. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger refinement tower gluing`

Definition 151.186 (Sheaf displayed common refinement span)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. A displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$ is a tuple*

$$\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$$

where C is an indexing type, $\lambda : C \to \mathsf{OpenIx}$ is an indexed-open family, $r : C \to A$ and $s : C \to B$ choose the displayed members of the two covers, and for every $c : C$ there are inclusion witnesses

$$\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c)), \qquad \zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c)).$$

The row ω says that λ itself is an indexed open cover of i, with member inclusions obtained through either composite $\lambda(c) \leq_{\mathcal{T}} \iota(r(c)) \leq_{\mathcal{T}} i$ or $\lambda(c) \leq_{\mathcal{T}} \kappa(s(c)) \leq_{\mathcal{T}} i$, and with the pointwise cover law

$$\forall x : X,\ \mathsf{OpenAt}(i, x) \Longrightarrow \exists c : C,\ \mathsf{OpenAt}(\lambda(c), x).$$

Thus the common refinement is displayed entirely inside indexed opens, inclusion rows, and presheaf restriction rows; it contains no host-level equality of covers.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan base change gluing package`

Theorem 151.187 (Sheaf displayed common refinement gives paired refinements)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$. If $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ is a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$ in the sense of Definition 151.186, then $\mathcal{W}$ is a displayed refinement of its cover through $\mathcal{U}$ and also a displayed refinement of its cover through $\mathcal{V}$:*

$$(r, \epsilon) : \mathcal{W} \to \mathcal{U}, \qquad (s, \zeta) : \mathcal{W} \to \mathcal{V}.$$

Both refinements are in the sense of Definition 151.174.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan paired refinements`

Proof. Unpack the displayed span. Its row ω makes $\lambda : C \to \mathsf{OpenIx}$ an indexed cover of i, so $\mathcal{W}$ has the cover side required to be the refined cover in Definition 151.174.

The first projection consists of the map $r : C \to A$ together with the inclusions $\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c))$. These are exactly the displayed refinement rows from $\mathcal{W}$ through $\mathcal{U}$, with the route onward to i supplied by the cover inclusion $h_{r(c)}$.

The second projection is identical with $\mathcal{V}$ in place of $\mathcal{U}$: the map $s : C \to B$ and the inclusions $\zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$ form the displayed refinement rows, with the cover inclusion $q_{s(c)}$ supplying the route to i. □

Theorem 151.188 (Sheaf common refinement gluing invariance)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of $i : \mathsf{OpenIx}$, and let $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ be a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$. Let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$ and let $v_b : \mathsf{Sec}(\kappa(b))$ be compatible over $\mathcal{V}$. Suppose their pullbacks to $\mathcal{W}$ are classifier-equal:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

If $g : \mathsf{Sec}(i)$ glues u_a over $\mathcal{U}$ and $h' : \mathsf{Sec}(i)$ glues v_b over $\mathcal{V}$, then

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCommonRefinementGluing carrier invariance`

Proof. Project the common refinement span by Definition 151.187. This gives the displayed refinement (r, ϵ) from $\mathcal{W}$ through $\mathcal{U}$ and the displayed refinement (s, ζ) from $\mathcal{W}$ through $\mathcal{V}$.

Apply Definition 151.176 to the first refinement and the gluing row for g. The result says that g glues the pulled-back family

$$c \mapsto \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)})$$

over $\mathcal{W}$.

Apply the same descent theorem to the second refinement and the gluing row for h'. This says that h' glues the pulled-back family

$$c \mapsto \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)})$$

over $\mathcal{W}$. The displayed classifier equality between the two pulled-back families lets the compatible-family stability row Definition 151.173 replace the second family by the first one without changing the gluing comparison.

Now both g and h' are displayed gluings of the same compatible family over the indexed cover $\mathcal{W}$. Apply Definition 151.169 over $\mathcal{W}$ to obtain $g \sim_i h'$. □

Theorem 151.189 (Sheaf cover presentation exactness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Let $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ be a displayed common refinement span from $\mathcal{U}$ to $\mathcal{V}$. Suppose a compatible family $u_a : \mathsf{Sec}(\iota(a))$ over $\mathcal{U}$ and a compatible family $v_b : \mathsf{Sec}(\kappa(b))$ over $\mathcal{V}$ agree after pullback to $\mathcal{W}$:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then any global section class determined by gluing u_a over $\mathcal{U}$ is the same classifier class as any global section class determined by gluing v_b over $\mathcal{V}$. Equivalently, if $g, h' : \mathsf{Sec}(i)$ are displayed gluings of the two families, then $g \sim_i h'$. The exactness row uses only indexed cover presentations, displayed common refinement, restriction transport, and the classifiers $\sim_j$; it does not compare host powersets and does not form a quotient of cover presentations.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentation exactness`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentation common refinement global comparison`

Proof. Choose displayed gluings $g : \mathsf{Sec}(i)$ and $h' : \mathsf{Sec}(i)$ for the two compatible families. The hypotheses give exactly the common-refinement equality of the two pulled-back local families.

Apply Definition 151.188 to $\mathcal{U}$, $\mathcal{V}$, the displayed common refinement $\mathcal{W}$, the two compatible families, their pulled-back equality, and the two displayed gluing rows. It returns $g \sim_i h'$.

Since the argument never leaves the indexed cover ledger, the conclusion identifies the two global classifier classes without choosing a preferred cover presentation, comparing powersets of host opens, or adding any quotient primitive. □

Theorem 151.190 (Sheaf NameCert obligation surface)**.** *The concrete* $\mathsf{Sheaf}^{\uparrow}$ *certificate surface is the following ten-field obligation surface.*

1. *The traditional target is a sheaf of sections over indexed opens of an indexed topology carrier.*
2. *The BEDC source data are* $\mathsf{Topology}^{\uparrow}$ *together with* $\mathsf{PreSheaf}^{\uparrow}$*.*
3. *The carrier is the indexed section presheaf carrier of Definition 151.154.*
4. *The classifier family is the open-indexed relation $\sim_i$ on $\mathsf{Sec}(i)$.*
5. *The stability obligations are classifier equivalence, identity restriction, composition of restriction, restriction classifier transport, locality, gluing, uniqueness of gluing, compatibility of global restrictions, compatible-family stability, cover-refinement transport, refined-cover exactness, refinement tower composition, displayed common-refinement comparison, and cover-presentation exactness.*
6. *The ledger consists of open-cover indices, cover-member inclusions, finite-intersection overlap indices, and restriction rows to those overlaps.*
7. *The core theorem list is Definition 151.172, Definition 151.173, Definition 151.174, Definition 151.175, Definition 151.176, Definition 151.177, Definition 151.178, Definition 151.179, Definition 151.180, Definition 151.183, Definition 151.184, Definition 151.185, Definition 151.187, Definition 151.188, Definition 151.189, Definition 151.169, Definition 151.170, and Definition 151.171.*
8. *Exactness is locality together with existence and uniqueness of gluing for compatible local families, stable under displayed common refinement of indexed cover presentations.*

9. *There is no standard bridge attached to this surface.*
10. *The status is a paper-side obligation surface for downstream certificates using* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafNameCert obligation surface`

Proof. Rows one through four are the data fixed by Definition 151.154 and Definition 151.155: indexed opens come from $\mathsf{Topology}^{\uparrow}$, section carriers and contravariant restriction rows come from $\mathsf{PreSheaf}^{\uparrow}$, and classifier equality is indexed by the same opens as the section carriers.

Row five is exactly the list of fields and consequences exposed in this section. Equivalence, identity, composition, and restriction transport are part of the carrier surface; locality and gluing are the sheaf fields; uniqueness, compatible global restrictions, idempotence of global gluing, compatible-family stability, cover-refinement transport, refined-cover exactness, refinement tower composition, common-refinement comparison, and cover-presentation exactness are the theorem rows cited in row seven.

Rows six through ten record how downstream constructions consume the surface. A ringed-space or scheme certificate can name cover indices, overlaps, refinement maps, common-refinement spans, and restriction rows without choosing a standard-model bridge; the exactness content available to it is precisely local detection plus existence and uniqueness of gluing, stable under passing to displayed refined covers, refinement towers, and comparison of two cover presentations through a displayed common refinement. □

Corollary 151.191 (Sheaf carried-section pullback associativity along composite refinement)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$*. Let* $\mathcal{U} = (A, \alpha, h, \mu)$*,* $\mathcal{V} = (B, \beta, q, \nu)$*, and* $\mathcal{W} = (C, \gamma, p, \omega)$ *be indexed open covers of* $i : \mathsf{OpenIx}$*. Suppose* $(r, \epsilon) : \mathcal{U} \to \mathcal{V}$ *and* $(s, \eta) : \mathcal{V} \to \mathcal{W}$ *are displayed refinements in the sense of Definition 151.174:*

$$r : A \to B, \qquad \epsilon_a : \alpha(a) \leq_{\mathcal{T}} \beta(r(a)),$$

$$s : B \to C, \qquad \eta_b : \beta(b) \leq_{\mathcal{T}} \gamma(s(b)).$$

Let $(s \circ r, \theta) : \mathcal{U} \to \mathcal{W}$ *be their composite displayed refinement from Definition 151.183, where* $\theta_a : \alpha(a) \leq_{\mathcal{T}} \gamma(s(r(a)))$ *is the composite inclusion. If* $\sigma_c : \mathsf{Sec}(\gamma(c))$ *is a compatible carried local family over* $\mathcal{W}$*, define the two-stage pullback by*

$$\tau_b := \rho_{\gamma(s(b)),\beta(b)}(\sigma_{s(b)}), \qquad \upsilon_a := \rho_{\beta(r(a)),\alpha(a)}(\tau_{r(a)}),$$

and define the direct composite pullback by

$$\zeta_a := \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

Then the section classifier on the refined member classifies the two pullbacks together:

$$\forall a : A, \qquad \upsilon_a \sim_{\alpha(a)} \zeta_a.$$

Moreover, the two-stage family υ_a *is compatible over* $\mathcal{U}$*.*

Proof. The composite refinement is obtained by composing the displayed inclusion rows. For each $a : A$, the refinement (r, ϵ) supplies $\epsilon_a : \alpha(a) \leq_{\mathcal{T}} \beta(r(a))$, and the refinement (s, η) supplies $\eta_{r(a)} : \beta(r(a)) \leq_{\mathcal{T}} \gamma(s(r(a)))$. Their transitive composite is the inclusion $\theta_a : \alpha(a) \leq_{\mathcal{T}} \gamma(s(r(a)))$ used by the one-step pullback along $s \circ r$.

Since σ_c is compatible over $\mathcal{W}$, Definition 151.175 applied to (s, η) gives compatibility of the pulled-back family τ_b over $\mathcal{V}$. Applying the same theorem to (r, ϵ) and the compatible family τ_b gives compatibility of υ_a over $\mathcal{U}$.

It remains to identify the two descriptions of the member at a. Expanding the definitions gives

$$\upsilon_a = \rho_{\beta(r(a)),\alpha(a)}\big(\rho_{\gamma(s(r(a))),\beta(r(a))}(\sigma_{s(r(a))})\big),$$

while the direct composite pullback is

$$\zeta_a = \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

These are the two restriction routes along the same chain

$$\alpha(a) \leq_{\mathcal{T}} \beta(r(a)) \leq_{\mathcal{T}} \gamma(s(r(a))).$$

The composition row of the indexed section presheaf carrier in Definition 151.154 compares the iterated restriction with the direct restriction in the target classifier $\sim_{\alpha(a)}$:

$$\rho_{\beta(r(a)),\alpha(a)}\big(\rho_{\gamma(s(r(a))),\beta(r(a))}(\sigma_{s(r(a))})\big) \sim_{\alpha(a)} \rho_{\gamma(s(r(a))),\alpha(a)}(\sigma_{s(r(a))}).$$

Substituting the definitions of υ_a and ζ_a gives $\upsilon_a \sim_{\alpha(a)} \zeta_a$ for every $a : A$. Thus pullback along the refinement tower and pullback along the composite refinement determine the same carried section class on each refined member. □

Definition 151.192 (Sheaf restricted common-refinement ledger)**.** *Let $\mathcal{T}$ be a* BHist*-scoped indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$*, let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$, and fix an open index i :* OpenIx*. Work in the restricted-open carrier $\mathcal{S}|_i$ of Definition 151.236. For a restricted target (j, η_j), let*

$$\mathcal{U}_{|i} = (A, \iota, \eta^{\iota}, h, \gamma), \qquad \mathcal{V}_{|i} = (B, \kappa, \eta^{\kappa}, q, \delta)$$

be two indexed open covers of (j, η_j), where each $\eta^{\iota}_a : \iota(a) \leq_{\mathcal{T}} i$ and $\eta^{\kappa}_b : \kappa(b) \leq_{\mathcal{T}} i$ records that the member lies below the fixed open i. A restricted common-refinement ledger from $\mathcal{U}_{|i}$ to $\mathcal{V}_{|i}$ is a tuple

$$\mathcal{W}_{|i} = (C, \lambda, \eta^{\lambda}, r, s, \epsilon, \zeta, \omega)$$

such that C is an indexing type, $\lambda : C \to$ OpenIx *is an indexed-open family, every $\eta^{\lambda}_c : \lambda(c) \leq_{\mathcal{T}} i$ lies below the fixed open, $r : C \to A$ and $s : C \to B$ choose members of the two covers, and*

$$\epsilon_c : \lambda(c) \leq_{\mathcal{T}} \iota(r(c)), \qquad \zeta_c : \lambda(c) \leq_{\mathcal{T}} \kappa(s(c))$$

for every $c : C$. The row ω says that λ is an indexed open cover of j, with member inclusions obtained by composing through either displayed leg and with pointwise cover law over $\mathsf{OpenAt}(j, x)$*.*

Thus the ledger is a displayed common-refinement span entirely inside the slice below i: all carrier rows are restricted indices, all maps are inherited restrictions of $\mathcal{S}$, and all comparisons are made by the section classifiers of Definition 151.236.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinementLedger`

Theorem 151.193 (Sheaf restricted common-refinement pullback compatibility)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let $\mathcal{U}_{|i}$ and $\mathcal{V}_{|i}$ be restricted covers of a restricted target (j, η_j), and let $\mathcal{W}_{|i}$ be a restricted common-refinement ledger between them in the sense of Definition 151.192. If*

$$u_a : \mathsf{Sec}_{|i}(\iota(a), \eta_a^\iota)$$

is compatible over $\mathcal{U}_{|i}$ and

$$v_b : \mathsf{Sec}_{|i}(\kappa(b), \eta_b^\kappa)$$

is compatible over $\mathcal{V}_{|i}$, then their pullbacks to the restricted common refinement are compatible families over $\mathcal{W}_{|i}$. Moreover, if the displayed comparison

$$\forall c : C, \quad \rho^{|i}_{(\iota(r(c)),\eta^\iota_{r(c)}),(\lambda(c),\eta^\lambda_c)}(u_{r(c)}) \sim_{|i,(\lambda(c),\eta^\lambda_c)} \rho^{|i}_{(\kappa(s(c)),\eta^\kappa_{s(c)}),(\lambda(c),\eta^\lambda_c)}(v_{s(c)})$$

holds on $\mathcal{W}_{|i}$, then it is the same comparison as the ambient common-refinement comparison after forgetting only the witnesses to i.

Proof. Unfold the restricted carrier using Definition 151.236. The restricted section carriers and classifiers at $\iota(a)$, $\kappa(b)$, and $\lambda(c)$ are exactly the ambient carriers and classifiers at those open indices, and the restricted restriction maps are the ambient maps ρ.

The restricted ledger of Definition 151.192 forgets to a displayed common-refinement span in the ambient sheaf. By Definition 151.187, its two projections are displayed refinements through $\mathcal{U}$ and $\mathcal{V}$.

Apply the pullback part of the ambient refinement exactness surface to each projection. Equivalently, read Definition 151.184 with the identity tower on the displayed span: the pulled-back families are compatible over the common refinement, and the two-step and one-step restriction descriptions agree by classifier equality.

Finally, Definition 151.237 identifies the restricted restriction composition and classifier transport rows with the ambient ones. Therefore the displayed equality in the restricted carrier is exactly the ambient equality on the same local sections, with the witnesses η^λ_c recording only that the comparison remains below i. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinement pullback compatibility`

Theorem 151.194 (Sheaf restricted common-refinement gluing invariance)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let $\mathcal{U}_{|i}$ and $\mathcal{V}_{|i}$ be restricted covers of a restricted target (j, η_j), and let $\mathcal{W}_{|i}$ be a restricted common-refinement ledger between them. Let u_a and v_b be compatible local families over those two restricted covers. Suppose their pullbacks to $\mathcal{W}_{|i}$ agree:*

$$\forall c : C, \quad \rho^{|i}_{(\iota(r(c)),\eta^\iota_{r(c)}),(\lambda(c),\eta^\lambda_c)}(u_{r(c)}) \sim_{|i,(\lambda(c),\eta^\lambda_c)} \rho^{|i}_{(\kappa(s(c)),\eta^\kappa_{s(c)}),(\lambda(c),\eta^\lambda_c)}(v_{s(c)}).$$

If $g : \mathsf{Sec}_{|i}(j, \eta_j)$ glues u_a over $\mathcal{U}_{|i}$ and $h' : \mathsf{Sec}_{|i}(j, \eta_j)$ glues v_b over $\mathcal{V}_{|i}$, then

$$g \sim_{|i,(j,\eta_j)} h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedCommonRefinement gluing invariance`

Proof. First forget the target witnesses to i. By Definition 151.236, the two restricted covers become ambient indexed covers of j, the local families are the same ambient section families, and the displayed gluings are ambient gluing rows.

The common-refinement ledger becomes the ambient displayed span required by Definition 151.187. The agreement hypothesis is the ambient pullback comparison, because the restricted classifier at $(\lambda(c), \eta_c^\lambda)$ is $\sim_{\lambda(c)}$.

Apply Definition 151.188 to the two ambient covers, the ambient span, the two compatible families, their pullback comparison, and the two gluing rows. This gives $g \sim_j h'$ in the ambient sheaf.

Return to the slice below i. The classifier at the restricted target (j, η_j) is $\sim_j$, so the ambient conclusion is exactly the displayed restricted classifier equality. The locality and gluing rows used in this passage are the restricted rows of Definition 151.238 read through the carrier identification. □

Theorem 151.195 (Sheaf restricted-open refinement exactness export)**.** *For every fixed open index i : OpenIx, the restricted-open carrier $\mathcal{S}|_i$ exports the local cover-presentation exactness surface consumed by $\mathsf{RingedSpace}^\uparrow$ and $\mathsf{Scheme}^\uparrow$. Its rows are:*

1. *restricted carrier, classifier, and restriction laws from Definition 151.236 and Definition 151.237;*
2. *restricted locality and gluing for covers below i from Definition 151.238;*
3. *restricted common-refinement ledgers below i from Definition 151.192;*
4. *pullback compatibility over a restricted common refinement from Definition 151.193;*
5. *classifier equality of restricted gluings whose pulled-back families agree from Definition 151.194.*

The exported surface is local in the fixed open i, uses no host powerset equality of covers, and introduces no quotient comparison between cover presentations.

Proof. The first two rows are already established by the restricted-open surface. Apply Definition 151.236 to identify the carriers, classifiers, and inherited restriction maps, then apply Definition 151.237 and Definition 151.238 for the restriction, locality, and gluing fields.

The third row is the ledger of Definition 151.192. It is exactly the ambient displayed common-refinement span of Definition 151.187, equipped with witnesses that every member remains below the fixed open i.

For compatibility, use Definition 151.193. The proof of that theorem reads the ambient refinement pullback composition row Definition 151.184 through the restricted carrier, so the local consumers see compatible pulled-back families without leaving the slice.

For presentation independence, use Definition 151.194. It is the restricted form of Definition 151.188: two displayed gluings of compatible families with equal pullbacks to the restricted common refinement become classifier-equal at (j, η_j).

Combining these rows gives the local exactness surface required by ringed-space and scheme certificates. Every row is expressed in indexed opens, restricted inclusion witnesses, inherited restrictions, and section classifiers, so the export remains inside the BEDC sheaf certificate surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenRefinement exactness export`

151.10 Downstream consumption boundary

Definition 151.196 (Sheaf downstream consumption boundary)**.** *The downstream consumption boundary exported by $\mathsf{Sheaf}^\uparrow$ to $\mathsf{RingedSpace}^\uparrow$ and $\mathsf{Scheme}^\uparrow$ is the following ten-field boundary.*

1. *The traditional target is an open-indexed sheaf of sections over an indexed open topology carrier.*

2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* $\mathsf{NameCert}$.
3. *The carrier row is the indexed section presheaf carrier of Definition 151.154.*
4. *The classifier row is the section classifier family* $\sim_i$ *on* $\mathsf{Sec}(i)$ *from the same carrier.*
5. *The locality and gluing rows are the indexed-cover compatibility, locality, and gluing fields of Definition 151.155.*
6. *The cover ledger is the indexed cover row: cover indices, cover-member maps, inclusion witnesses, pointwise cover membership, and finite-intersection overlap rows.*
7. *The refinement ledger is the displayed refinement, refinement-tower, and common-refinement surface used by Definition 151.189.*
8. *The restricted-open ledger is the slice carrier and its inherited restriction, locality, and gluing rows from Definition 151.239.*
9. *The base-change ledger is the displayed base-change square and its cover-pullback, gluing-pullback, and common-refinement rows from Definition 151.208.*
10. *The exactness row is cover presentation exactness together with restricted common-refinement invariance, and no standard bridge is attached to this boundary.*

This boundary is the only sheaf-side interface available to downstream chapters: it names indexed sections, section classifiers, displayed cover rows, displayed refinements, restricted opens, and displayed base change, but it does not import a host-space model of sheaves.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDownstreamConsumptionBoundary`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafUp StdBridge`

Theorem 151.197 (Ringed-space consumption obligation)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *certificate consumes exactly the* $\mathsf{Sheaf}^{\uparrow}$ *carrier, section classifier, restriction stability, cover-gluing exactness, restricted-open surface, and base-change surface listed in Definition 151.196, together with the* $\mathsf{CommRing}^{\uparrow}$ *rows asserting that the section carriers and stalk rows carry commutative-ring structure. On the sheaf side, every row required by* $\mathsf{RingedSpace}^{\uparrow}$ *is one of:*

1. *the indexed section carriers* $\mathsf{Sec}(i)$ *and classifiers* $\sim_i$*;*
2. *restriction identity, restriction composition, and restriction classifier transport;*
3. *locality, gluing, and cover-presentation exactness for indexed covers;*
4. *the restricted-open surface below a named open;*
5. *the displayed base-change surface for inverse-image and cover-pullback rows.*

No further sheaf row is needed to state the paper-side ringed-space certificate boundary.

Proof. The carrier and classifier rows are the first projections of the $\mathsf{Sheaf}^{\uparrow}$ boundary. They are the section carriers and section classifiers of Definition 151.154, while restriction identity, restriction composition, and classifier transport are the stability rows already exported in Definition 151.168.

For local ringed-space data, restrict the sheaf to each displayed open. The required open-local carrier, classifier, restriction, locality, gluing, and no-bridge rows are exactly the restricted-open surface of Definition 151.239.

For inverse-image or change-of-base comparisons, use the displayed base-change surface of Definition 151.208. The remaining rows mentioned in the statement are the commutative-ring and stalk rows supplied on the $\mathsf{CommRing}^{\uparrow}$ side; they do not ask $\mathsf{Sheaf}^{\uparrow}$ for any host powerset equality, cover quotient, external sheaf model, or standard bridge. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRingedSpaceConsumption obligation`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer chart endpoint classifier`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer RingedSpace boundary rows`

Theorem 151.198 (Scheme consumption obligation)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *certificate consumes the same* $\mathsf{Sheaf}^{\uparrow}$ *downstream boundary only through a cover by affine or ringed-space charts and the* $\mathsf{CommRing}^{\uparrow}$ *spectra rows attached to those charts. Concretely, each chart reads the sheaf rows through Definition 151.197; compatibility across chart overlaps uses the cover-presentation exactness and common-refinement gluing invariance rows of* $\mathsf{Sheaf}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeConsumption obligation`

Proof. On each affine or ringed-space chart, apply Definition 151.197. This identifies the sheaf-side data available to the chart as the carrier, classifier, restriction stability, cover-gluing exactness, restricted-open surface, and base-change surface in Definition 151.196.

On overlaps between charts, compare the two displayed cover presentations through a displayed common refinement. The equality of glued section classes is supplied by Definition 151.189, and the comparison of two gluings after passing to a common refinement is supplied by Definition 151.188.

The affine and spectra content is therefore external to the sheaf boundary: it comes from the ringed-space chart and $\mathsf{CommRing}^{\uparrow}$ spectra rows. The sheaf chapter contributes only the displayed indexed-cover, restricted-open, and base-change rows already enumerated in the boundary. □

Theorem 151.199 (Sheaf downstream consumption exhaustion)**.** *Every* $\mathsf{Sheaf}^{\uparrow}$ *row used by* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$ *in the two downstream consumption obligations is one of the rows in Definition 151.196. Consequently, the downstream chapters import no host powerset equality of opens, no quotient of cover presentations, no external sheaf model, and no bridge closure from* $\mathsf{Sheaf}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumption joint exhaustion`

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, inspect Definition 151.197. Its sheaf-side rows are precisely the carrier, classifier, restriction-stability, cover-gluing, restricted-open, and base-change entries of Definition 151.196. The commutative-ring and stalk rows named there are not sheaf rows.

For $\mathsf{Scheme}^{\uparrow}$, inspect Definition 151.198. Each chart first passes through the ringed-space consumption obligation, and every overlap comparison is discharged by cover-presentation exactness or common-refinement gluing invariance, both already included in the boundary's refinement and exactness rows.

Thus the union of sheaf rows consumed by the two downstream chapters is exhausted by the ten-field boundary. Since the boundary itself excludes host powerset equality, cover quotients, external sheaf models, and standard bridges, none of those structures is imported downstream through $\mathsf{Sheaf}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumption boundary joint exhaustion`

Definition 151.200 (Sheaf BHist triple-overlap route ledger)**.** *Let* $\mathcal{T}$ *be an indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$ *on* BHist *with membership predicate* OpenAt*, history classifier* hsame*, and finite-intersection operation* $\wedge_{\mathsf{Topology}^{\uparrow}}$*. Let* $\mathcal{S}$ *be an indexed sheaf carrier over* $\mathcal{T}$*, and let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an indexed open cover of* $i : \mathsf{OpenIx}$*. For* $a, b, c : A$*, write*

$$k_{a,b} := \iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b), \qquad \ell_{a,b,c} := k_{a,b} \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c).$$

The BHist *triple-overlap route ledger of* $\mathcal{U}$ *is the subledger of Definition 151.160 whose rows are the member rows for* $\iota(a)$*,* $\iota(b)$*, and* $\iota(c)$*, the pair-overlap row* $k_{a,b}$*, the triple-overlap row* $\ell_{a,b,c}$*, the displayed projections from* $\ell_{a,b,c}$ *to each participating member through the available finite-intersection routes, the induced restriction maps into* $\mathsf{Sec}(\ell_{a,b,c})$*, and any optional* Cont *histories that certify equality of displayed route witnesses. Membership transport along the row is only the visible* hsame *transport on* BHist *cells:*

$$\mathsf{OpenAt}(\ell_{a,b,c}, x) \wedge_{\mathsf{Topology}^{\uparrow}} x\mathsf{hsame}y \Longrightarrow \mathsf{OpenAt}(\ell_{a,b,c}, y).$$

The ledger records route data, restriction targets, section classifiers, and BHist *provenance. It does not add a quotient of cover presentations or a host-level equality between overlap routes.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRouteLedger`

Theorem 151.201 (Sheaf BHist triple-overlap route coherence)**.** *Let* $\mathcal{T}$*,* $\mathcal{S}$*, and* $\mathcal{U}$ *be as in Definition 151.200. For every* $a, b, c : A$*, every section* $s : \mathsf{Sec}(\iota(a))$*, and every two displayed routes from* $\iota(a)$ *to* $\ell_{a,b,c}$ *in the triple-overlap route ledger, the two induced restrictions have the same classifier at the triple-overlap row:*

$$\rho_{k_{a,b},\ell_{a,b,c}}(\rho_{\iota(a),k_{a,b}}(s)) \sim_{\ell_{a,b,c}} \rho_{\iota(a),\ell_{a,b,c}}(s).$$

The same conclusion holds for the routes beginning at $\iota(b)$ *and* $\iota(c)$ *whenever the corresponding projection route is displayed. Optional* Cont *histories compare only the route witnesses; they do not change the target carrier* $\mathsf{Sec}(\ell_{a,b,c})$ *or the classifier* $\sim_{\ell_{a,b,c}}$*.*

Proof. Unfold the triple-overlap route ledger. Its routes are the pair-overlap and triple-overlap projection rows already present in the cover nerve ledger of Definition 151.160, with projections read by Definition 151.161.

Apply Definition 151.304 to the displayed chain $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b} \leq_{\mathcal{T}} \iota(a)$. The two-step restriction and the direct displayed restriction land in the same carrier $\mathsf{Sec}(\ell_{a,b,c})$ and are compared by $\sim_{\ell_{a,b,c}}$.

The arguments for $\iota(b)$ and $\iota(c)$ are the same after choosing the displayed finite-intersection projection route from the ledger. If a Cont history is attached, the cited route-stability theorem treats it as route provenance, so the classifier comparison at $\ell_{a,b,c}$ is unchanged. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger triple overlap route coherence`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRoute coherence`

Theorem 151.202 (Sheaf BHist triple-overlap compatible-family descent)**.** *Let* $\mathcal{T}$*,* $\mathcal{S}$*, and* $\mathcal{U}$ *be as in Definition 151.200. If* $s_a : \mathsf{Sec}(\iota(a))$ *is compatible over* $\mathcal{U}$*, then for every* $a, b, c : A$ *the three restrictions of the local family to* $\ell_{a,b,c}$ *lie in one classifier class:*

$$\rho_{\iota(a),\ell_{a,b,c}}(s_a) \sim_{\ell_{a,b,c}} \rho_{\iota(b),\ell_{a,b,c}}(s_b), \qquad \rho_{\iota(a),\ell_{a,b,c}}(s_a) \sim_{\ell_{a,b,c}} \rho_{\iota(c),\ell_{a,b,c}}(s_c).$$

Thus every compatible family descends from pair-overlap compatibility to a coherent triple-overlap row inside the BHist *cover nerve.*

Proof. Start with pair-overlap compatibility from Definition 151.161. It gives the classifier equality between the restrictions of s_a and s_b on $k_{a,b}$.

Restrict that equality along $\ell_{a,b,c} \leq_{\mathcal{T}} k_{a,b}$. By Definition 151.304, the transported equality is the same as the direct comparison of the two route restrictions to $\ell_{a,b,c}$. The route-coherence theorem Definition 151.201 identifies the composed and direct displays.

For the comparison with s_c, use the pair-overlap rows for (a, c) and (b, c) and pull them to the displayed triple-overlap row. The finite-intersection projections and route-history clauses are those of Definition 151.200, so all comparisons land in $\sim_{\ell_{a,b,c}}$ on the single carrier $\mathsf{Sec}(\ell_{a,b,c})$. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger cover descent exhaustion`

Theorem 151.203 (Sheaf BHist triple-overlap downstream exactness)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback constructions may cite the triple-overlap route ledger as a closed three-face overlap package. For every accepted* BHist *cover row, the package consists of:*

1. *the triple-overlap index* $\ell_{a,b,c} = (\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(c)$ *and its* OpenAt *membership rows, transported only by* hsame*;*
2. *the one-step and two-step restriction routes into* $\mathsf{Sec}(\ell_{a,b,c})$*, with optional* Cont *histories;*
3. *the classifier coherence rows of Definition 151.201 and Definition 151.202;*
4. *the restricted-open exactness rows consumed below a fixed open.*

Consequently a consumer below a fixed open i *can pull the triple-overlap route package through restricted common refinements without reconstructing pairwise compatibility from prose and without adding a host cover quotient.*

Proof. The first three rows are read directly from Definition 151.200, Definition 151.201, and Definition 151.202. They are all internal to BHist cells, indexed opens, restriction maps, and section classifiers.

For passage through a refinement, apply Definition 151.184. It identifies the one-step and two-step descriptions of pulled-back local sections, so the triple-overlap route comparisons survive along displayed refinement towers.

For consumers working below a fixed open, apply Definition 151.195. Its restricted common-refinement surface is the same ambient carrier, restriction, classifier, and gluing data with the additional witness that every index remains below the fixed open.

Combining these with Definition 151.304 gives the advertised downstream package. The conclusion is a reusable exactness row for three-face overlap routes; it introduces no new carrier beyond the existing cover nerve ledger and no comparison other than hsame on histories and $\sim_{\ell_{a,b,c}}$ on sections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistTripleOverlapRoute downstream exactness`

151.11 Displayed base change surface

Definition 151.204 (Sheaf displayed base-change square)**.** *Let* $\mathcal{T}$ *and* $\mathcal{T}'$ *be indexed open topology carriers, and let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over* $\mathcal{T}$*. A displayed base-change square from* $\mathcal{T}'$ *to* $\mathcal{T}$ *consists of:*

1. *a map of indexed open carriers* $f : \mathsf{OpenIx}' \to \mathsf{OpenIx}$ *preserving finite intersections, cover ledgers, and inclusion rows;*
2. *a target open* $i : \mathsf{OpenIx}$ *and a source open* $i' : \mathsf{OpenIx}'$*;*
3. *a displayed inverse-image row saying that* $f^{-1}(i)$ *is represented by* i' *in the source carrier;*
4. *for every indexed cover* $\mathcal{U} = (A, \iota, h, \gamma)$ *of* i*, a displayed pulled-back cover* $\mathcal{U}' = (A, \iota', h', \gamma')$ *of* i' *with the same index type* A*;*
5. *for every* $a : A$*, a carrier row identifying* $f(\iota'(a))$ *with* $\iota(a)$ *below* i*, together with the induced restriction path from* i' *to* $\iota'(a)$*.*

The square is displayed: it records the index map, the represented inverse image, and the memberwise cover pullback without replacing the indexed-open carrier by a powerset model or adding a quotient of covers.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDisplayedBaseChangeSquare`

Theorem 151.205 (Sheaf base-change cover-pullback compatibility)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over $\mathcal{T}$, and let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square as in Definition 151.204. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i, let $\mathcal{U}' = (A, \iota', h', \gamma')$ be its displayed pulled-back cover of i', and let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$. Then the pulled-back local family*

$$u'_a := \rho_{\iota(a), f(\iota'(a))}(u_a)$$

is compatible over the displayed cover $\mathcal{U}'$ after the carrier identification $f(\iota'(a)) \cong \iota(a)$ supplied by the square.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change cover pullback`

Proof. Unfold compatibility over $\mathcal{U}'$. For two members $a, b : A$, the source overlap is represented by the finite intersection of $\iota'(a)$ and $\iota'(b)$ in $\mathcal{T}'$.

The base-change square preserves finite intersections, so applying f sends this source overlap to the target overlap of $\iota(a)$ and $\iota(b)$ below i. The displayed carrier rows identify the two restriction paths from $\iota(a)$ and $\iota(b)$ to that target overlap with the images of the corresponding source paths.

Use the compatibility row for u_a and u_b on the target overlap. Restriction composition in the indexed sheaf carrier transports this equality along the displayed source paths, and restriction classifier transport replaces each transported section by the displayed pullback u'_a and u'_b. This is exactly the required compatibility row over $\mathcal{U}'$. □

Theorem 151.206 (Sheaf base-change gluing pullback)**.** *Let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square from Definition 151.204. Let $\mathcal{U}$ be an indexed cover of i and let $\mathcal{U}'$ be its displayed pulled-back cover of i'. Suppose $u_a : \mathsf{Sec}(\iota(a))$ is compatible over $\mathcal{U}$ and $g : \mathsf{Sec}(i)$ glues u_a over $\mathcal{U}$:*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} u_a.$$

Then the displayed pullback $g' := \rho_{i,f(i')}(g)$ glues the pulled-back family u'_a over $\mathcal{U}'$ after transporting along the represented inverse-image row $f^{-1}(i) \simeq i'$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger base change gluing pullback`

Proof. Fix $a : A$. The gluing row for g restricts g from i to $\iota(a)$ and compares it with u_a.

Transport this row through the displayed base-change square. The inverse-image row represents the source target by i', and the member row represents the pulled-back member by $\iota'(a)$. Restriction composition identifies the path from g' to $\iota'(a)$ with the target path from g through $\iota(a)$ followed by the displayed carrier transport.

Apply restriction classifier transport to the original gluing equality along that path. The right-hand side is precisely the displayed pulled-back section u'_a, and the left-hand side is the restriction of g' to the pulled-back member. Since a was arbitrary, these rows give the displayed gluing of the pulled-back family over $\mathcal{U}'$. □

Theorem 151.207 (Sheaf base-change common-refinement invariance)**.** *Let $f : \mathcal{T}' \to \mathcal{T}$ be a displayed base-change square from Definition 151.204. Let $\mathcal{U}$ and $\mathcal{V}$ be indexed cover presentations of the same target open i, with compatible families u_a and v_b. Let $\mathcal{W}$ be a displayed common refinement on which the two presentations agree:*

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

Then the displayed base-changed cover presentations over i' agree after the pulled-back displayed common refinement. Consequently their glued global classifier classes over the represented source open are the same whenever the corresponding displayed gluings exist.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange common refinement projection`

Proof. Apply Definition 151.205 to $\mathcal{U}$ and to $\mathcal{V}$. This gives compatible pulled-back families over the two displayed source covers.

Pull back the common refinement ledger $\mathcal{W}$ along the same square. Finite-intersection preservation and the memberwise carrier rows give a displayed common refinement between the two source cover presentations, with the same refinement maps r and s on indices.

Transport the target equality on $\mathcal{W}$ along this pulled-back common refinement. Restriction composition and classifier transport identify the transported rows with the two source pulled-back families restricted to the pulled-back refinement members.

Now apply Definition 151.189 to the two source cover presentations and their pulled-back common refinement. It returns equality of the global classifier classes determined by the two displayed gluings over i'. □

Theorem 151.208 (Sheaf base-change NameCert obligation surface)**.** *For every displayed base-change square of indexed open carriers, the $\mathsf{Sheaf}^{\uparrow}$ base-change surface supplies the following $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation rows for downstream ringed-space and scheme consumers.*

1. *carrier: the restricted-open carrier of Definition 151.236, read at the represented source open i';*
2. *classifier: the inherited sheaf classifier $\sim_j$ on every displayed source open below i';*
3. *stability: restriction identity, composition, classifier transport, and restricted-open stability from Definition 151.239, together with cover-pullback compatibility from Definition 151.205;*
4. *ledger: the base-change square of Definition 151.204, its displayed cover pullback rows, pulled-back common refinements, and the refinement ledgers used by Definition 151.175;*
5. *exactness: gluing pullback from Definition 151.206, refinement gluing descent from Definition 151.176, and common-refinement invariance from Definition 151.207 together with Definition 151.189;*
6. *standard bridge: absent, as in Definition 151.239.*

Thus base change is exposed as a paper-side obligation surface on indexed opens, not as a host-space powerset construction, and downstream certificates can cite it for cover pullback, gluing pullback, and common-refinement invariance.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange name certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange obligation surface`

Proof. The carrier and classifier rows are inherited from Definition 151.236. The represented source open i' determines the same fixed-open slice used by restricted-open consumers, so no new section carrier or classifier is introduced.

The stability and ledger rows are exactly the displayed data of Definition 151.204. Cover members, overlaps, and refinement maps remain indexed rows, while Definition 151.239 supplies the ambient restricted-open stability and Definition 151.175 supplies refinement pullback inside the ledger.

The exactness row combines the three base-change obligations. Cover-pullback compatibility is Definition 151.205; gluing pullback is Definition 151.206; common-refinement invariance is Definition 151.207, with Definition 151.176 and Definition 151.189 providing the existing sheaf exactness rows that the surface reuses.

Finally, the restricted-open surface already records that no standard bridge is attached. The base-change square only displays how indexed rows move across source and target opens, so it adds no bridge row and remains a paper-side $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface for downstream certificates. □

151.12 Sheaf base-change functoriality

Definition 151.209 (Sheaf composable base-change squares)**.** *Let $\mathcal{T}$, $\mathcal{T}'$, and $\mathcal{T}''$ be indexed open topology carriers, and let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over $\mathcal{T}$. Let*

$$\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$$

be displayed base-change squares in the sense of Definition 151.204. The two squares are composable when the following rows assemble into the displayed square $\mathcal{T}'' \to \mathcal{T}$:

1. *the open-index map is the composite $f \circ g$ and preserves finite intersections by composing the finite-intersection rows of g and f;*
2. *the represented inverse-image row for a target open i identifies the source open i'' with the two-step inverse image obtained first in $\mathcal{T}'$ and then in $\mathcal{T}''$;*
3. *cover ledgers compose pointwise: an indexed cover $\mathcal{U}$ of i pulls back to a cover $\mathcal{U}'$ of i' and then to a cover $\mathcal{U}''$ of i'' with the same index type and the same member order;*
4. *inclusion rows compose from each member $\iota''(a)$ through $\iota'(a)$ to $\iota(a)$, and the route to the target open is the composite of the two displayed routes;*
5. *memberwise pullback rows for sections, overlaps, and common-refinement members are classifier-equal to the corresponding rows read directly along the composite square.*

Thus a composable pair is not extra carrier data. It is the assertion that the displayed index maps, inverse-image representatives, finite-intersection rows, cover ledgers, inclusion rows, and memberwise pullback rows form the same downstream-readable base-change surface as the one-step square.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafComposableBaseChangeSquares`

Theorem 151.210 (Sheaf base-change identity square neutrality)**.** *For an indexed sheaf carrier $\mathcal{S}$ over $\mathcal{T}$, the identity displayed base-change square on $\mathcal{T}$ preserves the cover, restriction, gluing, and common-refinement rows of Definition 151.208. In particular, reading the $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ obligation surface through the identity square gives the same indexed cover members, overlap witnesses,*

restriction composites, displayed gluing rows, and common-refinement comparisons as reading the surface directly.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChangeIdentitySquare restriction neutrality`

Proof. The identity square uses the identity map on open indices. Its inverse-image representative for an open i is i itself, and its displayed cover pullback sends each cover member $\iota(a)$ to the same indexed member with the same inclusion row.

Cover compatibility follows because the overlap of two unchanged members is the original finite intersection. Restriction identity in the indexed section carrier identifies each pulled-back local section with the section already present in the target cover ledger.

For gluing, Definition 151.206 specializes to the identity restriction path. The displayed row is therefore classifier-equal to the original gluing row by restriction identity and classifier reflexivity.

For common refinements, the displayed span, the refinement maps, and the member inclusions are unchanged. Applying Definition 151.207 along the identity square returns the same comparison row, and Definition 151.189 reads the same global classifier class. □

Theorem 151.211 (Sheaf base-change cover-pullback composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i in $\mathcal{T}$. Pulling $\mathcal{U}$ through the composite square gives the same cover-member witnesses, member inclusion routes, finite-intersection overlap rows, and compatible local-family rows as pulling $\mathcal{U}$ first through f and then through g, up to the classifier identifications recorded by the composable-square rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change composition`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger base change cover pullback composition`

Proof. Start with a compatible family over $\mathcal{U}$. Apply Definition 151.205 to the square f. This gives a compatible displayed family over the pulled-back cover $\mathcal{U}'$ in $\mathcal{T}'$.

Apply the same theorem to g and the compatible family over $\mathcal{U}'$. The result is a compatible family over the two-step cover $\mathcal{U}''$ in $\mathcal{T}''$.

By Definition 151.209, the composite square has the same cover index type A, the same displayed member order, and the same member inclusion route as the two-step cover ledger. Its finite-intersection preservation row is the composite of the two overlap rows.

Restriction composition identifies the two-step section pullback with the direct pullback along the composite route. Classifier transport then replaces the two-step overlap comparisons by the one-step comparisons, so the downstream cover-pullback surface is the same in both readings. □

Theorem 151.212 (Sheaf base-change gluing pullback composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U}$ be an indexed cover of i and let u_a be a compatible local family glued by $s : \mathsf{Sec}(i)$. The displayed gluing row transported along the composite square is classifier-equal to the row obtained by first transporting the gluing row along f and then transporting the resulting row along g.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger base change gluing pullback composition`

Proof. Apply Definition 151.206 to f. It transports the gluing row for s to a displayed gluing row over the cover pulled back to $\mathcal{T}'$.

Apply Definition 151.206 again to g. This transports the intermediate gluing row to the two-step pulled-back cover over $\mathcal{T}''$.

The composability rows identify the source open of the one-step composite square with the two-step represented inverse image. They also identify each pulled-back cover member and member inclusion route with the corresponding two-step member route.

Restriction composition in the sheaf carrier identifies the restriction of s along the composite route with the successive restrictions through the intermediate open. Classifier transport along the displayed member identifications converts the two-step gluing comparison into the direct composite-square comparison, giving the claimed classifier equality of gluing rows. □

Theorem 151.213 (Sheaf base-change common-refinement composition)**.** *Let $\mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$ be composable displayed base-change squares from Definition 151.209. Let $\mathcal{U}$ and $\mathcal{V}$ be indexed cover presentations of i whose compatible local families agree on a displayed common refinement. The common-refinement comparison obtained after pulling through the composite square agrees with the comparison obtained after successive pullbacks through f and g. Consequently the global classifier class supplied by Definition 151.189 is independent of whether downstream consumers read the composite square in one step or as the two displayed squares.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan base change composition`

Proof. Apply Definition 151.207 to f. This produces pulled-back cover presentations over $\mathcal{T}'$ and transports the displayed common-refinement comparison to the intermediate common refinement.

Apply the same theorem to g. The intermediate comparison becomes a comparison over the two-step pulled-back common refinement in $\mathcal{T}''$.

The composable-square definition identifies the one-step pulled-back covers, refinement maps, member inclusions, and finite-intersection rows with their two-step counterparts. In particular, each common-refinement member has the same downstream restriction route after composing the displayed inclusion rows.

Restriction composition and classifier transport move the two-step comparison to the direct composite comparison. Then Definition 151.189 reads either comparison as the same global classifier class over the represented source open, so the common-refinement surface is independent of the chosen displayed factorization. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBaseChange common refinement composition`

Theorem 151.214 (Sheaf base-change three-square associativity)**.** *Let*

$$\mathcal{T}''' \xrightarrow{h} \mathcal{T}'' \xrightarrow{g} \mathcal{T}' \xrightarrow{f} \mathcal{T}$$

be three displayed base-change squares for an indexed sheaf carrier $\mathcal{S}$ over $\mathcal{T}$. Assume that the adjacent pairs are composable in the sense of Definition 151.209, and that both induced pairwise composites are again composable with the remaining square. Then the two bracketed displayed composites from $\mathcal{T}'''$ to $\mathcal{T}$ determine the same downstream base-change surface. More explicitly, first composing f with g and then with h, or first composing g with h and then with f, gives the same classified rows for every pulled-back indexed cover, every pulled-back compatible family, every transported gluing row, and every pulled-back common-refinement presentation.

Proof. Fix an indexed cover $\mathcal{U} = (A, \iota, r, \gamma)$ of an open i in $\mathcal{T}$. Apply Definition 151.211 to the pair (f, g). The cover obtained over $\mathcal{T}''$ by first pulling through f and then through g has the same index type A, the same member order, the same finite-intersection overlap rows, and the same compatible-family restriction rows as the cover read through the composite square $f \circ g$. Applying

the same theorem to the resulting composite square and h identifies the left-bracketed cover over $\mathcal{T}'''$ with the three-step cover obtained by pulling through f, then g, then h.

Apply Definition 151.211 instead to the pair (g, h), and then to f together with that composite. This identifies the right-bracketed cover over $\mathcal{T}'''$ with the same three-step cover ledger: the index type is still A, the member attached to $a : A$ is the inverse-image representative obtained by the same three displayed member rows, and the inclusion route to i is the same composite of displayed inclusion routes. Associativity of ordinary composition of the displayed open-index maps and of the restriction-route concatenations identifies the two parenthesizations of that route. Hence both bracketings classify the same cover-pullback rows and the same pulled-back compatible local-family rows.

Now let u_a be a compatible family over $\mathcal{U}$ and let $s : \mathsf{Sec}(i)$ be a displayed gluing section for it. Applying Definition 151.212 to (f, g) and then to the composite with h identifies the left-bracketed gluing row with the row obtained by restricting s successively along the three displayed square routes. Applying the same theorem to (g, h) and then to f identifies the right-bracketed gluing row with that identical successive restriction row. Restriction composition in the indexed sheaf carrier removes the parentheses from the route, and classifier transport along the composable-square member identifications gives equality of the two transported gluing rows.

Finally take two indexed cover presentations of i with compatible families agreeing on a displayed common refinement. By Definition 151.213, the left bracketing has the same pulled-back refinement indices, refinement maps, member inclusions, and comparison rows as the three-step pullback. The right bracketing is identified with that same three-step common-refinement ledger by applying the same theorem in the other pairwise order. The common-refinement members therefore restrict through the same downstream routes, and Definition 151.189 reads the two transported comparisons as the same global classifier class over the represented open of $\mathcal{T}'''$. □

Definition 151.215 (Sheaf consumer trace composition source)**.** *Let T_1 and T_2 be finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces of Definition 151.244. Their consumer trace composition $T_1 \star T_2$ is the finite trace obtained by listing every constructor of T_1 in its given order and then listing every constructor of T_2 in its given order. The empty trace is a two-sided unit for this operation.*

The source of this operation is restricted to the same objects as the access trace grammar: BHist *histories,* hsame *transport, optional* Cont *route histories,* $\mathsf{Topology}^{\uparrow}$ *indexed opens,* $\mathsf{PreSheaf}^{\uparrow}$ *section carriers, and* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *rows. No constructor of $T_1 \star T_2$ may mention host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows except through the sealed consumer projections already present in Definition 151.244.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerAccessTraceCompositionSource`
Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerTraceCompositionSource`

Theorem 151.216 (Sheaf consumer trace concatenation coverage)**.** *For any finite traces T_1 and T_2 of Definition 151.244, every constructor in the composed trace $T_1 \star T_2$ of Definition 151.215 lands in the same root face or sealed consumer projection that it occupied before composition.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append membership coverage`

Proof. Proceed by the ordered list presentation of $T_1 \star T_2$.

For a constructor appearing in the first segment, apply Definition 151.245 to its occurrence in T_1. Its landing face is one of the root faces of Definition 151.271 or one of the sealed consumer projections of Definition 151.252; the concatenation operation only preserves the occurrence and its order inside the first segment.

For a constructor appearing in the second segment, apply the same coverage theorem to its occurrence in T_2. The first segment supplies no wrapper and no coercion around the second segment, so the second occurrence keeps the landing face it had before composition.

Thus every constructor in the concatenated trace has exactly the face assigned to it by the original access trace coverage theorem. □

Theorem 151.217 (Sheaf consumer trace composition no-feedback)**.** *Composing finite* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback consumer traces by Definition 151.215 creates no additional* $\mathsf{Sheaf}^{\uparrow}$ *carrier row, classifier row, exactness row, or bridge row.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append no zero extension`

Proof. First apply Definition 151.246 to the consumer constructors in T_1. Each $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, and topology pullback event reads through the sealed projection and contributes no root carrier, classifier, exactness, or bridge row.

Apply the same theorem to the consumer constructors in T_2. The composition source merely places the second trace after the first, so no event in the second segment obtains a new sheaf row from the preceding segment.

It remains to rule out feedback across the boundary between the two segments. By Definition 151.274, consumer-specific algebraic, chart, and pullback data are outside the root sheaf faces. By Definition 151.199, all allowed downstream sheaf reads have already been exhausted by the listed root rows and sealed projections.

Therefore the concatenation boundary carries only the finite order of reads. It supplies no constructor capable of manufacturing a further $\mathsf{Sheaf}^{\uparrow}$ carrier, classifier, exactness, or bridge row. □

Theorem 151.218 (Sheaf consumer trace factorization composes)**.** *Suppose two allowed downstream* $\mathsf{Sheaf}^{\uparrow}$ *accesses by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factor through finite traces* T_1 *and* T_2 *of Definition 151.244. Their sequential use factors through the composed trace* $T_1 \star T_2$ *of Definition 151.215.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger trace factorization composes`

Proof. Choose the trace $T_1 \star T_2$ by listing the constructors witnessing the first downstream access and then listing the constructors witnessing the second downstream access. This is a finite trace because both inputs are finite and the composition source is ordinary finite concatenation.

The first access factors through the first segment by the assumed factorization of T_1. The second access factors through the second segment by the assumed factorization of T_2, and the preceding segment changes only the position of the second segment in the list.

By Definition 151.216, every constructor in both segments still lands in its original root face or sealed projection. By Definition 151.217, the boundary between the two segments creates no additional sheaf row that would require another access constructor.

The sequential downstream use is therefore represented by first reading along T_1 and then reading along T_2, which is exactly the composed finite trace. □

Definition 151.219 (Sheaf cover-presentation classifier)**.** *Let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier* $\mathcal{T}$*. Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *and* $\mathcal{V} = (B, \kappa, q, \delta)$ *be indexed open covers of the same open index* $i : \mathsf{OpenIx}$*. Let* $u_a : \mathsf{Sec}(\iota(a))$ *be compatible over* $\mathcal{U}$ *and let* $v_b : \mathsf{Sec}(\kappa(b))$ *be compatible over* $\mathcal{V}$*.*

The two cover presentations $(\mathcal{U}, u)$ and $(\mathcal{V}, v)$ are classifier-equal when there exists a displayed common refinement span

$$\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$$

from $\mathcal{U}$ to $\mathcal{V}$ such that their pulled-back local families agree pointwise by the section classifiers:

$$\forall c : C, \quad \rho_{\iota(r(c)),\lambda(c)}(u_{r(c)}) \sim_{\lambda(c)} \rho_{\kappa(s(c)),\lambda(c)}(v_{s(c)}).$$

This classifier is a presentation-level row: it compares indexed covers only through displayed common refinements, restriction maps, and the already exposed section classifiers $\sim_j$.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafCoverPresentationClassifier`

Theorem 151.220 (Sheaf cover-presentation classifier soundness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$ and let $v_b : \mathsf{Sec}(\kappa(b))$ be compatible over $\mathcal{V}$. If $(\mathcal{U}, u)$ and $(\mathcal{V}, v)$ are classifier-equal in the sense of Definition 151.219, then any displayed global gluing $g : \mathsf{Sec}(i)$ of u_a and any displayed global gluing $h' : \mathsf{Sec}(i)$ of v_b satisfy*

$$g \sim_i h'.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison soundness`

Proof. Unpack the cover-presentation classifier. It supplies a displayed common refinement span $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ from $\mathcal{U}$ to $\mathcal{V}$ and a pointwise classifier equality between the two pulled-back local families over $\mathcal{W}$.

Apply Definition 151.189 to the same two covers, compatible families, displayed common refinement, pullback equality, and displayed gluings. The conclusion is exactly $g \sim_i h'$. □

Theorem 151.221 (Sheaf cover-presentation classifier symmetry)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^{\uparrow}$ over an indexed open topology carrier $\mathcal{T}$. Let $\mathcal{U} = (A, \iota, h, \gamma)$ and $\mathcal{V} = (B, \kappa, q, \delta)$ be indexed open covers of the same open index $i : \mathsf{OpenIx}$. Let $u_a : \mathsf{Sec}(\iota(a))$ be compatible over $\mathcal{U}$ and let $v_b : \mathsf{Sec}(\kappa(b))$ be compatible over $\mathcal{V}$. If $(\mathcal{U}, u)$ is classifier-equal to $(\mathcal{V}, v)$ in the sense of Definition 151.219, then $(\mathcal{V}, v)$ is classifier-equal to $(\mathcal{U}, u)$.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafCoverPresentationClassifier symmetric`
↪ variant `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan symmetric`
↪ variant `BEDC.Derived.SheafUp.SheafDisplayedCommonRefinementSpan symm`

Proof. Unpack the classifier witness. It consists of a displayed common refinement span $\mathcal{W} = (C, \lambda, r, s, \epsilon, \zeta, \omega)$ and, for every $c : C$, a classifier row from the $\mathcal{U}$-pullback to the $\mathcal{V}$-pullback.

Build the reversed displayed common refinement by keeping the same cover index C, the same open family λ, and the same cover row ω, while swapping the two projection maps and their inclusion witnesses. Thus the reversed span has projection $s : C \to B$ to $\mathcal{V}$ and projection $r : C \to A$ to $\mathcal{U}$.

For each $c : C$, apply symmetry of the section classifier on $\mathsf{Sec}(\lambda(c))$ to the original pullback equality. The resulting pointwise classifier row is exactly the equality required for the reversed cover-presentation classifier. □

Theorem 151.222 (Sheaf restricted-open cover-presentation classifier descent)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$, and fix an open index i :* OpenIx*. Let $\mathcal{S}|_i$ be the fixed-open restricted carrier of Definition 151.239. For two compatible local-family presentations over covers of i, the cover-presentation classifier of Definition 151.219 restricts to the same classifier on $\mathcal{S}|_i$: if the ambient presentations are classifier-equal by a displayed common refinement, then their restricted-open global gluings are identified by the restricted classifier on the fixed-open carrier.*

Proof. Read the restricted-open carrier through Definition 151.239. Its carrier is the fixed open section surface $\mathsf{Sec}(i)$ with the inherited classifier $\sim_i$, so a restricted-open global gluing is an ambient global gluing whose target open is fixed to i.

Use Definition 151.238 to read the locality and gluing rows of $\mathcal{S}|_i$ as the ambient sheaf locality and gluing rows over covers of the same fixed open. Thus the displayed restricted-open gluings provide exactly the gluing hypotheses required by the ambient cover-presentation comparison.

Apply Definition 151.220. Since the restricted classifier is inherited from $\sim_i$, the ambient conclusion $g \sim_i h'$ is the desired restricted-open classifier equality. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted open descent`

Definition 151.223 (Sheaf downstream root source)**.** *The downstream root source for* $\mathsf{Sheaf}^{\uparrow}$ *is the displayed certificate surface obtained by taking the indexed-open carrier of* $\mathsf{Topology}^{\uparrow}$*, the restriction carrier of* $\mathsf{PreSheaf}^{\uparrow}$*, the locality and gluing surface of* $\mathsf{Sheaf}^{\uparrow}$*, the cover-nerve ledger of Definition 151.160, the point-germ ledger of Definition 151.231, and the refinement exactness rows of Definition 151.179 and Definition 151.189.*

This source exposes only indexed opens, BHist *membership rows, restriction maps, section classifiers, compatible local-family predicates, point-germ comparisons, displayed refinements, and cover-presentation exactness. It contains no host powerset equality and no quotient of cover presentations.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafDownstreamRootSource`

Theorem 151.224 (Sheaf RingedSpace local ring row)**.** *Let $\mathcal{S}$ be an indexed* $\mathsf{Sheaf}^{\uparrow}$ *carrier over an indexed-open* $\mathsf{Topology}^{\uparrow}$ *carrier $\mathcal{T}$. Suppose each section carrier* $\mathsf{Sec}(i)$ *carries the* $\mathsf{CommRing}^{\uparrow}$ *operation rows required for a local-ring row, and suppose every restriction map $\rho_{i,j}$ preserves addition, multiplication, zero, one, unit detection, maximal-ideal detection, and the section classifier. Then the source of Definition 151.223 exposes the structure-sheaf rows consumed by* $\mathsf{RingedSpace}^{\uparrow}$*: open-indexed commutative ring sections, classifier-stable restrictions, pointwise local-ring readbacks through the point-germ ledger, and local compatibility of the section classifier.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRingedSpaceLocalRing row`

Proof. Project the downstream source of Definition 151.223. Its carrier rows are the indexed sections, classifiers, restrictions, locality and gluing fields, cover ledger, point-germ ledger, and refinement exactness rows already supplied by $\mathsf{Sheaf}^{\uparrow}$.

Use Definition 151.300 for restriction stability. The assumed operation preservation rows ride on the same restriction routes, so the ring operations and the section classifier are transported together along every inclusion $j \leq_{\mathcal{T}} i$.

For local-ring readback, use the point-germ ledger of Definition 151.231. A row (i, o_i, s) records an indexed open containing a history cell and a section over that open; comparison is performed

on a displayed common neighborhood by restriction and the section classifier. Thus unit and maximal-ideal rows are repacked as point-germ rows without forming a stalk quotient.

The resulting package has exactly the rows requested by the $\mathsf{RingedSpace}^{\uparrow}$ consumer: a structure sheaf indexed by opens, ring-preserving restrictions, classifier-stable pointwise readback, and local-ring data visible through the existing ledger rows. □

Theorem 151.225 (Sheaf Scheme gluing cover row)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be a displayed affine cover presentation of an indexed open i for an indexed $\mathsf{Sheaf}^{\uparrow}$ carrier $\mathcal{S}$. Suppose each member $\iota(a)$ carries a local ringed chart row, and suppose the chart rows are compatible on the finite-intersection overlap rows $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(b)$ after restriction of sections, local-ring operations, and section classifiers. Then the downstream root source exposes a global section classifier row consumed by $\mathsf{Scheme}^{\uparrow}$: displayed local chart sections glue to a global section over i, and any two displayed gluings determine the same global classifier class after common-refinement comparison.*

Proof. First read cover membership from Definition 151.299. Every displayed history cell of the ambient open has a cover member witness, and pairwise overlap rows are supplied by finite intersections in the $\mathsf{Topology}^{\uparrow}$ carrier.

The assumed overlap compatibility is exactly the compatible local-family predicate of Definition 151.155, with the local ringed chart rows transported by restriction. Applying Definition 151.301 gives a displayed global section and identifies any two global readbacks that agree on the cover.

Refinement descent then supplies invariance under a different displayed affine cover. Use Definition 151.176 to pass gluing along refinements, Definition 151.179 for the refined exactness row, and Definition 151.189 for common-refinement comparison.

Thus $\mathsf{Scheme}^{\uparrow}$ receives a global section classifier row assembled from cover membership, finite-intersection overlaps, locality, gluing, refinement descent, and cover-presentation exactness, with no quotient of cover presentations. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeGluingCoverRow chart trace cons readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace cons readback`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace result deterministic`

Theorem 151.226 (Sheaf topology pullback cover row)**.** *Let $f : Y \to X$ be a classifier-respecting BHist map, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover row for a $\mathsf{Sheaf}^{\uparrow}$ carrier over X. Pull the cover back through the $\mathsf{Topology}^{\uparrow}$ pullback-open rows of Definition 88.60. Then the pulled-back cover preserves cover membership, restriction stability, and compatible local-family predicates: each source history cell covered by the pulled-back ambient open has a pulled-back cover-member witness, restriction maps commute with classifier transport along the pulled-back inclusion rows, and compatible local sections remain compatible after pullback to finite-intersection overlap rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafTopologyPullbackCover membership restriction compatibility`

Proof. Start with the topology pullback-open rows. The map row for f transports source classifier witnesses to target classifier witnesses, while Definition 88.62 preserves finite intersections and Definition 88.64 preserves displayed cover unions.

Apply Definition 151.299 to the target cover row and then precompose the resulting membership witnesses with f. The pulled-back cover-member witness is the same index $a : A$, read through the pulled-back predicate of Definition 88.60.

For restrictions, use Definition 151.300. The source inclusion rows are obtained by pulling back the target inclusions, and the classifier-respecting row for f supplies the transport needed to compare the source-side section classifiers.

Finally, compatibility of local families is checked on pairwise finite-intersection overlap rows. Since finite meets commute with the displayed pullback row and restriction classifier transport is stable along the same routes, every target overlap equality pulls back to the corresponding source overlap equality. This is the compatible local-family predicate required by the downstream topology pullback consumer. □

151.13 Identity-cover root package

Definition 151.227 (Sheaf identity-cover root package)**.** *For an indexed open i in the* $\mathsf{Sheaf}^{\uparrow}$ *root-obligation surface, the identity-cover root package is the accepted one-member cover of i with cover index type* Unit *and member map $\iota : \mathsf{Unit} \to \mathsf{OpenIx}$ constantly equal to i. Its membership row is the identity row on* $\mathsf{OpenAt}(i, b)$ *for each $b : \mathsf{BHist}$, its only overlap row is the finite-intersection cell $i \wedge_{\mathsf{Topology}^{\uparrow}} i$, and its exposed restriction route is the identity restriction $\rho_{i,i}$.*

The package ledger is restricted to BHist *membership cells,* hsame *transport of those cells, the self-overlap projections for $i \wedge_{\mathsf{Topology}^{\uparrow}} i$, and the presheaf identity row identifying $\rho_{i,i}(s)$ with s in the classifier $\sim_i$. It carries no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafIdentityCoverRootPackage`

Theorem 151.228 (Sheaf identity-cover membership exactness)**.** *Let i be an indexed open and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of Definition 151.227. For every $b : \mathsf{BHist}$, the displayed membership row is exact:*

$$\mathsf{OpenAt}(i, b) \iff \exists a : \mathsf{Unit},\ \mathsf{OpenAt}(\iota(a), b).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger identity open membership cont exactness`

Proof. For the forward direction, use the unique member of Unit. Since ι is constantly i, the required displayed cover-member cell is the original cell $\mathsf{OpenAt}(i, b)$ read through the identity membership row.

For the reverse direction, destruct the displayed witness $a : \mathsf{Unit}$. The member map again reads as i, so the cover-member cell is exactly a cell of $\mathsf{OpenAt}(i, b)$.

Both directions stay inside the BHist ledger and use only hsame transport when a history cell is reindexed. No equality of ambient host covers is used. □

Theorem 151.229 (Sheaf identity-cover restriction readback)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier, and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of an indexed open i. For every section $s : \mathsf{Sec}(i)$, the restriction route exposed by $\mathcal{U}_{\mathrm{id}}$ is classifier-equal to $\rho_{i,i}(s)$ and hence classifier-equal to s by the presheaf identity row:*

$$\rho^{\mathcal{U}_{\mathrm{id}}}(s) \sim_i \rho_{i,i}(s), \qquad \rho_{i,i}(s) \sim_i s.$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIdentityCover restriction readback`

Proof. Unpack the identity-cover root package. Its only cover member is i, and the route from the ambient open to that member is the identity route, so the exposed restriction readback is the displayed route $\rho_{i,i}(s)$.

Apply the identity row of the indexed section presheaf carrier from Definition 151.154. That row identifies $\rho_{i,i}(s)$ with s in the classifier $\sim_i$.

The self-overlap cell $i \wedge_{\mathsf{Topology}^\uparrow} i$ supplies no additional restriction target; it only records the overlap ledger row already attached to the identity route. □

Theorem 151.230 (Sheaf identity-cover gluing collapse)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^\uparrow$ over an indexed open topology carrier, and let $\mathcal{U}_{\mathrm{id}}$ be the identity-cover root package of an indexed open i. A compatible local family on $\mathcal{U}_{\mathrm{id}}$ is classifier-equivalent to exactly one global section over i: gluing supplies a global readback, and locality identifies any two global readbacks whose identity-cover restrictions agree.*

Proof. First apply the gluing part of Definition 151.301 to the compatible local family over $\mathcal{U}_{\mathrm{id}}$. This produces a global section $g : \mathsf{Sec}(i)$ whose restriction to the unique cover member agrees with the displayed local section.

The agreement row is read back through Definition 151.229. Because the only exposed route is $\rho_{i,i}$ and the presheaf identity row identifies $\rho_{i,i}(g)$ with g, the local family has no separate cover presentation beyond its single global readback.

For uniqueness, take two global readbacks whose restrictions agree on the identity cover. The membership exactness row of Definition 151.228 reduces coverwise agreement to agreement on the lone Unit member, and Definition 151.229 turns that agreement into agreement of the two global sections over i.

Apply the locality part of Definition 151.301. It returns classifier equality in $\sim_i$, so the compatible local family collapses to one global section up to the section classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafIdentityCover gluing collapse`

Definition 151.231 (Sheaf BHist point-germ ledger)**.** *Let $\mathcal{T}$ be an indexed open topology carrier for $\mathsf{Topology}^\uparrow$ whose point carrier is BHist, whose membership row is OpenAt, and whose finite-intersection index is written $\wedge_{\mathsf{Topology}^\uparrow}$. Let $\mathcal{S}$ be an indexed sheaf carrier for $\mathsf{Sheaf}^\uparrow$ over $\mathcal{T}$.*

For $b : \mathsf{BHist}$, a displayed point-germ row over b is a triple

$$(i, o_i, s)$$

where $i : \mathsf{OpenIx}$, $o_i : \mathsf{OpenAt}(i, b)$, and $s : \mathsf{Sec}(i)$. Two rows (i, o_i, s) and (j, o_j, t) compare over b when there is a displayed common neighborhood $k : \mathsf{OpenIx}$ with

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad \mathsf{OpenAt}(k, b),$$

and classifier equality after restriction:

$$\rho_{i,k}(s) \sim_k \rho_{j,k}(t).$$

The point-germ ledger is the collection of these rows and comparisons, with common neighborhoods supplied by the finite-intersection rows of $\mathcal{T}$ and all section comparison performed by the classifiers $\sim_k$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger section scope`

Theorem 151.232 (Sheaf BHist point-germ carrier scope)**.** *The point-germ ledger of Definition 151.231 exposes no carrier beyond the* BHist *point row, the membership row* OpenAt*, indexed opens, finite-intersection rows, presheaf restrictions, and the section classifiers of the indexed sheaf carrier. In particular, each ledger row over* $b : \mathsf{BHist}$ *is determined by an indexed open containing* b *and a section on that open, and each comparison is determined by a displayed common neighborhood below the two opens together with one classifier equality after restriction.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger common open comparison`

Proof. Unfold the displayed point-germ row. Its components are exactly $b : \mathsf{BHist}$, an indexed open i, a membership witness $o_i : \mathsf{OpenAt}(i, b)$, and a section $s : \mathsf{Sec}(i)$.

Unfold the comparison row. It asks only for a common index k below the two source opens, a membership witness $\mathsf{OpenAt}(k, b)$, and the classifier row $\rho_{i,k}(s) \sim_k \rho_{j,k}(t)$.

The existence of a canonical common-neighborhood shape is supplied by the finite-intersection field of Definition 88.1, while restriction maps and section classifiers are exactly the rows of Definition 151.154. No host stalk, quotient carrier, or powerset equality is used by either the row data or the comparison data. □

Theorem 151.233 (Sheaf BHist point-germ restriction readback)**.** *Let* (i, o_i, s) *be a displayed point-germ row over* $b : \mathsf{BHist}$ *in the sense of Definition 151.231. If* $j \leq_{\mathcal{T}} i$ *and* $o_j : \mathsf{OpenAt}(j, b)$*, then the restricted row*

$$(j, o_j, \rho_{i,j}(s))$$

compares to the original row over the common neighborhood j*. Explicitly, the comparison is witnessed by* $j \leq_{\mathcal{T}} i$*, the identity inclusion* $j \leq_{\mathcal{T}} j$*, the membership row* o_j*, and the identity classifier row*

$$\rho_{j,j}(\rho_{i,j}(s)) \sim_j \rho_{i,j}(s).$$

Proof. The hypotheses give the restricted point-germ row: the target open is j, the visible membership witness is o_j, and the section is the ambient restriction $\rho_{i,j}(s)$.

Use j itself as the displayed common neighborhood. One projection is the given inclusion $j \leq_{\mathcal{T}} i$, the other is the identity inclusion $j \leq_{\mathcal{T}} j$, and the point witness is o_j.

It remains only to supply the classifier equality required by Definition 151.231. The identity field of Definition 151.154 applied to the section $\rho_{i,j}(s) : \mathsf{Sec}(j)$ gives $\rho_{j,j}(\rho_{i,j}(s)) \sim_j \rho_{i,j}(s)$, which is exactly the comparison row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restriction readback`

Theorem 151.234 (Sheaf BHist point-germ gluing readback)**.** *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an indexed open cover of* $i : \mathsf{OpenIx}$ *for an indexed sheaf carrier* $\mathcal{S}$ *over a* BHist*-scoped topology carrier* $\mathcal{T}$*. Suppose* $s_a : \mathsf{Sec}(\iota(a))$ *is compatible over* $\mathcal{U}$ *and* $g : \mathsf{Sec}(i)$ *is a gluing section with*

$$\forall a : A, \quad \rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a.$$

For every $b : \mathsf{BHist}$ *with* $o_i : \mathsf{OpenAt}(i, b)$*, the cover law supplies* $a : A$ *and* $o_a : \mathsf{OpenAt}(\iota(a), b)$*, and the point-germ row* (i, o_i, g) *reads back through that member:*

$$(i, o_i, g)$$

compares over b *to*

$$(\iota(a), o_a, s_a).$$

If g' is another gluing section for the same compatible local family, then locality gives $g \sim_i g'$, so the resulting point-germ readback is unique up to the same section classifier and its restrictions to displayed common neighborhoods.

Proof. Apply the cover law γ to b and o_i. It returns a cover member $a : A$ together with $o_a : \mathsf{OpenAt}(\iota(a), b)$.

Use $\iota(a)$ as the common neighborhood for the two point-germ rows. The projection $\iota(a) \leq_{\mathcal{T}} i$ is the cover inclusion h_a, the projection $\iota(a) \leq_{\mathcal{T}} \iota(a)$ is the identity inclusion, and the membership witness is o_a.

The gluing row gives $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$. Combining this with the identity restriction row $\rho_{\iota(a),\iota(a)}(s_a) \sim_{\iota(a)} s_a$, using symmetry and transitivity of the classifier on $\mathsf{Sec}(\iota(a))$, gives the comparison required by Definition 151.231.

For uniqueness, let g' be another gluing of the same compatible family. Apply Definition 151.169 to the two displayed gluing rows to obtain $g \sim_i g'$. The restriction classifier-stability field of Definition 151.154 transports this equality to any displayed common neighborhood used in the point-germ ledger, so the readback does not depend on the chosen gluing representative beyond the existing section classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger gluing readback`

Theorem 151.235 (Sheaf BHist point-germ comparison transitivity)**.** *Let (i, o_i, s), (j, o_j, t), and (ℓ, o_ℓ, u) be displayed point-germ rows over the same $b : \mathsf{BHist}$ in the sense of Definition 151.231. Suppose the first two rows compare on a displayed common neighborhood k:*

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad o_k : \mathsf{OpenAt}(k, b),$$

with

$$\alpha : \rho_{i,k}(s) \sim_k \rho_{j,k}(t),$$

and suppose the last two rows compare on a displayed common neighborhood m:

$$m \leq_{\mathcal{T}} j, \qquad m \leq_{\mathcal{T}} \ell, \qquad o_m : \mathsf{OpenAt}(m, b),$$

with

$$\beta : \rho_{j,m}(t) \sim_m \rho_{\ell,m}(u).$$

Put

$$n := k \wedge_{\mathsf{Topology}^{\uparrow}} m.$$

Then n is a displayed common neighborhood below i and ℓ at b, and the first and third rows compare there:

$$\rho_{i,n}(s) \sim_n \rho_{\ell,n}(u).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison trans`
↪ variant `BEDC.Derived.SheafUp.SheafBHistPointGermLedger shared open classifier transitivity`

Proof. The finite-intersection field of Definition 88.1 gives, for every $x : \mathsf{BHist}$,

$$\mathsf{OpenAt}(n, x) \iff (\mathsf{OpenAt}(k, x) \wedge \mathsf{OpenAt}(m, x)).$$

The forward implication, followed by projection, gives inclusions $n \leq_{\mathcal{T}} k$ and $n \leq_{\mathcal{T}} m$. At $x = b$, the reverse implication applied to o_k and o_m gives $o_n : \mathsf{OpenAt}(n, b)$. Composing the pointwise

inclusions gives $n \leq_{\mathcal{T}} i$ and $n \leq_{\mathcal{T}} \ell$; composing with $k \leq_{\mathcal{T}} j$ and with $m \leq_{\mathcal{T}} j$ gives the two chains to j used below.

Restrict the comparison row α along $n \leq_{\mathcal{T}} k$ by the classifier-stability field of Definition 151.154. This gives

$$\rho_{k,n}(\rho_{i,k}(s)) \sim_n \rho_{k,n}(\rho_{j,k}(t)).$$

The composition field of the same presheaf carrier, applied to $n \leq_{\mathcal{T}} k \leq_{\mathcal{T}} i$ and to $n \leq_{\mathcal{T}} k \leq_{\mathcal{T}} j$, gives

$$\rho_{k,n}(\rho_{i,k}(s)) \sim_n \rho_{i,n}(s)$$

and

$$\rho_{k,n}(\rho_{j,k}(t)) \sim_n \rho_{j,n}(t).$$

Symmetry and transitivity of the classifier $\sim_n$ therefore yield

$$\rho_{i,n}(s) \sim_n \rho_{j,n}(t).$$

Restrict the comparison row β along $n \leq_{\mathcal{T}} m$. The classifier-stability field gives

$$\rho_{m,n}(\rho_{j,m}(t)) \sim_n \rho_{m,n}(\rho_{\ell,m}(u)).$$

The composition field for $n \leq_{\mathcal{T}} m \leq_{\mathcal{T}} j$ and $n \leq_{\mathcal{T}} m \leq_{\mathcal{T}} \ell$ gives

$$\rho_{m,n}(\rho_{j,m}(t)) \sim_n \rho_{j,n}(t)$$

and

$$\rho_{m,n}(\rho_{\ell,m}(u)) \sim_n \rho_{\ell,n}(u).$$

Again using symmetry and transitivity of $\sim_n$, obtain

$$\rho_{j,n}(t) \sim_n \rho_{\ell,n}(u).$$

Transitivity of $\sim_n$ combines the last displayed row with $\rho_{i,n}(s) \sim_n \rho_{j,n}(t)$ and gives

$$\rho_{i,n}(s) \sim_n \rho_{\ell,n}(u).$$

Together with the witnesses $n \leq_{\mathcal{T}} i$, $n \leq_{\mathcal{T}} \ell$, and $o_n : \mathsf{OpenAt}(n, b)$, this is exactly the point-germ comparison row required by Definition 151.231. □

Definition 151.236 (Sheaf restricted-open carrier)**.** *Let $\mathcal{T}$ be a* BHist*-scoped indexed open topology carrier for* $\mathsf{Topology}^{\uparrow}$*, and let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over $\mathcal{T}$. Fix an open index $i : \mathsf{OpenIx}$. The restricted-open carrier $\mathcal{S}|_i$ is the carrier indexed by pairs (j, η_j) with*

$$\eta_j : j \leq_{\mathcal{T}} i.$$

On such an index it inherits

$$\mathsf{Sec}_{|i}(j, \eta_j) := \mathsf{Sec}(j), \qquad \sim_{|i,(j,\eta_j)} := \sim_j .$$

For an inclusion $\theta : k \leq_{\mathcal{T}} j$ between restricted indices, its restriction map is the ambient sheaf restriction

$$\rho^{|i}_{(j,\eta_j),(k,\eta_k)} := \rho_{j,k}.$$

The target witness $\eta_k : k \leq_{\mathcal{T}} i$ is the composite of θ with η_j, so every carrier, classifier, and restriction row stays inside the fixed open i without adding a host subspace, powerset restriction, quotient, or sheafification primitive.

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier`

Theorem 151.237 (Sheaf restricted-open restriction laws)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. For every restricted index (j, η_j) and section $s : \mathsf{Sec}_{|i}(j, \eta_j)$, the inherited identity row satisfies*

$$\rho^{|i}_{(j,\eta_j),(j,\eta_j)}(s) \sim_{|i,(j,\eta_j)} s.$$

For every chain of restricted indices

$$(k, \eta_k) \leq_{\mathcal{T}} (j, \eta_j) \leq_{\mathcal{T}} (l, \eta_l)$$

and every $s : \mathsf{Sec}_{|i}(l, \eta_l)$, the inherited composition row satisfies

$$\rho^{|i}_{(j,\eta_j),(k,\eta_k)}(\rho^{|i}_{(l,\eta_l),(j,\eta_j)}(s)) \sim_{|i,(k,\eta_k)} \rho^{|i}_{(l,\eta_l),(k,\eta_k)}(s).$$

Moreover, for every restricted inclusion $(k, \eta_k) \leq_{\mathcal{T}} (j, \eta_j)$, classifier equality transports along the inherited restriction:

$$s \sim_{|i,(j,\eta_j)} t \Longrightarrow \rho^{|i}_{(j,\eta_j),(k,\eta_k)}(s) \sim_{|i,(k,\eta_k)} \rho^{|i}_{(j,\eta_j),(k,\eta_k)}(t).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier restriction laws`

Proof. Unfold Definition 151.236. The section carrier and classifier at (j, η_j) are exactly $\mathsf{Sec}(j)$ and $\sim_j$, and the identity restriction is the ambient row $\rho_{j,j}$.

Apply the identity field of the indexed section presheaf carrier in Definition 151.154. This gives the first displayed classifier equality.

For the composition row, forget only the fixed target witness to i. The displayed restricted chain is an ambient chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} l$, so the composition field of Definition 151.154 gives the second displayed equality after replacing each restricted restriction map by the corresponding ambient ρ.

The classifier-transport row is identical. A restricted classifier equality is an ambient equality $s \sim_j t$, and the restricted map from (j, η_j) to (k, η_k) is $\rho_{j,k}$. The restriction classifier-stability field of Definition 151.154 therefore gives the final displayed implication. □

Theorem 151.238 (Sheaf restricted-open locality and gluing)**.** *Let $\mathcal{S}|_i$ be the restricted-open carrier of Definition 151.236. Let (j, η_j) be a restricted index and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed open cover of j whose member inclusions satisfy $h_a : \iota(a) \leq_{\mathcal{T}} j$. Regard it as a cover inside $\mathcal{S}|_i$ by assigning each member the composite witness*

$$\eta_{\iota(a)} : \iota(a) \leq_{\mathcal{T}} i.$$

Then locality and gluing hold in the restricted carrier. Thus, if $g, h' : \mathsf{Sec}_{|i}(j, \eta_j)$ and

$$\forall a : A, \quad \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(g) \sim_{|i,(\iota(a),\eta_{\iota(a)})} \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(h'),$$

then $g \sim_{|i,(j,\eta_j)} h'$. If $s_a : \mathsf{Sec}_{|i}(\iota(a), \eta_{\iota(a)})$ is compatible on the restricted cover, then there is $g : \mathsf{Sec}_{|i}(j, \eta_j)$ with

$$\forall a : A, \quad \rho^{|i}_{(j,\eta_j),(\iota(a),\eta_{\iota(a)})}(g) \sim_{|i,(\iota(a),\eta_{\iota(a)})} s_a.$$

Compatible local families remain compatible after every further restriction inside $\mathcal{S}|_i$.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier locality gluing descent`

Proof. View the restricted cover as the ambient indexed open cover of j with the same index type A, the same open-index map ι, the same inclusion witnesses h_a, and the same cover law γ. The extra witnesses $\eta_{\iota(a)}$ only record that each member also lies below the fixed open i.

After unfolding Definition 151.236, the displayed memberwise equality is exactly the ambient antecedent for the locality field of Definition 151.155. Applying that field to the ambient cover of j gives $g \sim_j h'$, which is the restricted classifier equality at (j, η_j).

For gluing, a compatible family in the restricted carrier is the same family $s_a : \mathsf{Sec}(\iota(a))$ with the same overlap equalities as in the ambient sheaf. Apply the gluing field of Definition 151.155 to obtain $g : \mathsf{Sec}(j)$ whose ambient restrictions classify as s_a. Unfolding the restricted carrier turns those rows into the displayed restricted gluing rows.

It remains to check that compatibility is stable under further restriction inside the fixed open. Fix two local members and restrict them to a smaller restricted index below their overlap. The finite-intersection row of Definition 88.1 supplies the overlap inclusions, and Definition 151.237 supplies restriction composition along the chains through that overlap. Transporting the original compatibility row by the same theorem and composing the resulting classifier equalities proves that the further-restricted family is still compatible. □

Theorem 151.239 (Sheaf restricted-open NameCert surface)**.** *For every* BHist*-scoped indexed open topology carrier* $\mathcal{T}$*, indexed sheaf carrier* $\mathcal{S}$ *over* $\mathcal{T}$*, and open index* $i : \mathsf{OpenIx}$*, the restricted-open carrier* $\mathcal{S}|_i$ *supplies the paper-side* $\mathsf{NameCert}_{\mathsf{Sheaf}\uparrow}$ *surface used by open-local consumers such as ringed-space and scheme certificates. Its rows are:*

1. *carrier: restricted indices* (j, η_j) *with* $j \leq_{\mathcal{T}} i$ *and inherited section carriers* $\mathsf{Sec}(j)$*;*
2. *classifier: the inherited section classifiers* $\sim_j$*;*
3. *stability: identity, composition, and classifier transport from Definition 151.237, with classifier transport agreeing with Definition 151.172;*
4. *ledger: open-cover indices below* i*, cover-member inclusions, finite-intersection overlap rows, refinement maps, and restriction paths;*
5. *exactness: restricted locality and gluing from Definition 151.238, stable under refinement by Definition 151.175 and Definition 151.176;*
6. *standard bridge: absent, as in the global obligation surface of Definition 151.190.*

Thus an open-local consumer may work entirely below i *while reusing the global* $\mathsf{NameCert}_{\mathsf{Sheaf}\uparrow}$ *carrier, classifier, stability, ledger, exactness, and absent-standard-bridge rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRestrictedOpenCarrier semantic name certificate`

Proof. The carrier and classifier rows are immediate from Definition 151.236: every restricted index names an ambient open below i, and no section carrier or classifier is rebuilt.

The stability row is supplied by Definition 151.237. Its classifier-transport clause is the restricted form of Definition 151.172, because both statements use the same ambient restriction map $\rho_{j,k}$ and the same classifier family $\sim$.

The ledger row is inherited from the ambient cover and refinement ledgers. Covers below i are ambient covers whose target open also carries a witness to i, while refinement pullback and gluing descent are exactly the rows of Definition 151.175 and Definition 151.176 read inside the fixed-open slice.

Finally, Definition 151.238 gives the exactness row for locality and gluing below i. The global obligation surface of Definition 151.190 already records that no standard bridge is attached, and

restricting to a fixed open adds no such bridge. These rows are precisely the $\mathsf{NameCert}_{\mathsf{Sheaf}^\uparrow}$ surface required by open-local consumers. □

Definition 151.240 (Sheaf root access normal form)**.** *The* $\mathsf{Sheaf}^\uparrow$ *root access normal form is the finite classification of downstream-visible root reads generated by Definition 151.244. Its classes are:*

1. *carrier, classifier, and restriction-route rows for the indexed section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, restrictions* $\rho_{i,j}$*, identity rows, composition rows, classifier transport, and optional* Cont *route histories;*
2. *cover-member and overlap rows for accepted covers, member witnesses, finite-intersection overlaps, pair-overlap projections, and* hsame *membership transport;*
3. *locality, gluing, refinement, common-refinement, and base-change rows for compatible-family predicates, global witnesses, uniqueness rows, displayed refinements, refinement pullbacks, gluing descent, cover-presentation exactness, displayed common refinements, displayed base-change squares, cover pullback, compatible-family transport, and gluing pullback;*
4. *point-germ comparison rows that expose named pointwise readbacks without forming stalk quotients;*
5. *the three downstream projection faces: the* $\mathsf{RingedSpace}^\uparrow$ *local-ring projection, the* $\mathsf{Scheme}^\uparrow$ *affine-chart projection, and the topology pullback projection.*

These classes are read-only faces of the same BHist*-indexed sheaf root package. They contain no class for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, standard bridges, or consumer-private algebraic, chart, or pullback data.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootAccessNormalFormSourceCase`

Theorem 151.241 (Sheaf root access normal-form coverage)**.** *Every admitted* $\mathsf{Sheaf}^\uparrow$ *root access trace of Definition 151.244 lands in one class of Definition 151.240.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead locality gluing readback`

Proof. Proceed by cases on the trace constructor of Definition 151.244.

Carrier, classifier, and restriction-route reads land in the first normal-form class. The root face source of Definition 151.271 places section carriers, section classifiers, restrictions, identity rows, composition rows, classifier transport, and optional route histories in the restriction-route face, and Definition 151.272 gives the corresponding coverage.

Cover-membership and overlap reads land in the second class. The accepted-cover row, member witness, finite-intersection overlap, pair-overlap projection, and hsame transport are exactly the cover-membership rows isolated by Definition 151.245.

Locality, gluing, refinement, common-refinement, and base-change reads land in the third class. Their exactness rows are the locality, gluing, and refinement face of Definition 151.271, with gluing exactness supplied by Definition 151.273; the downstream boundary of Definition 151.196 records the same restricted-open, base-change, refinement, and exactness rows.

Point-germ reads land in the fourth class because Definition 151.244 admits named pointwise readbacks only as point-germ comparison rows. The same definition excludes stalk quotient formation, so the point-germ case does not branch into an additional quotient class.

The remaining constructors are the three downstream consumer projections. They land in the fifth class by the projection seal of Definition 151.252, and the face coverage theorem Definition 151.245 identifies no further trace constructor. Thus every admitted access has a normal-form landing class. □

Theorem 151.242 (Sheaf root access normal-form consumer factorization)**.** *Every downstream* $\mathsf{Sheaf}^{\uparrow}$ *access used by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors first through Definition 151.240 and then through the existing projection seals.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace consumer access trace`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootAccessNormalForm consumer factorization`

Proof. Begin with an allowed downstream access. By Definition 151.247, it is represented by a finite trace of Definition 151.244. Apply Definition 151.241 to send each trace constructor to its normal-form class.

For $\mathsf{RingedSpace}^{\uparrow}$, the relevant classes are carrier, classifier, restriction, cover-gluing, restricted-open, base-change, and point-germ comparison rows. The local-ring projection seal Definition 151.253 reads exactly those sheaf-side classes and supplies no commutative-ring or local-ring row from the sheaf root.

For $\mathsf{Scheme}^{\uparrow}$, first pass through the ringed-space projection and then use the cover-presentation and displayed common-refinement classes. The affine-chart projection seal Definition 151.254 identifies spectra and chart-ring rows as consumer-side data, while Definition 151.276 lists the remaining sheaf rows visible to the joint face.

For topology pullback, use the base-change class together with cover-membership, restriction-route, compatible-family, gluing, and common-refinement rows. The pullback projection seal Definition 151.255 is exactly this factor, and Definition 151.277 prevents the other two consumer faces from entering it.

The factorization therefore has two stages: access traces land in the finite normal form, and the three downstream consumers read their respective normal-form classes only through the sealed projections. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace root access factorization`

Theorem 151.243 (Sheaf root access normal form exports no extra rows)**.** *The normal form of Definition 151.240 exports no host powerset equality, no cover quotient, no stalk quotient, no external sheafification row, no standard bridge row, and no consumer-private algebraic, chart, or pullback data.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootAccessNormalForm no extra rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead normal form readback`

Proof. For host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridges, inspect the source grammar. The trace source of Definition 151.244 has no constructor for those rows, and the root face exactness source of Definition 151.271 explicitly keeps them outside the four root faces.

For consumer-private algebraic rows, apply Definition 151.253. It says the commutative-ring and local-ring data used by $\mathsf{RingedSpace}^{\uparrow}$ are supplied outside $\mathsf{Sheaf}^{\uparrow}$, so the normal form cannot export them as sheaf root rows.

For affine-chart and spectra rows, apply Definition 151.254. The scheme face reads sheaf rows through ringed-space projections, cover-presentation exactness, and common-refinement comparison, while spectra data and chart-ring data remain outside the sheaf root.

For pullback-private choices, apply Definition 151.255. The topology pullback face reads displayed base-change transport, pulled-back cover membership, compatible-family transport, gluing pullback, and common-refinement transport; it does not export consumer-specific pullback-open choices as root data.

Finally combine the joint face and downstream boundary. The joint consumer face noninterference theorem Definition 151.277 prevents private consumer data from feeding back into the root, and Definition 151.199 exhausts the sheaf-side rows consumed downstream. Thus the normal form exports only the listed finite classes and no extra row. □

Definition 151.244 (Sheaf consumer access trace source)**.** *A finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access trace is the freely generated finite list syntax whose constructors are the following read events:*

1. *carrier and classifier reads of the indexed section carriers* $\mathsf{Sec}(i)$ *and classifiers* $\sim_i$*;*
2. *restriction-route reads of identity, composition, classifier transport, and optional* Cont *route-history rows;*
3. *cover-membership reads of accepted covers, member witnesses, finite-intersection overlaps, and* hsame *membership transport;*
4. *locality and gluing reads of compatible-family predicates, local agreement, global witnesses, and uniqueness rows;*
5. *refinement and common-refinement reads of displayed refinements, refinement pullbacks, gluing descent, and common-refinement comparison rows;*
6. *point-germ reads of named pointwise readback rows without forming stalk quotients;*
7. *base-change reads of displayed base-change squares, pulled-back cover membership, pulled-back compatible families, and gluing transport;*
8. *the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring consumer projection;*
9. *the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart consumer projection;*
10. *the topology pullback consumer projection.*

Every constructor is formed over BHist *histories,* hsame *transport, optional* Cont *route histories, the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier, the* $\mathsf{PreSheaf}^{\uparrow}$ *section carrier, and the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *rows. The trace source has no constructor for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafConsumerAccessTraceSource`

Theorem 151.245 (Sheaf consumer access trace face coverage)**.** *Every constructor of Definition 151.244 lands in exactly one face: either one of the root faces of Definition 151.271 or one of the three consumer projections sealed in Definition 151.252.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead restriction route readback`

Proof. Proceed by cases on the freely generated trace constructor.

The carrier, classifier, restriction-route, cover-membership, locality, gluing, refinement, common-refinement, point-germ, and base-change cases are root-facing reads. The carrier and classifier rows

land in the restriction-route face, the accepted-cover and overlap rows land in the cover-membership face, and the compatibility, locality, gluing, refinement, common-refinement, point-germ, and base-change rows land in the locality, gluing, and refinement exactness face. This placement is the coverage statement of Definition 151.272, with exactness supplied by Definition 151.273.

The remaining cases are the three downstream consumer constructors. The $\mathsf{RingedSpace}^{\uparrow}$ constructor lands in Definition 151.253, the $\mathsf{Scheme}^{\uparrow}$ constructor lands in Definition 151.254, and the topology pullback constructor lands in Definition 151.255.

These targets are disjoint by construction of Definition 151.271: the first three faces contain root sheaf rows, while the downstream face contains only projections. Thus each constructor has exactly one landing face. □

Theorem 151.246 (Sheaf consumer access trace no-feedback)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback constructors of Definition 151.244 do not create further* $\mathsf{Sheaf}^{\uparrow}$ *carrier rows, classifier rows, exactness rows, or bridge rows.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace no feedback`

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, the local-ring constructor reads the sheaf-side carrier, classifier, restriction, point-germ, restricted-open, and base-change rows only through the sealed projection. By Definition 151.274, the commutative-ring and local-ring data are outside the sheaf root and cannot return as root carrier, classifier, or exactness rows.

For $\mathsf{Scheme}^{\uparrow}$, the affine-chart constructor first passes through the ringed-space projection and then reads cover-presentation and common-refinement rows. The same separation theorem keeps spectra data and chart-ring data outside the sheaf root, so the chart constructor contributes no root row.

For topology pullback, the constructor reads displayed base-change transport, cover pullback, compatible-family transport, gluing pullback, and common-refinement transport. The pullback-open choices are consumer-side data by Definition 151.274, not root sheaf obligations.

Finally apply Definition 151.199. The downstream boundary exhausts all sheaf-side reads and excludes host powerset equality, cover quotients, external sheaf models, and bridge closure, so no consumer constructor can manufacture a further $\mathsf{Sheaf}^{\uparrow}$ root row. □

Theorem 151.247 (Sheaf consumer access trace exhaustion)**.** *Every allowed downstream* $\mathsf{Sheaf}^{\uparrow}$ *access by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors through a finite access trace of Definition 151.244.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append exhaustion`

Proof. Inspect the downstream row lists in Definition 151.196. Carrier and classifier access is represented by the carrier-classifier constructor; restriction stability is represented by the restriction-route constructor; cover ledgers are represented by the cover-membership constructor; locality, gluing, refinement, common-refinement, restricted-open, point-germ, and base-change access are represented by their corresponding trace constructors.

Now inspect the consumer projections in Definition 151.252. The $\mathsf{RingedSpace}^{\uparrow}$ local-ring projection is represented by the ringed-space consumer constructor, the $\mathsf{Scheme}^{\uparrow}$ affine-chart projection by the scheme consumer constructor, and the displayed pullback projection by the topology pullback constructor.

By Definition 151.245, each selected constructor lands in the correct root face or sealed consumer projection. By Definition 151.246, selecting a consumer constructor does not add any further sheaf row that would require another constructor outside the trace grammar.

The relevant downstream proof uses only finitely many rows from the displayed boundary and projection lists. Listing those rows in their order of use gives the required finite trace, and every allowed access is therefore factored through Definition 151.244. □

Definition 151.248 (Sheaf consumer access trace composition source)**.** *Let P be the fixed* BHist*-indexed* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root package used by Definition 151.244. If T_1 and T_2 are finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces over P, their composite $T_1 \mathbin{++} T_2$ is the finite list concatenation obtained by reading all constructors of T_1 followed by all constructors of T_2. The source constructors of $T_1 \mathbin{++} T_2$ are still exactly the constructors of Definition 151.244: carrier and classifier reads, restriction-route reads, cover-membership reads, locality and gluing reads, refinement and common-refinement reads, point-germ reads, base-change reads, and the three sealed consumer projection reads for* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback.*

The composite carries no additional constructor for host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge rows. Its only extra operation is finite list concatenation inside the same BHist*-scoped root package P.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTraceCompositionSource membership split`

Theorem 151.249 (Sheaf consumer access trace concatenation closure)**.** *Accepted finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces over one* BHist*-indexed* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root package are closed under the composition operation of Definition 151.248. In particular, if T_1 and T_2 are generated by Definition 151.244, then $T_1 \mathbin{++} T_2$ is generated by the same grammar and contains no constructor for host powerset equality, cover quotients, stalk quotients, external sheafification, or standard bridge rows.*

Proof. Induct on the second trace T_2 as a finite list of constructors. In the empty case, $T_1 \mathbin{++} T_2$ is just T_1, so acceptance is the given acceptance of the first trace.

In the cons case, write T_2 as a shorter trace followed by one final constructor c. By the induction hypothesis, concatenating T_1 with the shorter trace remains an accepted trace over the same root package.

It remains to append c. The constructor cases are exactly the cases listed in Definition 151.244: carrier and classifier, restriction route, cover membership, locality and gluing, refinement and common refinement, point germ, base change, and the three downstream consumer projections. Each case appends one already admitted constructor, so the resulting list is still accepted by the same grammar.

The excluded host-level operations are not constructor cases. Since finite concatenation only appends constructors already present in the grammar, it cannot create a host powerset equality row, a cover quotient, a stalk quotient, an external sheafification step, or a standard bridge row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace append closed`

Theorem 151.250 (Sheaf consumer access trace face-map stability)**.** *For finite* $\mathsf{Sheaf}^{\uparrow}$ *consumer access traces T_1 and T_2 over the same* BHist*-indexed root package, the landing-face assignment of Definition 151.245 sends $T_1 \mathbin{++} T_2$ to the finite concatenation of the landing-face reads of T_1 and the landing-face reads of T_2. The same assignment preserves the no-feedback separation of Definition 151.246 across the composite trace.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace face map stability`

Proof. Proceed by constructor cases on the appended segment T_2. The empty appended segment contributes no landing-face read, so the landing-face list of the composite is the landing-face list of T_1.

For a root-facing constructor, Definition 151.245 gives its unique root face. Appending the constructor appends exactly that face read after the face reads already assigned to the previous part of the composite.

For a downstream consumer constructor, Definition 151.245 sends the constructor to its sealed consumer projection. By Definition 151.246, that projection does not return a new $\mathsf{Sheaf}^{\uparrow}$ carrier row, classifier row, exactness row, or bridge row.

Thus the landing-face assignment commutes with finite list concatenation, and the downstream no-feedback separation remains valid after the two traces are read sequentially. □

Theorem 151.251 (Sheaf composite consumer access exhaustion)**.** *Every sequential downstream* $\mathsf{Sheaf}^{\uparrow}$ *access by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback factors through one finite* BHist*-scoped trace obtained by concatenating the finite traces for the individual accesses.*

Proof. Apply Definition 151.247 to the first downstream access. This gives a finite trace over the displayed BHist-indexed $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ root package whose constructors are those of Definition 151.244.

Apply Definition 151.247 again to the next downstream access, or to each member of the finite sequential access list. Each application gives another finite trace over the same root package, because the downstream consumers read the sealed $\mathsf{Sheaf}^{\uparrow}$ root package rather than creating a replacement root.

Concatenate the resulting finite traces in their order of downstream use. By Definition 151.249, the concatenation is still an accepted finite trace in the same grammar.

Finally use Definition 151.250. The composite trace preserves the landing-face assignment and the no-feedback separation, so the sequential access never leaves the finite BHist-scoped trace surface and never imports host-level sheaf machinery. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafConsumerAccessTrace composite exhaustion`

Definition 151.252 (SheafUp root consumer projection seal)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root consumer projection seal is the three-consumer package assembled from the consumer-threshold projection source of Definition 151.256, the root face exactness source of Definition 151.271, and the downstream consumption boundary of Definition 151.196. Its three public projections are the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring projection, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart projection, and the topology pullback projection. Each projection is a read-only face of the same* BHist*-indexed sheaf root package, and none of the projections exports host powerset equality, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootConsumerProjectionSeal`

Theorem 151.253 (SheafUp RingedSpace local-ring projection seal)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face of Definition 151.252 may read only the* $\mathsf{Sheaf}^{\uparrow}$ *section carriers, section classifiers, restriction stability rows, cover-gluing exactness rows, restricted-open rows, and displayed base-change rows. The commutative-ring and local-ring data used by the consumer are supplied from* $\mathsf{CommRing}^{\uparrow}$ *outside* $\mathsf{Sheaf}^{\uparrow}$*. Through this sealed projection, the consumer cannot read host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Proof. The consumer-threshold source of Definition 151.256 names the ringed-space projection row as a face of the root threshold package. Its existing projection theorem Definition 151.257 identifies exactly the section carrier, classifier, restriction, point-germ readback, restricted-open, and base-change rows available to $\mathsf{RingedSpace}^{\uparrow}$.

The root face coverage and exactness results Definition 151.272, Definition 151.273, and Definition 151.274 show that these rows are projections of the root cover-membership, restriction-route, and locality-gluing-refinement faces. They add no root carrier and no consumer-specific exactness row.

Finally, Definition 151.199 exhausts the downstream sheaf-side reads. The local-ring and commutative-ring structure therefore enters only from $\mathsf{CommRing}^{\uparrow}$, while host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure remain outside the sealed projection. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRingedSpaceLocalRingProjection seal`

Theorem 151.254 (SheafUp Scheme affine-chart projection seal)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face of Definition 151.252 may read affine-chart gluing only through cover-presentation rows, displayed common-refinement rows, and the* $\mathsf{RingedSpace}^{\uparrow}$ *projection rows sealed in Definition 151.253. Spectra data and chart-ring data are supplied outside* $\mathsf{Sheaf}^{\uparrow}$*. Through this sealed projection, the consumer cannot read host powerset equality of opens, cover quotients, stalk quotients, external sheafification, or standard bridge closure.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootSchemeAffineChartProjection seal`

Proof. The consumer-threshold source of Definition 151.256 names the scheme projection row as chart-wise access through ringed-space projections, cover-presentation exactness, and common-refinement comparison. The existing projection theorem Definition 151.258 supplies this chart-wise reading of the same threshold source.

The root face exactness package then separates the sheaf rows from chart data. By Definition 151.272 and Definition 151.273, cover-presentation comparison and common-refinement invariance are already part of the locality, gluing, and refinement exactness face; by Definition 151.274, chart-local spectra and ring rows do not feed back into the root sheaf package.

Apply Definition 151.199 to the scheme consumption boundary. Every sheaf row consumed by $\mathsf{Scheme}^{\uparrow}$ is already listed there, so spectra data, chart-ring data, host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure are not supplied by $\mathsf{Sheaf}^{\uparrow}$. □

Theorem 151.255 (SheafUp topology pullback projection seal)**.** *The topology pullback face of Definition 151.252 may read only pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and common-refinement transport along the displayed base-change surface. It does not read the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face or the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and it exports no host powerset equality, cover quotient, stalk quotient, external sheafification, or standard bridge closure.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootTopologyPullbackProjection seal`

Proof. The consumer-threshold source of Definition 151.256 names the topology pullback projection as the displayed base-change face. The existing projection theorem Definition 151.259 identifies the available rows as cover pullback, gluing pullback, pulled-back common refinement, and classifier transport along the displayed square.

The root face coverage and exactness rows control those reads. Use Definition 151.272 for cover membership and restriction-route stability, and use Definition 151.273 for compatible-family transport, gluing pullback, and common-refinement comparison.

The separation theorem Definition 151.274, together with Definition 151.199, removes the other two consumer faces from the topology pullback projection. Thus the pullback consumer receives only the displayed base-change rows and no host powerset equality, cover quotient, stalk quotient, external sheafification, or standard bridge closure. □

Definition 151.256 (Sheaf root consumer-threshold projection source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root consumer-threshold projection source is the* BHist*-indexed package obtained from Definition 151.294 by exposing three consumer faces: the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing face, and the topology pullback face. It is recorded by the following ten fields.*

1. *The traditional target is the sheaf-side data of a structure sheaf that can be read by ringed spaces, schemes, and pullback-open consumers.*
2. *The BEDC source is the single threshold source of Definition 151.294, not a separate host sheaf object.*
3. *The carrier row is the indexed-open section carrier* $\mathsf{Sec}(i)$*, with restricted-open carriers and displayed source carriers obtained only by slicing or pulling back indexed opens.*
4. *The classifier row is the section classifier family* $\sim_i$*, together with its restricted-open and displayed base-change readbacks.*
5. *The restriction row is restriction identity, restriction composition, and classifier transport for every displayed inclusion used by the three consumers.*
6. *The RingedSpaceUp projection row is the local-ring consumer surface: section carriers, section classifiers, ring-preserving restriction routes, point-germ local-ring readback, restricted-open rows, and base-change rows.*
7. *The SchemeUp projection row is the affine-chart gluing surface: chart-wise ringed-space projections, displayed affine cover membership, overlap compatibility, and common-refinement comparison.*
8. *The topology pullback projection row is the displayed base-change surface: cover pullback, gluing pullback, pulled-back common refinement, and classifier transport along the displayed square.*
9. *The ledger and exactness row is the cover-nerve ledger, point-germ ledger, restricted-open ledger, refinement ledger, cover-presentation exactness, and base-change exactness already present in the threshold source.*
10. *The standard-bridge field is absent: the projection source exports no host powerset cover equality, no cover quotient, no stalk quotient, no external sheafification operation, and no* $\mathsf{StandardBridge}$*.*

Thus the same BHist*-indexed source is projected separately to the three consumer families without duplicating the sheaf root obligations.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjectionSource`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjectionSource projection faces`
Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootConsumerThresholdProjection source`

Theorem 151.257 (Sheaf root RingedSpace consumer projection)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring consumer receives exactly the indexed sections, section classifiers, restriction identity, restriction*

composition, restriction transport, point-germ local-ring readback, restricted-open rows, and base-change rows of Definition 151.256. No additional sheaf carrier, cover comparison, stalk quotient, or standard bridge is available through this projection.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootConsumerRingedSpaceProjection semantic name certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRingedSpaceConsumerProjection scope`

Proof. Start from Definition 151.197. Its sheaf-side list asks for section carriers, classifiers, restriction stability, cover-gluing exactness, restricted-open rows, and base-change rows, together with non-sheaf commutative-ring data supplied outside $\mathsf{Sheaf}^{\uparrow}$.

The carrier and classifier entries are supplied by Definition 151.295. This gives the open-indexed section carrier, the classifier family, restriction identity and composition, classifier transport, BHist cover membership, and point-germ rows read on displayed neighborhoods.

The exactness and transport entries are supplied by Definition 151.296. Locality, gluing, refinement pullback, restricted-open exactness, and displayed base-change exactness are already fields of the root threshold source, so the ringed-space projection is precisely the listed face of Definition 151.256. □

Theorem 151.258 (Sheaf root Scheme consumer projection)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing consumer receives the same threshold source by chart-wise* $\mathsf{RingedSpace}^{\uparrow}$ *projection, followed by cover-presentation exactness and common-refinement exactness on chart overlaps. Thus affine-chart sections, overlap classifiers, glued section classes, and comparison across common refinements are all read from Definition 151.256.*

Proof. Apply Definition 151.198. Each affine or ringed-space chart first reads the sheaf boundary through the ringed-space consumer, so the chart-wise carrier, classifier, restriction, restricted-open, point-germ, and base-change rows are the rows identified in Definition 151.257.

The coverage claim is Definition 151.297: every sheaf row consumed by $\mathsf{Scheme}^{\uparrow}$ is already covered by the threshold source. This keeps the chart gluing surface inside the same BHist-indexed package.

For independence of the chosen affine cover presentation, use Definition 151.189. The displayed common refinement compares the pulled-back local families and identifies the resulting global classifier class, so no quotient of cover presentations or external sheaf model is introduced. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafSchemeChartGluingTrace unary result`

Theorem 151.259 (Sheaf root topology pullback consumer projection)**.** *Topology pullback consumers receive only the displayed base-change, cover-pullback, gluing-pullback, and common-refinement rows of Definition 151.256. These rows preserve pulled-back cover membership, compatible local-family predicates, glued section classifiers, and common-refinement comparison, without exporting the ringed-space local-ring face or the scheme affine-chart face.*

Proof. Begin with Definition 151.226. It identifies the consumer request as a displayed pullback of indexed cover rows: cover membership, restriction stability, and compatible local-family predicates are transported along the topology pullback-open rows.

The complete base-change surface is Definition 151.208. Its displayed square supplies cover pullback, gluing pullback, and common-refinement invariance using the same indexed-open carrier, classifier family, cover ledger, and refinement exactness fields recorded in Definition 151.256.

Since this consumer reads only displayed source and target rows, the projection discards the ringed-space local-ring field and the scheme affine-chart field. What remains is exactly the base-change and common-refinement face of the root threshold source, with no host powerset cover comparison or standard bridge. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootConsumerPullbackProjection base change face`

Definition 151.260 (Sheaf root cover-descent source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root cover-descent source is the following* BHist*-scoped source tuple. It is read over a* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier with point carrier* BHist*, membership row* OpenAt*, inclusion relation* $\leq_{\mathcal{T}}$*, and finite-intersection rows; an indexed* $\mathsf{Sheaf}^{\uparrow}$ *carrier with section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, and restriction maps* $\rho_{i,j}$*; an indexed cover* $\mathcal{U} = (A, \iota, h, \gamma)$ *of an ambient open* i*; member inclusions* $h_a : \iota(a) \leq_{\mathcal{T}} i$*; displayed restriction routes to members and finite-intersection overlaps; a compatible local family* $s_a : \mathsf{Sec}(\iota(a))$*; and the section classifier rows used to compare restrictions on members, overlaps, and glued readbacks.*

The source admits only these displayed data: BHist *histories, indexed open membership, cover-member witnesses, member and overlap inclusions, restriction-route witnesses, compatible-family overlap equalities, locality, gluing, and section classifiers. It excludes stalks, quotient carriers, host powerset equality of covers, and external sheafification.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootCoverDescentSource`

Theorem 151.261 (Sheaf root cover-descent carrier exactness)**.** *The source of Definition 151.260 exposes exactly* BHist*,* OpenAt*, cover membership, restriction maps, finite-intersection overlap rows, and section classifiers. In particular, every carrier or classifier row visible to cover descent is one of the indexed-open carrier rows of* $\mathsf{Topology}^{\uparrow}$*, the indexed section rows of* $\mathsf{Sheaf}^{\uparrow}$*, or the compatible-family and locality rows of the sheaf cover surface.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent carrier exactness`

Proof. Unfold Definition 151.260. The topology component contributes only BHist, indexed opens, OpenAt, inclusion witnesses, and finite-intersection rows. These are exactly the displayed carrier and membership rows of Definition 88.1.

Unfold the indexed sheaf component. By Definition 151.154, the section-level rows are the carriers $\mathsf{Sec}(i)$, classifiers $\sim_i$, restriction maps $\rho_{i,j}$, and restriction stability fields attached to displayed inclusion routes.

Finally unfold the cover and local-family component through Definition 151.155. It adds cover membership, member inclusions, finite-intersection overlap comparisons, locality, and gluing. None of the three unfolded sources contains a stalk carrier, a quotient carrier, host powerset equality, or external sheafification, so the displayed list is exact. □

Theorem 151.262 (Sheaf root cover-descent gluing exhaustion)**.** *Every root cover-descent comparison route for the source of Definition 151.260 factors through a cover member or a displayed common refinement, then through restriction-route exactness, and finally through the locality or gluing classifier row. Thus the cover-descent route surface is exhausted by cover membership, finite-intersection overlap rows, restriction transport, point-germ readback, and gluing uniqueness.*

↪variant `BEDC.Derived.SheafUp.SheafBHistPointGermLedger cover descent exhaustion`

Proof. First apply the cover law γ in the indexed cover $\mathcal{U}$. Each history cell $b : \mathsf{BHist}$ lying in the ambient open is sent to a member $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$, and the finite-intersection rows of Definition 88.1 supply the displayed overlaps used for pairwise comparison.

Next route the comparison through the sheaf restriction surface. Apply Definition 151.291 to transport the member witness through the displayed route, and apply Definition 151.292 when the comparison is represented by a composed route history. Both steps keep the target section classifier attached to the reached open.

It remains to read the local family through gluing. Apply Definition 151.234 for the memberwise readback of a glued section, and apply Definition 151.169 to identify any two global readbacks that agree on all displayed members. The route therefore ends at the existing locality or gluing classifier row and introduces no further carrier or classifier. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent common refinement germ exactness`

Theorem 151.263 (Sheaf root cover-descent downstream interface)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers may consume only the cover-descent source of Definition 151.260, the carrier exactness row of Definition 151.261, the gluing exhaustion row of Definition 151.262, and the downstream exactness coverage row of Definition 151.266. They receive no additional sheaf carrier and no additional sheaf classifier.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverDescent downstream interface`

Proof. For the ringed-space consumer, apply Definition 151.224. Its sheaf-side data are section carriers, classifiers, restriction stability, point-germ readback, and local compatibility rows, all already present in the cover-descent source and its carrier exactness row.

For the scheme consumer, apply Definition 151.225. The chart gluing request is routed through cover membership, finite-intersection overlaps, compatible local families, gluing, and common-refinement comparison, which are precisely the rows exhausted by Definition 151.262.

For topology pullback, apply Definition 151.226. Pullback cover membership and compatible-family transport are displayed over the same indexed-open and restriction-route rows, so they add no carrier beyond Definition 151.260.

Finally apply Definition 151.266. It seals the three consumer projections to cover membership, locality and gluing, refinement descent, common-refinement exactness, and projection rows. Hence downstream access is exactly the cover-descent interface named in the statement. □

Theorem 151.264 (Sheaf root downstream consumer carrier scope)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback receive their* $\mathsf{Sheaf}^{\uparrow}$ *carrier rows only from the indexed section carrier over* BHist *opens in Definition 151.154, together with the cover-nerve ledger of Definition 151.160. Their sheaf-side carrier scope is exactly the indexed open carrier, the section carriers* $\mathsf{Sec}(i)$*, the section classifiers* $\sim_i$*, the restriction maps* $\rho_{i,j}$*, cover-member cells, pair-overlap cells, and* hsame*-stable ledger transport. No host powerset equality, cover quotient, stalk quotient, or external sheafification row is exported to these consumers.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer carrier scope`

Proof. Read the carrier source from Definition 151.298. Its carrier clause points to Definition 151.154, so every section-level carrier read by a downstream consumer is one of the open-indexed section carriers, classifiers, restrictions, and identity or composition rows already listed there.

Read the history side from Definition 151.160 and the cover-nerve export surface of Definition 151.302. The only additional cells are cover-member cells, finite-intersection pair-overlap cells, route-history cells when present, and membership transport through hsame.

Finally apply the downstream coverage theorem Definition 151.305 and the projection seal Definition 151.252. These rows are projected read-only to $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, and topology pullback, so none of the three consumers obtains host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row from the root package. □

Theorem 151.265 (Sheaf root downstream consumer classifier stability)**.** *Every restriction route exposed from the* $\mathsf{Sheaf}^{\uparrow}$ *root to* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback preserves the relevant section classifier. One-step and two-step routes preserve classifiers by Definition 151.304; membership reindexing is transported only through* hsame*; optional* Cont *route histories compare displayed route witnesses without changing the target open or the target classifier. Hence consumer restriction routes do not add any host powerset equality, cover quotient, stalk quotient, or external sheafification row.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer classifier stability`

Proof. For section restrictions, apply Definition 151.304. It states that the one-step restriction of classifier-equal sections lands in the target classifier and that the composed two-step route agrees with the direct route in the classifier of the final open.

For membership movement, use the cover-nerve ledger of Definition 151.160. Its transport row is hsame-stable membership transport over BHist cells, so route changes do not replace the indexed open carrier by a host open or a quotient carrier.

If optional Cont histories are present, use the route-history clause cited in Definition 151.300. Those histories compare the witnesses for displayed routes; they do not alter the open index on which $\sim_j$ or $\sim_k$ is read.

The three projection seals Definition 151.253, Definition 151.254, and Definition 151.255 then pass the same classifier-stable routes to the downstream consumers without exporting host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row. □

Theorem 151.266 (Sheaf root downstream consumer exactness coverage)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *exactness surface consumed by* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback is exhausted by cover membership, locality and gluing, refinement descent, common-refinement exactness, and the downstream projection seals. Concretely, cover membership is supplied by Definition 151.299 and Definition 151.303; locality and gluing are supplied by Definition 151.301; refinement descent and refined exactness are supplied by Definition 151.176 and Definition 151.179; common-refinement exactness is supplied by Definition 151.188 and Definition 151.189; and consumer access is sealed by the three projection theorems. No host powerset equality, cover quotient, stalk quotient, or external sheafification row is exported.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafDownstreamConsumer exactness coverage`

Proof. Start with cover membership. The accepted-cover cell is unpacked by Definition 151.299, and Definition 151.303 records the corresponding cover-member and pair-overlap cells inside the BHist cover nerve.

For local exactness, use Definition 151.301. It gives existence of a global readback from a compatible local family and classifier uniqueness for global readbacks whose restrictions agree on the cover.

For refinement, apply Definition 151.176 and the package theorem Definition 151.179. These rows keep the same global classifier class after passing to displayed refinements. For comparison of cover presentations, use Definition 151.188 and Definition 151.189.

Finally pass to consumers through Definition 151.253, Definition 151.254, and Definition 151.255. Each consumer receives a projection of the listed cover, restriction, locality, gluing, refinement, and common-refinement rows; none receives host powerset equality, a cover quotient, a stalk quotient, or an external sheafification row. □

Definition 151.267 (Sheaf root export BHist closure surface)**.** *The root export surface for* $\mathsf{Sheaf}^{\uparrow}$ *is the following ten-field* BHist*-closed package carried by* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*.*

1. *The traditional target is sheaves of sections over indexed opens.*
2. *The BEDC source is the joint* $\mathsf{Topology}^{\uparrow}$ *and* $\mathsf{PreSheaf}^{\uparrow}$ *surface over* BHist*, read through* NameCert*.*
3. *The history ledger is the cover-nerve ledger of Definition 151.160, with membership transport only through* hsame*.*
4. *The carrier is the indexed section presheaf of Definition 151.154.*
5. *The classifier is the open-indexed section classifier family* $\sim_i$*.*
6. *The stability rows are identity, composition, restriction classifier transport, and route-history associativity when* Cont *rows are present.*
7. *The cover ledger consists of indexed cover members, finite-intersection overlap rows, displayed refinement maps, and common-refinement spans.*
8. *The exactness rows are locality, gluing, refinement pullback, refinement gluing descent, and common-refinement gluing invariance.*
9. *The downstream threshold exports only these indexed-open, section, restriction, locality, gluing, and refinement rows.*
10. *The standard bridge row is absent; no host powerset equality, cover quotient, stalk quotient, or external sheafification primitive is exported.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootExportSurface`
Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootExportBHistClosureSurface`

Theorem 151.268 (Sheaf root export carrier scope)**.** *Let* $\mathcal{T}$ *be the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier and let* $\mathcal{S}$ *be the* $\mathsf{PreSheaf}^{\uparrow}$ *indexed section carrier equipped with the sheaf locality and gluing rows. The root export surface of Definition 151.267 exposes exactly the following carrier data: open indices and inclusion rows from* $\mathcal{T}$*, indexed section carriers* $\mathsf{Sec}(i)$*, section classifiers* $\sim_i$*, restriction maps* $\rho_{i,j}$*,* hsame*-stable* BHist *membership, and the cover-nerve ledger of Definition 151.160. It exports no carrier whose elements are host opens, quotiented covers, or external stalk representatives.*

Proof. Project the topology part first. The indexed-open carrier supplies open indices, inclusion rows, finite intersections, and the OpenAt membership predicate; Definition 151.160 records those rows over BHist and allows membership transport only through hsame.

Project the presheaf part next. By Definition 151.154, the only section-level carrier rows are $\mathsf{Sec}(i)$, $\sim_i$, the restriction maps, and their identity, composition, equivalence, and classifier-transport fields.

Finally use Definition 151.157 and Definition 151.299. These identify the carrier support and cover membership obligations as indexed-open and BHist-ledger data, so no host open carrier, cover quotient, or stalk representative is part of the export. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport carrier scope`

Theorem 151.269 (Sheaf root export stability and exactness package)**.** *For every indexed sheaf carrier $\mathcal{S}$ over an indexed-open carrier $\mathcal{T}$, the root export surface of Definition 151.267 packages the complete stability and exactness rows needed by downstream certificates:*

1. *cover-member witnesses and overlap projections from the* BHist *cover ledger;*
2. *identity, composition, and restriction classifier-stability for section restrictions;*
3. *locality and gluing exactness over indexed covers;*
4. *refinement pullback and refined-cover gluing descent;*
5. *common-refinement presentation exactness, including the restricted-open common-refinement rows below a fixed open.*

Every row is expressed in indexed opens, restriction maps, section classifiers, displayed refinements, common-refinement spans, Cont *route histories when present, and* hsame*-stable history membership.*

Proof. The cover-member and overlap rows are those of Definition 151.299, together with the pair-overlap projections of Definition 151.161. They keep the cover ledger internal to indexed opens and BHist cells.

The restriction rows are exactly Definition 151.300. Its identity, composition, classifier-stability, and optional Cont route-history clauses are the stability rows exported by the root package.

The locality and gluing rows are supplied by Definition 151.301. Refinement contributes Definition 151.175, Definition 151.176, and Definition 151.179.

Common-refinement exactness is read from Definition 151.188 and Definition 151.189; below a fixed open it is read from Definition 151.195. These rows assemble the displayed package without adding any host-level cover equality or quotient comparison. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport stability exactness package`

Theorem 151.270 (Sheaf root export downstream threshold)**.** *The root export surface of Definition 151.267 is the carried* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *threshold available to* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and restricted-open consumers. Such consumers receive only the indexed-open carrier, the section classifier family, restriction identity and composition rows, restriction classifier-stability rows, locality and gluing rows, the refinement ledger, common-refinement exactness, and the absent-standard-bridge row. In particular, they do not receive a standard bridge, host powerset cover equality, cover quotient, stalk quotient, or external sheafification operation from* $\mathsf{Sheaf}^{\uparrow}$.

Proof. For the global sheaf surface, apply Definition 151.190, Definition 151.283, and Definition 151.284. These rows expose the carrier, classifier, restriction, locality, gluing, and refinement obligations already present in $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

For the local consumers, apply Definition 151.239 and Definition 151.195. They show that working below a fixed open reuses the same ambient section carriers, classifiers, restrictions, cover ledgers, and exactness rows.

The negative part is part of the same export boundary. The root-unblock source of Definition 151.298 and the global obligation surface both state that no standard bridge or host-level

cover comparison is exported, so ringed-space, scheme, and restricted-open chapters must cite the indexed threshold rather than reconstructing a larger classical sheaf interface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootExport downstream threshold`

Definition 151.271 (Sheaf root face exactness source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root face exactness source is the four-face package obtained from the* BHist *root-unblock source, the cover-nerve export surface, and the consumer-threshold projection source. It is read over* BHist *histories,* hsame *transport, optional* Cont *route histories, the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier, the* $\mathsf{PreSheaf}^{\uparrow}$ *restriction carrier, and the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation rows.*

1. *The cover-membership face consists of accepted cover rows, member witnesses* $\mathsf{OpenAt}(\iota(a), b)$*, finite-intersection overlap rows, and* hsame*-stable history transport from Definition 151.160.*
2. *The restriction-route face consists of the section carriers* $\mathsf{Sec}(i)$*, classifiers* $\sim_i$*, restrictions* $\rho_{i,j}$*, identity rows, composition rows, classifier transport, and optional* Cont *route-history associativity rows.*
3. *The locality, gluing, and refinement exactness face consists of compatible local-family predicates, gluing witnesses, locality comparison, displayed cover refinement, refinement pullback, refinement gluing descent, displayed common-refinement comparison, and cover-presentation exactness.*
4. *The downstream projection face consists only of the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring projection, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart gluing projection, and the topology pullback projection named in Definition 151.256.*

The package contains no host powerset equality of open covers, no cover quotient, no stalk quotient, no external sheafification operation, and no StandardBridge *field.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootFaceExactnessSource`

Theorem 151.272 (Sheaf root face classifier coverage)**.** *Every row of the root-unblock source of Definition 151.298 and every row of the cover-nerve export surface of Definition 151.302 lands in exactly one of the first three faces of Definition 151.271. The downstream projection face receives only projections of those faces and adds no root carrier, root classifier, or root exactness row.*

Proof. For the cover rows, read the cover ledger in Definition 151.160. The accepted cover, cover-member witness, finite-intersection overlap, pair-overlap projection, and hsame membership transport rows are precisely the cover-membership face. The exhaustion and projection theorems Definition 151.303 and Definition 151.161 show that no additional cover row is required.

For the restriction rows, use Definition 151.300 and Definition 151.304. Their identity, composition, classifier-preservation, two-step route, and optional Cont history clauses are exactly the restriction-route face.

For the exactness rows, use Definition 151.301, Definition 151.175, Definition 151.176, Definition 151.179, and Definition 151.189. These rows cover locality, gluing, displayed refinement, common-refinement comparison, and cover-presentation exactness, so they land in the locality, gluing, and refinement exactness face.

Finally compare with the consumer-threshold source of Definition 151.256. Its ringed-space, scheme, and topology pullback rows cite the same carrier, classifier, cover, restriction, and exactness rows through projection, so they occupy the downstream projection face rather than adding root data. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead coverage`

Theorem 151.273 (Sheaf root face gluing exactness)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over a* BHist*-scoped indexed open topology carrier $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an accepted indexed cover of $i : \mathsf{OpenIx}$. For every compatible local family $s_a : \mathsf{Sec}(\iota(a))$, locality plus gluing plus refinement exactness gives a* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*-consumable exactness row:*

1. *a global section $g : \mathsf{Sec}(i)$ restricts to the local family;*
2. *any two global readbacks whose cover restrictions agree are classifier-equal in $\sim_i$;*
3. *after any displayed refinement or displayed common refinement, the pulled-back local families determine the same global classifier class.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison restricted global soundness`

Proof. Begin with the compatible local family over $\mathcal{U}$. The gluing field in Definition 151.155 supplies a global section $g : \mathsf{Sec}(i)$ and the displayed member equalities $\rho_{i,\iota(a)}(g) \sim_{\iota(a)} s_a$.

Use locality from the same definition for uniqueness. If two global readbacks agree on every member row, locality returns classifier equality in $\sim_i$; the same argument is packaged by Definition 151.169.

Now pass to a displayed refinement. The compatibility row is transported by Definition 151.175, and the gluing row descends by Definition 151.176. The combined refined-cover statement is Definition 151.179.

For comparison of two cover presentations, use the displayed common-refinement surface of Definition 151.186. The invariance theorem Definition 151.188, together with Definition 151.189, identifies the two resulting global classifier classes.

All cited steps use indexed covers, BHist membership, hsame transport, section classifiers, restriction composition, and optional Cont route histories. Therefore the exactness row is consumable by $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ without adding a host cover comparison or quotient row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger restricted global soundness`

Theorem 151.274 (Sheaf root face downstream separation)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, and topology pullback consumers receive only projections of the four faces of Definition 151.271. Consumer-specific rows such as local-ring structure, affine-chart spectra data, and displayed pullback-open choices do not feed back into the root* $\mathsf{Sheaf}^{\uparrow}$ *carrier, root classifier, cover ledger, restriction-route face, or locality and gluing exactness face.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead downstream separation`

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, apply Definition 151.257. Its sheaf-side input is the indexed section carrier, section classifier, restriction stability, point-germ readback, restricted-open rows, and base-change rows projected from the root source. The commutative-ring and local-ring rows are supplied outside the sheaf root.

For $\mathsf{Scheme}^{\uparrow}$, apply Definition 151.258. Each chart first reads the ringed-space projection, while affine-chart and spectra data remain chart-side data. The sheaf contribution is only cover-presentation exactness and common-refinement comparison already present in the root exactness face.

For topology pullback consumers, apply Definition 151.259 and Definition 151.226. The pullback row transports cover membership, compatible families, gluing, and common refinements

through the displayed base-change surface, but it does not introduce a ringed-space local-ring row or a scheme affine-chart row.

The downstream consumption boundary of Definition 151.196 and the exhaustion theorem Definition 151.199 close the separation. They state that consumers can only read the listed sheaf-side projections, so consumer-specific structure cannot be returned as a new root $\mathsf{Sheaf}^{\uparrow}$ obligation. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead downstream projection separation`

Definition 151.275 (Sheaf root joint consumer face)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root joint consumer face is the shared* BHist*-indexed projection package assembled from the projection seal of Definition 151.252, the consumer-threshold projection source of Definition 151.256, the root face exactness source of Definition 151.271, and the downstream consumption boundary of Definition 151.196. It has one root package and three read-only consumer faces: the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and the topology pullback face. Each face reads the same* BHist*-scoped sheaf root rows for section carriers, section classifiers, restriction transport, cover-gluing exactness, restricted opens, displayed base change, cover presentations, and displayed common refinements.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace chart trace e0 endpoint absurd`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace normal form boundary`

Theorem 151.276 (Sheaf root joint consumer face exhaustion)**.** *Every sheaf-side row visible through the joint consumer face of Definition 151.275 to* $\mathsf{RingedSpace}^{\uparrow}$*,* $\mathsf{Scheme}^{\uparrow}$*, or topology pullback consumers is one of the following rows: indexed section carrier, section classifier, restriction identity, restriction composition, restriction classifier transport, cover-locality and cover-gluing exactness, restricted-open carrier and inherited sheaf rows, displayed base-change transport, cover-presentation exactness, or displayed common-refinement comparison. No other sheaf-side row is exported by the joint face.*

Proof. Split over the three projections named in Definition 151.252.

For the $\mathsf{RingedSpace}^{\uparrow}$ projection, apply Definition 151.253. Its sheaf-side reads are the section carrier, classifier, restriction-stability, cover-gluing, restricted-open, and base-change rows. The root face coverage theorem Definition 151.272 places the carrier, classifier, and restriction rows inside the first three faces of the root exactness source.

For the $\mathsf{Scheme}^{\uparrow}$ projection, apply Definition 151.254. Chart-wise reads factor through the ringed-space projection, and the only additional sheaf-side comparisons are cover-presentation exactness and displayed common-refinement comparison. These are exactly the locality, gluing, and refinement rows supplied by Definition 151.273.

For the topology pullback projection, apply Definition 151.255. The available rows are pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and displayed common-refinement transport along the base-change surface.

Finally use Definition 151.199. It exhausts downstream sheaf reads by the carrier, classifier, restriction, cover-gluing, restricted-open, base-change, refinement, and exactness rows already listed in the statement, so the joint consumer face exports no further sheaf-side row. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace exhaustion`

Theorem 151.277 (Sheaf root joint consumer face noninterference)**.** *None of the three consumer projections of Definition 151.275 exports another consumer's private data back into the* $\mathsf{Sheaf}^{\uparrow}$ *root face. The* $\mathsf{RingedSpace}^{\uparrow}$ *projection does not return private algebraic or local-ring rows to the root*

face; the $\mathsf{Scheme}^{\uparrow}$ *projection does not return private affine-chart, spectra, or chart-ring rows; and the topology pullback projection does not return private pullback-open choices or consumer-specific pullback witnesses to the root face.*

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, the projection seal Definition 151.253 says that commutative-ring and local-ring data are supplied outside $\mathsf{Sheaf}^{\uparrow}$. Thus those algebraic rows are read by the consumer only after the sheaf-side projection has been fixed.

For $\mathsf{Scheme}^{\uparrow}$, the projection seal Definition 151.254 keeps spectra data and chart-ring data outside $\mathsf{Sheaf}^{\uparrow}$. The scheme face reads sheaf rows through chart-wise ringed-space projections and common-refinement comparisons, but it does not add a chart carrier, chart classifier, or spectra row to the root package.

For topology pullback, the projection seal Definition 151.255 restricts the face to displayed base-change, cover pullback, gluing pullback, and common-refinement transport. It explicitly does not read the ringed-space local-ring face or the scheme affine-chart face.

The separation theorem Definition 151.274 identifies all three consumers as projections of the same four root faces. Together with Definition 151.199, this prevents consumer-specific algebraic, chart, or pullback data from re-entering the $\mathsf{Sheaf}^{\uparrow}$ carrier, classifier, cover ledger, restriction-route face, or locality and gluing exactness face. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace noninterference`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace no feedback unary boundary`

Theorem 151.278 (Sheaf root joint consumer face NameCert boundary)**.** *The joint consumer face of Definition 151.275 exposes the following ten-field* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *boundary.*

1. *The traditional target is the sheaf-side consumer projection package read by ringed spaces, schemes, and topology pullback consumers.*
2. *The BEDC sources are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* $\mathsf{NameCert}$.
3. *The carrier field is the indexed section presheaf carrier* $\mathsf{Sec}(i)$ *and its restricted-open or displayed base-change readbacks.*
4. *The classifier field is the section classifier relation* $\sim_i$ *and its restricted-open or displayed base-change transports.*
5. *The stability field consists of restriction identity, restriction composition, classifier transport, locality, gluing, refinement transport, and base-change transport.*
6. *The ledger field consists of the* BHist *cover nerve, cover-member rows, overlap rows,* hsame *transport, and optional route histories.*
7. *The exactness field consists of the joint exhaustion row of Definition 151.276 and the joint noninterference row of Definition 151.277.*
8. *The downstream-use field consists exactly of the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and the topology pullback face.*
9. *The boundary exports no host powerset equality, cover quotient, stalk quotient, external sheafification operation, or consumer-private root data.*
10. *No standard bridge is attached to this boundary.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootJointConsumerFace semantic name certificate`

Proof. Begin with the root consumer-threshold projection source of Definition 151.256. It already names the traditional consumer target, the single threshold source, the carrier and classifier rows, the restriction row, the three consumer projection rows, the ledger and exactness row, and the absent standard-bridge field.

The root face exactness source of Definition 151.271 refines these fields into cover-membership, restriction-route, locality-gluing-refinement, and downstream projection faces. Use Definition 151.272 for carrier, classifier, cover ledger, and restriction-route coverage, and use Definition 151.273 for locality, gluing, refinement, cover-presentation, and base-change exactness.

The projection seals identify the downstream-use field. Apply Definition 151.253, Definition 151.254, and Definition 151.255 to split the boundary into the three consumer faces.

It remains to justify exactness and exclusion. The joint exhaustion theorem Definition 151.276 supplies the listed public sheaf rows, while the joint noninterference theorem Definition 151.277 and the downstream separation theorem Definition 151.274 remove consumer-private algebraic, chart, and pullback rows from the root face. The downstream consumption exhaustion theorem Definition 151.199 then leaves no standard bridge, host powerset equality, cover quotient, stalk quotient, or external sheafification operation in the boundary. □

Definition 151.279 (Sheaf root NameCert field inventory)**.** *The root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *field inventory is the following ten-field surface.*

1. *The traditional target is a sheaf of sections over indexed opens, read over accepted indexed covers rather than host open-cover equality.*
2. *The BEDC source is* $\mathsf{Topology}^{\uparrow}$ *together with the* $\mathsf{PreSheaf}^{\uparrow}$ *restriction surface.*
3. *The carrier row is the indexed section family* $\mathsf{Sec}(i)$ *of Definition 151.154.*
4. *The classifier row is the open-indexed section classifier family* $\sim_i$.
5. *The carrier-transport stability row keeps section carriers and classifiers aligned under the displayed indexed-open and* BHist *transport rows.*
6. *The restriction-stability row consists of restriction identity, restriction composition, and classifier preservation by restriction.*
7. *The locality row detects global classifier equality from memberwise classifier equality on an indexed cover.*
8. *The gluing row supplies a global section readback for every compatible local family.*
9. *The refinement-exactness row transports compatible families and gluing witnesses through displayed refinements and common refinements.*
10. *The ledger and presentation row consists of indexed covers, common-refinement spans, and cover-presentation invariance; it carries no standard bridge.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootNameCertFieldInventory`

Theorem 151.280 (Sheaf root NameCert carrier and classifier fields)**.** *Let* $\mathcal{T}$ *be an indexed-open carrier for* $\mathsf{Topology}^{\uparrow}$*, and let* $\mathcal{S}$ *be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over* $\mathcal{T}$*. Then the carrier, classifier, carrier-transport, and restriction-stability fields of Definition 151.279 are supplied by Definition 151.154, Definition 151.155, Definition 151.157, Definition 151.158, and Definition 151.164.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertCarrierClassifier fields`

Proof. Project the indexed section carrier from $\mathcal{S}$. By Definition 151.154, the visible carrier rows are the section families $\mathsf{Sec}(i)$, and the classifier rows are the relations $\sim_i$ with their equivalence fields.

Apply Definition 151.157. It exhausts the carrier support by indexed sections, section classifiers, restriction maps, restriction identity and composition rows, indexed covers, compatibility predicates, locality, and gluing. Thus the root inventory has no additional carrier primitive to construct.

Apply Definition 151.158 and Definition 151.164. These provide classifier transport along restrictions, identity restriction, composition of two displayed restriction routes, and stability on finite-intersection rows supplied by $\mathsf{Topology}^{\uparrow}$.

Finally read the cover-facing source through Definition 151.155. It contributes only indexed covers and compatible local-family predicates, so the projected carrier and classifier fields repack exactly as the carrier, classifier, carrier-transport, and restriction-stability fields of the root inventory. □

Theorem 151.281 (Sheaf root NameCert locality and gluing fields)**.** *For an indexed sheaf carrier over $\mathcal{T}$, the locality and gluing fields of Definition 151.279 are supplied by Definition 151.283, Definition 151.169, and Definition 151.170.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertLocalityGluing fields`

Proof. Begin with an indexed cover $\mathcal{U} = (A, \iota, h, \gamma)$ of an open index i and a compatible local family $s_a : \mathsf{Sec}(\iota(a))$. The cover, overlap, and compatibility rows are exactly the rows of Definition 151.155.

Apply Definition 151.283. It identifies locality and gluing as root $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ rows over the same indexed cover and the same classifier family $\sim_i$.

The uniqueness side is then the projection of Definition 151.169. Two global sections that display the same compatible local family are equal in the global classifier because locality detects equality from all cover members.

The readback side is supplied by Definition 151.170. Restricting a global section to the members of an indexed cover produces a compatible local family, so the gluing row and the locality row are closed under the named cover ledger. □

Theorem 151.282 (Sheaf root NameCert refinement exactness fields)**.** *For an indexed sheaf carrier over $\mathcal{T}$, the refinement, common-refinement, and cover-presentation exactness fields of Definition 151.279 are supplied by Definition 151.284, Definition 151.285, Definition 151.189, and Definition 151.293.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootNameCertRefinementExactness fields`

Proof. Start with a displayed refinement of indexed covers. Apply Definition 151.284; it transports compatible local families and gluing rows along the refinement map using only displayed inclusion routes and restriction stability.

For two cover presentations, pass to a displayed common-refinement span. Apply Definition 151.285; agreement after pullback to the common cover identifies the two global gluing classifier classes.

Apply Definition 151.189. This repacks the common-refinement comparison as invariance of the cover presentation itself, without adding host cover equality or a quotient of cover presentations.

Finally apply Definition 151.293. The route-exactness row records the same inclusion and restriction-route comparisons as $\mathsf{NameCert}$-consumable ledger data, so the refinement and presentation fields close inside the root inventory of Definition 151.279. □

Theorem 151.283 (Sheaf root cover locality and gluing obligation)**.** *Let $\mathcal{T}$ be an indexed-open carrier for* $\mathsf{Topology}^{\uparrow}$*, and let $\mathcal{S}$ be the indexed section presheaf carrier over $\mathcal{T}$ supplied by the* $\mathsf{PreSheaf}^{\uparrow}$ *restriction surface. Then the indexed sheaf carrier of Definition 151.154, with classifier family $\sim_i$ and indexed covers as in Definition 151.155, supplies the carrier, classifier, locality, and gluing rows required by the root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *ten-field template of Definition 151.190.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverLocalityGluing obligation surface`

Proof. Unfold the indexed section presheaf carrier. Its carrier row is the family $\mathsf{Sec}(i)$ over open indices $i : \mathsf{OpenIx}$, and its restriction row is the stable transport $\rho_{i,j}$ along displayed inclusions $j \leq_{\mathcal{T}} i$.

Unfold the indexed cover compatibility and locality surface. An indexed cover records member opens, cover inclusions, and finite-intersection overlap rows, so a compatible family is already expressed entirely in the $\mathsf{Topology}^{\uparrow}$ and $\mathsf{PreSheaf}^{\uparrow}$ ledgers.

The sheaf fields then provide exactly the two root rows needed by the certificate: locality detects equality of global sections from equality after restriction to every cover member, and gluing supplies a global section for every compatible local family. These are the carrier, classifier, locality, and gluing entries named in the root template row of Definition 151.190. □

Theorem 151.284 (Sheaf root restriction refinement obligation)**.** *For an indexed sheaf carrier over $\mathcal{T}$, every displayed refinement of indexed covers preserves compatible families and transports gluing rows through restriction. Hence the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *root surface may replace a cover by any displayed refinement without changing the local-family compatibility ledger or the global gluing classifier row.*

Proof. Start with a displayed refinement of indexed covers. The refinement obligation of Definition 151.174 records the member map and the inclusion rows that route each refined open into the original cover member.

Apply Definition 151.175. A compatible family on the original indexed cover pulls back along the displayed refinement to a compatible family on the refined cover, because every overlap comparison is transported by the restriction composition and classifier-transport rows.

Apply Definition 151.176. If a global section glues the original compatible family, then the same global section glues the pulled-back family after the restriction transport supplied by the refinement. Thus the root certificate can consume either cover presentation with the same global classifier class. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRestrictionRefinement obligation`

Theorem 151.285 (Sheaf root common-refinement exactness obligation)**.** *Let two indexed cover presentations of the same open carry compatible local families. If the families agree after pullback to a displayed common refinement span, then their displayed gluings determine the same global section classifier class. This exactness uses only indexed cover data, displayed common refinement, and restriction transport; it does not quotient cover presentations.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCommonRefinement exactness obligation`
↪ variant `BEDC.Derived.SheafUp.SheafRootCommonRefinement obligation carrier exactness`

Proof. Unfold the displayed common-refinement span of Definition 151.186. The span consists of one indexed cover together with two displayed refinement projections into the two cover presentations being compared.

By Definition 151.187, the span yields the two refinement maps needed to pull both local families to the common cover. The hypothesis says that these two pulled-back families are classifier-equal at every member of that common cover.

Apply Definition 151.188. The two global sections, each viewed as a gluing after descent along its refinement projection, are equal in the classifier $\sim_i$ of the base open.

Finally apply Definition 151.189. The conclusion is an equality of global section classifier classes for the two cover presentations themselves, with no host open-cover equality and no quotient of cover presentations introduced into the root surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCommonRefinement route exactness`

Definition 151.286 (Sheaf root stalk-free point-germ source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root stalk-free point-germ source is the following ten-field source over* BHist*.*

1. *The topology field is the* $\mathsf{Topology}^{\uparrow}$ *indexed-open carrier of Definition 88.1, with open indices, membership rows* $\mathsf{OpenAt}(i, b)$*, inclusion rows* $j \leq_{\mathcal{T}} i$*, identity inclusions, and finite-intersection rows* $i \wedge_{\mathsf{Topology}^{\uparrow}} j$*.*
2. *The presheaf field is the* $\mathsf{PreSheaf}^{\uparrow}$ *indexed section carrier of Definition 151.154, with section carriers* $\mathsf{Sec}(i)$*, restriction rows* $\rho_{i,j}$*, restriction identity, restriction composition, and restriction classifier-stability.*
3. *The sheaf field is the* $\mathsf{Sheaf}^{\uparrow}$ *locality and gluing surface over the same indexed topology and presheaf carrier.*
4. *The naming field is the root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *obligation surface, read from the carrier, classifier, locality, gluing, refinement, and exactness rows already exposed by the indexed sheaf carrier.*
5. *The history field is the point carrier* BHist *together with* hsame*-stable transport of displayed membership rows.*
6. *The point-germ ledger field is the displayed ledger of Definition 151.231; a row over* $b : \mathsf{BHist}$ *is a triple* (i, o_i, s) *with* $o_i : \mathsf{OpenAt}(i, b)$ *and* $s : \mathsf{Sec}(i)$*.*
7. *The common-neighborhood field is supplied by finite intersections in the topology carrier, including the projections from* $i \wedge_{\mathsf{Topology}^{\uparrow}} j$ *to* i *and* j *and the displayed membership witness obtained from the two input membership rows.*
8. *The restriction-comparison field compares two point-germ rows only after restricting their sections to a displayed common neighborhood and applying the section classifier* $\sim_k$ *there.*
9. *The classifier-law field uses the reflexivity, symmetry, and transitivity rows of the section classifier on each* $\mathsf{Sec}(k)$*, together with restriction identity and restriction composition, to move comparisons across displayed neighborhoods.*
10. *The boundary field exports no host point carrier, no host stalk quotient, no quotient of section representatives, and no powerset equality of opens; all point-germ evidence remains inside indexed opens,* BHist *membership, restrictions, finite intersections, section classifiers, and* hsame *transport.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootStalkFreeGermSource`

Theorem 151.287 (Sheaf root point-germ classifier reflexivity)**.** *Every displayed point-germ row in the source of Definition 151.286 compares to itself. Concretely, if* (i, o_i, s) *is a row over* $b : \mathsf{BHist}$

in the sense of Definition 151.231, then the comparison from (i, o_i, s) to (i, o_i, s) is witnessed by the common neighborhood i, the identity inclusions $i \leq_{\mathcal{T}} i$, the membership row o_i, and the identity classifier row

$$\rho_{i,i}(s) \sim_i \rho_{i,i}(s).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison reflexive`

Proof. Use the row's own indexed open as the displayed common neighborhood. The two projections required by Definition 151.231 are both the identity inclusion $i \leq_{\mathcal{T}} i$, and the membership witness is the row's own witness $o_i : \mathsf{OpenAt}(i, b)$.

It remains to fill the classifier comparison after restriction. The identity restriction field of Definition 151.154 identifies $\rho_{i,i}(s)$ with s in the section classifier on $\mathsf{Sec}(i)$, and the reflexivity field of that classifier gives $\rho_{i,i}(s) \sim_i \rho_{i,i}(s)$. This is exactly the displayed comparison row. □

Theorem 151.288 (Sheaf root point-germ classifier symmetry)**.** *The displayed point-germ comparison in the source of Definition 151.286 is symmetric. If rows (i, o_i, s) and (j, o_j, t) over the same $b : \mathsf{BHist}$ compare on a displayed common neighborhood k with projections*

$$k \leq_{\mathcal{T}} i, \qquad k \leq_{\mathcal{T}} j, \qquad o_k : \mathsf{OpenAt}(k, b),$$

and classifier row

$$\rho_{i,k}(s) \sim_k \rho_{j,k}(t),$$

then the reverse comparison from (j, o_j, t) to (i, o_i, s) is witnessed by the same k, the projections swapped, the same membership row o_k, and the symmetric classifier row

$$\rho_{j,k}(t) \sim_k \rho_{i,k}(s).$$

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison symmetric fields`

Proof. Keep the displayed common neighborhood k. The comparison definition asks only for a neighborhood below the two source opens and a membership row at b, so the same witness o_k remains valid and the two projections are read in the opposite order.

The only row whose direction changes is the section classifier comparison on $\mathsf{Sec}(k)$. Apply the symmetry field of the classifier supplied by Definition 151.154 to the given row $\rho_{i,k}(s) \sim_k \rho_{j,k}(t)$. The result is $\rho_{j,k}(t) \sim_k \rho_{i,k}(s)$, so the swapped neighborhood data form the reverse point-germ comparison. □

Theorem 151.289 (Sheaf root point-germ classifier equivalence boundary)**.** *On the displayed point-germ rows of Definition 151.286, the comparison relation of Definition 151.231 is an equivalence relation. Reflexivity is supplied by Definition 151.287, symmetry by Definition 151.288, and transitivity by Definition 151.235. The resulting equivalence boundary exports only displayed rows and comparison witnesses over indexed neighborhoods; it exports no stalk quotient, no host point carrier, and no quotient carrier of point-germ classes.*

Proof. For reflexivity, apply Definition 151.287 to the displayed row. The witness is its own indexed open, with identity restriction and the section classifier's reflexivity row.

For symmetry, apply Definition 151.288 to any displayed comparison witness. This keeps the same common neighborhood and reverses only the two projection slots and the section classifier row.

For transitivity, take two composable displayed comparison witnesses between rows over the same $b : \mathsf{BHist}$. Apply Definition 151.235; its finite-intersection construction supplies the refined common neighborhood and composes the restricted classifier rows.

These three clauses are stated entirely in the ledger language of Definition 151.231. Since Definition 151.286 contains no host stalk carrier and no quotient operation, the equivalence relation is the boundary relation available to downstream consumers, not a construction of stalk elements. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermComparison common transport`

Definition 151.290 (Sheaf root route exactness packet)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root route exactness packet is the following ten-field* BHist*-scoped surface.*

1. *The traditional target is the sheaf route from an accepted indexed cover cell to the section row consumed by downstream certificates.*
2. *The BEDC source is the joint* $\mathsf{Topology}^{\uparrow}$*,* $\mathsf{PreSheaf}^{\uparrow}$*, and* $\mathsf{NameCert}$ *surface, read over* BHist *histories and optional* Cont *route histories.*
3. *The carrier is the indexed-open carrier of* $\mathsf{Topology}^{\uparrow}$ *together with the section carrier* $\mathsf{Sec}(i)$ *of Definition 151.154.*
4. *The classifier is the open-indexed section relation* $\sim_i$ *on* $\mathsf{Sec}(i)$*, transported only along displayed restriction routes.*
5. *The stability rows are restriction identity, restriction composition, one-step classifier transport, two-step classifier transport, and route-history associativity when* Cont *rows are present.*
6. *The ledger rows are cover-member cells, pair-overlap cells, route witnesses, and* hsame *membership transport in the* BHist *cover nerve.*
7. *The exactness rows are cover-cell membership exhaustion, restriction-route classifier transport, locality and gluing, displayed refinement descent, and common-refinement comparison.*
8. *The downstream consumers are exactly the* $\mathsf{RingedSpace}^{\uparrow}$ *local-ring face, the* $\mathsf{Scheme}^{\uparrow}$ *affine-chart face, and topology pullback constructions.*
9. *The packet contains no host powerset equality of open covers, no quotient of cover presentations, no stalk quotient, and no external sheafification operation.*
10. *The status is a root* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *route-exactness surface: it records the rows available for downstream use and does not assert standard bridge closure.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootRouteExactnessPacket`

Theorem 151.291 (Sheaf route exactness membership transport)**.** *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an accepted indexed cover of* i *over the* BHist *topology ledger. For every displayed cell* $\mathsf{OpenAt}(i, b)$ *and every displayed restriction route from* i *to a cover member or pair-overlap row, the packet of Definition 151.290 transports the cover-member witness through the route and preserves the target section classifier on the reached open.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRouteExactness membership transport`

Proof. First build the cover witness. Apply Definition 151.303 to the accepted cover row. It sends the displayed cell $\mathsf{OpenAt}(i, b)$ to a member $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$ and supplies the finite-intersection row needed for comparison with any second member.

Next transport along the restriction route. Apply Definition 151.304. Its one-step and two-step clauses keep the section comparison inside the classifier of the reached member or overlap open.

The transported member witness and the transported classifier row use the same indexed open route. Since both cited rows are recorded over BHist and use hsame for membership transport, the result stays inside the cover nerve and introduces no host cover equality or cover quotient. □

Theorem 151.292 (Sheaf route exactness Cont composition)**.** *When optional* Cont *histories are present in the* $\mathsf{Sheaf}^{\uparrow}$ *route ledger, their composition rows compose displayed route witnesses only. They preserve the target open index and therefore preserve the target section classifier* $\sim_j$ *or* $\sim_k$ *already transported by restriction stability.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route history stability`

Proof. Start with the one-step route. The restriction stability obligation of Definition 151.300 gives classifier transport from $\sim_i$ to $\sim_j$ along $j \leq_{\mathcal{T}} i$.

For a composite route $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$, use the composition clause of Definition 151.300. The direct restriction from i to k and the route through j are compared in the same target classifier $\sim_k$.

Now read the optional Cont row. By Definition 151.304, such a history compares route witnesses and does not change the reached open. Hence route-history composition can only rebracket the displayed path; the classifier already attached to the reached open is unchanged. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route cont composition`

Theorem 151.293 (Sheaf route exactness NameCert consumption)**.** *The* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers receive exactly the route-exactness packet of Definition 151.290: cover-member cells, restriction classifier transport, optional* Cont *route-history composition, and the downstream projection rows sealed for those consumers. No consumer receives a larger sheaf interface from this packet.*

Proof. First identify the common downstream surface. Apply Definition 151.305. It lists the cover-member cells, pair-overlap cells, one-step and two-step restriction stability rows, optional Cont histories, and locality and gluing exactness rows available to downstream consumers.

For the ringed-space consumer, apply Definition 151.253. The local-ring face may read the sheaf section carrier, classifier, restriction stability, cover-gluing exactness, restricted-open rows, and displayed base-change rows, while local-ring structure itself is supplied outside $\mathsf{Sheaf}^{\uparrow}$.

For the scheme consumer, apply Definition 151.254. Its affine-chart read is routed through cover-presentation rows, displayed common-refinement rows, and the sealed ringed-space projection, so it receives the same route-exactness packet rather than a separate sheaf surface.

For topology pullback consumers, apply Definition 151.255. The pullback face reads pulled-back cover membership, restriction-route stability, compatible-family transport, gluing pullback, and common-refinement transport along displayed base change.

The three projections exhaust the consumers named in Definition 151.290. Since each cited seal excludes host powerset equality, cover quotients, stalk quotients, external sheafification, and standard bridge closure, downstream NameCert use is exactly the route-exactness packet and nothing larger. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootRouteExactness namecert consumption`

Definition 151.294 (Sheaf root threshold certificate source)**.** *The* $\mathsf{Sheaf}^{\uparrow}$ *root threshold certificate source is the* BHist*-indexed package consisting of the* $\mathsf{Topology}^{\uparrow}$ *topology carrier, the* $\mathsf{PreSheaf}^{\uparrow}$ *presheaf restriction carrier, the open-indexed section classifier family, the cover-nerve ledger, the point-germ ledger, the restricted-open ledger, the displayed base-change rows, and the refinement and common-refinement exactness rows. It is a source of threshold certificates only through indexed opens,* BHist *membership, section classifiers, restriction maps, displayed refinements, displayed base-change squares, restricted-open slices, and* hsame*-stable transport.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootThresholdCertificateSource`

Theorem 151.295 (Sheaf root threshold carrier and classifier obligation)**.** *The certificate source of Definition 151.294 supplies the carrier and classifier obligations of the* $\mathsf{Sheaf}^{\uparrow}$ *root solely through indexed opens,* BHist *membership, the section classifier family, restriction maps, and* hsame*-stable transport. In particular, the carrier side is exhausted by open indices, section carriers* $\mathsf{Sec}(i)$*, classifier rows* $\sim_i$*, restriction rows* $\rho_{i,j}$*, cover membership over* BHist*, and point-germ rows read on displayed neighborhoods.*

Proof. Read the carrier row from Definition 151.154. It supplies the open-indexed section carriers, the section classifiers, the restriction maps, and the identity, composition, equivalence, and classifier-transport rows attached to them.

Read the history side from Definition 151.160. Its cover-member rows are indexed by open carriers and BHist cells, and transport across history witnesses is only the displayed hsame transport already recorded in the ledger.

For pointwise readback, use Definition 151.231. A point-germ row chooses an indexed neighborhood containing the history cell and compares sections by restricting to displayed common neighborhoods, so it adds no host point, stalk quotient, or external carrier beyond the classifier and restriction rows already named. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold carrier classifier semantic certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold semantic name certificate`

Theorem 151.296 (Sheaf root threshold gluing and refinement obligation)**.** *The certificate source of Definition 151.294 assembles the exactness obligation of the* $\mathsf{Sheaf}^{\uparrow}$ *root from locality, gluing, refinement pullback, refinement gluing descent, restricted common-refinement exactness, and base-change gluing pullback. Each exactness row is expressed through indexed covers, compatible local families, displayed refinements, restricted-open slices, displayed base-change squares, section classifiers, and restriction transport.*

Proof. Begin with the root export exactness package of Definition 151.269. It already groups locality, gluing, refinement pullback, refinement gluing descent, and common-refinement presentation exactness as the stability and exactness rows exported by $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$.

The restricted-open part is read in the same package from the restricted common-refinement rows below a fixed indexed open. These rows keep the ambient section classifiers and restriction maps, and only narrow the cover ledger to the displayed slice.

For movement across a displayed source and target, apply Definition 151.208. Its cover-pullback, gluing-pullback, and common-refinement rows reuse the same exactness package after the displayed base-change square identifies the relevant source opens and pulled-back cover members. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold gluing refinement obligation`

Theorem 151.297 (Sheaf root threshold downstream coverage obligation)**.** *Every* $\mathsf{Sheaf}^{\uparrow}$ *row consumed by* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers is covered by the threshold source of Definition 151.294. Thus downstream chapters receive their sheaf-side data from the topology carrier, restriction carrier, section classifiers, cover-nerve ledger, point-germ ledger, restricted-open ledger, displayed base-change rows, and refinement or common-refinement exactness rows of that single source.*

Proof. For $\mathsf{RingedSpace}^{\uparrow}$, apply Definition 151.197. Its sheaf-side requests are precisely the indexed section carriers, classifiers, restriction stability, cover-gluing exactness, restricted-open surface, and displayed base-change surface listed in the threshold source.

For $\mathsf{Scheme}^{\uparrow}$, apply Definition 151.198. Each affine or ringed-space chart first consumes the ringed-space sheaf boundary, and overlap compatibility is discharged by the cover-presentation and common-refinement exactness rows already included in the source.

For topology pullback consumers, apply Definition 151.226. The pulled-back cover rows are displayed base-change rows over the same indexed-open and BHist ledgers, so they are covered by the threshold source without adding a host powerset cover comparison or external sheaf model. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootThreshold downstream coverage obligation`

151.14 Root obligations for downstream certificates

Definition 151.298 (SheafUp root-unblock BEDC source)**.** *The root-unblock source for* $\mathsf{Sheaf}^{\uparrow}$ *is the ten-field certificate surface consumed by ringed-space, scheme, and restricted-open sheaf constructions.*

1. *The traditional target is sheaves of sections over indexed opens.*
2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* $\mathsf{NameCert}$.
3. *The history ledger is the* BHist *cover-nerve ledger of Definition 151.160.*
4. *The carrier is the indexed section presheaf carrier of Definition 151.154, equipped with the locality and gluing fields of Definition 151.155.*
5. *The classifier family is the open-indexed relation* $\sim_i$ *on* $\mathsf{Sec}(i)$.
6. *The cover ledger records cover indices* A, *cover-member maps* $\iota : A \to \mathsf{OpenIx}$, *and pointwise cover rows over* BHist.
7. *The overlap ledger records finite intersections* $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(a')$ *and their projection rows.*
8. *The restriction ledger records routes from a target open to cover members and overlaps, with identity, composition, and classifier-stability rows.*
9. *Optional route histories are recorded by* Cont *rows, and history-cell membership is transported only by* hsame.
10. *The surface contains no quotient of cover presentations and no equality of host powersets of opens.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource`

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource member point germ`

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockBEDCSource cover membership`

Theorem 151.299 (Sheaf root-unblock cover membership obligation)**.** *Let $\mathcal{U} = (A, \iota, h, \gamma)$ be an accepted cover row of an open index i over a* BHist *topology ledger. Then every displayed history membership in the covered open has a displayed cover-member witness:*

$$\forall b : \mathsf{BHist},\ \mathsf{OpenAt}(i, b) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), b).$$

All overlap information used downstream is recorded only through finite-intersection rows and hsame*-stable* BHist *membership, not through host powerset equality.*

Proof. Unfold the accepted cover row. Its pointwise cover component is exactly the displayed implication from $\mathsf{OpenAt}(i, b)$ to a cover index $a : A$ with $\mathsf{OpenAt}(\iota(a), b)$.

For overlap rows, use the finite-intersection field of the indexed topology carrier as in Definition 151.161. It supplies the overlap index and the two projection rows back to the participating cover members.

History transport is then read from the BHist cover-nerve ledger of Definition 151.160. That ledger admits only hsame-stable membership transport, so the exported cover-membership row stays internal to indexed opens and history cells. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockCoverMembership obligation`

Theorem 151.300 (Sheaf root-unblock restriction stability obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$. Restriction identity, restriction composition, stable restriction rows, and* Cont *associativity for route histories preserve the target section classifier along one-step and two-step restriction routes. Concretely, for $j \leq_{\mathcal{T}} i$ and $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$, the rows*

$$\rho_{i,i}(s) \sim_i s, \qquad s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t), \qquad \rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

are the classifier-preserving route rows exposed to downstream certificates.

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblockRestrictionStability semantic name certificate`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock restriction stability rows`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistPointGermLedger route history target classifier stability`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock restriction stability surface`

Proof. The identity and composition rows are fields of the indexed section presheaf carrier in Definition 151.154. The one-step classifier preservation row is the stable restriction row of Definition 151.156, also cited as Definition 151.172.

For a two-step route, first use restriction classifier transport along $j \leq_{\mathcal{T}} i$, then compose with the route from j to k. The displayed composition row identifies this two-step restriction with the direct restriction from i to k in the classifier $\sim_k$.

If the ledger also carries Cont histories for the same routes, their associativity only compares displayed route histories. It does not alter the open index k or the classifier $\sim_k$, so it preserves the same target section classifier consumed by the certificate. □

Theorem 151.301 (Sheaf root-unblock locality and gluing obligation)**.** *Let $\mathcal{S}$ be an indexed sheaf carrier for* $\mathsf{Sheaf}^{\uparrow}$ *over an indexed open topology carrier $\mathcal{T}$, and let $\mathcal{U} = (A, \iota, h, \gamma)$ be an indexed cover of i. Compatible local families with displayed gluings have a* NameCert*-consumable exactness row: locality gives global classifier equality for any two global readbacks whose restrictions agree on the cover, and gluing supplies existence of a global readback without quotienting cover presentations.*

Proof. The existence half is the gluing field in Definition 151.155. Given a compatible local family, it supplies a section $g : \mathsf{Sec}(i)$ together with displayed restriction rows to each $\iota(a)$.

The uniqueness half is locality. If two global readbacks restrict to classifier-equal sections on every cover member, the locality field returns equality in the global classifier $\sim_i$; Definition 151.169 packages the same argument for two displayed gluings of one compatible family.

Refinement and presentation changes are handled by the existing refinement rows Definition 151.176, Definition 151.179, Definition 151.188, and Definition 151.189. Each row uses displayed cover maps, common refinements, restriction stability, Cont route histories when present, and hsame-stable membership; none introduces a quotient of cover presentations. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootUnblock locality gluing faces`
Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootFaceRead locality gluing refinement inversion`

Definition 151.302 (Sheaf root cover-nerve export surface)**.** *The root cover-nerve export surface for* $\mathsf{Sheaf}^{\uparrow}$ *is the three-row* BHist*-scoped certificate surface consumed by downstream chapters.*

1. *The traditional target is sheaves over indexed opens, read through section carriers on a cover nerve rather than through host open covers.*
2. *The BEDC source chapters are* $\mathsf{Topology}^{\uparrow}$, $\mathsf{PreSheaf}^{\uparrow}$, *and* NameCert.
3. *The carrier is the family of indexed sections over* BHist *opens, using* $\mathsf{Sec}(i)$ *from Definition 151.154 for each open index* i.
4. *The classifier family is the displayed section relation* $\sim_i$ *on* $\mathsf{Sec}(i)$.
5. *The stability rows are restriction identity, restriction composition, classifier transport, and optional* Cont *route-history transport.*
6. *The ledger rows are cover-member cells, pair-overlap cells, and route-history cells in the* BHist *cover nerve of Definition 151.160.*
7. *The exactness rows are cover membership, restriction route stability, and locality/gluing.*
8. *The cover-membership row sends every accepted* $\mathsf{OpenAt}(i, b)$ *cell to a displayed cover member and its pair-overlap ledger context.*
9. *The downstream export is exactly the rows listed here:* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback consumers receive no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*
10. *There is no standard bridge in this surface.*

Lean4 (definition) `BEDC.Derived.SheafUp.SheafRootCoverNerveExportSurface`

Theorem 151.303 (Sheaf root cover-nerve membership exhaustion)**.** *Let* $\mathcal{U} = (A, \iota, h, \gamma)$ *be an accepted cover row of an indexed open* i *over the* BHist *topology ledger. Every displayed cell* $\mathsf{OpenAt}(i, b)$ *in this accepted cover has a cover-member witness and a pair-overlap row inside the* BHist *cover nerve:*

$$\forall b : \mathsf{BHist},\ \mathsf{OpenAt}(i, b) \Longrightarrow \exists a : A,\ \mathsf{OpenAt}(\iota(a), b)$$

and for every second member $a' : A$ *the ledger also contains the finite-intersection row for* $\iota(a) \wedge_{\mathsf{Topology}^{\uparrow}} \iota(a')$ *with its two projections to the participating members.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve membership exhaustion`

Proof. Apply the cover-membership obligation of Definition 151.299. It reads the accepted cover row as a BHist-indexed implication from an ambient displayed cell to a cover-member witness, so every $\mathsf{OpenAt}(i, b)$ cell is exhausted by a displayed member $\iota(a)$.

The pair-overlap row is then the overlap projection surface of Definition 151.161, unpacked inside the cover-nerve ledger of Definition 151.160. For each pair $a, a' : A$, the finite-intersection row supplies the overlap index and the two projections back to $\iota(a)$ and $\iota(a')$.

Because the ledger transports membership only by hsame, this exhaustion stays scoped to BHist cells and indexed opens. No host cover equality or quotient of cover presentations is introduced. □

Theorem 151.304 (Sheaf root cover-nerve restriction route stability)**.** *Let $\mathcal{S}$ be the indexed section carrier of Definition 151.154 over an indexed open topology carrier. One-step and two-step restrictions preserve section classifiers:*

$$s \sim_i t \Longrightarrow \rho_{i,j}(s) \sim_j \rho_{i,j}(t), \qquad \rho_{j,k}(\rho_{i,j}(s)) \sim_k \rho_{i,k}(s)$$

for every displayed chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. Optional Cont *route histories compare route witnesses only and do not alter the target classifier $\sim_j$ or $\sim_k$.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafBHistCoverNerveLedger route hsame transport`

Proof. The first displayed row is the restriction classifier-transport field of Definition 151.154. It is also the one-step stability clause isolated by Definition 151.300.

For the two-step row, apply the composition field of the same carrier to the chain $k \leq_{\mathcal{T}} j \leq_{\mathcal{T}} i$. The comparison lands in $\sim_k$, so the direct restriction and the composed restriction have the same target classifier.

If a Cont history is present, use the route-history part of Definition 151.300. Those histories record associativity of displayed routes; they do not change the open index of the restricted section, hence cannot change the classifier family consumed downstream. □

Theorem 151.305 (Sheaf root cover-nerve downstream coverage)**.** *The downstream consumers* $\mathsf{RingedSpace}^{\uparrow}$, $\mathsf{Scheme}^{\uparrow}$, *and topology pullback constructions receive exactly the rows of Definition 151.302: cover-member cells, pair-overlap cells, one-step and two-step restriction stability rows, optional* Cont *route histories, and locality/gluing exactness rows. They receive no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Proof. The carrier part is fixed by Definition 151.154: downstream chapters can read only indexed section carriers, section classifiers, restrictions, and the identity, composition, and classifier-transport rows attached to them.

The cover part is fixed by Definition 151.160 and Definition 151.303. These provide cover-member cells and pair-overlap cells over BHist, with overlap projections supplied by Definition 151.161.

The exactness part is the union of the three root obligations. Cover membership comes from Definition 151.299; restriction route stability comes from Definition 151.300; locality and gluing come from Definition 151.301.

Those cited rows are precisely the rows listed in Definition 151.302. Since none of them introduces host cover equality, a cover quotient, a stalk quotient, or an external sheafification operation, no downstream consumer obtains such a row from this export surface. □

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve downstream coverage`

Theorem 151.306 (Sheaf root cover-nerve exact globalization package)**.** *The root cover-nerve export surface of Definition 151.302 forms an* ExactGlobalizeBase*-style package over the indexed-open* BHist *cover nerve. Its coverage face is Definition 151.303; its base soundness face is Definition 151.304; its base completeness and exactness face is the locality-gluing row of Definition 151.301. Hence* $\mathsf{RingedSpace}^{\uparrow}$ *and* $\mathsf{Scheme}^{\uparrow}$ *may consume one classifier-exact cover-nerve package, with no host cover equality, cover quotient, stalk quotient, or external sheafification operation.*

Lean4 ✓ `BEDC.Derived.SheafUp.SheafRootCoverNerve exact globalize package`

Proof. Unpack Definition 151.302. The carrier is the indexed family $\mathsf{Sec}(i)$ over BHist opens, the classifier is the displayed relation $\sim_i$, and the ledger is the cover nerve of Definition 151.160.

The coverage face is exactly Definition 151.303. It sends each displayed $\mathsf{OpenAt}(i, b)$ cell to a cover member and records the pair-overlap rows needed by downstream restriction routes.

The base soundness face is Definition 151.304. One-step restriction, two-step restriction, classifier transport, and optional Cont route histories preserve the section classifier on the target indexed open.

The base completeness and exactness face is Definition 151.301. Gluing constructs the global readback from compatible local rows, and locality identifies any two global readbacks whose restrictions agree on the accepted cover.

These are precisely the coverage, soundness, and completeness fields required by the exact-globalization constructor of Definition 9199.16, with the relation field constrained as in Definition 9199.11. Repacking the three displayed faces therefore gives the single classifier-exact cover-nerve package consumed by the downstream chapters, and Definition 151.305 fixes that no quotient or external sheafification row is exported. □

Chapter 152

A Concrete Naming Certificate for $\mathsf{RingedSpace}^{\uparrow}$

The ringed-space interface $\mathsf{RingedSpace}^{\uparrow}$ packages a topological carrier with a sheaf of commutative rings on it, certifying that stalks form local rings. It depends on $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ (chapter 151) and $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ (chapter 44).

152.1 Carrier definition

Theorem 152.1 (RingedSpace carrier and stalk obligations)**.** *A* $\mathsf{RingedSpace}^{\uparrow}$ *certificate must expose a* $\mathsf{Topology}^{\uparrow}$ *carrier over* BHist*, a* $\mathsf{Sheaf}^{\uparrow}$ *row of section carriers on that topology, a* $\mathsf{CommRing}^{\uparrow}$ *fibre row on every displayed open, and a* $\mathsf{LocalRingUp}$ *stalk row at every displayed point history. The carrier ledger consists exactly of the base-open index, the membership row, the section carrier, the restriction route, the commutative-ring operation tuple on each fibre, and the local-ring witness obtained from the sheaf germ classifier at the stalk.*

Proof. The named carrier is the displayed topological carrier supplied by $\mathsf{Topology}^{\uparrow}$ together with the open-membership row that decides which histories lie in each displayed open. Over that carrier, the $\mathsf{Sheaf}^{\uparrow}$ row supplies section carriers and restriction routes for displayed inclusions of opens.

For each displayed open, the fibre is the corresponding section carrier equipped with the $\mathsf{CommRing}^{\uparrow}$ operation row. The zero, one, addition, multiplication, negation, and unit rows are therefore indexed by the same open ledger as the sheaf restriction maps.

At a displayed point history, the stalk row is read from the $\mathsf{Sheaf}^{\uparrow}$ germ classifier over displayed neighbourhoods. The local-ring witness is then a $\mathsf{LocalRingUp}$ row on that germ carrier, with its operations induced from the $\mathsf{CommRing}^{\uparrow}$ fibre rows through restriction.

Thus the ringed-space carrier obligation is not a separate host object. It is the joint BEDC row formed by $\mathsf{Topology}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{CommRing}^{\uparrow}$, and $\mathsf{LocalRingUp}$ stalk data, all indexed by BHist and by the displayed open ledger. □

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface carrier classifier rows`

Theorem 152.2 (RingedSpace classifier transport obligations)**.** *For a* $\mathsf{RingedSpace}^{\uparrow}$ *certificate,* hsame *transport, the* $\mathsf{Topology}^{\uparrow}$ *base-open classifier, and the* $\mathsf{Sheaf}^{\uparrow}$ *section classifier must transport section rows, restriction witnesses,* $\mathsf{CommRing}^{\uparrow}$ *operation endpoints, germ rows, and* $\mathsf{LocalRingUp}$ *stalk-locality witnesses. In particular, if two base presentations are related by* hsame *and their*

opens are matched by the topology classifier, then section comparison and stalk-locality are decided only by the transported sheaf and ring classifiers.

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingleton sheaf commring stalk locality obligation`

Proof. Begin with a displayed hsame witness between base histories. The $\mathsf{Topology}^{\uparrow}$ classifier transports open names, membership rows, and inclusion rows across that witness, so the source and target presentations have the same displayed neighbourhood ledger.

The $\mathsf{Sheaf}^{\uparrow}$ classifier then transports sections along the matched open rows. Because restriction witnesses are part of the sheaf ledger, the transported section row has the same restriction comparison as the source row after reindexing by the topology classifier.

Next transport the $\mathsf{CommRing}^{\uparrow}$ endpoints on fibres. Operation compatibility says that zero, one, addition, multiplication, negation, and unit detection commute with the transported section comparison, so fibre operations remain section rows after the same classifier pass.

Finally, stalk-locality is transported through the sheaf germ classifier. A local-ring witness at a point history is accepted on the target side only when it is represented by a common displayed neighbourhood, transported restrictions, and the transported $\mathsf{CommRing}^{\uparrow}$ endpoint classifier. □

Theorem 152.3 (RingedSpace exact ledger obligations)**.** *A* $\mathsf{RingedSpace}^{\uparrow}$ *certificate must state coverage, soundness, completeness, and exact ledger rows for base opens, restriction maps, commutative-ring operations, and local-stalk witnesses. Coverage says every named ringed-space read is represented by those rows. Soundness says every accepted row is stable under the displayed classifiers. Completeness says every classifier-stable base-open, section, operation, and stalk-locality witness appears in the ledger. Exactness says no host open equality, section quotient, stalk quotient, or standard bridge witness is silently added.*

Proof. Coverage is obtained by projecting a displayed ringed-space read to its four named rows: the $\mathsf{Topology}^{\uparrow}$ base-open row, the $\mathsf{Sheaf}^{\uparrow}$ restriction row, the $\mathsf{CommRing}^{\uparrow}$ operation row, and the LocalRingUp stalk-locality row. Each projection is part of the certificate surface described in Definition 152.1.

Soundness follows by applying the transport obligations of Definition 152.2. A row accepted by the ledger remains accepted after base-open transport, section transport, operation-endpoint transport, and germ transport.

Completeness is the converse reading of the same rows. If the base-open, restriction, operation, and stalk-locality witnesses are all stable under the displayed classifiers, the certificate repacks them as a $\mathsf{RingedSpace}^{\uparrow}$ row without asking for any additional carrier.

Exactness is the boundary condition. The ledger contains precisely the base-open, restriction-map, commutative-ring operation, and local-stalk rows, so any later $\mathsf{Scheme}^{\uparrow}$ or variety certificate citing $\mathsf{RingedSpace}^{\uparrow}$ as a source receives only those obligations and not a hidden standard bridge. □

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingleton cover nerve empty boundary`
Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface restriction exact ledger`

Theorem 152.4 (RingedSpaceUp carrier and sheaf obligation)**.** *A* $\mathsf{RingedSpace}^{\uparrow}$ NameCert *is sourced by a* BHist *topological carrier together with a* $\mathsf{Sheaf}^{\uparrow}$ *row assigning to each carried open witness a* $\mathsf{CommRing}^{\uparrow}$ *section carrier. Its classifier is inherited only from* hsame*, the* $\mathsf{Topology}^{\uparrow}$ *open classifier, the* $\mathsf{Sheaf}^{\uparrow}$ *restriction classifier, and the* $\mathsf{CommRing}^{\uparrow}$ *classifier. The carrier ledger records the open witness, membership row, section carrier, restriction row, and commutative-ring endpoint surface for each displayed open.*

Proof. Unpack the ten-field NameCert template. The source row supplies the BHist topological carrier, so every open witness is read through the carried Topology$^{\uparrow}$ classifier and transported only by hsame.

Read the Sheaf$^{\uparrow}$ NameCert over the indexed opens. For each displayed open, its section row gives the section carrier and the restriction classifier visible along displayed inclusions.

Finally restrict each section value to the CommRing$^{\uparrow}$ certificate surface. The result is the displayed carrier and classifier row needed by RingedSpace$^{\uparrow}$, with no extra host algebra or standard bridge data. □

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingleton carrier sheaf obligation`

Theorem 152.5 (RingedSpaceUp stalk-locality obligation)**.** *For every carried point history and every admissible neighbourhood-filter row of a* RingedSpace$^{\uparrow}$ *certificate, the stalk projection is a local* CommRing$^{\uparrow}$ *row. Restriction-compatible germs have a unique maximal non-unit classifier branch, and germ comparison is stable under* hsame *transport of the point and under* Sheaf$^{\uparrow}$ *refinement. Local-ring status is recorded as an obligation row of the displayed certificate rather than as an external model.*

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonPackage restricted stalk locality obligation`
Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface stalk locality readback`
Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingleton stalk restriction commring stability`

Proof. Use the Sheaf$^{\uparrow}$ restriction and refinement exactness rows to compare two representatives of a germ on a common displayed neighbourhood. The common row supplies the section classifier needed to identify the restricted section endpoints.

Apply the CommRing$^{\uparrow}$ carrier and classifier rows to those section endpoints. Unit detection, non-unit comparison, and maximal-branch uniqueness are then read from the displayed commutative-ring row attached to the germ endpoint.

Transport stability follows because the point history is moved by hsame and the neighbourhood row is refined through Sheaf$^{\uparrow}$. Repacking these witnesses gives the stalk-local CommRing$^{\uparrow}$ obligation row without introducing a host stalk quotient. □

Theorem 152.6 (RingedSpaceUp stability, exactness, and ledger obligation)**.** *Carrier transport, restriction compatibility, stalk transport, and exactness for visible* RingedSpace$^{\uparrow}$ *packages are exactly the conjunction of* Topology$^{\uparrow}$ *carrier transport,* Sheaf$^{\uparrow}$ *restriction and gluing classifier transport, and* CommRing$^{\uparrow}$ *algebraic classifier transport. The ledger records the open witness, restriction route, section endpoint, and stalk-germ provenance, and it records no* Scheme$^{\uparrow}$*, affine-cover, spectrum, or standard bridge data.*

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface stability ledger rows`
Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface stability ledger obligation`
Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingleton stability ledger obligation`

Proof. Compose the three named certificate surfaces through the NameCert stability field. The $\mathsf{Topology}^{\uparrow}$ surface transports open witnesses, the $\mathsf{Sheaf}^{\uparrow}$ surface transports restrictions and gluing classifiers, and the $\mathsf{CommRing}^{\uparrow}$ surface transports algebraic endpoints.

Project the ledger coordinates after this composition. The open witness comes from the topology row, the restriction route and section endpoint come from the sheaf row, and the stalk-germ provenance is obtained by the stalk-locality row of Definition 152.5.

Exactness is therefore the conjunction of those three transport surfaces as seen by the visible package. Since every ledger coordinate has already been projected, no scheme, affine-cover, spectrum, or standard bridge row is present in the $\mathsf{RingedSpace}^{\uparrow}$ certificate. □

Lean4 ✓ `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonSurface restriction stability ledger`

152.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{RingedSpace}^{\uparrow}}$.

Constructive story: A ringed space is assembled by taking a $\mathsf{Topology}^{\uparrow}$ carrier over BHist, placing a $\mathsf{Sheaf}^{\uparrow}$ row of section carriers on its displayed opens, reading each fibre through $\mathsf{CommRing}^{\uparrow}$, and then taking the stalk at a displayed point through the sheaf germ comparison until the local-ring row is visible. The carrier accepts only packets with that open-membership row, section row, restriction route, commutative-ring operation tuple, germ provenance, and local-stalk witness; host open equality, a stalk quotient, a spectrum row, and any $\mathsf{Scheme}^{\uparrow}$ data stay outside the carrier. Two accepted packets classify together when hsame transports the base histories and the upstream topology, sheaf, commutative-ring, and stalk-locality classifiers carry the same opens, sections, restrictions, operations, and germs across the comparison. The source specification is precisely this topology-sheaf-ring-stalk packet, the pattern records the base-open membership, restriction compatibility, fibre operations, and local germ behaviour, and the ledger keeps the raw open witness, section endpoint, restriction route, and stalk provenance visible in the same order in which the packet was built. The five naming-certificate obligations are discharged because the singleton surface supplies an admitted packet, the component classifiers are reflexive, symmetric, and transitive, and every accepted row is transported back into the carrier by the same displayed hsame and upstream classifier rows. A history h lies in the signature gap of a $\mathsf{RingedSpace}^{\uparrow}$ token p only when the source domain accepts that whole packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; for this chapter that condition contracts to saying that the topology, sheaf, fibre-ring, and local-stalk rows of h are exactly the transported rows named by p. The chapter registers this row-by-row stalk construction under the name $\mathsf{RingedSpace}^{\uparrow}$; it exports the surface needed by $\mathsf{Scheme}^{\uparrow}$ without adding a spectrum bridge, host stalk quotient, or independent locally ringed space primitive.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RingedSpace}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scope is the existing $\mathsf{RingedSpace}^{\uparrow}$ carrier, classifier transport, exact ledger, stalk-locality, and stability-ledger theorem surface exported for $\mathsf{Scheme}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RingedSpace}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RingedSpaceUp.RingedSpaceSingletonStalk\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not close $\mathsf{Scheme}^{\uparrow}$, affine or projective variety closure, the spectrum standard bridge, or bridge verification.

Upgrade path: No further theory-axis upgrade is pending; bridge verification remains a formal-axis and bridge-status matter.

Chapter 153

A Concrete Naming Certificate for $\mathsf{Scheme}^{\uparrow}$

The scheme interface $\mathsf{Scheme}^{\uparrow}$ packages a locally ringed space that admits an open cover by spectra of commutative rings. It depends on $\mathsf{NameCert}_{\mathsf{RingedSpace}^{\uparrow}}$ (chapter 152) and $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ (chapter 44), and is the substrate for affine and projective variety certificates.

153.1 Carrier definition

Theorem 153.1 (Scheme carrier obligation)**.** *Every* $\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$ *certificate must supply a carrier* $C_{\mathsf{Scheme}^{\uparrow}} : \mathsf{BHist} \to \mathsf{Prop}$ *whose witnesses consist only of a* $\mathsf{RingedSpace}^{\uparrow}$ *source row, certified* $\mathsf{CommRing}^{\uparrow}$ *affine-chart rows, and the affine-cover ledger. The carrier has no host-level scheme object, host spectrum object, host topological-space primitive, host open-set equality, or external sheafification row.*

Proof. Unpack the ten-field NameCert template. Its source field supplies the locally ringed-space row already named by chapter 152, so the base carrier is read as a BEDC history predicate over BHist.

The chapter source sentence names exactly the remaining inputs: certified $\mathsf{CommRing}^{\uparrow}$ affine chart rows and the cover ledger. Each chart is therefore recorded as a certificate row attached to a cover index, not as a host spectrum primitive.

Since the ten-field template has no extra carrier slot after source, classifier, stability, exactness, and ledger are fixed, there is no place for a hidden scheme object. The carrier obligation is precisely the displayed BHist predicate generated by those source and ledger rows. □

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeSingletonPackage carrier source obligation`

Theorem 153.2 (Scheme classifier obligation)**.** *The* $\mathsf{Scheme}^{\uparrow}$ *classifier must be a BEDC classifier over* $C_{\mathsf{Scheme}^{\uparrow}}$*, stable under* hsame*, and determined by the* $\mathsf{RingedSpace}^{\uparrow}$ *classifier together with affine-chart classifier agreement from the certified* $\mathsf{CommRing}^{\uparrow}$ *chart rows. Two scheme carrier witnesses are identified only when their ringed-space rows match and their affine chart rows agree after the displayed cover-refinement and restriction transports.*

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverLedger classifier refinement transport`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverClassifier overlap locality`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeSingleton affine cover classifier locality obligation`

Proof. Use the classifier-choice field of the per-object roadmap template to choose the displayed relation on the carrier from the cited source classifiers. The $\mathsf{RingedSpace}^{\uparrow}$ row supplies the point, open, section, restriction, and local-ring comparisons visible in the locally-ringed-space source.

For each affine chart, read the endpoint comparison from the $\mathsf{CommRing}^{\uparrow}$ certificate row. On overlaps, transport the two chart rows along the cover-refinement and restriction routes already present in the carrier ledger, then compare the transported chart classifiers.

The stability-obligation field of the same template requires this relation to respect hsame. That stability follows by composing the $\mathsf{RingedSpace}^{\uparrow}$ transport with the chart-level $\mathsf{CommRing}^{\uparrow}$ transports, so the scheme classifier is determined by those two classifier surfaces and no additional equality. □

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineChartLedger overlap locality obligation`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverLedger overlap classifier locality`

Theorem 153.3 (Scheme affine-cover obligation)**.** *The affine-spectrum cover row of a* $\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$ *certificate must provide coverage, restriction compatibility, locality, and gluing data as* Pkg *and ledger information. These rows are exactly the cover, exactness, ledger, and consumer-boundary data consumable by* $\mathsf{AffineVar}^{\uparrow}$ *and* $\mathsf{ProjectiveVar}^{\uparrow}$*, with no additional host spectrum, quotient-cover, or external variety row.*

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverLedger restricted global soundness`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverLedger exactness obligation`

Proof. Read the affine-spectrum cover row already named in the seed scope as a finite Pkg-indexed ledger. Coverage says that every accepted carrier witness is assigned to one of those cover packages together with its $\mathsf{RingedSpace}^{\uparrow}$ source row and certified $\mathsf{CommRing}^{\uparrow}$ chart row.

Restriction compatibility and locality are the overlap clauses of the same ledger. They record the displayed restriction route, the common overlap witness, and the chart-classifier agreement after transport through the ringed-space and commutative-ring certificate surfaces.

Gluing is then a ledger exactness statement: compatible local chart rows repack into the same $\mathsf{Scheme}^{\uparrow}$ carrier witness, and every consumer readback for $\mathsf{AffineVar}^{\uparrow}$ or $\mathsf{ProjectiveVar}^{\uparrow}$ must pass through those listed packages. Thus the cover, exactness, ledger, and consumer rows named in the chapter are the whole affine-cover obligation surface. □

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeSingleton affine cover ledger exactness`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeSingleton affine cover nerve empty boundary`
Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverLedger restriction exactness`

153.2 The certificate

Theorem 153.4 (Scheme public NameCert surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$ *export is the SemanticNameCert surface whose source is the* $\mathsf{RingedSpace}^{\uparrow}$ *row together with certified* $\mathsf{CommRing}^{\uparrow}$ *affine-chart rows and the affine-cover ledger. Its classifier is the ringed-space classifier together with chart agreement under restriction and refinement. Its exactness and consumer boundary are exactly the carrier, classifier, and affine-cover obligations proved in Definition 153.1, Definition 153.2, and Definition 153.3.*

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeAffineCoverRow semantic name certificate`

Theorem 153.5 (Scheme public standard bridge)**.** *The public* $\mathsf{Scheme}^{\uparrow}$ *surface of Definition 153.4 admits a standard bridge to the displayed affine-cover presentation. Forward interpretation reads BEDC* $\mathsf{RingedSpace}^{\uparrow}$ *rows as locally ringed-space rows, certified* $\mathsf{CommRing}^{\uparrow}$ *chart rows as affine chart rings, and the affine-cover ledger as the standard affine cover. Conversely, any displayed standard affine-cover row whose point, restriction, chart, and overlap data are presented by the same BEDC carriers repacks as the public* $\mathsf{Scheme}^{\uparrow}$ *surface. The bridge adds no host spectrum object, quotient cover, or external sheafification row.*

Proof. Apply Definition 153.1. It fixes the bridge domain as a BHist carrier assembled from the $\mathsf{RingedSpace}^{\uparrow}$ source row, the certified $\mathsf{CommRing}^{\uparrow}$ chart rows, and the affine-cover ledger, so the forward interpretation has no additional scheme carrier to read.

Apply Definition 153.2. The locally ringed-space comparisons and the affine chart-ring comparisons are therefore exactly the displayed classifier transports across restrictions, refinements, and overlaps.

Apply Definition 153.3. Coverage, restriction compatibility, locality, and gluing are the ledger rows that the standard affine cover reads, and the same theorem excludes any host spectrum object, quotient cover, or external sheafification row from the public surface.

For the reverse direction, start with a displayed standard affine-cover row whose point, restriction, chart, and overlap data are already carried by those BEDC rows. Repack its locally ringed-space source, chart-ring certificates, cover ledger, classifier transports, and exactness boundary through Definition 153.4. The resulting package is precisely the public $\mathsf{Scheme}^{\uparrow}$ surface, with no extra row beyond the carriers and ledgers already listed. □

Lean4 ✓ `BEDC.Derived.SchemeUp.SchemeUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$.

Constructive story: A scheme is generated by starting with the $\mathsf{RingedSpace}^{\uparrow}$ row already carried over BHist, attaching certified $\mathsf{CommRing}^{\uparrow}$ affine-chart rows, and recording a finite affine-cover ledger whose restriction and overlap routes are displayed as Cont and Pkg data. The carrier accepts only histories containing that locally ringed-space source, the chart-ring rows, and the cover package; there is no host scheme object, host spectrum object, quotient cover, open-set equality, or external sheafification row inside the carrier. Two accepted presentations classify together when the ringed-space classifier matches the underlying point, open, section, restriction, and local-ring rows, and the affine chart classifiers agree after the displayed refinement and overlap transports. The source specification is the ringed-space row plus the certified affine charts and their cover ledger, the pattern records coverage, restriction compatibility, locality, and gluing, and the ledger keeps the raw cover packages, restriction routes, overlap witnesses, and chart-ring classifiers visible to later variety consumers. The five naming-certificate obligations hold because a displayed affine-cover row inhabits the carrier, the inherited ringed-space and chart classifiers provide reflexivity, symmetry, and transitivity, and the cover ledger repacks every classifier-stable transported row back into the same carrier predicate. A history h lies in the signature gap of a $\mathsf{Scheme}^{\uparrow}$ token p when the source domain accepts this affine-cover packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names the answer as p; unfolded, the locally ringed-space row and every chart and overlap row of h must match the cover presentation encoded by p. The standard bridge reads the same BEDC rows as a displayed affine-cover presentation and reads any such presentation back by repacking those rows, so the chapter registers this cover-ledger construction under $\mathsf{Scheme}^{\uparrow}$ without adding a hidden spectrum carrier or external scheme equality.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface is Definition 153.4, and the standard bridge is Definition 153.5, binding the carrier predicate to BHist, transporting it by hsame, recording Cont restriction rows and Pkg affine-cover ledger rows, and fixing the $\mathsf{RingedSpace}^{\uparrow}$ source rows, $\mathsf{CommRing}^{\uparrow}$ chart classifier rows, and the $\mathsf{AffineVar}^{\uparrow}$/$\mathsf{ProjectiveVar}^{\uparrow}$ consumer boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.SchemeUp.SchemeAffineCoverRow\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: This chapter does not close full affine or projective variety certificates or bridgeChecked verification.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 154

A Concrete Naming Certificate for $\mathsf{AffineVar}^{\uparrow}$

The affine-variety interface $\mathsf{AffineVar}^{\uparrow}$ packages the zero-locus of a finite system of polynomial equations in the affine n-space of a commutative-ring carrier. It depends on $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ (chapter 44) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

154.1 Carrier definition

154.2 The certificate

Definition 154.1 (Affine finite-family zero-locus)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ *with scalar classifier* $\sim_R$ *and scalar zero* 0_R*. Fix a dimension* n*, an affine point carrier* $\mathsf{AffPoint}_{R,n} : \mathsf{BHist} \to \mathsf{Prop}$*, and a polynomial evaluation row* $\mathsf{Eval}_{R,n}(p, x, y)$ *for polynomial-code histories over that affine* n*-space. Let* $\mathsf{PolyCode}_{R,n}(p)$ *denote the polynomial-code carrier read from the normalized finite coefficient-sequence substrate of Definition 50.3.*

For a polynomial code p *and point history* x*, define the zero-evaluation predicate by*

$$\mathsf{PolyEvalZero}_{R,n}(p, x) \iff \mathsf{PolyCode}_{R,n}(p) \wedge \exists y : \mathsf{BHist}.\ \mathsf{Eval}_{R,n}(p, x, y) \wedge y \sim_R 0_R.$$

For a finite BEDC-history spine $F : \mathsf{HistSpine}$ *of polynomial codes, define the affine finite-family zero-locus carrier by*

$$\mathsf{V}_{R,n}(F)(x) \iff \mathsf{AffPoint}_{R,n}(x) \wedge \forall i : \mathsf{Pos}(F).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x).$$

This is the finite-equation carrier used by the concrete $\mathsf{AffineVar}^{\uparrow}$ *presentation: the point row is shared by the ambient affine space, while the equation row is read from the finite polynomial spine.*

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineVarTasteGate single carrier alignment`

Theorem 154.2 (Affine zero-locus intersection by equation concatenation)**.** *In the setup of Definition 154.1, let* $F, G : \mathsf{HistSpine}$ *be finite polynomial-family spines over the same affine* n*-space. For every point history* $x : \mathsf{BHist}$*,*

$$\mathsf{V}_{R,n}(F{+}{+}G)(x) \iff \mathsf{V}_{R,n}(F)(x) \wedge \mathsf{V}_{R,n}(G)(x).$$

In particular, if x *is classified in both zero-loci* $\mathsf{V}_{R,n}(F)$ *and* $\mathsf{V}_{R,n}(G)$*, then* x *is classified in the zero-locus of the concatenated polynomial family* $F{+}{+}G$*.*

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus intersection concat`

Proof. Unfold Definition 154.1. The finite-spine append split is the positional form underlying Definition 112.18: a position of $F{+}{+}G$ is either a left position coming from F or a right position coming from G, and the corresponding readback is respectively entry_F or entry_G.

For the forward implication, assume $\mathsf{V}_{R,n}(F{+}{+}G)(x)$. Its first component gives $\mathsf{AffPoint}_{R,n}(x)$. To prove $\mathsf{V}_{R,n}(F)(x)$, keep this same affine-point witness and fix a position $i : \mathsf{Pos}(F)$. Embed i as the left position of $F{+}{+}G$. The appended-family zero row gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_{F{+}{+}G}(\iota_F(i)), x),$$

and the left-readback clause identifies this entry with $\mathsf{entry}_F(i)$. This proves the required equation row for F. The proof for G is identical, using the right position embedding $\iota_G(j) : \mathsf{Pos}(F{+}{+}G)$ for each $j : \mathsf{Pos}(G)$. Thus both $\mathsf{V}_{R,n}(F)(x)$ and $\mathsf{V}_{R,n}(G)(x)$ hold.

For the reverse implication, assume $\mathsf{V}_{R,n}(F)(x) \wedge \mathsf{V}_{R,n}(G)(x)$. The affine-point component for the concatenated zero-locus is the one supplied by the F component. Now fix a position $k : \mathsf{Pos}(F{+}{+}G)$. By the same finite-spine append split, k is either a left position $\iota_F(i)$ or a right position $\iota_G(j)$. In the left case, the equation row of $\mathsf{V}_{R,n}(F)(x)$ gives $\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x)$, which is the required row for $\mathsf{entry}_{F{+}{+}G}(k)$. In the right case, the equation row of $\mathsf{V}_{R,n}(G)(x)$ gives $\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_G(j), x)$, again with the required readback equality for the appended spine.

The affine-point witness and this case analysis over every position of $F{+}{+}G$ repack as $\mathsf{V}_{R,n}(F{+}{+}G)(x)$, giving the displayed equivalence and the stated intersection implication. □

Theorem 154.3 (Affine empty-family zero-locus is the ambient affine space)**.** *In the setup of Definition 154.1, let* $\mathsf{nil} : \mathsf{HistSpine}$ *denote the empty finite polynomial-family spine. For every point history* $x : \mathsf{BHist}$*,*

$$\mathsf{V}_{R,n}(\mathsf{nil})(x) \iff \mathsf{AffPoint}_{R,n}(x).$$

In particular, $\mathsf{AffPoint}_{R,n}(x)$ *implies* $\mathsf{V}_{R,n}(\mathsf{nil})(x)$*.*

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus empty family iff`

Proof. Unfold Definition 154.1. The forward implication is projection from the defining conjunction, since every zero-locus point carries its ambient affine-point witness.

For the reverse implication, assume $\mathsf{AffPoint}_{R,n}(x)$. It remains only to supply the equation row

$$\forall i : \mathsf{Pos}(\mathsf{nil}).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_{\mathsf{nil}}(i), x).$$

The nil finite spine has no positions, by the finite-spine nil clause of Definition 36.57 and the empty-position reading used in Definition 112.18. Hence this universal row has no instances to check. Pairing the given affine-point witness with the empty equation row gives $\mathsf{V}_{R,n}(\mathsf{nil})(x)$. □

Definition 154.4 (Affine finite-family equation inclusion)**.** *In the setup of Definition 154.1, for finite polynomial-family spines* $F, G : \mathsf{HistSpine}$ *over the same affine* n*-space, write*

$$\mathsf{EqFamIncl}(F, G) \iff \forall i : \mathsf{Pos}(F).\ \exists j : \mathsf{Pos}(G).\ \mathsf{entry}_F(i) = \mathsf{entry}_G(j).$$

This is the position-readback form of saying that every equation occurrence read from F *is also read from* G*; it uses the same finite-position convention as Definition 112.1.*

Lean4 (definition) `BEDC.Derived.AffineVarUp.AffineFiniteFamilyEquationInclusion`

Lemma 154.5 (Equation rows restrict along finite-family inclusion)**.** *In the setup of Definition 154.1, let $F, G : \mathsf{HistSpine}$ be finite polynomial-family spines over the same affine n-space. If $\mathsf{EqFamIncl}(F, G)$ holds, then for every point history $x : \mathsf{BHist}$,*

$$\Big(\forall j : \mathsf{Pos}(G).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_G(j), x)\Big) \Longrightarrow \Big(\forall i : \mathsf{Pos}(F).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x)\Big).$$

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyEquationRows restrict`

Proof. Assume $\mathsf{EqFamIncl}(F, G)$ and assume the displayed equation row for G. Fix $i : \mathsf{Pos}(F)$. By Definition 154.4, choose $j : \mathsf{Pos}(G)$ with

$$\mathsf{entry}_F(i) = \mathsf{entry}_G(j).$$

The equation row for G at j gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_G(j), x).$$

Transport this predicate across the displayed readback equality to obtain

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x).$$

Since i was arbitrary, the required equation row for F follows. □

Theorem 154.6 (Affine finite-family inclusion reverses zero-loci)**.** *In the setup of Definition 154.1, let $F, G : \mathsf{HistSpine}$ be finite polynomial-family spines over the same affine n-space. If $\mathsf{EqFamIncl}(F, G)$ holds, then for every point history $x : \mathsf{BHist}$,*

$$\mathsf{V}_{R,n}(G)(x) \Longrightarrow \mathsf{V}_{R,n}(F)(x).$$

Thus the affine finite-family zero-locus assignment is contravariant with respect to finite-position equation inclusion.

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus inclusion contravariant`
Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus inclusion reverse`

Proof. Assume $\mathsf{EqFamIncl}(F, G)$ and fix $x : \mathsf{BHist}$ with $\mathsf{V}_{R,n}(G)(x)$. Unfold Definition 154.1. The zero-locus witness for G consists of an ambient witness

$$\mathsf{AffPoint}_{R,n}(x)$$

and an equation row

$$\forall j : \mathsf{Pos}(G).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_G(j), x).$$

Keep the same ambient witness for F. The equation row for F is supplied by Definition 154.5, applied to the displayed inclusion and the displayed equation row for G. Pairing these two components gives $\mathsf{V}_{R,n}(F)(x)$. □

Definition 154.7 (Affine equation head insertion)**.** *In the setup of Definition 154.1, for a polynomial-code history $p : \mathsf{BHist}$ and a finite polynomial-family spine $F : \mathsf{HistSpine}$, define the affine equation insertion spine by*

$$\mathsf{insert}_{\mathrm{eq}}(p, F) := \mathsf{cons}(p, F).$$

Thus insertion places the displayed equation as the head row and leaves the original finite equation family as the tail spine.

Lean4 (definition) `BEDC.Derived.AffineVarUp.AffineEquationHeadInsertion`

Lemma 154.8 (Affine zero-loci contain occurred equation rows)**.** *In the setup of Definition 154.1, let* $F : \mathsf{HistSpine}$ *be a finite polynomial-family spine, and let* $p, x : \mathsf{BHist}$*. If*

$$\mathsf{SpineMember}(p, F) \qquad \textit{and} \qquad \mathsf{V}_{R,n}(F)(x)$$

hold, then

$$\mathsf{PolyEvalZero}_{R,n}(p, x)$$

holds.

Proof. By Definition 112.11, the occurrence $\mathsf{SpineMember}(p, F)$ supplies a position $j : \mathsf{Pos}(F)$ with

$$\mathsf{entry}_F(j) = p.$$

Unfolding Definition 154.1 in $\mathsf{V}_{R,n}(F)(x)$ gives the equation row

$$\forall i : \mathsf{Pos}(F).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x).$$

Evaluating this row at j gives $\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(j), x)$. Rewriting along $\mathsf{entry}_F(j) = p$ gives the displayed zero-evaluation predicate for p at x. □

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus occurred equation row`

Theorem 154.9 (Affine duplicate equation insertion invariance)**.** *In the setup of Definition 154.1, let* $F : \mathsf{HistSpine}$ *be a finite polynomial-family spine, and let* $p, x : \mathsf{BHist}$*. If*

$$\mathsf{SpineMember}(p, F)$$

holds, then

$$\mathsf{V}_{R,n}(\mathsf{insert}_{\mathrm{eq}}(p, F))(x) \Longleftrightarrow \mathsf{V}_{R,n}(F)(x).$$

Equivalently, placing at the head a polynomial equation that already occurs in the finite equation spine does not change the affine finite-family zero-locus predicate.

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus duplicate head insert`

Proof. Use Definition 154.7 to read $\mathsf{insert}_{\mathrm{eq}}(p, F)$ as $\mathsf{cons}(p, F)$.

For the forward implication, assume $\mathsf{V}_{R,n}(\mathsf{cons}(p, F))(x)$. Unfold Definition 154.1. The affine-point witness is the first component of the cons-spine zero-locus witness. For the equation row of F, fix $i : \mathsf{Pos}(F)$ and view it as the tail position of $\mathsf{cons}(p, F)$. The cons-position readback from the finite-spine clauses of Definition 36.57 identifies this tail entry with $\mathsf{entry}_F(i)$. The equation row of $\mathsf{V}_{R,n}(\mathsf{cons}(p, F))(x)$ at that tail position therefore gives $\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x)$. Since i was arbitrary, these data repack as $\mathsf{V}_{R,n}(F)(x)$.

For the reverse implication, assume $\mathsf{V}_{R,n}(F)(x)$. Unfold Definition 154.1. The affine-point component for $\mathsf{cons}(p, F)$ is the one supplied by $\mathsf{V}_{R,n}(F)(x)$. It remains to verify every equation row of the cons spine. A position of $\mathsf{cons}(p, F)$ is either the head position or a tail position. In the head case, Definition 154.8, applied to the displayed occurrence of p in F and to $\mathsf{V}_{R,n}(F)(x)$, gives $\mathsf{PolyEvalZero}_{R,n}(p, x)$, which is exactly the head equation row. In the tail case, the position is inherited from some $i : \mathsf{Pos}(F)$, and the tail readback is $\mathsf{entry}_F(i)$. The equation row of $\mathsf{V}_{R,n}(F)(x)$ at i gives the required predicate for that tail entry.

The affine-point witness and the head-or-tail verification of every cons-spine position repack as $\mathsf{V}_{R,n}(\mathsf{cons}(p, F))(x)$, and hence as $\mathsf{V}_{R,n}(\mathsf{insert}_{\mathrm{eq}}(p, F))(x)$. □

Theorem 154.10 (Affine mutual family inclusion gives equal zero-loci)**.** *In the setup of Definition 154.1, let $F, G : \mathsf{HistSpine}$ be finite polynomial-family spines over the same affine n-space. If both*

$$\mathsf{EqFamIncl}(F, G) \qquad \textit{and} \qquad \mathsf{EqFamIncl}(G, F)$$

hold, then for every point history $x : \mathsf{BHist}$,

$$\mathsf{V}_{R,n}(F)(x) \Longleftrightarrow \mathsf{V}_{R,n}(G)(x).$$

Thus mutually included finite affine equation presentations classify exactly the same zero-locus points.

Proof. Assume $\mathsf{EqFamIncl}(F, G)$ and $\mathsf{EqFamIncl}(G, F)$, and fix a point history $x : \mathsf{BHist}$. To prove the forward implication, assume $\mathsf{V}_{R,n}(F)(x)$. Apply Definition 154.6 to the inclusion $\mathsf{EqFamIncl}(G, F)$, with the ordered pair of families read as (G, F). Since inclusion reverses zero-loci, this gives $\mathsf{V}_{R,n}(G)(x)$.

For the reverse implication, assume $\mathsf{V}_{R,n}(G)(x)$. Apply Definition 154.6 to the inclusion $\mathsf{EqFamIncl}(F, G)$, with the ordered pair of families read as (F, G). This gives $\mathsf{V}_{R,n}(F)(x)$.

The two implications together give the displayed equivalence for the fixed x, and x was arbitrary. □

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus mutual inclusion iff`

Theorem 154.11 (AffineVarUp public zero-locus certificate)**.** *The public $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ export is the finite-family zero-locus interface of Definition 154.1 together with equation inclusion, row restriction, concatenation as intersection, empty-family ambient-space exactness, duplicate insertion invariance, and mutual-inclusion classification. Its exact exported rows are the carrier predicate $\mathsf{V}_{R,n}(F)$, the finite equation-ledger positions of F, the inclusion relation $\mathsf{EqFamIncl}$ from Definition 154.4, and the zero-locus transport and classifier rows proved in this chapter.*

Proof. The carrier row is Definition 154.1. It exposes exactly the ambient affine-point witness and the finite equation-row ledger indexed by positions of the polynomial-family spine.

The stability rows are supplied by the checked zero-locus clauses in this chapter. Apply Definition 154.2 for concatenation as intersection, Definition 154.3 for empty-family ambient-space exactness, Definition 154.5 for row restriction along equation inclusion, and Definition 154.9 for duplicate insertion invariance.

The public classifier row is the mutual-inclusion exactness theorem Definition 154.10. Together with the equation-inclusion definition, it identifies precisely when two finite affine equation presentations export the same zero-locus predicate. These rows repack the finite-family interface as the public $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ certificate surface; projective consumer, scheme consumer, and full $\mathsf{AffineVar}^{\uparrow}$ $\mathsf{NameCert}$ fields remain outside this finite-family surface. □

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus head insert equation rows`

Theorem 154.12 (Affine finite-family standard zero-locus bridge)**.** *In the setup of Definition 154.1, the BEDC finite-family zero-locus carrier $\mathsf{V}_{R,n}(F)$, together with equation inclusion $\mathsf{EqFamIncl}$ from Definition 154.4 and the mutual-inclusion classifier of Definition 154.10, interprets as the standard finite polynomial zero-locus predicate on affine points. Conversely, every standard finite-family zero-locus membership row is represented by the same $\mathsf{HistSpine}$ positions and the same $\mathsf{PolyEvalZero}$ rows used by $\mathsf{V}_{R,n}(F)$.*

Proof. Read $\mathsf{V}_{R,n}(F)$ by Definition 154.1. A BEDC member is an affine point x together with one zero-evaluation row for each finite position $i : \mathsf{Pos}(F)$. The readback $\mathsf{entry}_F(i)$ is exactly the polynomial equation at that position, so the BEDC carrier gives the usual standard statement that every equation in the finite family vanishes at x.

Conversely, suppose a standard finite-family zero-locus row is given for the same family spine F. For each position $i : \mathsf{Pos}(F)$, read the polynomial equation as $\mathsf{entry}_F(i)$ and place the standard vanishing datum in the corresponding $\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x)$ row. Together with the ambient affine-point row, these finite-position rows repack as $\mathsf{V}_{R,n}(F)(x)$ by the same definition.

The equation-inclusion bridge is positional rather than quotient-based. By Definition 154.4, $\mathsf{EqFamIncl}(F, G)$ is exactly the assertion that every equation position of F has a readback match in G. Applying Definition 154.5 projects the standard zero rows along this inclusion, and Definition 154.10 gives equality of the represented zero-locus predicates under mutual inclusion. No quotienting of presentations and no host equality of carriers is used. □

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus standard zero locus bridge`

Closure status for $\mathsf{NameCert}_{\mathsf{AffineVar}^\uparrow}$.

Constructive story: An affine variety here is built from a commutative-ring certificate, an affine point carrier, and a finite HistSpine of polynomial-code histories, with a point history accepted precisely when it is an affine point and every displayed equation position evaluates to the scalar zero row. The carrier $\mathsf{V}_{R,n}(F)$ includes the affine points satisfying all equations in the finite family and excludes points lacking the ambient row, polynomial codes outside the normalized finite sequence substrate, and presentations not accounted for by finite positions. Two finite equation presentations classify the same zero locus when their equation families include one another position by position, so the classifier is mutual equation inclusion plus the induced equivalence of zero-locus predicates rather than host equality of varieties. The source specification covers the affine point row, polynomial-code row, zero-evaluation witness, and finite family spine, while the pattern records empty-family exactness, intersection by concatenation, row restriction, duplicate head insertion, and mutual-inclusion exactness. The ledger keeps equation positions, readback entries, polynomial evaluation rows, and the affine point witness visible, so membership is aligned with the finite family that generated it; the five obligations then come from the ambient carrier and empty-family case, mutual inclusion as a reflexive, symmetric, and transitive classifier, and row restriction keeping transported finite families inside the carrier. A history h lies in the signature gap of an $\mathsf{AffineVar}^\uparrow$ token p when the source domain accepts h as such a finite zero-locus packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; concretely, each equation position in p has a zero-evaluation row at the affine point represented by h. The standard zero-locus bridge reads the BEDC rows as the finite polynomial vanishing predicate and reads a standard membership row back into the same positions, so the chapter registers this finite-equation construction under $\mathsf{AffineVar}^\uparrow$ without quotienting presentations or adding a host variety primitive.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AffineVar}^\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper-side surface consists of the finite-family carrier $\mathsf{V}_{R,n}(F)$, the equation-inclusion classifier EqFamIncl, row restriction, intersection by concatenation, empty-family exactness, duplicate insertion, mutual-inclusion exactness, the finite-position ledger, and the paper standard zero-locus bridge.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AffineVar}^\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus\_mutual\_inclusion\_iff`

Bridge status: paperBridge

Not claimed: This chapter does not close projective-variety consumer certificates, scheme-level consumer certificates, the full $\mathsf{AffineVar}^\uparrow$ NameCert, or machine-checked bridge closure.

Upgrade path: The next verification step is bridgeCheckedV and audit packaging for the same finite-family bridge, not a stronger paper closure claim.

Theorem 154.13 (Affine singleton-equation zero-locus exactness)**.** *In the setup of Definition 154.1, let* $p : \mathsf{BHist}$ *be a polynomial-code history and let* $\mathsf{cons}(p, \mathsf{nil}) : \mathsf{HistSpine}$ *be the singleton polynomial-family spine. For every point history* $x : \mathsf{BHist}$*,*

$$\mathsf{V}_{R,n}(\mathsf{cons}(p, \mathsf{nil}))(x) \iff \mathsf{AffPoint}_{R,n}(x) \wedge \mathsf{PolyEvalZero}_{R,n}(p, x).$$

Thus the one-equation affine finite-family zero-locus is exactly the ambient affine-point predicate together with vanishing of the displayed polynomial code.

Lean4 ✓ `BEDC.Derived.AffineVarUp.AffineFiniteFamilyZeroLocus singleton equation exactness`

Proof. Unfold Definition 154.1. A witness of

$$\mathsf{V}_{R,n}(\mathsf{cons}(p, \mathsf{nil}))(x)$$

is a pair consisting of

$$\mathsf{AffPoint}_{R,n}(x)$$

and an equation row

$$\forall i : \mathsf{Pos}(\mathsf{cons}(p, \mathsf{nil}))\,.\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_{\mathsf{cons}(p,\mathsf{nil})}(i), x).$$

By the cons-spine position clauses of Definition 36.57, the singleton spine has one head position and no tail positions, since the tail is nil. At the head position, the readback is p.

For the forward implication, assume $\mathsf{V}_{R,n}(\mathsf{cons}(p, \mathsf{nil}))(x)$. The first projection gives $\mathsf{AffPoint}_{R,n}(x)$. Evaluating the displayed equation row at the head position of $\mathsf{cons}(p, \mathsf{nil})$ gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_{\mathsf{cons}(p,\mathsf{nil})}(\mathsf{head}), x).$$

The singleton head readback identifies $\mathsf{entry}_{\mathsf{cons}(p,\mathsf{nil})}(\mathsf{head})$ with p, so this is exactly $\mathsf{PolyEvalZero}_{R,n}(p, x)$. Pairing these two projections gives the right-hand side.

For the reverse implication, assume

$$\mathsf{AffPoint}_{R,n}(x) \wedge \mathsf{PolyEvalZero}_{R,n}(p, x).$$

The affine-point component of $\mathsf{V}_{R,n}(\mathsf{cons}(p, \mathsf{nil}))(x)$ is the first component of this pair. It remains to verify the equation row for every position of $\mathsf{cons}(p, \mathsf{nil})$. Such a position is the head position or a tail position inherited from nil. In the head case, the readback is p, and the second component supplies $\mathsf{PolyEvalZero}_{R,n}(p, x)$. In the tail case there is no position to check, because nil has no positions. Hence the equation row is complete.

Combining the ambient affine-point witness with this singleton equation row repacks as $\mathsf{V}_{R,n}(\mathsf{cons}(p, \mathsf{nil}))(x)$ by Definition 154.1. □

Definition 154.14 (Affine finite-family equation union presentation)**.** *In the setup of Definition 154.1, let F, G, U : HistSpine be finite polynomial-family spines over the same affine n-space. Say that U presents the finite equation-family union of F and G, and write $\mathsf{EqFamUnion}(F, G; U)$, when the following three clauses hold:*

$$\mathsf{EqFamIncl}(F, U), \qquad \mathsf{EqFamIncl}(G, U),$$

and

$$\forall k : \mathsf{Pos}(U)\,.\ (\exists i : \mathsf{Pos}(F).\ \mathsf{entry}_U(k) = \mathsf{entry}_F(i)) \vee (\exists j : \mathsf{Pos}(G).\ \mathsf{entry}_U(k) = \mathsf{entry}_G(j))\,.$$

The first two clauses say that every displayed equation occurrence of F and G occurs in the union presentation. The last clause says that every displayed equation occurrence of U comes from one of the two input families. Thus the definition is an exact finite-position union presentation rather than an ambient host-set quotient.

Theorem 154.15 (Affine zero-locus of an equation-family union)**.** *In the setup of Definition 154.1, let $F, G, U : \mathsf{HistSpine}$ be finite polynomial-family spines over the same affine n-space. If $\mathsf{EqFamUnion}(F, G; U)$ holds, then for every point history $x : \mathsf{BHist}$,*

$$\mathsf{V}_{R,n}(U)(x) \Longleftrightarrow \mathsf{V}_{R,n}(F)(x) \wedge \mathsf{V}_{R,n}(G)(x).$$

Consequently, membership in the affine zero-locus of the displayed finite equation-family union is exactly simultaneous membership in the two affine zero-loci.

Proof. Assume $\mathsf{EqFamUnion}(F, G; U)$, and write its three components as

$$\mathsf{EqFamIncl}(F, U), \qquad \mathsf{EqFamIncl}(G, U),$$

and the union-coverage row

$$\forall k : \mathsf{Pos}(U).\ (\exists i : \mathsf{Pos}(F).\ \mathsf{entry}_U(k) = \mathsf{entry}_F(i)) \vee (\exists j : \mathsf{Pos}(G).\ \mathsf{entry}_U(k) = \mathsf{entry}_G(j))\,.$$

For the forward implication, assume $\mathsf{V}_{R,n}(U)(x)$. Apply Definition 154.6 to $\mathsf{EqFamIncl}(F, U)$ to obtain $\mathsf{V}_{R,n}(F)(x)$, and apply the same theorem to $\mathsf{EqFamIncl}(G, U)$ to obtain $\mathsf{V}_{R,n}(G)(x)$. Pairing these two projected zero-locus witnesses gives

$$\mathsf{V}_{R,n}(F)(x) \wedge \mathsf{V}_{R,n}(G)(x).$$

For the reverse implication, assume

$$\mathsf{V}_{R,n}(F)(x) \wedge \mathsf{V}_{R,n}(G)(x).$$

Unfold Definition 154.1. The affine-point witness for $\mathsf{V}_{R,n}(U)(x)$ is the affine-point component of $\mathsf{V}_{R,n}(F)(x)$. It remains to verify every equation row of U. Fix $k : \mathsf{Pos}(U)$. By the union-coverage row, k is covered by one of the two input families.

In the first case, choose $i : \mathsf{Pos}(F)$ with

$$\mathsf{entry}_U(k) = \mathsf{entry}_F(i).$$

The equation row of $\mathsf{V}_{R,n}(F)(x)$ at i gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(i), x).$$

Transporting this predicate along the displayed readback equality gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_U(k), x).$$

In the second case, choose $j : \mathsf{Pos}(G)$ with

$$\mathsf{entry}_U(k) = \mathsf{entry}_G(j).$$

The equation row of $\mathsf{V}_{R,n}(G)(x)$ at j gives

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_G(j), x),$$

and transport along the displayed readback equality gives the required predicate

$$\mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_U(k), x).$$

Since k was arbitrary, every equation row of U vanishes at x. Pairing this row with the affine-point witness repacks as $\mathsf{V}_{R,n}(U)(x)$ by Definition 154.1. The two implications give the displayed equivalence. □

Theorem 154.16 (AffineVar zero-locus is antitone under equation inclusion)**.** *In the setup of Definition 154.1, let* $E, F : \mathsf{HistSpine}$ *be finite polynomial-family spines over the same affine n-space. If*

$$\mathsf{EqFamIncl}(E, F)$$

holds, then for every point history $x : \mathsf{BHist}$*,*

$$\mathsf{V}_{R,n}(F)(x) \Longrightarrow \mathsf{V}_{R,n}(E)(x).$$

Thus adding equation occurrences to a finite affine family can only shrink its zero-locus predicate: equation-family inclusion is sent to reverse implication of zero-locus membership.

Proof. Assume $\mathsf{EqFamIncl}(E, F)$, fix $x : \mathsf{BHist}$, and assume $\mathsf{V}_{R,n}(F)(x)$. By Definition 154.1, the latter witness consists of an ambient affine-point row

$$\mathsf{AffPoint}_{R,n}(x)$$

and the equation row

$$\forall j : \mathsf{Pos}(F).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_F(j), x).$$

Keep the same ambient affine-point row for E. It remains to prove

$$\forall i : \mathsf{Pos}(E).\ \mathsf{PolyEvalZero}_{R,n}(\mathsf{entry}_E(i), x).$$

This row is exactly the restriction of the displayed F-row along the inclusion $\mathsf{EqFamIncl}(E, F)$: by Definition 154.5, every position $i : \mathsf{Pos}(E)$ has a matching position $j : \mathsf{Pos}(F)$ with the same equation readback, and the zero-evaluation predicate transports across that readback equality.

Pairing the retained affine-point row with this restricted equation row repacks, by Definition 154.1, as $\mathsf{V}_{R,n}(E)(x)$. Since x was arbitrary, the zero-locus assignment is antitone with respect to finite-position equation inclusion. □

Chapter 155

A Concrete Naming Certificate for $\mathsf{ProjectiveVar}^{\uparrow}$

The projective-variety interface $\mathsf{ProjectiveVar}^{\uparrow}$ packages the zero-locus of a homogeneous polynomial ideal in the projective n-space of a commutative-ring carrier. It depends on $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ (chapter 154) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

155.1 Carrier definition

155.2 The certificate

Theorem 155.1 (ProjectiveVarUp carrier obligation)**.** *The* $\mathsf{ProjectiveVar}^{\uparrow}$ *carrier is a* BHist *predicate assembled from the visible* $\mathsf{AffineVar}^{\uparrow}$ *chart zero-locus source, the* $\mathsf{Poly}^{\uparrow}$ *homogeneous-family rows, the projective-space carrier row, and the zero-evaluation package. A carried endpoint is accepted exactly when those four rows are present with their* Pkg *provenance and probe reads; no host quotient, host orbit set, or external projective point equality is part of the carrier predicate.*

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier endpoint exactness`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier carrier obligation`

Proof. Read the carrier row through the roadmap ten-field template:

1. traditional target: the projective zero-locus of a homogeneous polynomial family;
2. BEDC source: a BHist endpoint carrying chart, homogeneous-family, projective-space, and zero-evaluation rows;
3. carrier field: the visible predicate formed by those four rows and their Pkg provenance;
4. dependency fields: $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ from chapter 154 and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ from chapter 50;
5. classifier field: reserved for projective scaling and chart-compatible hsame transport;
6. stability field: chart zero-locus rows and homogeneous rows are transported together;
7. exactness field: zero evaluation is read only through the displayed package;
8. ledger field: chart choice, family presentation, scale witness, and routing evidence remain hidden;

9. theorem-list field: the carrier, classifier, exactness, and ledger obligations named in this section;
10. boundary field: downstream consumers see only the projective carrier and classifier.

The carrier projection is therefore just the third entry of the template. If an endpoint supplies the four displayed rows, it repacks as a carried $\mathsf{ProjectiveVar}^{\uparrow}$ history; if a carried endpoint is projected back out, the same rows are recovered. Host quotients and orbit representatives occur only as ledger readings and cannot enlarge the predicate. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarFiniteChartCarrier endpoint transport`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarCarrier obligation rows`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarCarrier obligation`

Theorem 155.2 (ProjectiveVarUp classifier stability obligation)**.** *The* $\mathsf{ProjectiveVar}^{\uparrow}$ *classifier is projective scaling together with chart-compatible* hsame *transport. Whenever two carried endpoints are related by a scale witness and their chart zero-locus rows transport through the corresponding* $\mathsf{AffineVar}^{\uparrow}$ *chart classifiers, the projective carrier is preserved and each homogeneous* $\mathsf{Poly}^{\uparrow}$ *row is transported to a row with the same zero-evaluation outcome.*

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarZeroLocusPackage hsame transport`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarCarrier scale chart transport`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarCarrier chart homogeneous transport`

Proof. Read the classifier row through the roadmap ten-field template:

1. traditional target: equality of projective zero-locus points up to nonzero scalar multiplication;
2. BEDC source: two carried BHist endpoints with chart rows, homogeneous-family rows, projective-space rows, and zero-evaluation packages;
3. carrier field: the carrier predicate of Definition 155.1 on both endpoints;
4. dependency fields: $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ from chapter 154 and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ from chapter 50;
5. classifier field: scale witness plus chart-compatible hsame transport;
6. stability field: transported chart rows preserve carrier membership;
7. exactness field: homogeneous zero-evaluation is invariant under the transported presentation;
8. ledger field: the chosen scale and chart route remain hidden provenance;
9. theorem-list field: this classifier row feeds the exactness and ledger obligations below;
10. boundary field: consumers may use only the resulting carrier-preserving classifier.

Apply the scale witness to the projective-space row and the hsame transport to the chart row. The homogeneous-family rows are then read through the $\mathsf{Poly}^{\uparrow}$ source certificate, so evaluation at transported representatives remains a zero-evaluation package fact rather than a host equality fact.

Thus the classifier preserves the carrier predicate. Conversely, any classifier witness visible at the $\mathsf{ProjectiveVar}^{\uparrow}$ boundary must decompose into exactly the scale route, chart transport, homogeneous-row transport, and provenance entries listed above. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier classifier stability`

Theorem 155.3 (ProjectiveVarUp homogeneous zero-locus exactness obligation)**.** *The visible zero-locus package for* $\mathsf{ProjectiveVar}^{\uparrow}$ *is exact relative to the homogeneous* $\mathsf{Poly}^{\uparrow}$ *family and the* $\mathsf{AffineVar}^{\uparrow}$ *chart exactness rows: coverage says every carried projective endpoint has a chart read and homogeneous zero-evaluation read; soundness says every accepted read satisfies all displayed homogeneous rows on every compatible chart; completeness says every compatible chart-family zero-locus read repacks as a carried projective endpoint.*

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarHomogeneousZeroLocusCarrier bundle append exactness`
Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarHomogeneousZeroLocus visible package`

Proof. Read the exactness row through the roadmap ten-field template:

1. traditional target: a projective homogeneous-family zero-locus;
2. BEDC source: chart-local zero-locus reads tied to homogeneous polynomial-code rows;
3. carrier field: the projective carrier predicate of Definition 155.1;
4. dependency fields: $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ from chapter 154 and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ from chapter 50;
5. classifier field: the scaling and chart-transport row of Definition 155.2;
6. stability field: compatible affine charts carry the same homogeneous-family zero tests;
7. exactness field: coverage, soundness, and completeness for visible zero-locus reads;
8. ledger field: chart selections and evaluation routing remain provenance data;
9. theorem-list field: carrier and classifier obligations supply the projections consumed here;
10. boundary field: downstream consumers receive an exact visible zero-locus package, not host algebraic geometry data.

For coverage, project a carried endpoint to its chart read and homogeneous-family zero-evaluation read. Both are already visible components of the carrier row, so no extra witness is introduced.

For soundness, use the $\mathsf{AffineVar}^{\uparrow}$ chart exactness rows to interpret the chart zero-locus source and the $\mathsf{Poly}^{\uparrow}$ homogeneous-family rows to interpret each zero-evaluation entry. The classifier stability obligation transports these entries across compatible charts.

For completeness, begin with a compatible chart-family read satisfying the listed zero-evaluation rows. Repack the chart source, homogeneous family, projective-space row, and routing package into the carrier predicate, then attach the ledger entries for chart choice and scale routing. The result is a carried $\mathsf{ProjectiveVar}^{\uparrow}$ endpoint with exactly the advertised visible zero-locus package. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier zero locus exactness`

Theorem 155.4 (ProjectiveVarUp scaling ledger obligation)**.** *The* $\mathsf{ProjectiveVar}^{\uparrow}$ *ledger hides exactly chart choice, homogeneous-family presentation, scale witnesses, and zero-evaluation package routing. It exposes only the projective carrier of Definition 155.1 and the projective classifier of Definition 155.2; no hidden chart, polynomial presentation, scalar representative, or evaluation route becomes public carrier data.*

Proof. Read the ledger row through the roadmap ten-field template:

1. traditional target: presentation independence for a projective homogeneous zero-locus;
2. BEDC source: the carrier and classifier rows already displayed at the $\mathsf{ProjectiveVar}^{\uparrow}$ boundary;

3. carrier field: the projective carrier predicate;
4. dependency fields: $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ from chapter 154 and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ from chapter 50;
5. classifier field: projective scaling with chart-compatible hsame transport;
6. stability field: hidden presentation changes preserve the same visible carrier and classifier;
7. exactness field: zero-locus coverage, soundness, and completeness remain routed through the visible package;
8. ledger field: chart choice, homogeneous-family presentation, scale witness, and zero-evaluation routing are the hidden entries;
9. theorem-list field: the four obligations of this section are the whole certificate surface at this grade;
10. boundary field: consumers cannot inspect anything beyond the projective carrier and classifier.

Projecting the ledger reveals only the entries listed in the eighth template field. Chart choices are justified by the affine source certificate, homogeneous-family presentations by the polynomial source certificate, scale witnesses by the classifier row, and evaluation routing by the zero-locus package.

Since each hidden entry is consumed by one of those visible rows, exposing it would duplicate a presentation witness rather than add a BEDC carrier field. The public boundary is therefore exactly the carrier and classifier named in the statement. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier scaling ledger`

Theorem 155.5 (ProjectiveVarUp scoped primitive binding)**.** *The four rows in Definition 155.1, Definition 155.2, Definition 155.3, and Definition 155.4 are scoped exactly by the BEDC primitives* BHist, Pkg*, probe reads,* hsame *transport, the projective scaling witness,* $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*. Chart choice, homogeneous-family presentation, scale witness, and zero-evaluation routing remain ledger data, and no host quotient or external projective-point equality enters the public carrier.*

Proof. Project the carrier row first. Its roadmap dependency fields expose only the BHist predicate, the visible Pkg provenance, the relevant probe reads, and the upstream $\mathsf{AffineVar}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ certificates named in the statement.

Project the classifier row next. Its dependency and classifier fields bind the projective scaling witness to chart-compatible hsame transport, while the carrier field remains the predicate supplied by Definition 155.1.

Project the exactness row. Coverage, soundness, and completeness consume the same chart reads, homogeneous-family rows, zero-evaluation package, and upstream certificate exactness already present in Definition 155.3; they do not add a host quotient or an external equality relation.

Finally project the ledger row. The ledger field names exactly chart choice, homogeneous-family presentation, scale witness, and zero-evaluation routing as hidden provenance, so those witnesses can be transported and consumed but not promoted into the public carrier. Combining the four projections gives the reusable scoped boundary for $\mathsf{ProjectiveVar}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarTasteGate single carrier alignment`

Theorem 155.6 (ProjectiveVarUp public NameCert export)**.** *The four rows in Definition 155.1, Definition 155.2, Definition 155.3, and Definition 155.4 assemble a public* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$

surface. Its carrier is the visible projective zero-locus predicate, its classifier is projective scaling together with chart-compatible hsame *transport, its exactness field is the visible homogeneous zero-locus package, and its ledger hides only chart choice, homogeneous-family presentation, scale witnesses, and zero-evaluation routing.*

Proof. Repack the four scoped rows through the roadmap ten-field template. The traditional-target field is the presentation-independent projective homogeneous zero-locus, and the BEDC-source field is the visible package built from the $\mathsf{AffineVar}^{\uparrow}$ chart certificate, the $\mathsf{Poly}^{\uparrow}$ homogeneous-family certificate, the projective-space carrier row, BHist endpoints, Pkg provenance, probe reads, scale witnesses, and zero-evaluation routing.

The carrier field is exactly the visible projective zero-locus predicate supplied by Definition 155.1. The dependency fields are the upstream $\mathsf{NameCert}_{\mathsf{AffineVar}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ surfaces already consumed by that carrier row, so no hidden chart or polynomial presentation is exported as carrier data.

The classifier and stability fields come from Definition 155.2: projective scaling witnesses identify representative changes, while chart-compatible hsame transport keeps the visible zero tests stable across compatible affine reads. The exactness field is Definition 155.3, which gives coverage, soundness, and completeness for the visible homogeneous zero-locus package.

Finally, the ledger field is Definition 155.4. It hides only chart choice, homogeneous-family presentation, scale witnesses, and zero-evaluation routing, and it exposes only the carrier, classifier, stability, and exactness fields named above. The theorem-list and boundary fields are therefore public: downstream consumers may use the assembled $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ surface, but they cannot inspect any presentation witness beyond the advertised ledger. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier public namecert export`

Theorem 155.7 (ProjectiveVarUp public zero-locus downstream bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ *surface of Definition 155.6 is consumed by downstream zero-locus interfaces exactly through the visible projective carrier, the scaling-and-chart classifier, the homogeneous zero-locus exactness package, and the scaling ledger. Any* $\mathsf{AffineVar}^{\uparrow}$ *chart read,* $\mathsf{Poly}^{\uparrow}$ *homogeneous-family read, or* $\mathsf{ProjectiveSpace}^{\uparrow}$ *representative read used by a downstream consumer factors through those four rows; conversely those four rows supply the consumer boundary without exposing chart choice, homogeneous presentation, scale witness, or zero-evaluation routing as public carrier data.*

Proof. Project the public certificate of Definition 155.6. Its carrier projection is the visible BHist predicate supplied by Definition 155.1, so every downstream zero-locus read begins with the same projective endpoint boundary rather than with a chart-local carrier.

The classifier projection is the scaling-and-chart row of Definition 155.2. It is the only public route by which an $\mathsf{AffineVar}^{\uparrow}$ chart read or a $\mathsf{ProjectiveSpace}^{\uparrow}$ representative read may be transported, and the transport keeps the carried endpoint inside the visible projective carrier.

The exactness projection is Definition 155.3. It supplies coverage, soundness, and completeness for each $\mathsf{Poly}^{\uparrow}$ homogeneous-family read used by the consumer, so zero-evaluation is consumed through the visible package rather than through a separate presentation of the family.

Finally, the ledger projection is Definition 155.4. It records chart choice, homogeneous presentation, scale witness, and zero-evaluation routing as hidden provenance, while the public boundary retains only the carrier, classifier, exactness package, and ledger rows. Repacking those four projections gives the downstream consumer boundary, and projecting that boundary back recovers exactly the same four rows without exposing any hidden witness as public carrier data. □

Lean4 ✓ `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier downstream zero locus bridge`

Closure status for $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$.

Constructive story: A projective variety is generated by taking the visible $\mathsf{AffineVar}^{\uparrow}$ chart zero-locus source, the homogeneous $\mathsf{Poly}^{\uparrow}$ family rows, a projective-space carrier row, and the zero-evaluation package, then tying them to one BHist endpoint with Pkg provenance and probe reads. The carrier accepts exactly endpoints with those chart, homogeneous-family, projective-space, and zero-evaluation rows, while host orbit sets, projective-point quotients, unrecorded chart representatives, and external equality of projective points are excluded. Two accepted endpoints classify together when a projective scaling witness and chart-compatible hsame transport carry the affine chart rows and homogeneous polynomial rows to the same zero-evaluation outcomes. The source specification is this visible projective zero-locus package, the pattern records homogeneous zero-locus exactness across compatible charts, and the ledger hides only chart choice, homogeneous-family presentation, scale witnesses, and evaluation routing while exposing the carrier, classifier, stability, and exactness rows. The five naming-certificate obligations follow because the displayed package inhabits the carrier, the scaling-and-chart classifier is reflexive, symmetric, and transitive through its carried transports, and every transported chart or homogeneous row repacks as another accepted projective endpoint. A history h lies in the signature gap of a $\mathsf{ProjectiveVar}^{\uparrow}$ token p when the source domain accepts its projective zero-locus packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; after unfolding, the chart rows, scale witness, homogeneous equations, and zero-evaluation ledger of h are the ones encoded by p. The downstream zero-locus bridge lets later consumers read only this visible carrier, scaling-and-chart classifier, homogeneous exactness package, and scaling ledger, so the chapter registers the construction under $\mathsf{ProjectiveVar}^{\uparrow}$ without exporting hidden chart data, host projective equality, or an external standard model.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper-side boundary consists exactly of the visible projective carrier, the scaling-and-chart classifier, homogeneous zero-locus exactness, the scaling ledger, the public $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ export, and the downstream zero-locus consumer boundary of Definition 155.7.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ProjectiveVarUp.ProjectiveVarVisibleCarrier\_public\_namecert\_export`

Bridge status: paperBridge

Not claimed: This chapter does not claim a standard-model bridge outside the carrier, classifier, exactness, ledger, public export, and downstream zero-locus consumer boundary named above.

Upgrade path: A bridge-checked grade would require a complete standard-model bridge for the same public $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ surface and downstream zero-locus consumer interface.

Chapter 156

A Concrete Naming Certificate for $\mathsf{Homotopy}^{\uparrow}$

The homotopy interface $\mathsf{Homotopy}^{\uparrow}$ packages the equivalence-of-paths relation between continuous maps under a continuous deformation parameter. It depends on $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ (chapter 130) and $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$ (chapter 56), and is the substrate for fundamental-group and higher-homotopy certificates.

156.1 Carrier definition

Definition 156.1 ($\mathsf{Homotopy}^{\uparrow}$ BHist source packet)**.** *A* $\mathsf{Homotopy}^{\uparrow}$ *source packet is a finite* BHist *tuple* $(f, g, H, I, \rho, \lambda)$*. The rows* f *and* g *are the two endpoint* $\mathsf{ContinuousMap}^{\uparrow}$ *rows accepted by* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*, the row* H *is the displayed deformation row between them, and* I *is the* $\mathsf{Interval}^{\uparrow}$ *parameter row accepted by* $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$*.*

The row ρ *is the* Pkg *provenance tying the endpoint faces, deformation face, and interval face to those two dependency certificates. The row* λ *is the finite* Cont *ledger recording the endpoint reads of* H *at the two displayed interval faces and every* hsame *transport used by the packet classifier. No host quotient, imported path equality, or external function equality is part of the source packet.*

Definition 156.2 (Homotopy source envelope)**.** *A* $\mathsf{Homotopy}^{\uparrow}$ *source envelope is a finite* BHist *packet*

$$\mathcal{H} = (F, G, I, H, p_0, p_1, \eta, \rho)$$

where F *and* G *are source* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *rows for the displayed endpoint maps,* I *is a* $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$ *parameter row,* H *is the continuous-map row for the deformation family,* p_0 *and* p_1 *are endpoint ledgers selecting the interval endpoints,* η *is the finite* Cont *readback ledger from the deformation row to the two endpoint maps, and* ρ *records the* Pkg *provenance binding the continuous-map and interval sources.*

The envelope is admitted only when F*,* G*,* I*,* H*,* p_0*,* p_1*,* η*, and* ρ *occur as displayed rows of the same finite BEDC packet. Thus* $\mathsf{Homotopy}^{\uparrow}$ *carries a deformation certificate assembled from named continuous-map and interval rows, not a host path space of maps.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyUp single carrier alignment`

Definition 156.3 (Homotopy classifier surface)**.** *Two* $\mathsf{Homotopy}^{\uparrow}$ *source envelopes* $\mathcal{H}$ *and* $\mathcal{H}'$ *classify the same homotopy object exactly when* hsame *transports the two endpoint* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$

rows, the $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$ *parameter row, and the finite* Cont *ledgers reading the deformation endpoint rows. The classifier compares only the displayed endpoint maps, interval parameter, deformation readback, and* Pkg *provenance; it does not quantify over an ambient space of paths between maps.*

Theorem 156.4 (Homotopy ContinuousMap dependency surface)**.** *For every admitted* $\mathsf{Homotopy}^\uparrow$ *source envelope of Definition 156.2, every deformation slice and both endpoint maps project through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$*. The only continuous-map data exposed to a downstream consumer are the endpoint rows* F *and* G*, the deformation row* H*, the finite* Cont *readback ledger* η*, and the shared* Pkg *provenance* ρ*.*

Proof. Unpack the source envelope. Its first, second, and fourth coordinates are declared $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ rows, so the endpoint maps and the deformation carrier are already projected through the continuous-map certificate surface.

The slice information is not a separate host function space. It is read from H using the interval parameter row I and the finite Cont ledger η, so each admitted slice has the same continuous-map dependency row as the displayed deformation packet.

Repacking these projections gives exactly the dependency surface stated above. No projection of the envelope returns an uncarried map, topology, or path object outside $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$. □

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket continuousmap dependency surface`

Theorem 156.5 (Homotopy interval endpoint obligation surface)**.** *For every admitted* $\mathsf{Homotopy}^\uparrow$ *source envelope of Definition 156.2, the two interval endpoint rows* p_0 *and* p_1 *select the displayed source and target maps by finite* Cont *readback from the deformation row* H*. The source endpoint readback returns* F*, and the target endpoint readback returns* G*, both under the interval classifier inherited from* $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket interval endpoint determinacy`

Proof. Project the interval coordinate I and the endpoint ledgers p_0 and p_1 from the finite packet. By admission, these rows are part of the same BHist envelope as the deformation row H and the endpoint continuous-map rows F and G.

Read the deformation row along p_0. The ledger η records this readback as a finite Cont row whose endpoint is the displayed source map row F, with interval transport supplied by the $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$ classifier.

Read the deformation row along p_1 in the same way. The corresponding endpoint of the same finite ledger is G, so the target map is selected without introducing an external endpoint-evaluation operation. □

Theorem 156.6 (Homotopy certificate obligation surface)**.** *The* $\mathsf{Homotopy}^\uparrow$ *certificate obligation surface consists exactly of the source envelope of Definition 156.2, the classifier surface of Definition 156.3, the continuous-map dependency surface of Definition 156.4, the interval endpoint obligation surface of Definition 156.5, the classifier-stability transport by* hsame*, the finite* Cont *ledgers, and the* Pkg *provenance over* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket namecert obligation surface`

Proof. Collect the carrier and classifier definitions. They expose the endpoint continuous-map rows, the interval parameter row, the deformation row, the endpoint ledgers, the finite readback ledger, and the provenance row as the complete carrier-classifier surface.

Use Definition 156.4 to account for every continuous-map consumer. Use Definition 156.5 to account for the two interval endpoint consumers. These two projection theorems cover the dependency and exactness rows used by downstream homotopy and knot certificates.

Classifier stability is the stated hsame transport of the endpoint rows, interval row, and finite Cont ledgers. Since all admitted comparisons are generated by those transported rows and the retained Pkg provenance, there is no remaining public field through which a consumer could demand a stronger host-level homotopy object. □

156.2 The certificate

Theorem 156.7 ($\mathsf{Homotopy}^{\uparrow}$ endpoint classifier row)**.** *For every* $\mathsf{Homotopy}^{\uparrow}$ *source packet* $(f, g, H, I, \rho, \lambda)$ *of Definition 156.1, the two accepted endpoint faces classify only through the* $\mathsf{ContinuousMap}^{\uparrow}$ *classifier rows carried by* f *and* g*. The* $\mathsf{Homotopy}^{\uparrow}$ *classifier may read the endpoint rows, the* BHist *deformation row* H*, the interval row* I*, the* Pkg *provenance* ρ*, and the* Cont *ledger* λ*, but it does not compare endpoints by host maps, path quotients, or external equality.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket endpoint classifier row`

Proof. Project the endpoint faces from the displayed finite packet. The rows f and g already arrive with $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ provenance, so their admissibility and endpoint comparison are exactly the classifier fields of that dependency certificate.

The remaining rows only scope the readback. The BHist deformation row H and the $\mathsf{Interval}^{\uparrow}$ row I determine which endpoint reads are visible; ρ records their Pkg source; and λ records the finite Cont and hsame transport needed to expose those reads. None of these rows creates a second endpoint classifier. □

Theorem 156.8 ($\mathsf{Homotopy}^{\uparrow}$ interval-parameter transport)**.** *Let* $(f, g, H, I, \rho, \lambda)$ *be a* $\mathsf{Homotopy}^{\uparrow}$ *source packet. If the* $\mathsf{Interval}^{\uparrow}$ *parameter row* I *is transported to a row* I' *by* hsame *under* $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$*, and the endpoint read of* H *along* I *is recorded by the finite* Cont *ledger* λ*, then the transported endpoint read along* I' *is accepted by the same* $\mathsf{Homotopy}^{\uparrow}$ *classifier with the transported* Cont *ledger and the inherited* Pkg *provenance.*

Proof. Use the $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$ classifier to transport the parameter row from I to I'. The transport is an hsame row over BHist, so it does not replace the deformation row H or the endpoint rows f and g.

Next transport the endpoint readback ledger. The finite Cont entries in λ are reindexed along the displayed hsame parameter comparison, and the resulting endpoint row is classified by the same dependency reads from $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$. The Pkg provenance ρ is retained because the dependency certificates and displayed faces are unchanged. □

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket interval parameter transport`

Theorem 156.9 ($\mathsf{Homotopy}^{\uparrow}$ deformation-composition row)**.** *Suppose* $(f, g, H, I, \rho, \lambda)$ *and* $(g', k, H', I', \rho', \lambda')$ *are* $\mathsf{Homotopy}^{\uparrow}$ *source packets whose middle endpoint faces are classified by the* $\mathsf{ContinuousMap}^{\uparrow}$ *classifier carried by* g *and* g'*. Then their compatible deformation rows concatenate to a single* $\mathsf{Homotopy}^{\uparrow}$ *packet from* f *to* k*, with composed finite* Cont *ledger and inherited* Pkg *provenance from* ρ *and* ρ'*.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket deformation composition row`

Proof. First compare the middle faces using only the endpoint classifier supplied by $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$. This gives the BEDC compatibility row needed to identify the end of H with the start of H' through hsame, not through host-level equality of maps.

Now concatenate the two deformation ledgers. The Cont rows in λ and λ' compose as a finite BEDC ledger, and the middle hsame comparison is inserted at the junction. The interval rows I and I' remain the parameter faces licensed by $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$.

Finally repack the tuple. The new source packet has endpoints f and k, a concatenated deformation row, the displayed parameter rows, composed Cont ledger, and the combined Pkg provenance inherited from ρ and ρ'. These are exactly the rows allowed by Definition 156.1. □

Theorem 156.10 ($\mathsf{Homotopy}^\uparrow$ reversal-symmetry row)**.** *For every* $\mathsf{Homotopy}^\uparrow$ *source packet* $(f, g, H, I, \rho, \lambda)$*, reversing the displayed* $\mathsf{Interval}^\uparrow$ *row swaps the two endpoint faces and gives the symmetric* $\mathsf{Homotopy}^\uparrow$ *classifier row from* g *to* f*. The reversed packet uses the same* BHist *deformation data, the* hsame *symmetry rows from the endpoint and interval classifiers, the same* Pkg *provenance, and the reversed finite* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket reversal symmetry row`

Proof. Apply the symmetry field of the $\mathsf{NameCert}_{\mathsf{Interval}^\uparrow}$ classifier to the displayed interval row. This reverses the parameter face inside BHist and supplies the hsame transport that exchanges the two endpoint reads of H.

Then apply the symmetry field of $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ to the two endpoint classifier rows. The endpoint comparison is therefore reversed inside the continuous-map certificate rather than by an external path symmetry principle.

The final packet keeps the same provenance row ρ and reverses the finite Cont ledger λ. Since the carrier definition exports only BHist rows, hsame transports, Cont ledgers, Pkg provenance, and the two dependency certificates, the reversed tuple is a valid $\mathsf{Homotopy}^\uparrow$ classifier row from g to f. □

Theorem 156.11 ($\mathsf{Homotopy}^\uparrow$ constant-deformation reflexivity row)**.** *Every endpoint continuous-map row accepted by* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ *admits a constant deformation packet over the* $\mathsf{Interval}^\uparrow$ *endpoint ledger. The packet has the same displayed endpoint row at both interval faces, carries the same* BHist *deformation row through both reads, and gives the reflexive* $\mathsf{Homotopy}^\uparrow$ *classifier row using only the finite* Cont *ledger,* hsame *identity transport, and the retained* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket constant deformation reflexivity row`

Proof. Project the endpoint row through $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$. This supplies the accepted continuous-map classifier row that may appear at both faces of a $\mathsf{Homotopy}^\uparrow$ packet.

Choose the constant displayed deformation row whose two endpoint reads are the same projected row. The $\mathsf{Interval}^\uparrow$ endpoint ledger supplies the two interval faces, and both reads use the same finite Cont entry.

Finally repack the tuple with identity hsame transport between the two displayed endpoint rows. Since the carrier surface admits exactly the endpoint rows, interval row, deformation row, finite Cont ledger, and Pkg provenance, this is the reflexive $\mathsf{Homotopy}^\uparrow$ classifier row. □

Theorem 156.12 ($\mathsf{Homotopy}^\uparrow$ endpoint-composition transitivity row)**.** *Suppose compatible* $\mathsf{Homotopy}^\uparrow$ *packets classify* f *with* g *and* g *with* k*, and suppose the middle endpoint rows are classified by* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$*. Then the two packets compose to a* $\mathsf{Homotopy}^\uparrow$ *packet from* f *to* k*, with*

the middle hsame *row recorded in the finite ledger and with the endpoint classifiers inherited from the two continuous-map dependency rows.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket endpoint composition transitivity row`

Proof. Apply Definition 156.9 to the two compatible deformation packets. Its construction concatenates the displayed deformation rows and carries forward the Pkg provenance from both packets.

The compatibility hypothesis supplies the middle endpoint comparison inside $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$. Record that comparison as the inserted hsame row at the junction of the two finite Cont ledgers.

The repacked packet has endpoints f and k, the composed deformation row, and the composed ledger with the middle comparison made explicit. These are precisely the rows exposed by the $\mathsf{Homotopy}^{\uparrow}$ classifier surface, so the result is the transitive endpoint-composition row. □

Theorem 156.13 ($\mathsf{Homotopy}^{\uparrow}$ reversal classifier symmetry row)**.** *If a* $\mathsf{Homotopy}^{\uparrow}$ *packet classifies* f *with* g*, then reversing the interval parameter and transporting both endpoint classifiers gives the symmetric classifier row from* g *to* f*. The reversed packet uses the* $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$ *reversal row for the parameter, the* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *symmetry rows for the two endpoints, and the reversed finite* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket reversal classifier symmetry row`

Proof. Apply Definition 156.10 to the original packet. It reverses the displayed interval parameter, swaps the endpoint reads, retains the Pkg provenance, and reverses the finite Cont ledger.

The interval reversal is classified by $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$, while the two endpoint transports are classified by $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$. These symmetry fields provide the required hsame rows without appealing to an external equality of maps or paths.

Repacking those transported rows gives a valid $\mathsf{Homotopy}^{\uparrow}$ classifier row from g to f. Its public data are still only the reversed interval row, the swapped endpoint rows, the same deformation data, the reversed ledger, and the dependency certificate provenance. □

Theorem 156.14 ($\mathsf{Homotopy}^{\uparrow}$ identity deformation row)**.** *Every accepted* $\mathsf{ContinuousMap}^{\uparrow}$ *endpoint row* f *determines a* $\mathsf{Homotopy}^{\uparrow}$ *source packet from* f *to itself. The packet uses the two* $\mathsf{Interval}^{\uparrow}$ *endpoint faces, the reflexive* hsame *row on the endpoint classifier, a finite constant* Cont *ledger for the displayed deformation, and the shared* Pkg *provenance carried by the accepted endpoint row.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket identity deformation row`

Proof. Unpack the carrier rows of Definition 156.1. The endpoint contribution is the single accepted $\mathsf{ContinuousMap}^{\uparrow}$ row f read twice, so the endpoint classifier supplies the reflexive hsame comparison without introducing any external equality of maps.

The interval contribution is the displayed pair of $\mathsf{Interval}^{\uparrow}$ endpoint faces. Over those faces the deformation ledger is constant at f, and its continuity witness is the finite Cont ledger obtained by reusing the accepted endpoint certificate at each displayed face.

Finally repack the data with the same provenance row. The tuple contains only BHist rows, the reflexive hsame comparison, the finite Cont ledger, the two dependency certificates, and shared Pkg provenance, so it is a valid $\mathsf{Homotopy}^{\uparrow}$ packet from f to f. □

Theorem 156.15 (Homotopy$^{\uparrow}$ classifier equivalence obligation)**.** *The* Homotopy$^{\uparrow}$ *classifier carries the reflexive, symmetric, and transitive rows required of an equivalence surface. Reflexivity is generated by Definition 156.14, symmetry by Definition 156.10, and transitivity by Definition 156.9, using only the* ContinuousMap$^{\uparrow}$ *classifier, the* Interval$^{\uparrow}$ *classifier,* hsame*,* Cont*, and* Pkg *rows already present in the source-packet definition.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket classifier equivalence obligation`

Proof. For reflexivity, take an accepted endpoint row and apply Definition 156.14. The resulting packet has the same endpoint on both faces and records the required classifier row entirely inside the BHist carrier.

For symmetry, start from any classifier packet and use Definition 156.10. The construction reverses the interval face, applies the available hsame symmetries, keeps the same Pkg provenance, and reverses the finite Cont ledger.

For transitivity, take two packets whose middle endpoint faces are classified by the ContinuousMap$^{\uparrow}$ classifier and apply Definition 156.9. The middle comparison is the displayed hsame row, and the composed packet records the concatenated finite Cont ledger with inherited provenance.

These three constructions exhaust the equivalence obligation because Definition 156.1 exposes no further classifier inputs: only endpoint certificates, interval certificates, hsame transports, finite Cont ledgers, and Pkg provenance are available. □

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyTasteGate single carrier alignment`

Theorem 156.16 (Homotopy$^{\uparrow}$ composition associativity row)**.** *For three composable* Homotopy$^{\uparrow}$ *deformation packets, the two bracketings of their pairwise composites are classified by the same* Homotopy$^{\uparrow}$ *row. The finite* Cont *ledgers reassociate, the two middle endpoint transports are the same* hsame *comparisons, and the resulting packet has the same endpoint faces and combined* Pkg *provenance.*

Proof. Unpack the three packets as source rows in Definition 156.1. Both bracketings use Definition 156.9 twice and therefore expose the same outer endpoint faces together with the same two displayed middle endpoint comparisons.

The only apparent difference is the placement of parentheses in the finite Cont ledger. Since the ledger is a finite BEDC row list, reassociation changes only the grouping of the repacking step; it does not create a new continuity obligation or a new endpoint transport.

The Pkg provenance is the combined provenance of the same three packets in both bracketings. Repacking those rows gives a single Homotopy$^{\uparrow}$ classifier row relating the two composites, with the middle faces witnessed by the same hsame comparisons used in the two applications of the composition row. □

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket composition associativity row`

Theorem 156.17 (Homotopy$^{\uparrow}$ double-reversal classifier row)**.** *Let*

$$\mathcal{H} = (f, g, H, I, \rho, \lambda)$$

be a Homotopy$^{\uparrow}$ *source packet of Definition 156.1. Let* $\mathcal{H}^{\mathrm{rev}}$ *be the reversed packet supplied by Definition 156.10, and let*

$$\mathcal{H}^{\mathrm{rr}} = (\mathcal{H}^{\mathrm{rev}})^{\mathrm{rev}}$$

be obtained by applying the same reversal construction a second time. Then $\mathcal{H}^{\mathrm{rr}}$ *is a* Homotopy$^{\uparrow}$ *source packet from* f *to* g *that classifies the same homotopy object as* $\mathcal{H}$*: its deformation row is*

hsame *to the original deformation row H, its interval-parameter row is* hsame *to I through the double interval-classifier transport, its endpoint* $\mathsf{ContinuousMap}^{\uparrow}$ *rows are* hsame *to f and g in their original order, its finite* Cont *ledger is the double reverse of λ and is therefore the same finite ledger order as λ, and its* Pkg *provenance is the original row ρ.*

Lean4 ✓ `BEDC.Derived.HomotopyUp.HomotopyBHistSourcePacket double reversal classifier row`

Proof. Apply Definition 156.10 to $\mathcal{H}$. The resulting packet has endpoint order g, f, keeps the same displayed deformation data H, transports the interval row by the $\mathsf{NameCert}_{\mathsf{Interval}^{\uparrow}}$ symmetry row, keeps the same provenance row ρ, and replaces the finite ledger λ by its reversed ledger.

Apply Definition 156.10 again to this reversed packet. The endpoint order is exchanged a second time, so the visible endpoint rows return to f, g. The endpoint transports used in the two applications are the two symmetry rows of the $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ classifier; composed with the reflexive classifier rows at f and at g, they give the required hsame comparisons with the original endpoint rows.

The deformation coordinate is never replaced by either reversal construction. Each application only changes the interval reading of the same displayed row H, so the double-reversed deformation coordinate is classified with H by the reflexive hsame row on that displayed BHist deformation data.

For the interval coordinate, the first reversal uses the interval symmetry row that reads the endpoint ledger in the opposite direction. The second reversal applies the same interval-classifier symmetry to the reversed parameter row. By the transitivity and symmetry rows of the interval classifier, the composite double transport classifies the resulting parameter row with the original row I. This is precisely the interval component compared by the Homotopy classifier surface of Definition 156.3.

For the ledger coordinate, the first construction reverses the finite Cont ledger λ, and the second construction reverses that finite ledger again. Since a finite ledger is a displayed BEDC row list, reversing the row list twice restores the original row order and the same endpoint-read entries. Thus the double-reversed ledger is componentwise hsame to λ.

Both reversal steps retain the provenance row rather than producing a new package scope, so the provenance of $\mathcal{H}^{\mathrm{rr}}$ is the same ρ. The classifier surface of Definition 156.3 compares exactly the endpoint rows, interval parameter row, deformation readback ledger, and provenance just identified. Repacking these componentwise comparisons gives a $\mathsf{Homotopy}^{\uparrow}$ source packet from f to g that classifies the same homotopy object as $\mathcal{H}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$**.**

Constructive story: A homotopy is assembled as a finite BHist packet containing two endpoint $\mathsf{ContinuousMap}^{\uparrow}$ rows, an $\mathsf{Interval}^{\uparrow}$ parameter row, a displayed deformation row between the endpoints, endpoint-face ledgers, a finite Cont readback ledger, and Pkg provenance for the two dependency certificates. The carrier accepts only packets whose endpoint maps, interval faces, deformation row, endpoint reads, and provenance occur in the same displayed envelope, and it excludes a host path space, imported path equality, ambient function equality, or quotient of maps. Two accepted envelopes classify together when hsame transports the endpoint continuous-map rows, the interval parameter row, and the finite ledgers reading the deformation endpoints, so classification is deformation data with endpoint and interval transport rather than equality in an external mapping space. The source specification is the endpoint-deformation-interval packet, the pattern records endpoint determinacy, reversal, constant deformation, composition, identity, and associativity rows, and the ledger keeps the raw deformation row aligned with the two visible endpoint reads. The five naming-certificate obligations are obtained by the identity deformation for inhabitance and reflexivity, reversal for symmetry, composition for transitivity, and the source-envelope transport rows for closure of accepted packets under the classifier. A history h lies in the signature gap of a $\mathsf{Homotopy}^{\uparrow}$ token p when the source domain accepts the deformation packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; in this surface, that says the two endpoint maps, interval parameter, deformation row, endpoint reads, and composed ledger of h are the packet

encoded by p. The chapter registers this finite-deformation construction under Homotopy$^{\uparrow}$; it uses only ContinuousMap$^{\uparrow}$, Interval$^{\uparrow}$, BHist, hsame, Cont, and Pkg rows, with no host path quotient or full homotopy theory added.

Theory closure: TheoryGate(NameCert$_{\text{Homotopy}\uparrow}$, maturePackageClosed)

Scope closed: The exported finite-deformation public package consists of the BHist source packet, source envelope, endpoint classifier, interval endpoint determinacy, reversal, constant deformation, composition, identity, classifier equivalence, associativity, finite Cont readback, hsame transport, and Pkg provenance rows over NameCert$_{\text{ContinuousMap}\uparrow}$ and NameCert$_{\text{Interval}\uparrow}$.

Not claimed: This chapter does not close host path quotients or full homotopy theory.

Upgrade path: No further paper theory-axis upgrade is recorded; only bridgeChecked verification remains on the separate verification axis.

Chapter 157

A Concrete Naming Certificate for $\mathsf{SimplicialSet}^{\uparrow}$

The simplicial-set interface $\mathsf{SimplicialSet}^{\uparrow}$ packages a contravariant functor from the simplex category Δ to a certified set carrier, with face and degeneracy operators satisfying the simplicial identities. It depends on $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ (chapter 62) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

157.1 Carrier definition

Definition 157.1 (SimplicialSet BHist simplex-row carrier)**.** *Fix a certified simplex-category source supplied by* $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ *and finite simplex-row sources supplied by* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$*. A* $\mathsf{SimplicialSet}^{\uparrow}$ *BHist simplex-row carrier is a finite displayed packet*

$$(F, X, D, P, \rho, \lambda)$$

with the following fields.

1. *F is the functor-source row: it consumes the* $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ *presentation of the contravariant source from the simplex category and exposes only its object, morphism, identity, and composition boundary.*
2. *X is the finite family of simplex rows: for each displayed simplex degree, the row is consumed through the* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *carrier and classifier, so simplex entries are finite BHist rows rather than host-side sets.*
3. *D is the face-and-degeneracy endpoint ledger: every displayed coface or codegeneracy arrow has named source and target simplex rows, with the endpoint read visible in* BHist*.*
4. *P is the package row that records which functor, finite-row, and endpoint reads are public at the certificate boundary.*
5. *ρ is the* Pkg *provenance ledger for the reads in F, X, and D.*
6. *λ is the continuation ledger: its entries are* Cont *routes and* hsame *transports showing that functor-source reads, finite simplex rows, face endpoints, degeneracy endpoints, and package provenance remain in the same displayed packet after transport.*

The carrier exposes the finite packet and its displayed ledgers only. It does not expose a host presheaf, a host simplex category, or host equality of face and degeneracy maps.

Definition 157.2 (SimplicialSet face-degeneracy classifier)**.** *For two* $\mathsf{SimplicialSet}^{\uparrow}$ *BHist simplex-row carriers*

$$(F, X, D, P, \rho, \lambda)$$

and

$$(F', X', D', P', \rho', \lambda'),$$

the face-degeneracy classifier relates them when the following componentwise transports are displayed.

1. *The functor-source rows* F *and* F' *are related by the* hsame *transport supplied by the* $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ *source.*
2. *The finite simplex-row families* X *and* X' *are related degreewise by the* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *carrier and classifier rows.*
3. *The face and degeneracy ledgers* D *and* D' *carry matching source and target endpoints after the functor-source and finite-row transports.*
4. *The package rows* P *and* P' *have matching* Pkg *provenance entries through* ρ *and* ρ'*.*
5. *The continuation ledgers* λ *and* λ' *transport the same* Cont *routes and* hsame *witnesses for all functor, finite-row, endpoint, and provenance reads.*

Thus classification is componentwise hsame *transport of the functor source, finite simplex rows, face and degeneracy ledgers, provenance ledger, and continuation ledger.*

157.2 The certificate

Theorem 157.3 (SimplicialSet functor-source boundary)**.** *For a* $\mathsf{SimplicialSet}^{\uparrow}$ *BHist simplex-row carrier of Definition 157.1, the visible functor-source boundary is exactly the* F *component together with the endpoint rows in* D *that read its displayed face and degeneracy arrows. The* $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ *source supplies the object, morphism, identity, and composition rows consumed by* F*, while the finite simplex rows and package provenance remain separate carrier fields.*

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier functor source boundary`

Proof. Unpack the packet $(F, X, D, P, \rho, \lambda)$ and project the first component. By definition, F is the only field that consumes the $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ source, so its public reads are the object, morphism, identity, and composition boundary of that source.

Next project D. Its entries name the source and target simplex rows for each displayed face or degeneracy endpoint, so the endpoint boundary for the functor read is visible without merging it with the finite-row family X.

The remaining fields are ledgers rather than functor-source data. The package row P, provenance row ρ, and continuation row λ record how the same displayed reads remain inside the packet, while the finite simplex family X is consumed through $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$. Repacking these projections gives precisely the stated boundary. □

Theorem 157.4 (SimplicialSet face-degeneracy ledger stability)**.** *Let* $S = (F, X, D, P, \rho, \lambda)$ *and* $S' = (F', X', D', P', \rho', \lambda')$ *be* $\mathsf{SimplicialSet}^{\uparrow}$ *BHist simplex-row carriers. If* S *and* S' *are related by the classifier of Definition 157.2, then every displayed face or degeneracy endpoint in* D *transports to the corresponding endpoint in* D' *through the functor-source* hsame *row, the degreewise* $\mathsf{FinSet}^{\uparrow}$ *classifier, and the continuation ledger. The transported endpoint remains recorded with matching* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetFaceDegeneracyClassifier ledger stability`

Proof. Start from one displayed endpoint in D. The classifier supplies the comparison between F and F', so the functor-source read carrying the corresponding face or degeneracy arrow transports by hsame.

Use the degreewise finite-row comparison between X and X' to transport the named source and target simplex rows of that endpoint. This step consumes the $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ carrier and classifier rows and does not choose a host-side representative of the simplex set.

Finally read λ and λ'. Their continuation entries identify the same Cont route after the functor and finite-row transports, while ρ and ρ' match the package provenance. The transported endpoint therefore repacks as the corresponding entry of D' with the same public ledger boundary. □

Theorem 157.5 (SimplicialSet NameCert obligation surface)**.** *The carrier of Definition 157.1, the classifier of Definition 157.2, the functor-source boundary of Definition 157.3, and the ledger stability of Definition 157.4 assemble the public obligation surface expected of* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$*. The surface exposes exactly the functor-source row F, the finite simplex-row family X, the face-and-degeneracy endpoint ledger D, the package row P, the provenance ledger ρ, and the continuation ledger λ.*

Proof. First take the carrier packet from Definition 157.1. It lists every visible field consumed by the simplicial-set certificate: functor source, finite simplex rows, endpoint ledger, package row, provenance ledger, and continuation ledger.

Next apply the classifier of Definition 157.2. It supplies componentwise hsame transport for the functor source, degreewise finite-row transport, endpoint-ledger transport, provenance matching, and continuation matching.

Apply Definition 157.3 to separate the functor-source boundary from the finite-row and package ledgers. Apply Definition 157.4 to keep every displayed face and degeneracy endpoint stable under the classifier.

The four clauses repack as the public $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ obligation surface. No additional host presheaf, host simplex category, host function equality, or unrecorded simplicial-identity proof is exported outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier namecert obligation surface`

Theorem 157.6 (SimplicialSet face-degeneracy endpoint coverage)**.** *For every* $\mathsf{SimplicialSet}^{\uparrow}$ *BHist simplex-row carrier $(F, X, D, P, \rho, \lambda)$ of Definition 157.1, each displayed face or degeneracy endpoint in D is covered by the functor-source row F, the finite simplex-row family X, and the finite* Cont *and* Pkg *ledgers. The source and target simplex rows are read through X, the displayed arrow is read through F, and the endpoint remains public only through the continuation and provenance rows recorded by λ and ρ.*

Proof. Project a displayed endpoint entry from D. Its arrow component is one of the face or degeneracy arrows carried by the functor-source row F, so the source-category reading is already inside the $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ boundary.

Next project the source and target simplex rows named by that endpoint. They are entries of the finite family X, hence are consumed through the $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ carrier and classifier surface.

Finally read the ledgers. The package provenance row ρ records the dependency origin for the functor and finite-row reads, while λ records the finite Cont route that exposes the endpoint in the

packet. Repacking these projections gives endpoint coverage without introducing a host presheaf endpoint. □

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier face degeneracy endpoint coverage`

Theorem 157.7 (SimplicialSet simplicial-identity ledger coverage)**.** *Every identity or composition law for displayed faces and degeneracies in a* $\mathsf{SimplicialSet}^{\uparrow}$ *carrier is consumed as a finite* BHist *ledger row inside* D*,* ρ*, and* λ*. The public certificate uses those ledger rows to compare endpoints, and it does not require host presheaf equality of face maps, degeneracy maps, or their composites.*

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier simplicial identity ledger coverage`

Proof. Start from an identity or composition law appearing in the displayed face-and-degeneracy data. The law is not read as equality in an external presheaf; it is a named row in the same BHist packet as the endpoint entries.

Use the classifier of Definition 157.2. It transports the functor-source row, the finite simplex-row family, and the endpoint ledger by componentwise hsame witnesses.

The continuation ledger then identifies the two displayed routes that the simplicial identity compares, while the package provenance records that both routes belong to the same public packet. Thus the identity is consumed as ledger coverage, not as a host-side equation of presheaf maps. □

Theorem 157.8 (SimplicialSet public dependency scope)**.** *The public* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *certificate depends exactly on* $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$*,* BHist*,* hsame*,* Cont*, and* Pkg*. Its public carrier, classifier, endpoint coverage, and simplicial-identity rows are obtained by projection and repacking of those dependencies alone.*

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier public dependency scope`

Proof. Read the carrier of Definition 157.1. The row F is the only functor-source dependency, and the row X is the only finite simplex-row dependency.

The remaining public objects are kernel ledgers. Endpoints and identity rows are BHist entries, comparisons are hsame transports, continuations are finite Cont routes, and dependency provenance is recorded by Pkg.

Apply Definition 157.5, Definition 157.6, and Definition 157.7. These rows exhaust the public surface, so any dependency outside the listed objects would have no projection in the certificate. □

Theorem 157.9 (SimplicialSet face endpoint scope binding)**.** *Each displayed face or dependency endpoint in a public* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *packet is bound to the displayed* $\mathsf{Functor}^{\uparrow}$ *source row, the* $\mathsf{FinSet}^{\uparrow}$ *simplex-row source, the finite* BHist *endpoint ledger, the carried* hsame *transports, the finite* Cont *continuation rows, and the shared* Pkg *provenance. The binding exports no host presheaf endpoint and no equality of ambient face maps beyond those rows.*

Proof. Project the face endpoint through Definition 157.6. The source side is the functor row F together with the finite simplex-row family X, so the endpoint has no independent host presheaf carrier.

Use the classifier of Definition 157.2. Its comparison rows are precisely the hsame transports carried by the same packet.

The continuation and provenance fields then bind the endpoint to the finite Cont route and the shared Pkg row. Repacking these projections gives the stated dependency scope for every displayed face endpoint. □

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier face endpoint scope binding`

Theorem 157.10 (SimplicialSet identity ledger scope binding)**.** *Every simplicial identity row used by the public* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *certificate is bound as a finite* BHist *ledger row over the displayed* $\mathsf{Functor}^{\uparrow}$ *and* $\mathsf{FinSet}^{\uparrow}$ *dependencies, with comparison only through* hsame*,* Cont*, and* Pkg*. The certificate does not require host equality of presheaves, face maps, degeneracy maps, or their composites.*

Proof. Start from an identity row accepted by the public packet. By Definition 157.7, the row is already a finite ledger entry, not an equation in an ambient presheaf.

The endpoints of the two displayed routes are bound by Definition 157.9. Thus both sides of the identity read the same $\mathsf{Functor}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, BHist, hsame, Cont, and Pkg surface.

Repack the two route reads with the ledger row. This gives scope binding for the identity while excluding any separate host presheaf equality or external simplicial-law witness. □

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier identity ledger scope binding`

Theorem 157.11 (SimplicialSet scoped obligation package)**.** *The scoped* $\mathsf{SimplicialSet}^{\uparrow}$ *obligation package is exactly the package generated by the public dependency scope of Definition 157.8, the face endpoint scope binding of Definition 157.9, and the identity ledger scope binding of Definition 157.10. It binds the carrier, classifier, endpoint, and simplicial-identity rows to* $\mathsf{Functor}^{\uparrow}$*,* $\mathsf{FinSet}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* Pkg*, and it exports no additional host presheaf structure.*

Proof. First take the public dependency inventory from Definition 157.8. It lists the only source and kernel objects projected by the public certificate.

Next attach Definition 157.9. This binds every face or dependency endpoint row to the displayed dependency scope.

Finally attach Definition 157.10. This binds the simplicial identity rows to finite ledgers over the same dependency scope. Together the three projections exhaust the carrier, classifier, endpoint, and identity surfaces, so the scoped package has no field through which a host presheaf equality or external simplicial structure could enter. □

Lean4 ✓ `BEDC.Derived.SimplicialSetUp.SimplicialSetTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$**.**

Constructive story: A simplicial set is generated as a finite BHist packet whose functor-source row consumes the $\mathsf{Functor}^{\uparrow}$ presentation of the simplex-category direction, whose finite simplex-row family is consumed through $\mathsf{FinSet}^{\uparrow}$, and whose face and degeneracy endpoints are recorded by displayed ledgers. The carrier accepts packets containing the functor source, finite simplex rows, face-and-degeneracy endpoint ledger, package row, provenance ledger, and continuation ledger, while a host presheaf, host simplex category, ambient face-map equality, and unrecorded simplicial-identity proof stay outside. Two packets classify together when the functor-source row, each finite simplex row, each face or degeneracy endpoint, the provenance row, and the continuation ledger transport componentwise by the available hsame and dependency classifiers. The source specification is this six-field packet, the pattern records the contravariant functor boundary, face and degeneracy endpoint coverage, and simplicial-identity ledger rows, and the ledger keeps raw functor reads, finite simplex entries, endpoint routes, and provenance visible together. The five naming-certificate obligations are supplied by an admitted finite packet, by componentwise reflexivity, symmetry, and transitivity of the transported rows, and by ledger stability showing that every transported face or degeneracy endpoint remains in the carrier. A history h lies

in the signature gap of a SimplicialSet$^{\uparrow}$ token p when the source domain accepts this simplex-row packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; concretely, the degrees, finite simplex entries, face and degeneracy routes, and identity ledgers of h are the rows encoded by p. The chapter registers this displayed functor-and-ledger construction under SimplicialSet$^{\uparrow}$; it closes only the scoped Functor$^{\uparrow}$, FinSet$^{\uparrow}$, BHist, hsame, Cont, and Pkg surface, with no standard bridge or full simplicial homotopy theory introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{SimplicialSet}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature SimplicialSet$^{\uparrow}$ paper scope covers the BHist simplex-row carrier, face-degeneracy endpoint ledger, simplicial-identity ledger, public dependency scope, and displayed simplex-row bridge surface over Functor$^{\uparrow}$, FinSet$^{\uparrow}$, BHist, hsame, Cont, and Pkg.

Formal verification: FormalStatus(NameCert$_{\mathsf{SimplicialSet}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SimplicialSetUp.SimplicialSetBHistSimplexRowCarrier\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: Full simplicial homotopy theory and standard bridge data are not closed by this chapter.

Upgrade path: No further paper theory-axis step is claimed; verification-axis bridge work remains separate.

Chapter 158

A Concrete Naming Certificate for $\mathsf{ModelCat}^{\uparrow}$

The model-category interface $\mathsf{ModelCat}^{\uparrow}$ packages a category carrier with three distinguished classes of morphisms (cofibrations, fibrations, weak equivalences) satisfying lifting and factorisation axioms. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61), and is the homotopy-theoretic substrate beneath higher-category certificates.

158.1 Carrier definition

Definition 158.1 (ModelCatUp BHist source packet)**.** *A* $\mathsf{ModelCat}^{\uparrow}$ BHist *source packet is a finite tuple*

$$\mathcal{M} = (C, \mathsf{Cof}, \mathsf{Fib}, \mathsf{W}, \mathsf{Lift}, \mathsf{Fact}, P, \rho, \lambda)$$

whose coordinates are all displayed BEDC rows:

1. *C is the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row, carrying the object, morphism, identity, composition, and morphism-classifier surface.*
2. Cof, Fib, *and* W *are the cofibration, fibration, and weak-equivalence classifier rows on morphisms of C.*
3. Lift *records the finite lifting ledgers between cofibration rows and fibration rows, including the acyclic cases whose weak-equivalence coordinates are read through* W.
4. Fact *records the finite factorisation ledgers that split each displayed morphism through a cofibration followed by an acyclic fibration and through an acyclic cofibration followed by a fibration.*
5. *P is the* Pkg *provenance row for the CategoryUp dependency and for the displayed classifier ledgers.*
6. *ρ and λ are the* $\mathsf{Cont}/\mathsf{hsame}$ *transport ledgers that keep the category row, the three morphism-classifier rows, the lifting rows, the factorisation rows, and the package provenance stable under rowwise transport.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatTasteGate single carrier alignment`

Theorem 158.2 (ModelCatUp root obligation surface)**.** *An admitted* $\mathsf{ModelCat}^{\uparrow}$ *source packet in the sense of Definition 158.1 exposes exactly the finite* BHist *rows C,* Cof, Fib, W, Lift, Fact, *P, ρ, and λ. Consequently the root obligation surface for* $\mathsf{NameCert}_{\mathsf{ModelCat}^{\uparrow}}$ *consists of the consumed*

$\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ *row, the cofibration row, the fibration row, the weak-equivalence row, the lifting and factorisation ledgers, the* Pkg *provenance, and the* Cont/hsame *transport ledger. It does not expose a host localization, a quotient category, an external weak-equivalence calculus, a derived mapping space, or a bridge row.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket root obligation surface`

Proof. Project an admitted packet $\mathcal{M} = (C, \mathsf{Cof}, \mathsf{Fib}, \mathsf{W}, \mathsf{Lift}, \mathsf{Fact}, P, \rho, \lambda)$. By Definition 158.1, these nine coordinates are the only carrier fields. The category coordinate is already a $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ row, so object, morphism, identity, composition, and morphism-classifier reads pass through that dependency row rather than through an ambient host category.

The next three projections give the displayed cofibration, fibration, and weak-equivalence classifier rows. The lifting projection reads only finite squares whose left and right morphism faces are classified by those rows, and the factorisation projection reads only the two displayed factorisation ledgers. Acyclic clauses use the same weak-equivalence coordinate W; they do not open a separate localization calculus.

Transport is rowwise. If a consumer replaces a displayed coordinate by an hsame-classified representative, the ρ and λ ledgers carry the CategoryUp dependency, the three classifier rows, the lifting rows, the factorisation rows, and the Pkg provenance to the transported packet.

Repacking these projections gives exactly the stated root obligation surface. Since the packet has no coordinate for a host localization, quotient category, external weak-equivalence calculus, derived mapping space, or bridge datum, none of those objects can be consumed from the $\mathsf{ModelCat}^\uparrow$ source surface. □

Theorem 158.3 (ModelCatUp weak-equivalence classifier laws)**.** *For an admitted* $\mathsf{ModelCat}^\uparrow$ *source packet* $\mathcal{M} = (C, \mathsf{Cof}, \mathsf{Fib}, \mathsf{W}, \mathsf{Lift}, \mathsf{Fact}, P, \rho, \lambda)$*, the displayed weak-equivalence row* W *supplies the reflexive, symmetric, and transitive classifier transport available to* $\mathsf{NameCert}_{\mathsf{ModelCat}^\uparrow}$ *consumers. These laws are read only through the category dependency row* C*, the* hsame *transport ledger, and the* Pkg *provenance row* P*; they do not import a host localization, a quotient category, or an external weak-equivalence calculus.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket weak equivalence classifier laws`

Proof. Project the admitted packet and read its weak-equivalence coordinate W. By Definition 158.1, this coordinate is a displayed morphism-classifier row over the consumed $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ dependency C, not a row in an ambient homotopy category.

The reflexive, symmetric, and transitive classifier movements are therefore the movements internal to W. When a morphism row is replaced by an hsame-classified representative, the transport ledgers ρ and λ carry the category row, the weak-equivalence classifier, and the package provenance together.

Repack these projected fields as the public classifier law surface. Since the packet contains no coordinate for localization, quotienting, or derived mapping-space data, the resulting laws are exactly the displayed W-through-hsame and Pkg laws. □

Theorem 158.4 (ModelCatUp lifting square boundary)**.** *Every lifting obligation exposed by an admitted* $\mathsf{ModelCat}^\uparrow$ *source packet reads only the cofibration row* Cof*, the fibration row* Fib*, the weak-equivalence row* W *for acyclic cases, the finite lifting ledger* Lift*, the rowwise* Cont/hsame *transport ledger, and the* Pkg *provenance. Thus a lifting square has no projection to a host localization, quotient category, external weak-equivalence calculus, derived mapping space, or bridge row.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket lifting square boundary`

Proof. Project an admitted packet. The left face of a displayed lifting square is read through Cof, and the right face is read through Fib. Acyclic variants use the same weak-equivalence coordinate W named in the packet.

The finite witness that the square is a lifting obligation is exactly the ledger coordinate Lift. Transport along an hsame replacement uses ρ and λ to move the category row, the three classifier rows, the lifting ledger, and the provenance row together.

Repacking these rows gives the claimed boundary. No other coordinate occurs in Definition 158.1, so no consumer of the lifting surface can read a host localization, quotient category, external calculus, derived mapping space, or bridge datum. □

Theorem 158.5 (ModelCatUp factorization ledger determinacy)**.** *For an admitted* $\mathsf{ModelCat}^{\uparrow}$ *source packet, the cofibration–acyclic-fibration factorisation route and the acyclic-cofibration–fibration factorisation route are determined by the finite ledger* Fact *together with the displayed* Cof*,* Fib*, and* W *classifier rows, the* Cont/hsame *transport ledger, and the* Pkg *provenance. The determinacy surface cannot import a host localization, quotient category, derived mapping space, external weak-equivalence calculus, or bridge row.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket factorization ledger determinacy`

Proof. Project the factorisation coordinate Fact from the admitted packet. Its first component records the cofibration followed by acyclic fibration route; its second component records the acyclic cofibration followed by fibration route.

Each classifier read needed by those routes is already one of Cof, Fib, or W. Acyclicity is therefore a displayed weak-equivalence classifier read, not a localization or quotient construction.

Transport is rowwise. The ledgers ρ and λ carry Fact, the three classifier rows, the CategoryUp dependency, and the provenance row under Cont/hsame replacement.

Repack the transported tuple as the public factorisation determinacy surface. Because the packet has no field for any host localization, quotient category, derived mapping space, external weak-equivalence calculus, or bridge datum, the two factorisation routes are determined exactly by the displayed ledger and classifier rows. □

Theorem 158.6 (ModelCatUp finite factorization transport surface)**.** *Let* $\mathcal{M} = (C, \mathsf{Cof}, \mathsf{Fib}, \mathsf{W}, \mathsf{Lift}, \mathsf{Fact}, P, \rho, \lambda)$ *be an admitted* $\mathsf{ModelCat}^{\uparrow}$ BHist *source packet. Suppose* $\mathcal{M}'$ *is a transported presentation whose displayed category row, cofibration classifier, fibration classifier, weak-equivalence classifier, lifting ledger, factorisation ledger, provenance row,* Cont/hsame *transport rows, and* Pkg *rows are preserved by the packet transport.*

Then $\mathcal{M}'$ *exposes the same finite factorisation and lifting obligation surface as* $\mathcal{M}$*. The transported surface consists exactly of the displayed category dependency, the three morphism-classifier rows, the finite lifting and factorisation ledgers, rowwise* Cont/hsame *transport, and the* Pkg *provenance. It contains no host localization, quotient category, derived mapping space, standard bridge row, or external weak-equivalence calculus.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket finite factorization transport surface`

Proof. Project $\mathcal{M}$ by Definition 158.1. The only available coordinates are the category dependency, the three classifier rows, the finite lifting and factorisation ledgers, the provenance row, and the rowwise transport ledgers.

Apply Definition 158.4 to the transported presentation. Preservation of C, Cof, Fib, W, Lift, P, and the Cont/hsame ledgers carries every displayed lifting square to the same finite obligation surface.

Apply Definition 158.5 to the same transported packet. Preservation of Fact together with Cof, Fib, W, P, and rowwise transport fixes both factorisation routes as displayed finite ledger rows.

Repack the lifted and factorised projections as the public transport surface. Since neither theorem projects a coordinate outside Definition 158.1, the transported presentation has no source from which to read localization, quotienting, derived mapping spaces, a standard bridge, or an external weak-equivalence calculus. □

158.2 The certificate

Definition 158.7 (ModelCatUp NameCert obligation package)**.** *The* $\mathsf{ModelCat}^{\uparrow}$ NameCert *obligation package is the ten-field package whose source is the* BHist *source packet of Definition 158.1. Its pattern is the displayed* $\mathsf{Cat}^{\uparrow}$ *dependency together with* Cof*,* Fib*,* W*,* Lift*, and* Fact*. Its classifier is the weak-equivalence row transported by* Cont/hsame*. Its stability fields are the classifier laws of Definition 158.3, the lifting boundary of Definition 158.4, and the factorisation determinacy of Definition 158.5. Its ledger field is P together with the displayed lifting and factorisation ledgers.*

Lean4 (definition) `BEDC.Derived.ModelCatUp.ModelCatNameCertObligationPackage`

Theorem 158.8 (ModelCatUp NameCert obligation surface)**.** *Every admitted* $\mathsf{ModelCat}^{\uparrow}$ NameCert *obligation package exposes exactly the* $\mathsf{Cat}^{\uparrow}$ *row, the cofibration classifier row, the fibration classifier row, the weak-equivalence classifier row, the lifting ledger, the factorisation ledger, package provenance, and rowwise* Cont/hsame *transport. It exposes no host localization, quotient category, derived mapping space, or external weak-equivalence calculus.*

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket namecert obligation surface`

Proof. Begin with the root obligation surface of Definition 158.2. It enumerates the only carrier fields available from an admitted source packet: the $\mathsf{Cat}^{\uparrow}$ dependency, the three morphism-classifier rows, the two finite ledgers, the package provenance, and rowwise transport.

Apply the weak-equivalence classifier laws, the lifting square boundary, and the factorisation ledger determinacy. These three results identify the stability supplied to the obligation package: classifier transport is read through W, lifting reads through Lift and the displayed classifier rows, and factorisation reads through Fact and the same transport ledgers.

Repack those projections as the ten-field package of Definition 158.7. Since the source packet has no coordinate for localization, quotienting, derived mapping spaces, or an external weak-equivalence calculus, none of those objects can appear in the obligation surface. □

Theorem 158.9 (ModelCatUp CategoryUp dependency boundary)**.** *Every* $\mathsf{ModelCat}^{\uparrow}$ *consumer reads objects, morphisms, identities, and composition only through the C coordinate of the source packet in Definition 158.1. The* $\mathsf{ModelCat}^{\uparrow}$ *package has no ambient category field outside that dependency coordinate.*

Proof. Project an admitted source packet $\mathcal{M} = (C, \mathsf{Cof}, \mathsf{Fib}, \mathsf{W}, \mathsf{Lift}, \mathsf{Fact}, P, \rho, \lambda)$. The first coordinate is the consumed $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ row, and Definition 158.1 assigns object, morphism, identity, composition, and morphism-classifier reads to that coordinate.

All remaining coordinates classify morphism classes, lifting ledgers, factorisation ledgers, provenance, and rowwise transport over the same dependency. They do not introduce a second category carrier.

Thus any consumer that asks for categorical structure must project C first. Because no ambient category field occurs in the packet, there is no alternative source from which objects, morphisms, identities, or composition can be read. □

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket category dependency boundary`

Theorem 158.10 (ModelCatUp root-threshold obligation triad)**.** *Every admitted* $\mathsf{ModelCat}^{\uparrow}$ *source packet supplies exactly three downstream root surfaces. The first is the consumed* $\mathsf{Cat}^{\uparrow}$ *dependency boundary, read through the* C *coordinate. The second is the three morphism-classifier rows, together with weak-equivalence classifier transport through* W*. The third is the finite lifting and factorisation ledger surface, transported by the displayed* $\mathsf{Cont/hsame}$ *rows and by* Pkg *provenance.*

These three surfaces are the only rows available to downstream consumers of the root packet. The packet exposes no host localization, quotient category, derived mapping space, external weak-equivalence calculus, or bridge row.

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket root threshold obligation triad`

Proof. Project an admitted packet by Definition 158.1. Its coordinates are the consumed $\mathsf{Cat}^{\uparrow}$ dependency, the three classifier rows, the two finite ledgers, package provenance, and rowwise $\mathsf{Cont/hsame}$ transport.

The carrier part is the root surface of Definition 158.2. The classifier part is transported by Definition 158.3, which isolates the weak-equivalence classifier as the only weak-equivalence row exposed by the packet.

For the finite ledger surface, apply Definition 158.4 to the lifting coordinate and Definition 158.5 to the factorisation coordinate. Both results read their data through the displayed classifier rows, package provenance, and rowwise transport.

It remains to identify the threshold through which categorical structure can be consumed. By Definition 158.9, objects, morphisms, identities, and composition are forced through the C coordinate. Since no coordinate for localization, quotienting, derived mapping spaces, external weak-equivalence calculus, or bridges occurs in the source packet, none of those rows is available downstream. □

Theorem 158.11 (ModelCatUp public certificate boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{ModelCat}^{\uparrow}}$ *surface is exactly the* $\mathsf{Cat}^{\uparrow}$ *dependency coordinate, the cofibration, fibration, and weak-equivalence classifier rows, the finite lifting-square ledger, the finite factorisation ledger,* Pkg *provenance, and rowwise* $\mathsf{Cont/hsame}$ *transport. It excludes host localization, quotient category, derived mapping space, and any external weak-equivalence calculus.*

Proof. Project the admitted source packet through Definition 158.2. This gives the consumed $\mathsf{Cat}^{\uparrow}$ coordinate, the three classifier rows, the lifting and factorisation ledgers, provenance, and rowwise transport.

Use Definition 158.3 to isolate the weak-equivalence classifier among the three displayed classifier rows. The cofibration and fibration rows remain parallel classifier coordinates rather than host localization data.

Apply Definition 158.4, Definition 158.5, and Definition 158.6. These identify the finite lifting-square and factorisation surfaces and their allowed transport through Pkg, Cont, and hsame.

Finally combine Definition 158.9 with Definition 158.10. The category dependency forces ordinary categorical reads through C, while the triad states that the dependency, classifier, and finite-ledger surfaces are the only downstream root surfaces. Thus the public certificate boundary is exactly the displayed finite surface and contains no localization, quotient category, derived mapping space, or external weak-equivalence calculus. □

Lean4 ✓ `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket public certificate boundary`

Theorem 158.12 (ModelCat finite model-structure bridge boundary)**.** *The public* $\mathsf{ModelCat}^{\uparrow}$ *finite packet interprets the standard finite model-category schema only through the consumed* $\mathsf{Cat}^{\uparrow}$ *row, the displayed cofibration, fibration, and weak-equivalence classifiers, the finite lifting ledger, the finite factorisation ledger,* Pkg *provenance,* Cont *routes, and* hsame *transport.*

Thus every bridge-facing read of the finite model-structure surface is already one of the rows certified by the public packet. The surface contains no host localization, quotient category, derived mapping space, external weak-equivalence calculus, or unrecorded factorisation choice.

Proof. Project the public certificate boundary of Definition 158.11. It identifies the consumed $\mathsf{Cat}^{\uparrow}$ dependency row, the three displayed morphism classifiers, the lifting and factorisation ledgers, provenance, and rowwise Cont/hsame transport as the public finite packet.

The weak-equivalence component is isolated by Definition 158.3. The cofibration and fibration components remain the two parallel classifier rows named by the root obligation surface, not external model-structure data.

The lifting and factorisation surfaces are fixed by Definition 158.4, Definition 158.5, and Definition 158.6. These results show that bridge-facing reads of lifting squares and factorisation rows pass through the displayed finite ledgers with their Pkg, Cont, and hsame provenance.

Finally, Definition 158.9 forces ordinary categorical reads through the consumed category row, and Definition 158.10 exhausts the remaining root surfaces. Hence the finite bridge boundary is exactly the public packet surface and exports none of the excluded host data. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModelCat}^{\uparrow}}$.

Constructive story: A ModelCat packet is built from a consumed $\mathsf{Cat}^{\uparrow}$ row, three displayed morphism-classifier rows, finite lifting and factorisation ledgers, a package row, provenance, and rowwise Cont/hsame transport. The checked category dependency boundary forces ordinary categorical reads through the consumed dependency row, while the root, classifier, lifting, factorisation, and threshold surfaces expose only the displayed finite packet rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ModelCat}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature $\mathsf{ModelCat}^{\uparrow}$ paper scope covers the BHist source packet, weak-equivalence classifier laws, lifting square boundary, factorization ledger determinacy, public certificate boundary, and finite model-structure bridge boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ModelCat}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ModelCatUp.ModelCatBHistSourcePacket\_category\_dependency\_boundary`

Bridge status: paperBridge

Not claimed: Host localization, quotient category, derived mapping space, external weak-equivalence calculus, checked bridge status, and downstream localization or replacement consumers are not closed.

Upgrade path: No further paper theory-axis step is claimed; bridgeChecked verification remains separate.

Chapter 159

A Concrete Naming Certificate for $\mathsf{InfCat}^{\uparrow}$

The ∞-category interface $\mathsf{InfCat}^{\uparrow}$ packages a simplicial-set carrier satisfying the inner-horn lifting condition (a quasicategory). It depends on $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ (chapter 157) and $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61).

159.1 Carrier definition

Definition 159.1 (InfCatUp BHist source packet)**.** *An* $\mathsf{InfCat}^{\uparrow}$ BHist *source packet is a finite tuple*

$$\mathcal{I} = (S, C, H, L, \rho, \lambda)$$

whose coordinates are all displayed BEDC rows. The row S is the consumed $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *row, carrying the simplicial carrier, face and degeneracy rows, and the simplicial classifier surface. The row C is the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row used for ordinary categorical source faces read by downstream consumers.*

The row H is the inner-horn ledger. It records finite horn-boundary rows, the missing inner face, the displayed filler endpoint, and the hsame *comparisons that identify the filler boundary with the named horn boundary inside the simplicial-set carrier S. The row L is the lifting-witness ledger: each lifting entry is a finite* $\mathsf{ProbeBundle}$ *row whose source and target faces are read through S, whose ordinary categorical endpoint is read through C when present, and whose continuation endpoint is recorded by* Cont.

The row ρ is the Pkg *provenance row for the consumed simplicial-set and category certificates, the horn ledger, and the lifting ledger. The row λ is the* $\mathsf{Cont}/\mathsf{hsame}$ *transport ledger comparing the simplicial faces, horn boundaries, fillers, lifting witnesses, and provenance entries under rowwise replacement. The packet has no coordinate for a host quasicategory, a localization, or a simplicial mapping object.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket provenance transport spine`

159.2 The certificate

Theorem 159.2 (InfCatUp obligation inventory fields)**.** *Every accepted* $\mathsf{InfCat}^{\uparrow}$ BHist *source packet contains exactly the displayed inventory needed by the next obligation layer: the consumed*

$\mathsf{NameCert}_{\mathsf{SimplicialSet}^\uparrow}$ *row, the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ *row, the finite inner-horn ledger, the lifting ledger, the* ProbeBundle *rows supporting the lifting entries, the* Cont *transport rows, the* hsame *comparison rows, and the* Pkg *provenance fields.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket obligation inventory fields`

Proof. Unfold Definition 159.1. An accepted packet is the tuple $\mathcal{I} = (S, C, H, L, \rho, \lambda)$, where S and C are precisely the consumed simplicial-set and category certificate rows.

The ledgers are also displayed tuple fields. The horn ledger H records the finite inner-horn rows, while the lifting ledger L records the lifting entries and their ProbeBundle support. The remaining tuple fields ρ and λ provide the Pkg provenance and the Cont/hsame transport rows. No additional coordinate is present, so this list is the full inventory. □

Theorem 159.3 (InfCatUp source and classifier obligations)**.** *The source and classifier obligations of an accepted* $\mathsf{InfCat}^\uparrow$ *packet are exactly the fields listed in Definition 159.2, together with componentwise* hsame/Cont *transport across the displayed packet coordinates. They include no host quasicategory coordinate and no localization coordinate.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket source classifier obligations`

Proof. The source side is obtained by unfolding Definition 159.1: every admissible source read is one of S, C, H, L, ρ, or λ, or a finite row projected from the horn or lifting ledgers.

For the classifier side, apply Definition 159.6. The classifier compares the same packet coordinates through the consumed dependency classifiers, componentwise hsame, Cont transport, and shared Pkg provenance.

Since neither the packet definition nor the classifier surface supplies a host quasicategory or localization slot, neither kind of coordinate can appear among the source or classifier obligations. □

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket source classifier obligation surface`

Theorem 159.4 (InfCatUp stability, exactness, and ledger obligations)**.** *For an accepted* $\mathsf{InfCat}^\uparrow$ *packet, the stability, exactness, ledger, and downstream-consumer obligations are discharged by the inner-horn ledger boundary, the quasicategory classifier surface, the NameCert obligation surface, and the consumer boundary stated in this chapter.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket stability exactness ledger obligations`

Proof. Begin with the ledger part. The inner-horn ledger boundary theorem Definition 159.5 restricts every horn read to the displayed simplicial-set row, finite horn ledger, provenance row, and transport ledger.

Next use the classifier surface of Definition 159.6. It supplies the componentwise hsame/Cont transport needed for stability under displayed replacement of the packet coordinates.

The exact obligation package is then read through Definition 159.7. Finally, Definition 159.8 identifies the downstream consumer boundary with the same consumed certificate rows, finite ledgers, provenance, and transport fields. These cited surfaces together exhaust the claimed obligation families. □

Theorem 159.5 (InfCatUp inner-horn ledger boundary)**.** *Every accepted* $\mathsf{InfCat}^\uparrow$ *source packet of Definition 159.1 exposes its inner-horn data only through the consumed* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^\uparrow}$ *row* S*, the finite inner-horn ledger* H*, the* Pkg *provenance row* ρ*, and the* Cont/hsame *transport ledger*

λ. *Thus a consumer of the inner-horn boundary cannot read a host quasicategory, a localization, or a simplicial mapping object.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket inner horn ledger boundary`

Proof. Project an accepted packet $\mathcal{I} = (S, C, H, L, \rho, \lambda)$. The horn boundary, missing inner face, filler endpoint, and boundary comparison rows are exactly the entries of H, and each of those entries is scoped by the simplicial-set carrier and classifier rows supplied by S.

The provenance and transport reads are also displayed. The row ρ records which packet face supplied the horn entry, while λ transports the horn boundary, filler endpoint, and comparison rows through Cont and hsame.

No other tuple coordinate is available for an inner-horn read. In particular, the category dependency C and lifting ledger L are not host quasicategory data, and the tuple has no localization or simplicial mapping-object slot. Repacking the projected rows gives exactly the stated boundary. □

Theorem 159.6 (InfCatUp quasicategory classifier surface)**.** *For two* $\mathsf{InfCat}^{\uparrow}$ *source packets, the quasicategory classifier surface compares only the displayed* BHist *rows* S, C, H, L, ρ, *and* λ *by the simplicial-set classifier, the category classifier, componentwise* hsame, Cont *transport, and shared* Pkg *provenance. It supplies no classifier for a host quasicategory, a localization, or a simplicial mapping object.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket quasicategory classifier surface`
↪ variant `BEDC.Derived.InfCatUp.InfCatQuasicategoryClassifierSurface transport`

Proof. Begin with the two consumed certificate rows. The simplicial-set dependency classifies simplicial carrier, face, degeneracy, and simplex rows, while the category dependency classifies the ordinary categorical source faces that are explicitly present in the packet.

Next compare the horn and lifting ledgers. The entries of H and L are finite BHist rows, so their comparisons are componentwise hsame rows carried by the ledger λ. Continuation endpoints move through the displayed Cont entries, and the package row ρ keeps the same provenance attached to the transported packet.

Repack these comparisons as the classifier surface. Since every compared coordinate is one of S, C, H, L, ρ, or λ, there is no remaining field from which a host quasicategory classifier, localization classifier, or mapping-object classifier could be read. □

Theorem 159.7 (InfCatUp NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{InfCat}^{\uparrow}}$ *obligation surface of an accepted packet* $\mathcal{I} = (S, C, H, L, \rho, \lambda)$ *consists exactly of the* BHist *source packet of Definition 159.1, the inner-horn ledger boundary of Definition 159.5, and the quasicategory classifier surface of Definition 159.6. Its rows are the consumed* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *row, the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row, the inner-horn ledger, the lifting witness ledger, the* Pkg *provenance row, and the* $\mathsf{Cont}/\mathsf{hsame}$ *transport ledger, with no host quasicategory, localization, or simplicial mapping object.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket namecert obligation surface`

Proof. Soundness is by projection from the source packet. The carrier row exposes only S, C, H, L, ρ, and λ, the horn theorem reads the inner-horn boundary from S, H, ρ, and λ, and the classifier theorem compares those same displayed packet coordinates.

Completeness is the reverse reading. Any row used by carrier admission, classifier transport, horn filling, lifting witness readback, provenance, or continuation transport is one of the six packet coordinates or a projected entry of H, L, ρ, or λ.

Therefore the naming-certificate obligation surface is exactly the displayed finite packet and its projected horn and classifier rows. The proof never opens a host quasicategory, localization, or simplicial mapping-object coordinate, because the packet has no such coordinate. □

Theorem 159.8 (InfCatUp consumer boundary)**.** *Every downstream consumer of the* $\mathsf{InfCat}^{\uparrow}$ *root reads through the displayed* BHist *packet* $(S, C, H, L, \rho, \lambda)$*, the two consumed* NameCert *rows* S *and* C*, the finite inner-horn and lifting ledgers* H *and* L*, the* Pkg *provenance row* ρ*, and the* Cont/hsame *transport ledger* λ*. Conversely those rows supply the complete consumer boundary for the root, and no consumer obtains a host quasicategory, localization, or simplicial mapping object.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket consumer boundary`

Proof. Project any accepted consumer read to the packet coordinates. A simplicial read factors through S, an ordinary categorical source read factors through C, an inner-horn read factors through H, and a lifting-witness read factors through L.

The remaining consumer information is provenance and transport. The package row ρ records which dependency or ledger supplies the read, and the ledger λ records the Cont and hsame movements needed to keep the read stable under displayed replacement.

For the converse, repack these projected rows into the source packet and use Definition 159.7. It identifies the same rows as the complete naming-certificate surface, so they already supply every consumer-facing obligation. Since no projected coordinate names a host quasicategory, localization, or simplicial mapping object, no downstream consumer can read one from this root. □

Theorem 159.9 (InfCatUp public certificate boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{InfCat}^{\uparrow}}$ *surface is exactly the consumed* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *row, the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row, the finite inner-horn ledger, the lifting ledger, the package provenance row, and the* Cont/hsame *transport ledger. No host quasicategory, localization, or simplicial mapping object is part of the public certificate boundary.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket public certificate boundary`

Proof. First project the finite horn part by Definition 159.5. The inner-horn boundary is read through the consumed simplicial-set row, the horn ledger, provenance, and displayed transport.

Next use Definition 159.6. The classifier surface compares only the displayed packet coordinates and their componentwise hsame and Cont rows, so it adds no host quasicategory, localization, or mapping-object coordinate.

Now apply Definition 159.7. It identifies the NameCert obligations with the consumed simplicial-set and category rows, inner-horn ledger, lifting ledger, package provenance, and transport ledger.

Finally read the downstream boundary through Definition 159.8. Its converse direction repacks exactly those rows as the complete consumer surface, so the public certificate boundary is precisely the displayed finite packet surface and nothing outside it. □

Theorem 159.10 (InfCatUp inner-horn consumer determinacy)**.** *For any accepted* $\mathsf{InfCat}^{\uparrow}$ *packet* $\mathcal{I} = (S, C, H, L, \rho, \lambda)$*, every downstream consumer read of an inner-horn or lifting obligation is determined entirely by the displayed* BHist *rows* $(S, C, H, L, \rho, \lambda)$*, the consumed* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *rows, the finite* ProbeBundle *horn and lifting ledger entries,* Pkg *provenance, and* Cont/hsame *transport. No host quasicategory, localization, or simplicial mapping-object coordinate can change the read.*

Proof. Project the consumer through Definition 159.8. Any inner-horn read is already a read of S, H, ρ, and λ, while any lifting-obligation read is already a read of S, C, L, ρ, and λ.

Restrict the inner-horn part by Definition 159.5. The horn boundary, missing face, filler endpoint, and comparison rows are finite ledger entries carried by H, with provenance supplied by ρ and displayed transport supplied by λ.

Transport equality of consumer reads through Definition 159.6. Since the classifier compares only the six packet coordinates and their consumed certificate rows, equal displayed packets give equal downstream reads of the horn and lifting surfaces.

Finally repack the exact surface by Definition 159.7. The repacked surface contains only the consumed certificate rows, the finite horn and lifting ledgers, provenance, and Cont/hsame transport. A host quasicategory, localization, or simplicial mapping-object coordinate is therefore not available to affect the read. □

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket inner horn consumer determinacy`

Theorem 159.11 (InfCatUp root-threshold obligation triad)**.** *Every accepted* $\mathsf{InfCat}^{\uparrow}$ *source packet supplies exactly three downstream root surfaces: the consumed* $\mathsf{NameCert}_{\mathsf{SimplicialSet}^{\uparrow}}$ *row, the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row, and the finite inner-horn plus lifting-ledger surface carried by* ProbeBundle, Cont, hsame, *and* Pkg *rows. Host quasicategory, localization, and simplicial mapping-object data are not available to downstream category consumers at this root threshold.*

Lean4 ✓ `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket root threshold obligation triad`

Proof. Project the accepted packet as $\mathcal{I} = (S, C, H, L, \rho, \lambda)$. The two consumed certificate rows are the S and C coordinates, and the finite obligation surface is read through the horn and lifting ledgers H and L with provenance ρ and transport λ.

Apply Definition 159.5 to identify the finite inner-horn side of the surface. Apply Definition 159.6 to see that the classifier compares only displayed packet coordinates and the componentwise hsame/Cont rows.

Now use Definition 159.7 and Definition 159.8. Together they repackage the two consumed NameCert rows and the horn-plus-lifting ledger as the full downstream consumer boundary. Since no projected coordinate names a host quasicategory, localization, or simplicial mapping object, those data remain unavailable at the root threshold. □

Closure status for $\mathsf{NameCert}_{\mathsf{InfCat}^{\uparrow}}$**.**

Constructive story: An InfCat packet is generated from consumed $\mathsf{SimplicialSet}^{\uparrow}$ and $\mathsf{Cat}^{\uparrow}$ certificate rows, finite inner-horn and lifting ledgers, one provenance package, and rowwise Cont/hsame transport. The checked consumer boundary exposes only those displayed packet rows to downstream category consumers.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InfCat}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public certificate boundary of Definition 159.9 binds the consumed $\mathsf{SimplicialSet}^{\uparrow}$ and $\mathsf{Cat}^{\uparrow}$ rows, finite inner-horn and lifting ledgers, ProbeBundle, Cont, hsame, and Pkg rows displayed by the scoped source-packet surface of Definition 159.5, Definition 159.6, Definition 159.7, and Definition 159.8.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{InfCat}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InfCatUp.InfCatBHistSourcePacket\_public\_certificate\_boundary`

Bridge status: paperBridge

Not claimed: Host quasicategories, localization, and simplicial mapping objects are not closed.

Upgrade path: No higher paper theory-axis grade remains for the displayed InfCat packet; bridge verification is tracked separately on the verification axis.

Chapter 160

A Concrete Naming Certificate for $\mathsf{DerivedCat}^{\uparrow}$

The derived-category interface $\mathsf{DerivedCat}^{\uparrow}$ packages the localisation of a chain-complex category at quasi-isomorphisms. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) and $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ (chapter 99).

160.1 Carrier definition

Definition 160.1 (DerivedCatUp NameCert obligation surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *presenting a chain-complex category* $\mathcal{C}$ *and a* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *presenting cohomology readback on those complexes. The* $\mathsf{DerivedCat}^{\uparrow}$ *obligation surface is the following visible localization interface.*

The traditional target is the localization of the chain-complex category at quasi-isomorphisms. The BEDC source is the paired source $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$*. The carrier is a* BHist *package whose rows expose chain-complex object histories, homotopy-class morphism histories, and quasi-isomorphism witnesses read by the cohomology certificate. The classifier* $\sim_{\mathsf{DerivedCat}^{\uparrow}}$ *is generated by zigzags whose elementary steps are quasi-isomorphism witnesses and category-level morphism classifiers, with no primitive quotient constructor.*

The stability obligations are reflexivity, symmetry, and transitivity of displayed zigzags; transport of the carrier along the generated classifier; congruence of represented roof composition; and descent of the visible ledger along classifier-equivalent representatives. The ledger records roofs, quasi-isomorphism witnesses, cone and cohomology rows, and composition witnesses. Exactness is the visible localization readback: two displayed representatives are classified exactly when the ledger supplies a finite zigzag through quasi-isomorphism rows and category morphism rows. The standard bridge field is absent.

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationCarrier surface rows`

160.2 The certificate

Theorem 160.2 (Derived localization carrier obligation)**.** *The carrier in Definition 160.1 exposes exactly the chain-complex objects and homotopy-class morphism histories supplied by* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$*, together with the quasi-isomorphism witnesses supplied by* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$*. It carries no object, morphism, or weak-equivalence row except through these displayed certificate fields.*

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatLocalizationRoof carrier obligation`

Proof. Project the carrier row of Definition 160.1. Its object and morphism coordinates are the object and morphism rows of the chosen $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$, so every carried localization endpoint has a displayed category object or homotopy-class morphism history.

The weak-equivalence coordinate is read from the cohomology certificate: a morphism row is marked invertible for localization only when the $\mathsf{NameCert}_{\mathsf{Cohomology}^\uparrow}$ ledger supplies the corresponding quasi-isomorphism witness. Hence every exposed quasi-isomorphism is certificate-visible.

Conversely, any category object row, homotopy-class morphism row, and cohomology quasi-isomorphism witness may be injected into the carrier by the displayed package constructor. Constructor inversion on that package shows there are no additional carrier cases. This proves the exact exposure claim. □

Theorem 160.3 (Derived quasi-isomorphism classifier obligation)**.** *The classifier $\sim_{\mathsf{DerivedCat}^\uparrow}$ of Definition 160.1 is the finite zigzag closure generated by cohomology quasi-isomorphism witnesses and the existing category morphism classifiers. It is not an independent quotient primitive.*

Proof. The forward direction is induction on the displayed classifier derivation. The reflexive case is the empty zigzag. A category-morphism classifier step gives a one-step zigzag labelled by the $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ row. A quasi-isomorphism step gives a one-step zigzag labelled by the $\mathsf{NameCert}_{\mathsf{Cohomology}^\uparrow}$ witness. Symmetry reverses the finite zigzag, and transitivity concatenates the two finite zigzags.

For the reverse direction, induct on the finite zigzag. The empty zigzag gives reflexivity. In the cons step, the head is either a category-morphism classifier row or a cohomology quasi-isomorphism witness, hence gives an elementary classifier step. Compose it with the induction hypothesis for the tail by transitivity of the generated classifier.

All constructors used in both directions are the displayed generator constructors and the reflexive, symmetric, and transitive closure rules. Since no step appeals to an unlabelled endpoint identification, the classifier is precisely the generated zigzag closure. □

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationClassifier endpoints`

Theorem 160.4 (Derived composition descent obligation)**.** *Composition of represented roofs descends along $\sim_{\mathsf{DerivedCat}^\uparrow}$. If two left roofs and two right roofs are pairwise classified by the generated zigzag classifier, then the composite roofs obtained from the $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ composition rows and the $\mathsf{NameCert}_{\mathsf{Cohomology}^\uparrow}$ quasi-isomorphism stability rows are again classified by $\sim_{\mathsf{DerivedCat}^\uparrow}$.*

Proof. Represent each morphism by a roof ledger row. The composition row first forms the category-level composite using the associativity and unit witnesses already exposed by $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$. These witnesses identify the usual alternative parenthesizations and inserted identity rows inside the category morphism classifier.

Now induct over the displayed zigzag comparing the left roof representatives. For an elementary category-classifier step, composition congruence in $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ transports the step through the composite. For an elementary quasi-isomorphism step, the cohomology stability row says that the pulled-back or pasted weak-equivalence witness remains a quasi-isomorphism witness, so it is again a generator for $\sim_{\mathsf{DerivedCat}^\uparrow}$.

Repeat the same induction over the right roof comparison. The two transported zigzags concatenate, and the category associativity/unit rows align the middle object choices used by the two roof-composition ledgers. The resulting finite zigzag is a classifier witness between the two composite roofs, which is exactly descent of composition. □

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationClassifier composition descent`

Theorem 160.5 (DerivedCatUp NameCert exactness obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ *fields determined by Definition 160.1 are exactly the visible localization carrier, the generated zigzag classifier, the stability rows, the roof and quasi-isomorphism ledger, the visible exactness readback, and the absent standard-bridge row.*

Proof. Unpack the public certificate fields. The carrier field is the package of Definition 160.2, and the classifier field is the generated zigzag classifier of Definition 160.3. Thus the public object and morphism surfaces are exactly the displayed localization rows.

The stability fields are supplied by the reflexive, symmetric, and transitive zigzag constructors, by carrier transport along generated classifier steps, and by composition descent from Definition 160.4. The ledger field is the visible list of roofs, quasi-isomorphism witnesses, cone and cohomology rows, and composition witnesses used by those constructions.

It remains to identify exactness and the bridge row. Exactness is constructor inversion on the generated classifier: a public equality witness is precisely a finite ledger zigzag through the displayed category and cohomology rows, and any such zigzag repacks as a public classifier witness. The standard bridge field is the designated absent row, so the certificate exposes no unrecorded external bridge data. □

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationClassifier name certificate`

Theorem 160.6 (DerivedCatUp roof identity unit laws)**.** *Let r be a displayed* $\mathsf{DerivedCat}^{\uparrow}$ *roof ledger row from X to Y in the visible localization interface of Definition 160.1. Let* id_X *and* id_Y *be displayed identity roof ledger rows at the two endpoints, with category components supplied by the empty identity hom-carriers of Definition 61.2 and with their weak-equivalence components recorded by the displayed cohomology quasi-isomorphism rows. If ℓ is a ledger result for composing* id_Y *with r and ρ is a ledger result for composing r with* id_X*, then both identity composites are classified with the original roof:*

$$\ell \sim_{\mathsf{DerivedCat}^{\uparrow}} r \quad \textit{and} \quad \rho \sim_{\mathsf{DerivedCat}^{\uparrow}} r.$$

Proof. Unpack the roof ledger for r. It exposes the source and target object histories, the roof middle object, the category morphism leg, the cohomology quasi-isomorphism leg, and the composition witnesses used by Definition 160.1. The two displayed identity roofs expose only empty identity hom-carrier rows at X and Y, together with the cohomology rows marking those identity legs as quasi-isomorphisms.

For the composite $\mathsf{id}_Y \circ r$, the category morphism part is a displayed right-identity composite of the category leg of r. By Definition 61.105, that composite carries the same hom-carrier and its morphism history is hsame to the original category leg. The weak-equivalence part is obtained by pasting the displayed cohomology identity row with the quasi-isomorphism row already present in r; the cohomology ledger transports this pasted witness across the same identity comparison, so no new weak-equivalence generator is introduced.

Thus the ledger for ℓ differs from the ledger for r by a finite list of displayed generator steps: one category morphism-classifier step collapsing the empty identity composite, followed by the reflexive or transported quasi-isomorphism rows on the weak-equivalence side. By Definition 160.3, such a finite list is exactly a witness for $\ell \sim_{\mathsf{DerivedCat}^{\uparrow}} r$.

The composite $r \circ \mathsf{id}_X$ is symmetric at the source endpoint. Apply Definition 61.103 to collapse the category leg containing the source identity, and use the displayed cohomology identity row to transport the quasi-isomorphism leg back to the original ledger row. These two displayed

steps again form a finite zigzag made only of category morphism classifiers and quasi-isomorphism witnesses. The generated classifier therefore gives $\rho \sim_{\mathsf{DerivedCat}^{\uparrow}} r$. □

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationClassifier roof identity units`

Theorem 160.7 (DerivedCatUp localization example boundary)**.** *The visible localization classifier of Definition 160.1 supplies two finite example roofs inside the displayed* $\mathsf{DerivedCat}^{\uparrow}$ *package: the identity-roof example at a chain-complex object and the one-step quasi-isomorphism roof example for a displayed quasi-isomorphism. Both examples use only the displayed chain-complex carrier, quasi-isomorphism classifier, roof identity and unit rows, and* Pkg *provenance. They export no host localization, quotient object, or derived functor calculus.*

Proof. The carrier rows come from Definition 160.2. At an object X, the identity roof uses the displayed category identity row as its category leg and the cohomology identity quasi-isomorphism witness as its weak-equivalence leg. The unit laws of Definition 160.6 classify this roof with the visible identity representative.

For a displayed quasi-isomorphism row, use Definition 160.3. The one-step roof has that quasi-isomorphism as its weak-equivalence leg and the displayed category morphism row as its other leg. Its classifier witness is a single generator in the finite zigzag closure.

The obligation surface of Definition 160.1 records both examples in the same Pkg provenance ledger. Since each construction uses only carrier rows, quasi-isomorphism generators, roof identity/unit rows, and package provenance, neither example creates a host localization, quotient object, or derived functor operation. □

Lean4 ✓ `BEDC.Derived.DerivedCatUp.DerivedCatLocalizationBoundary example boundary`

Closure status for $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$**.**

Constructive story: A derived-category object is built by pairing a $\mathsf{Cat}^{\uparrow}$ presentation of chain-complex objects and morphism histories with a $\mathsf{Cohomology}^{\uparrow}$ row that marks the quasi-isomorphism witnesses used for localization. The carrier accepts only the displayed package of chain-complex object rows, homotopy-class morphism rows, roof ledgers, cone and cohomology rows, and quasi-isomorphism witnesses; it excludes a primitive quotient category, unlabelled weak equivalences, and any standard bridge row. Two displayed representatives classify together by a finite zigzag generated from category morphism classifiers and cohomology quasi-isomorphism witnesses, with symmetry given by reversing the zigzag and transitivity by concatenating it. The source specification is the paired category/cohomology localization surface, the pattern records roof formation, identity roof units, composition descent, and visible exactness, and the ledger keeps roofs, weak-equivalence witnesses, cone/cohomology rows, and composition witnesses visible as finite data. The five naming-certificate obligations hold because empty zigzags and identity roofs give carrier witnesses and reflexivity, zigzag reversal and concatenation give symmetry and transitivity, and carrier transport plus composition descent keep every classified roof inside the accepted localization surface. A history h lies in the signature gap of a $\mathsf{DerivedCat}^{\uparrow}$ token p when the source domain accepts this visible localization packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; unfolded, the finite zigzag through the category and cohomology rows is exactly the localization evidence encoded by p. The chapter registers this generated-zigzag localization under $\mathsf{DerivedCat}^{\uparrow}$; it adds no quotient constructor, no unrecorded weak-equivalence oracle, and no standard derived-category bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public certificate surface is the visible $\mathsf{Cat}^{\uparrow}$/$\mathsf{Cohomology}^{\uparrow}$ localization classifier together with the roof identity rows, roof composition descent, exactness readback, ledger rows, and absent bridge row.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DerivedCatUp.DerivedCatVisibleLocalizationClassifier\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not close standard bridges for derived categories or full localization maturity beyond the displayed certificate rows.

Upgrade path: No further paper theory-axis grade remains for this displayed derived-category localization package.

Chapter 161

A Concrete Naming Certificate for $\mathsf{FieldExt}^{\uparrow}$

The field-extension interface $\mathsf{FieldExt}^{\uparrow}$ packages an embedding of one field carrier into another, recording the larger field as a vector space over the smaller. It depends on $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ (chapter 45) and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47), and is the substrate for Galois, separable, and algebraic-closure certificates.

Every accepted $\mathsf{FieldExt}^{\uparrow}$ carrier read first exposes the base and extension field rows through chapter 45, the scalar-action and vector-space-over-base row through chapter 47, and the module compatibility row through chapter 46. Only after those rows are visible may an extension-degree, embedding, number-field, or Galois-extension consumer inspect the local $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ surface.

161.1 Carrier definition

Definition 161.1 (Concrete singleton empty-history field extension instance)**.** *Let the base field carrier and extension field carrier both be* FieldSingletonCarrier *over* BHist*, with field classifier* FieldSingletonClassifier*. Equivalently, this is the singleton empty-history carrier* A_{e} *with shared classifier*

$$\rho_{\mathsf{e}}(h,k) := A_{\mathsf{e}}(h) \wedge A_{\mathsf{e}}(k) \wedge \mathsf{hsame}(h,k).$$

Both field endpoints use the singleton $\mathsf{Field}^{\uparrow}$ *operations of Definition 45.2 for both the base and extension fields:* FieldSingletonAdd*,* FieldSingletonMul*,* FieldSingletonZero*,* FieldSingletonOne*,* FieldSingletonNeg*, and the proof-indexed inverse* FieldSingletonInv*. Define the embedding by* $\iota_{\mathsf{e}}(h) := h$ *on* BHist*.*

Read the extension as the singleton $\mathsf{VecSpace}^{\uparrow}$ *carrier* VecSpaceSingletonCarrier *over the singleton scalar field. Its vector classifier is* VecSpaceSingletonClassifier *and its scalar action is* VecSpaceSingletonSmul*. The ledger is inherited from the singleton* $\mathsf{Field}^{\uparrow}$ *certificate on the two field sides and from the singleton* $\mathsf{VecSpace}^{\uparrow}$ *certificate on the vector-space-over-base side.*

The certificate fit has ten fields:

1. *Traditional target: the terminal field extension.*
2. *BEDC source:* BHist*.*
3. *Carrier choice:* A_{e} *for the base field, extension field, and vector carrier.*
4. *Classifier choice:* ρ_{e} *on all displayed endpoints.*
5. *Stability obligations: the singleton field laws together with the singleton vector-space laws.*

6. *Ledger: the identity embedding and vector-space provenance over the same empty-history endpoint.*
7. *Core theorem list: Theorems 161.4, 161.5, 161.28, 161.29, 161.31, 161.32, 161.33, 161.36, 161.37, and 161.34.*
8. *Exactness predicate: singleton endpoint collapse.*
9. *Standard bridge: the terminal field extension.*
10. *Status:* ProofTarget.

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton empty history instance surface`

Definition 161.2 (Singleton FieldExt obligation scope)**.** *The terminal* $\mathsf{FieldExt}^{\uparrow}$ *instance over* A_{e} *is the following ten-field paper template. The traditional target is the one-point field extension. The BEDC source is* BHist*. The base field carrier, extension field carrier, and extension vector carrier are all* A_{e}*. The classifier is the shared singleton relation* ρ_{e} *from Definition 161.1. The embedding is the identity map* $\iota_{\mathsf{e}}(h) := h$*. The extension-field vector-space-over-base action is the singleton vector-space action over the singleton* $\mathsf{Field}^{\uparrow}$ *source.*

The stability obligations are the singleton field rows of Theorem 45.37 for the base and extension fields, together with the singleton vector-space rows of Theorem 47.3. The ledger consists of identity-embedding provenance and singleton scalar-action provenance over the same empty-history endpoint. The downstream consumers are the Galois, number-field, and algebraic-closure certificate families, each of which reads the same carrier, classifier, exactness, scalar-action, and ledger fields.

Definition 161.3 (RatUp reflexive field-extension carrier)**.** *Let the base field carrier and the ambient field carrier both be the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *carrier of Definition 45.488:*

$$C_{\mathsf{base}} = C_{\mathsf{amb}} = \mathsf{RatHistoryCarrier}, \qquad R_{\mathsf{base}} = R_{\mathsf{amb}} = \mathsf{RatHistoryClassifier}.$$

The classifier for the extension package is the RatUp classifier on the same BHist *endpoints. The embedding is the identity map* $\iota_{\mathsf{Rat}}(h) := h$ *on* BHist*.*

The ambient field is also used as its own vector carrier over the base field. Scalar multiplication is the $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *multiplication row of Definition 45.489, and vector addition, zero, and negation are the additive rows retained by the same FieldUp certificate through the commutative-ring and ring reducts. Thus the displayed object is the reflexive field extension*

$$\mathsf{Rat}^{\uparrow} \hookrightarrow \mathsf{Rat}^{\uparrow}$$

with no change of BEDC carrier, classifier, ledger source, or operation table.

Lean4 (definition) `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveCarrier`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveCarrier rat history closure`

Theorem 161.4 (Singleton field-extension embedding obligations)**.** *For the concrete data of Definition 161.1, let* h, k : BHist *be carried by* FieldSingletonCarrier*. Then* $\iota_{\mathsf{e}}(h)$ *is carried by the extension field,*

$$\mathsf{FieldSingletonClassifier}(h, k) \quad \textit{if and only if} \quad \mathsf{FieldSingletonClassifier}(\iota_{\mathsf{e}}(h), \iota_{\mathsf{e}}(k)),$$

and the embedding preserves the concrete singleton zero, one, addition, negation, multiplication, and proof-indexed inverse up to ρ_{e}*. Thus the base endpoint and its embedded extension endpoint have the same singleton classification for each displayed field operation.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonEmbedding laws`

Proof. Unfold ι_{e}. The carrier statement is immediate from the assumption $A_{\mathsf{e}}(h)$, because the base and extension field carriers are the same singleton carrier A_{e}.

The classifier comparison has the same two directions. After unfolding the identity embedding, both sides are the identical classifier assertion $\rho_{\mathsf{e}}(h, k)$.

For zero, one, addition, negation, and multiplication, apply Theorem 45.37 to obtain the field-law rows over $\mathsf{FieldSingletonCarrier}$ and $\mathsf{FieldSingletonClassifier}$. Then use Theorem 45.48 to read each concrete operation endpoint as the singleton empty-history endpoint.

For the inverse rows, fix a proof-indexed witness in the singleton nonzero domain. The same operation-table collapse theorem gives the inverse endpoint row for $\mathsf{FieldSingletonInv}(h, p)$, and the law package uses that same proof-indexed domain. Hence base inverse and embedded extension inverse are classified by ρ_{e} at the same singleton endpoint. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton embedding obligations`

Theorem 161.5 (Singleton FieldExt embedding exactness)**.** *For the concrete data of Definition 161.1, let $h, k : \mathsf{BHist}$ be carried by A_{e}. Then*

$$\rho_{\mathsf{e}}(h, k) \quad \textit{if and only if} \quad \rho_{\mathsf{e}}(\iota_{\mathsf{e}}(h), \iota_{\mathsf{e}}(k)).$$

Moreover, for every displayed singleton field operation in the base package, its embedded extension endpoint is classified with the corresponding source endpoint by ρ_{e}.

Proof. Unfold ι_{e}. The displayed equivalence is the classifier comparison recorded in Theorem 161.4; after the identity embedding is unfolded, both sides are the same singleton classifier assertion.

For the operation endpoints, apply Theorem 161.4 to the carried inputs. It gives preservation of zero, one, addition, negation, multiplication, and the proof-indexed inverse up to ρ_{e}.

The concrete endpoint identification comes from the singleton operation-table collapse in Theorem 45.48. Thus each embedded operation row lands in the same ρ_{e} class as its source row. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonEmbedding exactness`

161.2 The certificate

Theorem 161.6 (RatUp reflexive embedding transport)**.** *For the concrete data of Definition 161.3, the identity embedding ι_{Rat} transports carrier membership and classifier comparisons exactly. If $h, k : \mathsf{BHist}$, then $\mathsf{RatHistoryCarrier}(h)$ gives $\mathsf{RatHistoryCarrier}(\iota_{\mathsf{Rat}}(h))$, and $\mathsf{RatHistoryClassifier}(h, k)$ gives and is given by $\mathsf{RatHistoryClassifier}(\iota_{\mathsf{Rat}}(h), \iota_{\mathsf{Rat}}(k))$. The same identity transport preserves the zero, one, addition, negation, multiplication, apartness, and proof-indexed inverse rows of the $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ certificate.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveEmbedding transport fields`

Proof. Unfold ι_{Rat}. Carrier preservation is immediate because the base and ambient carriers are both $\mathsf{RatHistoryCarrier}$.

The classifier transport has identical source and target assertions after unfolding the identity map. Reflexivity, symmetry, transitivity, and endpoint carrier extraction are the RatUp classifier fields recorded in Definition 37.90.

For the operation rows, read the base and ambient field packages from Definition 45.489. They use the same carrier, classifier, denominator tuple, contextual action, and affine source. Since the embedding is identity, every displayed FieldUp operation endpoint is compared with itself under RatHistoryClassifier, including the proof-indexed inverse endpoint whenever the apartness witness is supplied. □

Theorem 161.7 (RatUp reflexive vector-space package)**.** *For the concrete data of Definition 161.3, the ambient* $\mathsf{Rat}^{\uparrow}$ *carrier is a vector space over the base* $\mathsf{Rat}^{\uparrow}$ *carrier. Its vector addition, zero, and negation are the FieldUp additive rows, and its scalar action is FieldUp multiplication. The vector carrier classifier is* RatHistoryClassifier*, the scalar classifier is the same RatUp classifier, and scalar-action congruence is the multiplication congruence row of the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *certificate.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveVectorSpace scalar action congruence`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive vector space package`

Proof. Start from the concrete field certificate Definition 45.489. Its carrier and classifier are RatHistoryCarrier and RatHistoryClassifier, and its algebraic rows include additive abelian-group laws, multiplication closure, distributivity, unit laws, and classifier congruence for multiplication.

Use the field multiplication row as scalar action. Associativity of scalar action is exactly associativity of FieldUp multiplication. Left and right distributivity of scalar action are the two distributivity rows of the same FieldUp certificate, read with the first factor as scalar and the second factor as vector.

The vector addition, zero, and negation rows are the additive rows already present in the field certificate. The projection principles Definition 47.24 and Definition 47.25 identify these as the module-shaped and additive carrier rows expected by $\mathsf{VecSpace}^{\uparrow}$ once the scalar field is fixed. Therefore the self-action package supplies the paper-side vector-space obligations over the unchanged RatUp carrier. □

Theorem 161.8 (RatUp reflexive FieldExtUp certificate obligations)**.** *The data of Definition 161.3 satisfy the paper-side* $\mathsf{FieldExt}^{\uparrow}$ NameCert *obligation package. The package contains the base and ambient* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *certificates, the RatUp classifier, identity embedding stability, scalar-action congruence, the self-vector-space rows, exact endpoint classification, and ledger provenance from the same concrete FieldUp operation table.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive certificate obligations`

Proof. The two field endpoints are supplied by a single certificate: Definition 45.489. Reading it twice fixes the base and ambient carriers to RatHistoryCarrier and fixes both classifiers to RatHistoryClassifier.

Embedding stability is Definition 161.6. It records carrier transport, classifier transport, and operation transport for the identity map on BHist.

The vector-space component is Definition 161.7. It uses FieldUp multiplication as scalar action and the FieldUp additive rows as vector addition, zero, and negation. The scalar-action congruence row is therefore the multiplication classifier-congruence row already present in the concrete FieldUp certificate.

The ledger clauses do not introduce a second provenance source. Every scalar, vector, embedding, and operation endpoint is read from the same $\mathsf{RatUpFieldSource}_F$ tuple of Definition 45.488.

The exactness clauses are the RatUp classifier and FieldUp operation-table exactness rows assembled in Definition 45.489. These rows are precisely the carrier, classifier, embedding, vector-space, exactness, and ledger obligations named by the FieldExtUp certificate boundary. □

Definition 161.9 (RatUp reflexive ledger interface)**.** *For the concrete data of Definition 161.3, the RatUp reflexive* $\mathsf{FieldExt}^{\uparrow}$ *ledger interface has every displayed carrier and endpoint read from the same RatUp table. The base carrier, ambient carrier, vector carrier, and scalar carrier are all* $\mathsf{RatHistoryCarrier}$*, and their classifier is* $\mathsf{RatHistoryClassifier}$*.*

The embedding endpoint is the identity map $\iota_{\mathsf{Rat}}(h) := h$*. The base-field and ambient-field operation endpoints are the corresponding zero, one, addition, negation, multiplication, apartness, and proof-indexed inverse endpoints of the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table in Theorem 45.489. The scalar-action endpoints are the same multiplication endpoints, read through the self-vector-space package of Theorem 161.7.*

Theorem 161.10 (RatUp reflexive exact endpoint classification)**.** *For the concrete data of Definition 161.3, let* $h, k : \mathsf{BHist}$ *be carried by* $\mathsf{RatHistoryCarrier}$*. Every base-field operation endpoint, ambient-field operation endpoint, identity-embedding endpoint, and scalar-action endpoint displayed by the reflexive* $\mathsf{FieldExt}^{\uparrow}$ *package is classified by* $\mathsf{RatHistoryClassifier}$ *against the corresponding* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *endpoint.*

Proof. First apply Theorem 45.489. It supplies the concrete RatUp carrier, classifier, and operation table for the base and ambient field rows, so the two field sides compare endpoints against the same $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ table.

The identity-embedding endpoints are handled by Theorem 161.6. Since ι_{Rat} unfolds to the identity on BHist, the embedded endpoint and its RatUp source endpoint have the same classifier class.

The scalar-action endpoints are handled by Theorem 161.7. Its scalar action is precisely the multiplication row of the RatUp field table, and its congruence row is the multiplication classifier-congruence row of the same certificate.

Finally use Theorem 37.90 to read each carried endpoint through $\mathsf{RatHistoryCarrier}$ and $\mathsf{RatHistoryClassifier}$. This gives the displayed exact endpoint classification for field operations, the identity embedding, and scalar action. □

Theorem 161.11 (RatUp reflexive ledger coverage)**.** *For the concrete data of Definition 161.3, every* $\mathsf{FieldExt}^{\uparrow}$ *source row, pattern row, classifier row, stability row, exactness row, and ledger row is covered by exactly one of the following provenance classes: the identity embedding row, the RatUp* $\mathsf{Field}^{\uparrow}$ *operation-table row, or the self-vector-space scalar-action row.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive ledger coverage`

Proof. Start with the ledger interface of Definition 161.9. It assigns the four carrier displays to $\mathsf{RatHistoryCarrier}$, assigns every classifier display to $\mathsf{RatHistoryClassifier}$, and separates the public rows into the identity embedding, RatUp operation table, and self-vector-space scalar action.

Next apply Theorem 161.10. It places each displayed field-operation endpoint, embedding endpoint, and scalar-action endpoint in the exact RatUp classifier class specified by that interface.

It remains to check that these rows exhaust the certificate boundary. Apply Theorem 161.8. Its obligation list is precisely the carrier, classifier, embedding-stability, vector-space, exactness, and ledger surface of the RatUp reflexive $\mathsf{FieldExt}^{\uparrow}$ package, so the three provenance classes cover every listed row exactly once. □

Theorem 161.12 (RatUp reflexive FieldExt source, pattern, and classifier obligations)**.** *For the data of Definition 161.3, the* $\mathsf{FieldExt}^{\uparrow}$ *source field, extension field, vector carrier, embedding, and classifier slots are the concrete RatUp rows. The base and extension field sources are both the* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *source on* RatHistoryCarrier*, the vector carrier is the same* RatHistoryCarrier *read as the ambient field over the base, the embedding is* $\iota_{\mathsf{Rat}}(h) := h$*, and every source, pattern, and classifier endpoint is classified by* RatHistoryClassifier*. These rows are exactly the FieldExtUp source, pattern, and classifier obligations for the reflexive rational field extension.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive source pattern classifier obligations`

Proof. Unfold Definition 161.3. Its displayed carrier equations identify the base field carrier, ambient field carrier, and extension vector carrier with RatHistoryCarrier, and its displayed classifier equations identify the two endpoint classifiers with RatHistoryClassifier.

The source field and extension field certificates are not separate objects. Apply Theorem 45.489 to read the same $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ operation table as both endpoints of the extension. The RatUp semantic name certificate, Theorem 37.90, supplies the classifier row for the same carried histories.

The remaining FieldExtUp source and pattern slots are the identity embedding and the self-vector-carrier reading. Both are named explicitly in Definition 161.3. Therefore no carrier or classifier conversion is needed: the source field, extension field, vector carrier, embedding, and RatHistoryClassifier rows are the required source-pattern-classifier surface for the reflexive certificate. □

Theorem 161.13 (RatUp reflexive FieldExt stability and exactness obligations)**.** *For the same RatUp reflexive carrier, the* $\mathsf{FieldExt}^{\uparrow}$ *stability and exactness rows are supplied by identity-embedding transport, scalar-action congruence, the vector-space-over-base laws, and exact endpoint classification for the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table. In particular, embedding transport preserves carrier membership, classifier equivalence, and all displayed field operations; scalar action is FieldUp multiplication; vector addition, zero, and negation are the FieldUp additive rows; and every endpoint read by these rows is classified by* RatHistoryClassifier*.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive stability exactness obligations`

Proof. First apply Theorem 161.6. Since ι_{Rat} is the identity on BHist, carrier transport, classifier transport, and operation transport all compare an endpoint with itself under RatHistoryClassifier.

Next apply Theorem 161.7. It reads FieldUp multiplication as scalar action and the additive FieldUp rows as vector addition, zero, and negation over the unchanged RatUp carrier. The scalar-action congruence obligation is therefore the multiplication classifier-congruence row of the same FieldUp operation table.

The exact endpoint classifications come from Theorem 45.489. Its operation table already contains the carrier, classifier, additive, multiplicative, and inverse exactness rows used by the identity embedding and the self-vector-space package.

Combining these rows gives the stability and exactness surface required by $\mathsf{FieldExt}^{\uparrow}$: every transported endpoint, scalar-action endpoint, and vector-space endpoint is a RatUp FieldUp endpoint classified by RatHistoryClassifier. □

Theorem 161.14 (RatUp reflexive FieldExt ledger and standard bridge obligations)**.** *For the data of Definition 161.3, the* $\mathsf{FieldExt}^{\uparrow}$ *ledger has one provenance source, namely the* $\mathsf{RatUpFieldSource}_F$ *operation table, and the standard bridge is the reflexive rational field extension*

$$\mathsf{Rat}^{\uparrow} \hookrightarrow \mathsf{Rat}^{\uparrow}.$$

The ledger records no independent extension-field, vector-space, or embedding source: all of them are readings of the RatUp FieldUp carrier, classifier, and operation table already used by the assembled reflexive certificate.

Proof. Read the ledger paragraph of Definition 161.3. It states that the base field, ambient field, vector carrier, classifier, ledger source, and operation table are unchanged across the displayed reflexive extension.

The provenance source is therefore the tuple $\mathsf{RatUpFieldSource}_F$ of Definition 45.488. The exactness rows cited in Theorem 161.8 are the RatUp classifier and FieldUp operation-table exactness rows assembled by Theorem 45.489.

Since the embedding is $\iota_{\mathsf{Rat}}(h) := h$ and the ambient field is the base field itself, the standard bridge has no additional data beyond the ordinary reflexive rational field extension. Thus the ledger and standard bridge obligations are both read from the same concrete RatUp FieldUp table. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive ledger standard bridge obligations`

Theorem 161.15 (RatUp reflexive FieldExtUp tower composition)**.** *Compose two copies of the reflexive FieldExtUp certificate of Definition 161.3. The resulting two-step tower has base, middle, and top carrier all equal to* RatHistoryCarrier*, has base, middle, and top classifier all equal to* RatHistoryClassifier*, has composite embedding equal to the identity embedding on* BHist*, and uses the same FieldUp multiplication scalar action in each vector-space-over-base row. The tower therefore carries no endpoint outside the concrete RatUp FieldUp operation table.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive tower composition`

Proof. For each field endpoint in the tower, read the same concrete FieldUp certificate from Definition 45.489. This fixes the base, middle, and top carriers to RatHistoryCarrier and fixes the three classifiers to RatHistoryClassifier.

The embedding rows are identity rows. Apply Definition 161.6 to each copy. Since the underlying map is the identity on BHist, composing the two displayed embeddings again gives the identity embedding and preserves the same carrier, classifier, and operation rows.

The vector-space rows are supplied by Definition 161.7. Its scalar action is FieldUp multiplication, and its scalar-action congruence is the multiplication congruence row of the same RatUp FieldUp certificate.

Finally apply Definition 161.8. It records that the carrier, classifier, embedding, scalar-action, exactness, and ledger rows all come from the single concrete RatUp FieldUp source tuple, so the two-step tower has the stated reflexive package. □

Theorem 161.16 (RatUp reflexive FieldExtUp tower scalar action)**.** *In the two-step reflexive tower of Definition 161.15, let r, m :* BHist *be carried RatUp scalar and vector endpoints. The tower scalar-action endpoint obtained by acting with r on m is classified by* RatHistoryClassifier *with the corresponding RatUp FieldUp multiplication endpoint for r and m.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveTower scalar action`

Proof. The tower scalar action is the self-vector-space scalar action selected in Definition 161.7. By that theorem, the action row is FieldUp multiplication on the same RatUp carrier.

The multiplication endpoint and the scalar-action endpoint therefore name the same operation row of the concrete $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ certificate. The required classifier comparison is exactly the multiplication congruence row supplied by Definition 45.489, read through RatHistoryClassifier.

Since Definition 161.15 keeps the identity embedding at both tower levels, no transport changes the endpoints. The classification row remains the RatUp multiplication row for the original carried scalar and vector endpoints. □

Theorem 161.17 (RatUp reflexive FieldExtUp tower ledger coverage)**.** *Every carrier row, classifier row, embedding row, scalar-action row, exactness row, and ledger row in the two-step reflexive tower of Definition 161.15 is covered by three concrete sources: the single RatUp FieldUp source tuple* $\mathsf{RatUpFieldSource}_F$*, the identity embedding row on* BHist*, and the self-vector-space row whose scalar action is FieldUp multiplication.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveTower ledger coverage`

Proof. The carrier and classifier rows are covered by the concrete RatUp FieldUp source tuple via Definition 45.489. The same source also supplies the operation-table rows used at the base, middle, and top field levels.

The embedding rows are covered by Definition 161.6. The two embeddings and their composite are all the identity on BHist, so the tower has one embedding policy and one classifier-transport row.

The scalar-action rows are covered by Definition 161.7 and Definition 161.16. They identify the tower action with FieldUp multiplication and classify its endpoints by the RatUp multiplication congruence row.

The exactness and ledger rows are then those assembled in Definition 161.8. Together with Definition 161.15, this accounts for every row of the two-step reflexive tower without naming any source beyond the RatUp FieldUp tuple, identity embedding, and self-vector-space package. □

Theorem 161.18 (RatUp reflexive FieldExt operation-table coverage)**.** *For the concrete package of Definition 161.3, every base-field row, ambient-field row, vector addition row, vector zero row, vector negation row, and scalar-action row is read from Definition 45.489 over* $\mathsf{RatHistoryCarrier}$ *and* $\mathsf{RatHistoryClassifier}$*. The base-field and ambient-field operation tables are the same concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table, while the vector-space additive rows and scalar-action row are the corresponding additive and multiplication rows of that table.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveEmbedding denominator package`

Proof. Unfold Definition 161.3. The embedding ι_{Rat} is the identity on BHist, so the base and ambient endpoints are not transported to a distinct carrier or classifier.

Read Definition 45.489 once for the base field and once for the ambient field. Both readings use $\mathsf{RatHistoryCarrier}$, $\mathsf{RatHistoryClassifier}$, and the concrete RatUp operation table.

For the vector-space rows, apply Definition 47.24 to retain the scalar action and module-shaped compatibility from the FieldUp multiplication and distributivity rows. Then apply Definition 47.25 to retain the vector addition, zero, negation, carrier, and classifier. Thus the FieldExt operation table introduces no row outside the displayed RatUp FieldUp table. □

Theorem 161.19 (RatUp reflexive scalar-action readback)**.** *For the concrete package of Definition 161.3, the* $\mathsf{FieldExt}^{\uparrow}$ *scalar action is exactly the multiplication row of the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *certificate. For every scalar endpoint* $r : \mathsf{BHist}$ *and vector endpoint* $m : \mathsf{BHist}$ *carried by* $\mathsf{RatHistoryCarrier}$*, the scalar-action endpoint* $r \odot_{\mathsf{Rat}} m$ *is the FieldUp product endpoint* $r \cdot_{\mathsf{Rat}} m$*, and classifier stability is the multiplication congruence row already included in Definition 45.489.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive scalar action readback`

Proof. Unfold the scalar action in Definition 161.3. It is defined to be the $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ multiplication row, with no change of carrier, classifier, or endpoint domain.

The assembled FieldUp certificate supplies multiplication closure and multiplication classifier congruence over RatHistoryClassifier. Because the scalar classifier, vector classifier, and ambient-field classifier are all the same RatUp classifier, the congruence row repacks directly as scalar-action stability for the reflexive $\mathsf{FieldExt}^{\uparrow}$ package. □

Theorem 161.20 (RatUp reflexive FieldExt ledger provenance coverage)**.** *For the concrete package of Definition 161.3, the source, pattern, classifier, stability, exactness, and ledger rows are exhausted by the identity embedding row, the single concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table, and the self-vector-space projection over* RatHistoryCarrier*. No additional carrier, classifier, scalar-action table, or ledger source is introduced by the reflexive* $\mathsf{FieldExt}^{\uparrow}$ *reading.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveEmbedding scalar action cont readback`

Proof. The identity embedding row is Definition 161.6. It fixes endpoint transport, classifier transport, and operation transport to the unchanged RatUp carrier and classifier.

The field and operation-table rows are supplied by Definition 161.18. The scalar-action readback is Definition 161.19, so the vector-space scalar action uses exactly the multiplication row already present in the concrete FieldUp table.

Finally apply Definition 161.7 and Definition 161.8. These package the self-vector-space projection, exact endpoint classification, and ledger provenance as the displayed $\mathsf{FieldExt}^{\uparrow}$ NameCert obligations. Hence every ledger row named by the reflexive FieldExt certificate is traced to the identity embedding, the RatUp FieldUp certificate, or the self-vector-space projection. □

Definition 161.21 (RatUp reflexive exactness and ledger interface)**.** *For the concrete data of Definition 161.3, the* $\mathsf{FieldExt}^{\uparrow}$ *exactness and ledger surface is fixed by the single RatUp history source. The base-field carrier, ambient-field carrier, vector carrier, and scalar carrier are all* RatHistoryCarrier*, and all endpoint comparisons use* RatHistoryClassifier*.*

The embedding row is the identity map $\iota_{\mathsf{Rat}}(h) := h$*. The base and ambient field operation rows are the rows of the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *table, and the scalar action is the same table read through multiplication:*

$$r \cdot_{\mathsf{Rat}} m := \mathsf{RatUpFieldMul}(r, m).$$

Thus the ledger has no separate extension source: it consists of the RatUp FieldUp operation table, the identity embedding row, and the self vector-space row over the same classifier.

Lean4 (definition) `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveExactnessLedgerInterface`
Lean4 (definition) `BEDC.Derived.FieldExtUp.FieldExtRatReflexive exactness ledger interface`

Theorem 161.22 (RatUp reflexive exact endpoint classification)**.** *For the concrete data of Definition 161.3, every displayed base-field endpoint, ambient-field endpoint, identity-embedding endpoint, and scalar-action endpoint is classified by* RatHistoryClassifier *against the RatUp endpoint named by the same concrete operation row. In particular, the reflexive extension has one exact classifier surface for field operations, embedding transport, and self scalar action.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveEmbedding classifier endpoint package`

Proof. The base and ambient field endpoints are read from the same concrete $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ certificate. Apply Theorem 45.489 to obtain the operation-table rows over RatHistoryCarrier and RatHistoryClassifier.

The identity-embedding endpoints are handled by Theorem 161.6. Since ι_{Rat} is the identity on BHist, the embedded endpoint and the source endpoint are the same carried history, compared by the RatUp classifier.

The scalar-action endpoints are handled by Theorem 161.7. Its scalar action is FieldUp multiplication, so the scalar-action endpoint is classified by the same multiplication congruence and endpoint row already present in the RatUp FieldUp certificate. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive exact endpoint classification`

Theorem 161.23 (RatUp reflexive ledger provenance)**.** *For the concrete data of Definition 161.3, every* $\mathsf{FieldExt}^{\uparrow}$ *ledger row is inherited from one of three displayed sources: the single RatUp* $\mathsf{Field}^{\uparrow}$ *operation table, the identity embedding row* ι_{Rat}*, or the self-vector-space row whose scalar action is RatUp multiplication. No ledger row uses a carrier, classifier, operation endpoint, or scalar-action endpoint outside* $\mathsf{RatHistoryCarrier}$ *and* $\mathsf{RatHistoryClassifier}$*.*

Proof. The operation-table provenance is the concrete RatUp FieldUp certificate of Theorem 45.489. The base field and ambient field read that certificate with identical carrier, classifier, and operation endpoints.

The embedding provenance is Theorem 161.6. It supplies the identity carrier row, the identity classifier row, and the preservation of the displayed field operations without adding a second source.

The self-vector-space provenance is Theorem 161.7. It uses the FieldUp additive rows for vector addition, zero, and negation, and uses the FieldUp multiplication row as scalar action. These are exactly the remaining ledger rows required by the reflexive $\mathsf{FieldExt}^{\uparrow}$ package. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive ledger provenance`

Theorem 161.24 (RatUp reflexive public NameCert interface)**.** *The RatUp reflexive construction exposes the public paper-side* $\mathsf{FieldExt}^{\uparrow}\ \mathsf{NameCert}$ *interface with carrier* $\mathsf{RatHistoryCarrier}$*, classifier* $\mathsf{RatHistoryClassifier}$*, identity embedding* ι_{Rat}*, base and ambient* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *certificates, self-vector-space rows, exact endpoint classification, and ledger provenance over the RatUp operation table.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive public name certificate`

Proof. The carrier and classifier are fixed by Definition 161.3. The base and ambient field certificates are the two readings of Theorem 45.489.

The stability component is supplied by Theorem 161.6, and the vector-space component is supplied by Theorem 161.7. Together they give the identity embedding and self scalar-action surface.

The exactness and ledger interface is Definition 161.21. Its two coverage theorems, Theorems 161.22 and 161.23, assemble the remaining public rows into the displayed $\mathsf{FieldExt}^{\uparrow}\ \mathsf{NameCert}$ interface. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive semantic name certificate`

Theorem 161.25 (RatUp reflexive FieldExt source-pattern lock)**.** *For the reflexive package of Definition 161.3, every displayed source and pattern field is fixed by the concrete RatUp data already named in Definition 45.488 and certified by Theorem 45.489. The base field carrier, ambient field carrier, and vector carrier are* $\mathsf{RatHistoryCarrier}$ *over* BHist*; the field classifier, extension classifier, and vector classifier are* $\mathsf{RatHistoryClassifier}$*; the embedding is the identity map* $\iota_{\mathsf{Rat}}(h) := h$*; the scalar action is the* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *multiplication row; and the ledger source is the same concrete FieldUp source tuple on both endpoints.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexiveEmbedding ledger source lock`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive source pattern lock`

Proof. Unfold Definition 161.3. Its base field, ambient field, and vector carrier clauses are not separate choices: each names RatHistoryCarrier over BHist, and each classifier clause names RatHistoryClassifier.

The embedding row is locked by Theorem 161.6. Since ι_{Rat} is identity on BHist, the source endpoint and the displayed embedded endpoint are the same RatUp history.

The vector and action rows are locked by Theorem 161.7. It reads vector addition, zero, and negation from the additive FieldUp rows and reads scalar action from FieldUp multiplication. Hence the package has no carrier, classifier, embedding, action, or ledger source outside the RatUp FieldUp certificate boundary. □

Theorem 161.26 (RatUp reflexive FieldExt operation-table source coverage)**.** *In the reflexive FieldExt package of Definition 161.3, the zero, one, addition, negation, multiplication, apartness, and proof-indexed inverse rows of the base and ambient fields are read from the same concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table. The vector addition, vector zero, vector negation, and scalar-action rows are read from that same table: the vector additive rows are the FieldUp additive rows, and scalar action is the FieldUp multiplication row over* RatHistoryCarrier *and* RatHistoryClassifier*.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive embedded scalar action source readback`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive operation table source coverage`

Proof. Apply Theorem 45.489. It provides the concrete $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ operation table over RatHistoryCarrier and RatHistoryClassifier, including zero, one, addition, negation, multiplication, apartness, and the proof-indexed inverse.

The reflexive package reads the same certificate twice, once as the base field and once as the ambient field. Therefore every displayed field-operation row on either endpoint has the same operation-table source.

For the vector part, use Theorem 161.7. Its self-vector-space package takes vector addition, zero, and negation from the FieldUp additive rows and takes scalar action from FieldUp multiplication. Thus the complete operation surface of the reflexive FieldExt package is covered by the single RatUp FieldUp operation table. □

Theorem 161.27 (RatUp reflexive FieldExt certificate row exhaustion)**.** *For the concrete data of Definition 161.3, every displayed* $\mathsf{FieldExt}^{\uparrow}$ *source, pattern, classifier, stability, exactness, scalar-action, and ledger row for the RatUp reflexive package is covered by exactly one of the following concrete row families:*

1. *the two reads of the* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *endpoint certificate from Theorem 45.489;*
2. *the identity embedding row of Theorem 161.6;*
3. *the self-vector-space and scalar-action row of Theorem 161.7.*

No additional carrier, classifier, operation table, exactness source, or ledger source is used by the reflexive certificate.

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtRatReflexive certificate row exhaustion`

Proof. The source and pattern clauses are fixed by Theorem 161.25. It assigns the base field, ambient field, vector carrier, classifiers, identity embedding, scalar action, and ledger source to the concrete RatUp FieldUp data.

The operation clauses are covered by Theorem 161.26. It accounts for the two field endpoint reads and for the vector additive and scalar-action rows read from the same operation table.

Finally apply Theorem 161.8. Its obligation list consists only of the base and ambient FieldUp certificates, identity embedding stability and exactness, self-vector-space compatibility, scalar-action congruence, exact endpoint classification, and ledger provenance. These are precisely the three row families listed above, so the displayed RatUp reflexive FieldExt certificate has no uncovered row. □

Theorem 161.28 (Singleton field extension as a vector space over its base)**.** *For the concrete data of Definition 161.1, the extension carrier read as* VecSpaceSingletonCarrier *with scalar action* VecSpaceSingletonSmul *satisfies the* $\mathsf{VecSpace}^{\uparrow}$ *row over the base* $\mathsf{Field}^{\uparrow}$ *source. Moreover, for every base scalar* $r : \mathsf{BHist}$ *and extension vector endpoint* $m : \mathsf{BHist}$ *carried by* VecSpaceSingletonCarrier*, scalar multiplication by the embedded scalar agrees, up to the singleton classifier, with singleton field multiplication in the extension field.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton vector space over base`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton vector action field mul context readback`

Proof. The vector-space rows are exactly Theorem 47.3, applied to the same scalar carrier, vector carrier, and classifier displayed in Definition 161.1. Its semantic certificate packaging is recorded by Theorem 47.14.

The scalar-action endpoint collapses to e by Theorem 47.4. The extension-field multiplication endpoint also collapses to e by Theorem 45.48.

Since both endpoints are carried by A_{e} and identified with the same empty-history endpoint, the classifier ρ_{e} relates the scalar-action endpoint to the extension-field multiplication endpoint. This gives the compatibility of embedded scalar multiplication with the singleton extension field product. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonVectorSpace smul mul compatible`

Theorem 161.29 (Singleton FieldExt embedded scalar-action collapse)**.** *For the concrete data of Definition 161.1, let* $r, m : \mathsf{BHist}$ *be carried by* A_{e}*. The vector-space scalar action of the embedded singleton scalar* $\iota_{\mathsf{e}}(r)$ *on* m *and the singleton extension-field multiplication endpoint for* r *and* m *lie in the same* ρ_{e} *class.*

Proof. Apply Theorem 161.28. It gives the semantic compatibility statement between embedded scalar multiplication and extension-field multiplication for carried scalar and vector endpoints.

The vector-space action endpoint collapses to e by Theorem 47.4. The extension-field multiplication endpoint collapses to e by Theorem 45.48.

Since both endpoints are carried by A_{e} and both collapse to the same empty-history endpoint, the shared classifier ρ_{e} relates them. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton scalar action mul endpoint classified`

Definition 161.30 (Singleton field-extension ledger policy)**.** *For the concrete data of Definition 161.1, the endpoint ledger records exactly the base carrier* A_{e}*, the extension carrier* A_{e}*, the vector carrier* A_{e}*, the identity embedding* $\iota_{\mathsf{e}}(h) := h$*, the singleton field operations on the base and extension fields, the singleton vector action over the base field, and empty-history endpoint provenance for each displayed row.*

The ledger classifier attached to every carrier, embedding, field-operation, and vector-action endpoint is the concrete classifier

$$\rho_{\mathsf{e}}(h,k) := A_{\mathsf{e}}(h) \wedge A_{\mathsf{e}}(k) \wedge \mathsf{hsame}(h,k).$$

No additional endpoint object is recorded by the singleton field-extension certificate.

Lean4 (definition) `BEDC.Derived.FieldExtUp.FieldExtSingletonLedgerPolicy`

Theorem 161.31 (Singleton field-extension carrier coincidence)**.** *For the concrete data of Definition 161.1 and the ledger policy of Definition 161.30, the base field carrier, extension field carrier, and vector carrier are all A_{e}. The embedding ι_{e} preserves and reflects carrier membership:*

$$A_{\mathsf{e}}(h) \quad \textit{if and only if} \quad A_{\mathsf{e}}(\iota_{\mathsf{e}}(h)).$$

Every displayed classifier in the field-extension certificate is the concrete ρ_{e} classifier.

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonCarrier coincidence`

Proof. Unfold the concrete carrier definition and the ledger policy. The three carrier slots are all assigned the same singleton predicate A_{e}, so the carrier coincidence is definitional.

The embedding is the identity on histories. Hence preserving and reflecting carrier membership both reduce to the same assertion $A_{\mathsf{e}}(h)$.

The classifier rows are the rows already used by Theorem 161.4 and Theorem 161.28. Each row is displayed with the same concrete predicate ρ_{e}, so no transport across distinct classifiers is required. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonLedgerPolicy carrier coincidence`

Theorem 161.32 (Singleton identity field-extension tower composition)**.** *Compose two copies of the singleton field-extension certificate of Definition 161.1, both governed by the ledger policy of Definition 161.30. The composite tower again has base carrier A_{e}, middle carrier A_{e}, top carrier A_{e}, identity composite embedding $\iota_{\mathsf{e}} \circ \iota_{\mathsf{e}} = \iota_{\mathsf{e}}$, singleton field-operation rows, and the same singleton vector-space-over-base scalar action. All embedding and scalar-action rows in the composite tower are classified by ρ_{e}.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonEmbedding identity tower package`

Proof. The embedding part follows from Theorem 161.4. Since both embeddings are the identity on BHist, their composite is again the identity embedding ι_{e}.

The field-operation rows in the base, middle, and top fields collapse to the same singleton endpoint by Theorem 45.48. Thus tower composition introduces no field endpoint beyond the empty-history endpoint.

The scalar-action rows are supplied by Theorem 161.28. The endpoint collapse for the singleton vector action is exactly Theorem 47.4, so the composite tower keeps the same ρ_{e} classifier on its action rows. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton identity tower continuation classified`

Theorem 161.33 (Singleton field-extension exact endpoint ledger)**.** *For the concrete data of Definition 161.1 and the ledger policy of Definition 161.30, every embedding endpoint, every extension-field operation endpoint, and every vector-space-over-base action endpoint recorded in the ledger collapses to the empty history e and is classified by ρ_{e}.*

Proof. For embedding endpoints, apply Theorem 161.4. The embedding is the identity, so the only carried endpoint is the same singleton history already classified by ρ_{e}.

For extension-field operation endpoints, apply Theorem 45.48. The zero, one, addition, negation, multiplication, and proof-indexed inverse rows all collapse to e in the singleton field table.

For vector-space-over-base action endpoints, use Theorem 161.28 together with Theorem 47.4. The scalar action collapses to the same empty-history endpoint as the compatible extension-field multiplication row.

The ledger policy records no further endpoint kind. Therefore every recorded endpoint row in the singleton field-extension certificate is exact at e and classified by ρ_{e}. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonLedgerPolicy exact endpoint ledger`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton exact endpoint ledger`

Theorem 161.34 (Singleton field-extension certificate obligation package)**.** *The concrete data of Definition 161.1 assemble the paper-side* $\mathsf{FieldExt}^{\uparrow}$ *obligation package: base field source, extension field source, embedding stability and exactness, vector-space-over-base row, exact endpoint classification, and inherited ledger provenance.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton certificate obligation package`
Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton semantic name certificate`

Proof. The source field certificate and extension field certificate are both supplied by Theorem 45.81, because the base and extension field carriers are the same singleton field package.

Embedding stability is supplied by Theorem 161.4. It records carrier preservation, classifier preservation, and preservation of the singleton field operations up to $\mathsf{FieldSingletonClassifier}$. Exactness is the same identity-on-BHist fact: every carried base endpoint is already the extension endpoint named by ι_{e}.

Vector-space-over-base compatibility is supplied by Theorem 161.28, whose vector-space component is the law package of Theorem 47.3. Its paper-side semantic packaging is recorded by Theorem 47.14.

Exactness and ledger provenance are supplied by Theorems 161.36 and 161.37. These clauses assemble the listed $\mathsf{FieldExt}^{\uparrow}$ $\mathsf{NameCert}$ obligations for the concrete singleton field-extension carrier. □

Definition 161.35 (Singleton field-extension exactness and ledger interface)**.** *For the concrete data of Definition 161.1, the* $\mathsf{FieldExt}^{\uparrow}$ *exactness and ledger interface is read entirely through the singleton carrier* A_{e} *and classifier* ρ_{e}*. Thus the displayed base-field carrier, extension-field carrier, identity embedding endpoint, vector scalar-action endpoint, and extension-field multiplication endpoint all have the same source* A_{e}*, and every endpoint comparison used by the certificate is a* ρ_{e} *row over that source.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtUp StdBridge`

Theorem 161.36 (Singleton field-extension exact endpoint classification)**.** *For the concrete data of Definition 161.1, every displayed base-field operation endpoint, every displayed extension-field operation endpoint, the vector scalar-action endpoint, and the identity embedding endpoint are carried by* A_{e} *and classified with* e *by* ρ_{e}*. In particular, the operation table of the base field, the operation table of the extension field, and the scalar-action table of the extension vector space have one exact endpoint class.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton exact endpoint classification`

Proof. For the base and extension field operation endpoints, apply Theorem 45.48. Both field structures in Definition 161.1 use the same singleton $\mathsf{Field}^{\uparrow}$ operation table.

For the vector scalar-action endpoint, apply Theorem 47.4. Its scalar-action clause reads the endpoint as e over the same A_{e} and ρ_{e}.

The embedding endpoint is immediate from $\iota_{\mathsf{e}}(h) := h$. If h is carried by A_{e}, then the singleton carrier identifies h with e, and unfolding ρ_{e} gives the displayed classifier row. □

Theorem 161.37 (Singleton field-extension ledger provenance)**.** *For the concrete data of Definition 161.1, the* $\mathsf{FieldExt}^{\uparrow}$ *ledger records only the identity embedding row together with the singleton field and vector-space provenance rows. The field rows are the two copies of the singleton empty-history field certificate, the vector row is the singleton empty-history vector-space semantic certificate, and the embedding row is the identity stability package for* ι_{e}*.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton ledger provenance`

Proof. The two field ledger rows are supplied by Theorem 45.81, once for the base field and once for the extension field. The two uses have identical carrier, classifier, and singleton operation endpoints.

The vector-space provenance row is supplied by Theorem 47.14. It uses the same scalar source, vector source, classifier, and empty-history scalar-action endpoint as the displayed $\mathsf{FieldExt}^{\uparrow}$ data.

The embedding row is supplied by Theorem 161.4. Since ι_{e} is the identity on histories, no additional ledger source is introduced beyond the singleton field and vector-space rows. □

↪ variant `BEDC.Derived.FieldExtUp.FieldExtSingleton ledger provenance`

Theorem 161.38 (Singleton field-extension certificate projections)**.** *For the concrete data of Definition 161.1, the* $\mathsf{FieldExt}^{\uparrow}$ *certificate has the following three projections over the shared singleton carrier* A_{e} *and classifier* ρ_{e}*:*

1. *its source-field projection is the singleton* $\mathsf{Field}^{\uparrow}$ *certificate on* A_{e}*;*
2. *its extension-field projection is the singleton* $\mathsf{Field}^{\uparrow}$ *certificate on the same* A_{e}*;*
3. *its vector-space projection is the singleton* $\mathsf{VecSpace}^{\uparrow}$*-over-base certificate whose scalar carrier, vector carrier, and endpoint classifier are again* A_{e} *and* ρ_{e}*.*

The embedding row connecting the first two projections is the identity map $\iota_{\mathsf{e}}(h) := h$*.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton certificate projections`

Proof. The source and extension projections use the same displayed singleton field data. Apply Theorem 45.81 once for the source field and once for the extension field.

The vector-space projection is the semantic singleton vector-space package. Apply Theorem 47.14 with the scalar carrier, vector carrier, and classifier specified in Definition 161.1.

The projection map from the source field into the extension field is ι_{e}. By its definition, it is the identity on histories, so it preserves the displayed carrier and classifier rows without introducing a second endpoint choice. □

Theorem 161.39 (Singleton field-extension operation readback exactness)**.** *For the concrete data of Definition 161.1, every zero, one, addition, negation, multiplication, proof-indexed inverse, and scalar-action endpoint in the singleton field-extension package reads back to the singleton empty-history endpoint. Each such endpoint is classified by* ρ_{e} *against the corresponding embedded source-field endpoint or extension-field endpoint displayed by the* $\mathsf{FieldExt}^{\uparrow}$ *package.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonOperation readback exactness`

Proof. For the field operations, apply Theorem 45.48. It collapses zero, one, addition, negation, multiplication, and the proof-indexed inverse endpoint to the singleton empty-history endpoint.

The embedding comparison is supplied by Theorem 161.4. Since the embedding is the identity on histories, the embedded source endpoint and the corresponding extension-field endpoint are compared by the same classifier ρ_{e}.

For scalar action, apply Theorem 47.4 to read the vector-space action endpoint as the singleton empty-history endpoint. Then apply Theorem 161.28 to identify that scalar-action endpoint with the matching extension-field multiplication endpoint up to ρ_{e}. □

Theorem 161.40 (Singleton field-extension nonzero domain absurdity)**.** *For the concrete data of Definition 161.1, no base-field or extension-field proof-indexed inverse domain is inhabited. Equivalently, if a : BHist is carried by the singleton field carrier and $\mathsf{FieldSingletonNonZero}(a)$ is the displayed nonzero premise used by the base or extension field inverse row, then contradiction follows from the singleton carrier collapse of a to e.*

Proof. Unfold the concrete singleton nonzero predicate. Its witness simultaneously places a at the empty history endpoint and at the endpoint $\mathsf{e0}(\mathsf{e})$.

The singleton carrier clause supplies the collapse of the same history to e. Composing the two endpoint identifications gives $\mathsf{e} \sim \mathsf{e0}(\mathsf{e})$ in the history classifier.

This is impossible by the constructor no-confusion principle for BHist: the empty history constructor and the one-step empty-marker constructor are distinct. Hence the assumed nonzero proof parameter has no inhabitant, both for the source field and for the extension field, because those two projected fields use the same singleton carrier and the same singleton nonzero predicate. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonNonzeroDomain absurd`

Theorem 161.41 (Singleton field-extension inverse-row vacuous exactness)**.** *For the concrete data of Definition 161.1, every proof-indexed inverse obligation in the source field and in the extension field is exact. The exactness is vacuous: before any inverse endpoint can be chosen, its nonzero proof parameter belongs to the empty domain identified in Theorem 161.40.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingletonInverse row vacuous exactness`

Proof. Fix any displayed inverse obligation in either projected singleton field. Its input consists of a history a together with a proof that $\mathsf{FieldSingletonNonZero}(a)$ holds.

Apply Theorem 161.40 to that proof parameter. The resulting contradiction closes the obligation immediately, so no separate endpoint case for inverse evaluation remains.

The same argument covers the base and extension projections because Definition 161.1 gives them the same singleton field data. Thus every proof-indexed inverse source, stability, and exactness row is exact over an empty domain. □

Theorem 161.42 (Singleton field-extension inverse ledger coverage)**.** *For the concrete data of Definition 161.1, the inverse rows in the $\mathsf{FieldExt}^{\uparrow}$ source, stability, exactness, and ledger fields are covered by the same empty-domain class. They introduce no endpoint beyond the singleton field operation table already used for the zero, one, addition, negation, and multiplication rows.*

Proof. The source and extension inverse rows first reduce to their proof-indexed nonzero premises. By Theorem 161.41, those premises are uninhabited, so the corresponding inverse obligations are exact without selecting a new endpoint.

For the remaining operation rows, apply Theorem 161.39. It assigns all displayed field endpoints to the singleton empty-history operation table and compares them by ρ_{e}.

Finally combine this empty-domain inverse class with Theorem 161.43. The ledger coverage therefore contains the identity embedding row, the singleton field operation table row, the singleton vector-space scalar-action row, and no additional inverse endpoint class. □

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton inverse ledger coverage`

Theorem 161.43 (Singleton field-extension exactness and ledger coverage)**.** *For the concrete data of Definition 161.1, every* $\mathsf{FieldExt}^{\uparrow}$ *source row, pattern row, classifier row, stability row, exactness row, and ledger row is covered by exactly one of the following provenance classes: the identity embedding row, the singleton field operation table row, or the singleton vector-space scalar-action row.*

Lean4 ✓ `BEDC.Derived.FieldExtUp.FieldExtSingleton exactness ledger coverage`

Proof. First take the projected certificate rows from Theorem 161.38. These account for the source-field, extension-field, and vector-space certificate surfaces over the common A_{e} and ρ_{e}.

Next use Theorem 161.39. It assigns the field operation endpoints to the singleton field operation table row and the scalar-action endpoints to the singleton vector-space scalar-action row, with all endpoint comparisons made by ρ_{e}.

It remains to account for the cross-carrier rows. The identity embedding row from Definition 161.1 and Theorem 161.4 covers carrier preservation, classifier preservation, and embedded source-operation stability.

Finally apply Theorem 161.34. Its assembled $\mathsf{FieldExt}^{\uparrow}$ $\mathsf{NameCert}$ obligation list is precisely the union of these three provenance classes, so the source, pattern, classifier, stability, exactness, and ledger rows are all covered. □

161.3 Sibling dependency lattice

The $\mathsf{FieldExt}^{\uparrow}$ carrier consumes the base and ambient field surfaces from chapter 45. Its reflexive and singleton instances read both endpoints through the displayed $\mathsf{Field}^{\uparrow}$ operation tables, classifiers, and ledger rows rather than through a separate host-field equality.

The vector-space-over-base row is supplied by chapter 47. This is the row that lets the ambient field be read as a module over the base field while keeping scalar action, vector addition, zero, negation, classifier stability, and provenance visible as $\mathsf{VecSpace}^{\uparrow}$ data.

Downstream Galois, number-field, separability, algebraic-closure, and tower consumers therefore read $\mathsf{FieldExt}^{\uparrow}$ through a horizontal dependency lattice: two $\mathsf{Field}^{\uparrow}$ endpoints, one $\mathsf{VecSpace}^{\uparrow}$-over-base row, one embedding row, and the local $\mathsf{FieldExt}^{\uparrow}$ naming ledger. No downstream consumer may replace this lattice by an ambient tower object whose base field, extension field, or vector-space row is not displayed.

Theorem 161.44 (FieldExt downstream dependency lattice exactness)**.** *For either concrete* $\mathsf{FieldExt}^{\uparrow}$ *packet displayed in this chapter, namely the singleton packet of Definition 161.1 or the RatUp reflexive packet of Definition 161.3, the* $\mathsf{FieldExt}^{\uparrow}$ *input part of any accepted downstream Galois, number-field, separability, algebraic-closure, or tower read is accepted exactly through the following five-coordinate lattice:*

1. *the displayed base* $\mathsf{Field}^{\uparrow}$ *endpoint row;*
2. *the displayed ambient* $\mathsf{Field}^{\uparrow}$ *endpoint row;*
3. *the displayed* $\mathsf{VecSpace}^{\uparrow}$*-over-base row for the ambient carrier;*
4. *the displayed embedding row from the base endpoint into the ambient endpoint;*
5. *the local* $\mathsf{FieldExt}^{\uparrow}$ *naming ledger for the same packet.*

Equivalently, the consumer-visible $\mathsf{FieldExt}^{\uparrow}$ *readback is the finite packet obtained by repacking these five rows. A read that replaces any one of them by an ambient tower object whose base field, extension field, or vector-space-over-base row is not displayed is not an accepted* $\mathsf{FieldExt}^{\uparrow}$ *input read.*

Proof. Start with the singleton packet. Its carrier definition fixes the base field, extension field, vector carrier, identity embedding, scalar action, and ledger in Definition 161.1. The obligation scope in Definition 161.2 names the same carrier, classifier, exactness, scalar-action, and ledger fields as the rows read by downstream certificate families.

The five projections are explicit. The two field endpoints are the two singleton $\mathsf{Field}^{\uparrow}$ readings supplied by Definition 161.38. The $\mathsf{VecSpace}^{\uparrow}$-over-base coordinate is Definition 161.28. The embedding coordinate is Definition 161.4, and its endpoint exactness is Definition 161.5. The ledger coordinate is Definition 161.37. Finally, Definition 161.43 exhausts every source, pattern, classifier, stability, exactness, and ledger row of the singleton $\mathsf{FieldExt}^{\uparrow}$ package by the identity embedding row, the singleton field operation-table row, and the singleton vector-space scalar-action row. Thus there is no sixth singleton coordinate through which a downstream read can enter the packet.

For the RatUp reflexive packet, the carrier definition Definition 161.3 identifies the base field, ambient field, and vector carrier with the same RatUp history carrier and identifies the embedding with the identity map. The two endpoint rows are the two readings of the concrete $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ certificate recorded in Definition 161.18. The $\mathsf{VecSpace}^{\uparrow}$-over-base row is Definition 161.7; its scalar action is the RatUp FieldUp multiplication row. The embedding row is Definition 161.6. The naming ledger is fixed by Definition 161.23 and exposed through the public interface in Definition 161.24.

The RatUp reflexive exhaustion theorem Definition 161.27 says that every displayed source, pattern, classifier, stability, exactness, scalar-action, and ledger row is covered by exactly the two endpoint FieldUp reads, the identity embedding row, and the self-vector-space row. The tower case does not add an escape coordinate: by Definition 161.15 and Definition 161.17, even a two-step reflexive tower keeps the same RatUp FieldUp table, identity embedding, and self-vector-space scalar action.

Combining the singleton and RatUp cases gives the stated inversion for every concrete $\mathsf{FieldExt}^{\uparrow}$ packet displayed in this chapter. If a downstream read is accepted as a $\mathsf{FieldExt}^{\uparrow}$ input, the cited projection and exhaustion rows recover the base FieldUp endpoint, ambient FieldUp endpoint, VecSpaceUp-over-base row, embedding row, and local naming ledger. Conversely, when those five rows are present, the corresponding obligation package is assembled by Definition 161.34 in the singleton case and by Definition 161.8 in the RatUp reflexive case. Therefore the accepted $\mathsf{FieldExt}^{\uparrow}$ input surface is exactly the displayed five-coordinate lattice, and an ambient tower object with any undisplayed endpoint or vector-space row has no coordinate in the accepted readback packet. □

Theorem 161.45 (FieldExt field and vector-space sibling dependency)**.** *Every accepted* $\mathsf{FieldExt}^{\uparrow}$ *carrier read must pass through the displayed base* $\mathsf{Field}^{\uparrow}$ *row, the displayed extension* $\mathsf{Field}^{\uparrow}$ *row,*

the embedding row between them, and the $\mathsf{VecSpace}^{\uparrow}$ *scalar-action row before any extension consumer reads the local* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *surface. The field endpoints are the substantive algebraic dependencies of chapter 45, and the scalar-action row is the substantive vector-space dependency of chapter 47. A consumer that reads the extension as an ambient tower while omitting one of these rows is not reading the accepted* $\mathsf{FieldExt}^{\uparrow}$ *packet.*

Proof. Project the displayed carrier rows. The base and extension endpoints are both $\mathsf{Field}^{\uparrow}$ rows, and the embedding row is typed between those endpoints, so its exactness cannot be read before both field tables are present.

The scalar-action coordinate is then read as a $\mathsf{VecSpace}^{\uparrow}$ row over the base field. It supplies the module-facing action consumed by extension consumers, while the embedding row supplies the endpoint comparison consumed by field consumers.

The local $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ row is reached only after those four sibling rows are displayed. Thus the read route is the base field, extension field, embedding, vector-space action, and local naming ledger, with no coordinate for an undisplayed host-field tower. □

Closure status for $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$.

Constructive story: A field extension at this boundary is built by taking the already certified one-point field surface and the one-point vector-space surface, then using the identity embedding so every accepted endpoint is the same empty-history carrier viewed simultaneously as base field, extension field, and scalar module. The classifier therefore asks for both the field classifier and the vector-space classifier on the same displayed history, which collapses to hsame at the empty endpoint rather than to equality of host fields or quotient presentations. The source covers exactly the singleton field carrier, while the pattern and ledger keep the vector-space-over-base row, the identity embedding row, scalar-action readbacks, exact endpoint classification, and RatUp-reflexive tower rows visible through the same Cont and Pkg provenance. Because e inhabits the carrier, hsame supplies reflexivity, symmetry, and transitivity, and both component carriers are closed under the displayed classifier, the five naming-certificate obligations are discharged by projecting and repacking the same singleton rows. A history h lies in the signature GAP of a $\mathsf{FieldExt}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer endpoint and evidence ledger, and token introduction identifies that answer as p; here the three tests reduce to the statement that h is the identity-extension endpoint whose scalar action and field multiplication both read back to e. The paper bridge sends this package to the ordinary terminal field extension and reads it back by the identity embedding, so the chapter registers the construction as $\mathsf{FieldExt}^{\uparrow}$ without adding nontrivial towers, Galois data, separability data, algebraic closure, or a separate extension carrier.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature singleton field-extension package is exactly the semantic certificate, vector-space-over-base row, identity embedding obligations, exact endpoint classification, ledger rows, and RatUp-reflexive tower rows displayed in this chapter.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.FieldExtUp.FieldExtSingleton\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: Nontrivial extension towers, Galois, separability, algebraic-closure claims, and bridgeChecked verification are not claimed here.

Upgrade path: No further upgrade: chapter is at the top of the formal axis.

Chapter 162

A Concrete Naming Certificate for $\mathsf{AlgClosure}^{\uparrow}$

The algebraic-closure interface $\mathsf{AlgClosure}^{\uparrow}$ packages a field extension in which every nonconstant polynomial over the base field has a root. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

162.1 Carrier definition

An $\mathsf{AlgClosure}^{\uparrow}$ carrier packet is a finite BHist row family over the consumed $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ sources. It contains a field-extension row F, a nonconstant polynomial request row p, a displayed root endpoint r, a classifier transport row H, a finite root ledger L, and a package provenance row $\Pi : \mathsf{Pkg}$.

Theorem 162.1 (AlgClosureUp carrier source obligation)**.** *Every accepted* $\mathsf{AlgClosure}^{\uparrow}$ *carrier packet is sourced by a* $\mathsf{FieldExt}^{\uparrow}$ *extension row, a* $\mathsf{Poly}^{\uparrow}$ *nonconstant-polynomial request row over that extension, the displayed root endpoint row, the* hsame *classifier transport row, the shared* Pkg *provenance row, and the finite root-ledger rows. Conversely, these rows repack as the carrier surface of the same* $\mathsf{AlgClosure}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket source obligation`

Proof. Unpack the carrier packet into its displayed BHist coordinates. The $\mathsf{FieldExt}^{\uparrow}$ row supplies the base and extension histories, and the $\mathsf{Poly}^{\uparrow}$ row supplies the finite coefficient and nonconstant-request histories over that same extension row.

The root endpoint is not read from a host algebraic closure. It is a carried history endpoint whose acceptance is recorded by the finite ledger L, whose transport is the displayed hsame row H, and whose provenance is the single package row Π.

For the converse, take precisely those six row families and place them back into the packet slots. The carrier predicate asks for no further data, so the same rows reconstruct the accepted carrier surface. □

Theorem 162.2 (AlgClosureUp polynomial-root classifier obligation)**.** *Two accepted* $\mathsf{AlgClosure}^{\uparrow}$ *root-witness packets classify together exactly when their* $\mathsf{FieldExt}^{\uparrow}$ *source rows classify together, their* $\mathsf{Poly}^{\uparrow}$ *nonconstant request rows classify over the transported field-extension source, their displayed root endpoints are related by the packet* hsame *row, and their finite root ledgers and* Pkg *provenance rows are the corresponding transported rows.*

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket polynomial root classifier obligation`

Proof. Read the two packets through Definition 162.1. Each packet exposes the same six kinds of rows: field-extension source, polynomial request, root endpoint, classifier transport, root ledger, and provenance.

Compare the field-extension projections first. The $\mathsf{FieldExt}^{\uparrow}$ classifier binds the base and extension histories, so the polynomial request in the second packet is read over the transported extension source rather than over a fresh ambient field.

Now compare the polynomial and root projections. The $\mathsf{Poly}^{\uparrow}$ classifier transports the nonconstant request row, the displayed hsame row transports the root endpoint, and the ledger/provenance clauses say that L and Π are carried along the same comparison. These are all classifier fields, hence the packets classify together exactly under this componentwise finite comparison. □

Theorem 162.3 (AlgClosureUp ledger readback obligation)**.** *The visible root-certificate ledger of an accepted* $\mathsf{AlgClosure}^{\uparrow}$ *packet is exactly the finite family consisting of the* $\mathsf{FieldExt}^{\uparrow}$ *source row, the* $\mathsf{Poly}^{\uparrow}$ *nonconstant-polynomial request row, the displayed root endpoint row, the root-satisfaction row, the* hsame *classifier transport row, and the* Pkg *provenance row. No other root certificate row is visible downstream.*

Proof. Begin with the carrier source obligation. It identifies the only source and endpoint rows in the packet, namely F, p, r, H, L, and Π.

Project the finite root ledger L. Its readback rows are exactly the polynomial request, the displayed endpoint, and the carried satisfaction history witnessing that the request has the endpoint as a root. The same ledger also records the hsame transport used by the classifier obligation.

Since the packet has only one provenance coordinate, every visible ledger row returns to $\Pi : \mathsf{Pkg}$. Thus downstream readback is exhausted by the listed finite family. □

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket ledger readback obligation`

Theorem 162.4 (AlgClosureUp root-witness transport coverage)**.** *If two accepted* $\mathsf{AlgClosure}^{\uparrow}$ *root-witness packets classify together, then every visible root-satisfaction row in the first packet transports to a visible root-satisfaction row in the second packet over the transported* $\mathsf{FieldExt}^{\uparrow}$ *and* $\mathsf{Poly}^{\uparrow}$ *sources. The transported row keeps the same* Pkg *provenance, and it introduces no ambient algebraic-closure object and no quotient root.*

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket root witness transport coverage`

Proof. First unpack both root-witness packets through Definition 162.1. Each side exposes only the field-extension source row, the nonconstant polynomial request, the displayed root endpoint, the classifier transport row, the finite ledger, and the package provenance.

Next apply Definition 162.2. The packet classifier transports the $\mathsf{FieldExt}^{\uparrow}$ source first, then reads the $\mathsf{Poly}^{\uparrow}$ request over that transported source, and then carries the endpoint, ledger, and provenance rows along the same comparison.

Finally re-read the target packet ledger with Definition 162.3. The root-satisfaction row is one of the visible ledger rows, so the transported endpoint and polynomial request determine the corresponding visible satisfaction row in the second packet. Because the readback ledger contains only finite BEDC rows and the single Pkg coordinate, no ambient algebraic closure or quotient root is exported. □

Theorem 162.5 (AlgClosureUp standard boundary obligation)**.** *The* $\mathsf{AlgClosure}^{\uparrow}$ *carrier packet contains no host algebraic-closure object, no quotient root object, and no uncarried root set. Its boundary is exactly the finite* BHist, Cont, hsame, $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$, *and* Pkg *surface displayed by the accepted packet.*

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket standard boundary obligation`

Proof. Use Definition 162.3 to list the visible root-certificate rows. Each row is a carried history, a continuation ledger entry, an hsame transport, a consumed naming certificate, or a package provenance row.

A host algebraic closure would require an additional carrier object with global roots for all polynomials. A quotient root object would require an additional quotient equality or orbit representative. Neither field is present in the accepted packet, and neither is part of the readback ledger.

Therefore the boundary is the displayed BEDC surface alone. The chapter records root existence only as finite carried certificates for the requested nonconstant polynomial rows. □

Theorem 162.6 (AlgClosureUp downstream consumer obligation)**.** *Every downstream consumer of an accepted* $\mathsf{AlgClosure}^{\uparrow}$ *packet may read only the finite* $\mathsf{FieldExt}^{\uparrow}$ *source rows,* $\mathsf{Poly}^{\uparrow}$ *nonconstant-polynomial request rows, displayed root rows, classifier transport rows, finite root ledger rows, and* Pkg *provenance rows. A consumer receives no ambient algebraic closure, root quotient, or unlisted host-algebra datum.*

Proof. First apply Definition 162.1. This fixes the carrier-facing rows available to the consumer: the field-extension source, the polynomial request, the root endpoint, transport, ledger, and provenance.

Next apply Definition 162.2. Any consumer-side comparison must use the same $\mathsf{FieldExt}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ source comparisons, the displayed root hsame row, and the transported ledger and provenance rows.

Finally apply Definition 162.5. It removes host algebraic closures, quotient roots, and uncarried root sets from the consumer interface. The downstream surface is therefore exactly the finite row family listed in the statement. □

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket downstream consumer obligation`

162.2 The certificate

Theorem 162.7 (AlgClosureUp root carrier obligation surface)**.** *An* $\mathsf{AlgClosure}^{\uparrow}$ *carrier row is exactly a* $\mathsf{FieldExt}^{\uparrow}$ *source row together with a* $\mathsf{Poly}^{\uparrow}$ *root-ledger row over the BEDC primitives* BHist, hsame, Cont, *and* Pkg. *The carrier exposes the base and extension histories, the nonconstant polynomial request, the displayed root endpoint, the transported classifier row, the finite satisfaction ledger, and the package provenance, and it exposes no ambient algebraic-closure carrier outside those rows.*

Proof. Unpack the seed carrier packet. Its first projection is the consumed $\mathsf{FieldExt}^{\uparrow}$ source, so the base-field and extension histories are already fixed as displayed BHist rows with their classifier transport.

Project the polynomial side next. The consumed $\mathsf{Poly}^{\uparrow}$ request supplies the finite coefficient ledger and the nonconstant-row witness over the same field-extension source, while the root endpoint and satisfaction row are carried as finite histories connected by the displayed hsame and Cont data.

Repack these projections with the single Pkg provenance row. The packet has no constructor for a host algebraic closure or unlisted root carrier, so the listed $\mathsf{FieldExt}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ rows are the whole carrier obligation surface. □

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket root carrier obligation surface`

Theorem 162.8 (AlgClosureUp polynomial root ledger obligation)**.** *Every admitted polynomial-root row in an* $\mathsf{AlgClosure}^{\uparrow}$ *packet projects to the displayed* $\mathsf{Poly}^{\uparrow}$ *coefficient ledger, the inherited* $\mathsf{Field}^{\uparrow}$ *operation rows carried by the* $\mathsf{FieldExt}^{\uparrow}$ *source, and the* hsame *transport that relates the displayed root endpoint to the polynomial satisfaction row. The projection preserves the same finite* BHist *ledger and the same* Pkg *provenance.*

Proof. Start from the admitted root row and read it through Definition 162.1. This gives the $\mathsf{FieldExt}^{\uparrow}$ source, the $\mathsf{Poly}^{\uparrow}$ request, the endpoint, transport, ledger, and provenance coordinates.

The $\mathsf{Poly}^{\uparrow}$ projection is the coefficient ledger for the requested nonconstant polynomial. Since that request is over the displayed field extension, its scalar operations are exactly the inherited $\mathsf{Field}^{\uparrow}$ rows available through the $\mathsf{FieldExt}^{\uparrow}$ source rather than operations from a host field object.

Finally project the root endpoint and satisfaction row from the finite ledger. The hsame coordinate transports the endpoint along the classifier comparison, and the ledger repacks with the same BHist rows and Pkg provenance. No quotient root or choice-selected representative is read by this projection. □

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureTasteGate single carrier alignment`

Theorem 162.9 (AlgClosureUp FieldExt consumer boundary)**.** *Downstream* $\mathsf{FieldExt}^{\uparrow}$ *and* $\mathsf{Poly}^{\uparrow}$ *consumers of an accepted* $\mathsf{AlgClosure}^{\uparrow}$ *packet read only the displayed field-extension rows, polynomial coefficient ledgers, root endpoint rows, satisfaction ledgers,* hsame *transports, finite* Cont *readbacks, and* Pkg *provenance. They do not receive a quotient field, a classical algebraic closure, or a choice-picked root outside the displayed BEDC rows.*

Proof. First apply Definition 162.7. This confines every consumer-facing carrier read to the consumed $\mathsf{FieldExt}^{\uparrow}$ source, the polynomial request, the displayed endpoint, transport, ledger, and provenance rows.

Next apply Definition 162.8. It identifies the coefficient ledger, inherited $\mathsf{Field}^{\uparrow}$ operations, root satisfaction row, and hsame transport available to polynomial consumers.

The remaining consumer read is a boundary question. Use Definition 162.6 to repack the projected rows as the exported surface. Since each projection came from the finite packet coordinates, no quotient field, classical algebraic closure, or choice-picked root is present. □

Theorem 162.10 (AlgClosure public root-witness export)**.** *The carrier obligation, the polynomial-root ledger obligation, and the* $\mathsf{FieldExt}^{\uparrow}$ *consumer boundary jointly export the public* $\mathsf{AlgClosure}^{\uparrow}$ *root-witness surface over* $\mathsf{FieldExt}^{\uparrow}$*,* $\mathsf{Poly}^{\uparrow}$*,* BHist*,* Cont*,* hsame*, and* Pkg*. The exported surface consists exactly of the displayed field-extension source, polynomial request, root endpoint, root-satisfaction ledger, transport rows, finite readbacks, and provenance. It exports no ambient algebraic closure, quotient root, host algebraic-closure object, or choice-picked root.*

Lean4 ✓ `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket public root witness export`

Proof. The carrier obligation supplies the accepted finite packet: a displayed $\mathsf{FieldExt}^{\uparrow}$ source, a $\mathsf{Poly}^{\uparrow}$ request over that source, a root endpoint, transport rows, a finite satisfaction ledger, and Pkg provenance.

The polynomial-root ledger obligation identifies which rows a polynomial consumer may read. It exposes the coefficient ledger, inherited field-extension operations, root endpoint, satisfaction row, and hsame transport without leaving the displayed packet.

Finally apply the $\mathsf{FieldExt}^{\uparrow}$ consumer boundary. It repacks the carrier and ledger rows as the public consumer surface over $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, BHist, Cont, hsame, and Pkg. Since no step supplies an ambient algebraic closure, quotient root, host algebraic-closure object, or choice-picked root, none belongs to the exported surface. □

Theorem 162.11 (AlgClosure finite root-witness consumer completeness)**.** *Every finite polynomial-root consumer read available from this* $\mathsf{AlgClosure}^{\uparrow}$ *chapter is exhausted by the displayed* $\mathsf{FieldExt}^{\uparrow}$ *source, the* $\mathsf{Poly}^{\uparrow}$ *request, the root endpoint, the root-satisfaction ledger, the transport rows, the finite readbacks, and the* Pkg *provenance. The consumer surface also contains the component rows needed to read those data: the carrier packet, the polynomial-root classifier obligation, the transported root-witness coverage, the standard boundary, and the public root-witness export.*

There is no ambient algebraic closure, quotient root, host algebraic-closure object, choice-picked root, or unlisted carrier available to such a finite consumer.

Proof. Start with Definition 162.7 and Definition 162.1. These identify the accepted carrier as a finite packet over the displayed $\mathsf{FieldExt}^{\uparrow}$ source, $\mathsf{Poly}^{\uparrow}$ request, root endpoint, root-satisfaction ledger, transports, finite readbacks, and Pkg provenance.

Next apply Definition 162.2 and Definition 162.8. They say that a polynomial-root consumer reads the coefficient and satisfaction ledgers through the same source and classifier rows, with no additional field object or separate root representative.

The transport and boundary rows are supplied by Definition 162.4 and Definition 162.5. These keep the root endpoint, ledger, and provenance inside the finite packet while excluding host algebraic closures, quotient roots, and uncarried root sets.

Finally apply Definition 162.10. The export theorem repacks the carrier, classifier, transport, boundary, and downstream consumer rows as the public finite root-witness surface. Hence every available consumer read is one of the listed BEDC rows, and no ambient algebraic closure, quotient root, host algebraic-closure object, choice-picked root, or unlisted carrier is exposed. □

Closure status for $\mathsf{NameCert}_{\mathsf{AlgClosure}^{\uparrow}}$**.**

Constructive story: A root witness is generated only after a $\mathsf{FieldExt}^{\uparrow}$ extension row and a $\mathsf{Poly}^{\uparrow}$ nonconstant-polynomial request row have both been displayed over the same BEDC source. The carrier accepts the finite packet containing that field-extension row, the polynomial request, a carried root endpoint, the hsame transport row, the finite root-satisfaction ledger, and the single Pkg provenance row; anything needing an ambient algebraic-closure object, a quotient root, or an unlisted root carrier is outside the packet. Two accepted packets classify together by transporting the field-extension source first, reading the polynomial request over that transported source, and then carrying the root endpoint, root ledger, and provenance along the same componentwise comparison. The source specification is the consumed field-extension and polynomial-request surface, the pattern specification is satisfaction of the requested non-constant polynomial by the displayed endpoint, and the ledger keeps the coefficient rows, inherited field operations, root endpoint, satisfaction row, transport, and provenance visible. The five name-certificate obligations are inherited from the dependency classifiers and the finite repacking theorems: an accepted packet inhabits the carrier, hsame gives reflexive, symmetric, and transitive transport componentwise, and transported root-satisfaction rows repack as accepted packets. A packet history h lies in the signature gap of an $\mathsf{AlgClosure}^{\uparrow}$ token p when the source-domain accepts its field-extension and polynomial request rows, the signature relation pairs it with an answer root packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the root endpoint and satisfaction row are exactly the finite root witness encoded by p. The chapter registers this finite polynomial-root packet under the name $\mathsf{AlgClosure}^{\uparrow}$; it introduces no global algebraic-closure carrier, no quotient root object, and no choice-picked host root.

Theory closure: TheoryGate(NameCert$_{\mathsf{AlgClosure}\uparrow}$, maturePackageClosed)

Scope closed: Definition 162.10 binds the public root-witness surface from the carrier, polynomial-root classifier, finite root ledger readback, transport coverage, standard boundary, and downstream consumer rows over FieldExt$^{\uparrow}$, Poly$^{\uparrow}$, BHist, Cont, hsame, and Pkg.

Formal verification: FormalStatus(NameCert$_{\mathsf{AlgClosure}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.AlgClosureUp.AlgClosureCarrierPacket\_public\_root\_witness\_export`

Bridge status: paperBridge

Not claimed: This chapter does not close ambient algebraic closures, quotient roots, host algebraic-closure objects, or unlisted root carriers.

Upgrade path: No paper-axis grade remains; formal bridge checking remains a separate verification-axis obligation for the cited Lean target.

Chapter 163

A Concrete Naming Certificate for $\mathsf{GaloisExt}^{\uparrow}$

The Galois-extension interface $\mathsf{GaloisExt}^{\uparrow}$ packages a normal and separable field extension. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161) and $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ (chapter 166).

163.1 Carrier definition

Definition 163.1 (GaloisExtUp BHist source packet)**.** *A* $\mathsf{GaloisExt}^{\uparrow}$ *source packet is a finite* BHist *tuple* $(F, S, n, s, a, c, \rho, \lambda)$*. The row* F *is the consumed* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *dependency packet, and the row* S *is the consumed* $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ *dependency packet over the same displayed field extension carrier. The row* n *is the normality and root-splitting row: each conjugate endpoint and each displayed root-splitting endpoint is a* BHist *endpoint read through the carrier, classifier, exactness, and ledger rows of* F*. The row* s *is the separability row: it is the minimal-polynomial simple-root row of* S *after transport into the carrier displayed by* F*.*

The row a *is the automorphism source row consumed by the Galois-group interface. It is a finite* BHist *row whose domain and codomain endpoints are read through the FieldExtUp carrier rows, whose base-fixing comparisons are* hsame *rows over the displayed base carrier, whose action on displayed roots is named by a finite* Cont *action ledger, and whose source is recorded by the same* Pkg *provenance that records the FieldExtUp dependency.*

The row c *is the classifier row binding the FieldExtUp and SeparableExtUp dependency packets. It records that their endpoint comparisons are read by* hsame *on the same finite history endpoints, with no host-field equality and no quotient endpoint. The row* ρ *is the* Pkg *provenance showing which dependency packet supplies each displayed face. The finite ledger* λ *is the* Cont *list containing exactly the FieldExtUp dependency row, the SeparableExtUp dependency row, the normality row, the separability row, the automorphism source row, the base-fixing rows, the root-orbit action rows, the classifier row, the stability rows, and the exactness rows consumed by the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *interface.*

Lean4 (definition) `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket`

Definition 163.2 (GaloisExtUp source classifier)**.** *For two* $\mathsf{GaloisExt}^{\uparrow}$ *source packets*

$$P = (F, S, n, s, a, c, \rho, \lambda) \qquad \text{and} \qquad P' = (F', S', n', s', a', c', \rho', \lambda'),$$

the source classifier $P \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P'$ *is the finite agreement row consisting of the following data:*

1. *an* hsame *transport row between the FieldExtUp dependency faces of F and F';*
2. *an* hsame *transport row between the SeparableExtUp dependency faces of S and S' over the same displayed field-extension endpoints;*
3. *an* hsame *transport row carrying the normality and root-splitting row n to n';*
4. *an* hsame *transport row carrying the separability row s to s';*
5. *an* hsame *transport row carrying the automorphism source row a to a';*
6. *an* hsame *transport row carrying the classifier row c to c';*
7. *a shared* Pkg *provenance row comparing ρ with ρ';*
8. *a finite* Cont *ledger comparison comparing λ with λ' entry by entry;*
9. *a* SigRel *row asserting that these transported FieldExtUp, SeparableExtUp, normality, separability, automorphism, classifier, provenance, and ledger faces belong to one finite* $\mathsf{GaloisExt}^{\uparrow}$ *signature surface.*

Lean4 (definition) `BEDC.Derived.GaloisExtUp.GaloisExtSourceClassifier`

Theorem 163.3 (GaloisExtUp source classifier reflexivity)**.** *Every* $\mathsf{GaloisExt}^{\uparrow}$ *source packet* $P = (F, S, n, s, a, c, \rho, \lambda)$ *satisfies* $P \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P$.

Proof. Project the packet to its eight displayed rows. The FieldExtUp dependency face, the SeparableExtUp dependency face, the normality row, the separability row, the automorphism source row, and the classifier row each compare with itself by the reflexive hsame row on the corresponding BHist endpoint.

The provenance and ledger data are retained without alteration. Use the same Pkg row ρ and the same finite Cont list λ, comparing each ledger entry with itself.

Finally repack these componentwise reflexive rows into the SigRel surface named in Definition 163.2. Since every face is the original face of P, the finite signature surface is again the displayed $\mathsf{GaloisExt}^{\uparrow}$ source surface. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourceClassifier reflexive`

Theorem 163.4 (GaloisExtUp source classifier symmetry)**.** *For* $\mathsf{GaloisExt}^{\uparrow}$ *source packets P and P', if* $P \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P'$, *then* $P' \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P$.

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourceClassifier symmetric`

Proof. Unpack the classifier row of Definition 163.2. The FieldExtUp face, the SeparableExtUp face, the normality row, the separability row, the automorphism source row, and the classifier row are all transported by displayed hsame comparisons between finite BHist endpoints.

Reverse each of those comparisons by symmetry of hsame. The shared Pkg provenance row is the same provenance surface read in the opposite direction, and the finite Cont comparison is reversed entry by entry along the same ledger.

The SigRel row already states that the two displayed packets lie on one finite $\mathsf{GaloisExt}^{\uparrow}$ signature surface. Repack the reversed endpoint comparisons, the reversed ledger comparison, and the same signature surface to obtain $P' \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P$. □

Theorem 163.5 (GaloisExtUp source classifier transitivity)**.** *For* $\mathsf{GaloisExt}^{\uparrow}$ *source packets P, P', and P'', if* $P \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P'$ *and* $P' \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P''$, *then* $P \sim^{\mathrm{src}}_{\mathsf{GaloisExt}^{\uparrow}} P''$.

Proof. Unpack the two classifier rows. Their FieldExtUp dependency comparisons share the middle endpoint F', and their SeparableExtUp dependency comparisons share the middle endpoint S' over the same displayed field-extension surface. Transitivity of hsame composes these two dependency transports.

Apply the same transitive hsame composition to the normality rows, the separability rows, the automorphism source rows, and the classifier rows. The middle packet contributes no additional public data; it only supplies the endpoint at which the two transport chains meet.

For provenance and ledgers, compose the displayed Pkg comparisons and the entrywise Cont comparisons through the middle rows. The two SigRel witnesses describe compatible finite $\mathsf{GaloisExt}^{\uparrow}$ signature surfaces sharing the middle packet, so their outer faces repack into one finite signature surface for P and P''. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourceClassifier transitive`

163.2 The certificate

Theorem 163.6 (GaloisExtUp normality obligation row)**.** *For a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the normality face of* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *is accepted exactly when every displayed conjugate witness and every displayed root-splitting witness in* n *is read from the* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *packet* F *through finite* BHist *endpoints,* Cont *ledger rows,* Pkg *provenance rows, and the classifier rows retained by* F*.*

Proof. First read the normality row n from the source packet. By Definition 163.1, its endpoints are not independent field elements; they are displayed BHist endpoints whose carrier, classifier, exactness, and ledger provenance are supplied by F.

For the forward direction, acceptance of the normality face exposes exactly the conjugate and root-splitting entries carried by n. Project each entry to its Cont row and then to its Pkg source. The definition of the packet sends those projections back to the FieldExtUp dependency row, so the accepted face contains only rows read from F.

For the reverse direction, assume every displayed conjugate and root-splitting witness is read from F with the stated history, ledger, and provenance support. Repack those rows as the tuple entry n, attach the classifier row c, and use the same finite ledger λ. This constructs the normality face required by $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ without introducing any endpoint outside the FieldExtUp packet. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket normality obligation row`

Theorem 163.7 (GaloisExtUp separability obligation row)**.** *For a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the separability face of* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *is precisely the minimal-polynomial simple-root row of the consumed* $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ *packet* S*, transported by the classifier row* c *into the same FieldExtUp carrier displayed by* F*.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket separability obligation row`

Proof. Read the row s from the source packet. The definition states that s is the simple-root row of S after it has been placed over the carrier displayed by F.

The classifier row c supplies the needed transport. It compares the FieldExtUp and SeparableExtUp endpoints by hsame on the common BHist source, so the minimal-polynomial endpoint, the root endpoint, and the simple-root witness remain the same finite history rows after transport.

Thus the separability face has no independent certificate data. Projecting it recovers the simple-root row of S, and repacking that row with c, ρ, and λ gives the separability face consumed by $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$. □

Theorem 163.8 (GaloisExtUp classifier transport row)**.** *Let* $(F, S, n, s, a, c, \rho, \lambda)$ *and* $(F', S', n', s', a', c', \rho', \lambda')$ *be two* $\mathsf{GaloisExt}^{\uparrow}$ *source packets. If the FieldExtUp dependency rows of* F *and* F' *are transported by* hsame*, and the SeparableExtUp dependency rows of* S *and* S' *are transported by* hsame *over the same finite* BHist *endpoints, then the normality and separability faces are transported from* (n, s) *to* (n', s') *by the classifier rows* c *and* c' *without host field equality or quotienting.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtClassifier transport row`

Proof. Start with the FieldExtUp transport. The hypothesis identifies the carrier, classifier, exactness, and ledger endpoints of F and F' by hsame. Therefore every conjugate and root-splitting witness read from F has the corresponding displayed endpoint in F'.

Next use the SeparableExtUp transport. It identifies the minimal-polynomial simple-root rows of S and S' over the same history endpoints. The classifier rows c and c' place those rows in the FieldExtUp carriers already matched in the previous paragraph.

Combining the two transports sends n to n' and s to s'. Since all comparisons are hsame comparisons on finite BHist endpoints, the argument never requires equality of ambient host fields, quotient representatives, or an external field carrier. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket classifier transport`

Theorem 163.9 (GaloisExtUp normal separable stability)**.** *Every* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *source packet of Definition 163.1 is stable under replacing its displayed rows by* hsame*-classified* BHist *rows through the same* Pkg *provenance. The stable rows are exactly the* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *field-extension dependency, the* $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ *separability dependency, the finite normality and root-splitting row, the finite automorphism source row, the base-fixing rows, the root-orbit action rows, and the finite* Cont *ledgers belonging to the enclosing* NameCert *packet.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket normal separable stability`
Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket endpoint empty inversion`

Proof. Apply the classifier transport row of Definition 163.8 to the transported FieldExtUp and SeparableExtUp dependency rows. This handles the carrier, classifier, exactness, and ledger endpoints through the inherited classifiers of the two dependency packets.

For the normality component, transport every conjugate and root-splitting row along the displayed hsame comparisons and retain the finite Cont ledger that reads those rows from the field-extension source F.

For the automorphism component, transport the endpoint rows of a along the same FieldExtUp carrier comparisons. The base-fixing rows are already hsame rows over the base carrier, and the action ledger is a finite Cont row, so it is carried by the same provenance-preserving repacking.

For the separability component, use the displayed $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ dependency and its simple-root row. The shared Pkg provenance row ρ is carried through the repacking, so the transported packet has the same certificate surface as the original packet. □

Theorem 163.10 (GaloisExtUp public obligation boundary)**.** *For a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *obligation surface is exactly the following finite row family: the carrier row from* F*, the normality row* n*, the separability row* s*, the automorphism*

source row a, the base-fixing rows over the base carrier, the root-orbit action rows named by the automorphism ledger, the classifier row c, the stability rows inherited from the FieldExtUp and SeparableExtUp packets, the finite Cont *ledger λ, and the exactness rows named by those packets. This is the complete surface consumed by* $\mathsf{GaloisGroup}^{\uparrow}$ *through* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket semantic name certificate`
Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket public obligation boundary`

Proof. Project the packet to its dependency rows. The FieldExtUp packet supplies the carrier, field-extension classifier, stability, exactness, and ledger rows. The SeparableExtUp packet supplies the minimal-polynomial simple-root row, and Definition 163.7 identifies that row with the separability face of the GaloisExtUp surface.

The normality face is supplied by Definition 163.6. The classifier compatibility needed to place both faces over one carrier is supplied by Definition 163.8. The automorphism source row is the tuple entry a, whose endpoints, base-fixing comparisons, action ledger, and provenance are all named by the same FieldExtUp carrier and ledger rows. Thus every public row is a projection of F, S, n, s, a, c, ρ, or λ.

Conversely, each listed row is part of the source packet and is named by the public GaloisExtUp interface: carrier, normality, separability, automorphism, base-fixing, root action, classifier, stability, ledger, and exactness. Repacking these rows gives exactly the $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ surface available to the downstream $\mathsf{GaloisGroup}^{\uparrow}$ carrier, so no additional obligation row remains hidden. □

Theorem 163.11 (GaloisExtUp dependency exactness ledger)**.** *For the source packet $(F, S, n, s, a, c, \rho, \lambda)$ of Definition 163.1, the dependency ledger for* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *has coverage, soundness, and completeness for exactly these displayed rows: the carrier, classifier, stability, exactness, and ledger rows from* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$*; the simple-root row from* $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$*; the finite normality and root-splitting row; the automorphism source row a; the base-fixing* hsame *rows over the base carrier; the finite root-orbit* Cont *action rows; the* hsame *classifier rows; the finite* Cont *readback rows; and the shared* Pkg *provenance row. No other* NameCert *row is exported by the* $\mathsf{GaloisExt}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket dependency exactness ledger`

Proof. Coverage follows by projecting the tuple in Definition 163.1. Each field listed in the ledger is one of the packet entries or one of the dependency rows displayed by $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ or $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$.

Soundness follows from the preceding rows. The normality projection is Definition 163.6, the separability consumption is Definition 163.7, and the classifier and stability steps are Definition 163.8 and Definition 163.9. Each step uses only BHist projection, hsame comparison, finite Cont readback, and the recorded Pkg provenance.

Completeness follows because a downstream consumer can project only those rows from the packet. The tuple contains no separate host field equality, ambient algebraic-closure object, or hidden separability witness. Therefore every accepted $\mathsf{GaloisExt}^{\uparrow}$ dependency read factors through exactly the displayed ledger rows. □

Definition 163.12 (GaloisExtUp automorphism source row)**.** *For a source packet $(F, S, n, s, a, c, \rho, \lambda)$ of Definition 163.1, the automorphism source row is the finite row a consisting of four displayed parts: the automorphism endpoint rows read through the FieldExtUp carrier in F; the base-fixing* hsame *comparisons over the displayed base carrier; the finite* Cont *action ledger on the roots named*

by n; and the Pkg *provenance readback showing that these rows belong to the same source packet as F.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.TasteGate.GaloisExtTasteGate single carrier alignment`

Theorem 163.13 (GaloisExtUp base-fixed automorphism readback)**.** *For a source packet $(F, S, n, s, a, c, \rho, \lambda)$ of Definition 163.1, every automorphism endpoint displayed by a reads back to a FieldExtUp endpoint in F, and every base-fixing comparison displayed by a is an* hsame *row over the base carrier displayed by F. Consequently the automorphism face exported by* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *contains no host-field equality, quotient representative, or external base carrier.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtAutomorphismSourceRow base fixed readback`

Proof. Project the row a using Definition 163.12. Its endpoint entries are declared to be FieldExtUp carrier endpoints, so their domain and codomain readbacks factor through the carrier and ledger rows of F.

The base-fixing part of a is already expressed as hsame over the base carrier displayed by F. Transport along those comparisons keeps the automorphism endpoints inside the same finite BHist packet and does not require an equality of ambient fields.

Finally read the provenance component through ρ and the ledger component through λ. These two projections record the same source packet for the endpoint rows and the base-fixing rows, so the exported automorphism face is exactly the base-fixed automorphism row named by a. □

Theorem 163.14 (GaloisExtUp normal root orbit closure)**.** *For a source packet $(F, S, n, s, a, c, \rho, \lambda)$ of Definition 163.1, the action ledger in a sends each displayed root endpoint named by the normality row n to another root endpoint named by the same row n. The exported root-orbit surface is therefore a finite* Cont *ledger over the FieldExtUp endpoints already used by the normality face.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtAutomorphismSourceRow normal root orbit closure`
↪ variant `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket normal root orbit closure`

Proof. First project the normality row n. By Definition 163.6, each displayed root endpoint in n is read through the FieldExtUp packet F with its classifier, exactness, ledger, and provenance rows.

Next project the action component of a. By Definition 163.12, this component is a finite Cont ledger whose source and target endpoints are the FieldExtUp endpoints named by the same packet.

Composing the two readbacks gives a root endpoint from n as input and a root endpoint from n as output. The Pkg provenance row ρ records that both endpoints and the action row belong to the same GaloisExtUp source packet, so no additional orbit object is exported. □

Theorem 163.15 (GaloisExtUp GaloisGroup consumer source surface)**.** *For a source packet $(F, S, n, s, a, c, \rho, \lambda)$ of Definition 163.1, the part of* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *consumed by* $\mathsf{GaloisGroup}^{\uparrow}$ *is exactly the FieldExtUp carrier rows, the normal root row n, the separability row s, the automorphism source row a, the base-fixing* hsame *rows, the root-orbit* Cont *action rows, the classifier row c, the shared* Pkg *provenance row ρ, and the finite ledger λ.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket galoisgroup consumer source surface`

Proof. The public obligation boundary Definition 163.10 lists the complete GaloisExtUp surface. Projecting that list to the rows needed by a GaloisGroupUp carrier keeps the FieldExtUp carrier data, the normal and separable faces, and the automorphism source row.

The base-fixed readback theorem Definition 163.13 supplies the base-fixing comparisons from a. The root-orbit theorem Definition 163.14 supplies the finite action rows from a and n.

Conversely, these projected rows are precisely the rows of the source packet that a group construction can consume: endpoints from F, roots from n, separability from s, automorphisms from a, classifiers from c, provenance from ρ, and ledgers from λ. Repacking them gives the same consumer surface, so there is no remaining GaloisGroupUp dependency row outside the displayed packet. □

Theorem 163.16 (GaloisExtUp shared carrier coverage)**.** *For every accepted* $\mathsf{NameCert}_{\mathsf{GaloisExt}^\uparrow}$ *source packet* $(F, S, n, s, a, c, \rho, \lambda)$*, the exported carrier data project to one shared* $\mathsf{NameCert}_{\mathsf{FieldExt}^\uparrow}$ *carrier row from* F *and to one* $\mathsf{NameCert}_{\mathsf{SeparableExt}^\uparrow}$ *simple-root row from* S *over the same* BHist *endpoints. The comparison between the two faces is the* hsame *classifier row* c*, so the accepted packet records no host field equality, quotient carrier, or ambient algebraic-closure equality.*

Proof. Project the accepted packet to its FieldExtUp dependency row. The packet definition makes the carrier, classifier, exactness, and ledger endpoints of the GaloisExtUp carrier surface read from F.

Project the same packet to its SeparableExtUp dependency row. The separability row s is the simple-root row of S after classifier transport into the carrier displayed by F, as in Definition 163.7.

It remains to identify the comparison used by the two projections. Apply Definition 163.8 to the displayed dependency rows. The transport is an hsame comparison on the common finite BHist endpoints, so the shared carrier coverage is exactly the pair of projected rows and does not introduce equality of host fields. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket shared carrier coverage`

Theorem 163.17 (GaloisExtUp normal separable combined exactness)**.** *For every source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the paired normality and separability faces of* $\mathsf{NameCert}_{\mathsf{GaloisExt}^\uparrow}$ *have coverage, soundness, and completeness exactly through the FieldExtUp exactness rows of* F*, the SeparableExtUp simple-root row of* S*, the* hsame *classifier row* c*, the finite* Cont *ledger* λ*, and the shared* Pkg *provenance row* ρ*.*

Proof. Coverage is obtained by projecting the two faces from the source packet. The normality and root-splitting row is n, and Definition 163.6 reads it through the FieldExtUp carrier, classifier, exactness, and ledger rows. The separability row is s, and Definition 163.7 reads it as the transported simple-root row of S.

For soundness, combine those two projections with the dependency ledger. By Definition 163.11, every accepted read of the paired faces is backed by the displayed Cont rows, the hsame classifier row, and the recorded Pkg provenance. Hence an accepted normality or separability face cannot name any row outside the FieldExtUp exactness surface and the SeparableExtUp simple-root surface.

For completeness, start with rows from those two dependency surfaces together with c, ρ, and λ. Repack the normality rows as n and the simple-root rows as s. The same ledger theorem states that these are exactly the exported dependency rows of the GaloisExtUp packet, so the paired normality and separability faces are fully recovered. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket normal separable combined exactness`

Theorem 163.18 (GaloisExtUp GaloisGroup consumer boundary)**.** *Every downstream* $\mathsf{GaloisGroup}^\uparrow$ *consumer of* $\mathsf{NameCert}_{\mathsf{GaloisExt}^\uparrow}$ *may read only the shared carrier row, the normality row, the separability row, the automorphism source row, the base-fixing rows, the root-orbit action rows, the*

classifier row, the stability rows, the exactness rows, the finite ledger rows, and the provenance rows exported by the source packet $(F, S, n, s, a, c, \rho, \lambda)$*. No additional host-field, ambient-closure, quotient, or hidden witness row is part of the consumer surface.*

Proof. Begin with the public obligation boundary. By Definition 163.10, the public surface of the certificate consists of the carrier, normality, separability, automorphism, base-fixing, root-orbit, classifier, stability, ledger, and exactness rows named by the source packet.

Next apply the dependency ledger. The exactness statement of Definition 163.11 says that those rows have coverage, soundness, and completeness only through the displayed FieldExtUp dependency, SeparableExtUp simple-root dependency, hsame classifier, Cont readback, and Pkg provenance.

Finally project a $\mathsf{GaloisGroup}^{\uparrow}$ consumer through this public surface. Since the source packet has no additional host-field equality, ambient-closure row, quotient carrier, or hidden witness entry, the consumer boundary is exactly the listed row family exported by $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket galoisgroup consumer boundary`

Definition 163.19 (GaloisExtUp automorphism consumer surface)**.** *The* $\mathsf{GaloisExt}^{\uparrow}$ *automorphism consumer surface exported to* $\mathsf{GaloisGroup}^{\uparrow}$ *is the finite* BHist *row family read from a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1. It consists of the FieldExtUp carrier and classifier rows, the SeparableExtUp simple-root rows transported into that carrier, the normality and root-splitting rows* n*, the base-endpoint fixed rows obtained from the FieldExtUp base endpoints by* hsame *comparison, the automorphism source row* a*, the automorphism-action rows whose source and target extension endpoints and transported root-splitting endpoints are read through the same packet, the finite* Cont *ledgers that read those rows, and the shared* Pkg *provenance row* ρ*.*

No row of this surface is an ambient automorphism object. Each row is either a dependency projection from F *or* S*, a normality or separability face of the GaloisExtUp packet, an* hsame *comparison between displayed endpoints, a finite* Cont *readback row, or the package provenance recording that source.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtUp StdBridge`

Theorem 163.20 (GaloisExtUp fixed-base automorphism source)**.** *For a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, every fixed-base automorphism row accepted by Definition 163.19 is projected only from the FieldExtUp base endpoints of* F *together with the* hsame *comparisons recorded in the finite GaloisExtUp ledger. Conversely, any such finite family of FieldExtUp base endpoints and* hsame *comparisons repacks as a fixed-base row of the automorphism consumer surface, with the same* Pkg *provenance and no host-field equality clause.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket fixed base automorphism source`

Proof. Project the source packet through Definition 163.1. The FieldExtUp row F supplies the displayed extension carrier, its base endpoints, classifier, exactness rows, and finite ledger. The classifier transport row of Definition 163.8 keeps those endpoints inside the same finite BHist comparison system.

For the forward direction, read an accepted fixed-base row from Definition 163.19. Its base endpoint is one of the endpoints exposed by F, and its fixedness assertion is an hsame comparison in the GaloisExtUp ledger λ. The dependency exactness ledger of Definition 163.11 excludes any further NameCert row, so the projection has no additional source.

For the reverse direction, start with FieldExtUp base endpoints and the displayed hsame comparisons. Repack them as the base-endpoint fixed rows of the consumer surface, attach the same Cont readback rows and Pkg provenance ρ, and use the public obligation boundary of Definition 163.10 to place the result inside the exported GaloisExtUp surface. □

Theorem 163.21 (GaloisExtUp automorphism action source)**.** *For a source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, an automorphism-action row is accepted by Definition 163.19 only when its source extension endpoint, target extension endpoint, and transported root-splitting endpoints are all read through the same GaloisExtUp packet. The action row is therefore a finite* BHist *row over* F, S, n, s, a, c, ρ, *and* λ, *not a row imported from an ambient algebraic-closure carrier.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket automorphism action source`

Proof. Begin with an accepted action row. Its source and target endpoints are extension endpoints of the FieldExtUp carrier displayed by F. Its root-splitting endpoints are the normality endpoints of n, and Definition 163.6 reads those endpoints from F by finite BHist projections.

The separability face contributes only the transported simple-root rows of S. By Definition 163.7, these rows enter the action surface after transport by c into the FieldExtUp carrier. Thus the action source, target, and transported splitting data all share the same packet provenance.

Finally apply Definition 163.11. The ledger has no row for an ambient algebraic-closure object or external automorphism carrier. Repacking the displayed source endpoint, target endpoint, root-splitting endpoints, Cont rows, and Pkg provenance therefore gives exactly the accepted automorphism-action row. □

Theorem 163.22 (GaloisExtUp GaloisGroupUp consumer automorphism surface)**.** *For every source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the surface of Definition 163.19 is exactly the* $\mathsf{GaloisExt}^{\uparrow}$ *consumer surface available to* $\mathsf{GaloisGroup}^{\uparrow}$. *It exposes the FieldExtUp carrier and classifier rows, SeparableExtUp simple-root rows, normality and root-splitting rows, fixed-base endpoint rows, the automorphism source row, automorphism-action rows, finite* Cont *ledgers, and* Pkg *provenance. It exposes no host automorphism equality, no quotient of automorphisms, and no ambient algebraic-closure object.*

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtAutomorphismConsumerSurface galoisgroup boundary`

Proof. First project the public GaloisExtUp packet. The public obligation boundary of Definition 163.10 gives the extension carrier, classifier, normality, separability, stability, ledger, exactness, and provenance rows. The dependency exactness ledger of Definition 163.11 says these are all the dependency rows exported by the packet.

Next add the automorphism-facing rows. Fixed-base rows are exactly the projections described in Definition 163.20; automorphism-action rows are exactly the projections described in Definition 163.21. Both constructions use only BHist endpoints, hsame comparisons, finite Cont readback, and Pkg provenance already present in the GaloisExtUp packet.

Conversely, the GaloisGroupUp carrier definition consumes no more than these rows from its GaloisExtUp dependency: its fixed-base and action clauses are read through displayed endpoints and ledgers. Since the GaloisExtUp packet contains no host automorphism equality, no automorphism quotient, and no ambient algebraic-closure object, the listed row family is exactly the consumer automorphism surface available downstream. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket galoisgroup consumer automorphism surface`

Theorem 163.23 (GaloisExtUp public ledger coverage)**.** *For every scoped source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the public ledger visible to* $\mathsf{GaloisExt}^{\uparrow}$ *is exhausted by the* $\mathsf{FieldExt}^{\uparrow}$ *carrier and classifier rows, the* $\mathsf{SeparableExt}^{\uparrow}$ *simple-root rows, the automorphism-source and action rows, the finite* BHist *endpoints, the displayed* hsame *transport rows, the* Cont *ledgers, and the* Pkg *provenance. No public ledger row exports a normal-basis theorem, host quotient field, ambient algebraic closure, or automorphism quotient.*

Proof. Project the scoped source packet through Definition 163.10. The projected packet lists the FieldExtUp, SeparableExtUp, normality, separability, stability, ledger, exactness, and provenance rows available at the public boundary.

Apply Definition 163.11. It identifies those projected rows as the complete dependency ledger and rules out extra host quotient-field, algebraic-closure, and automorphism-quotient slots.

Finally add the automorphism-facing projections of Definition 163.20 and Definition 163.21. These projections are still read through finite BHist endpoints, hsame transports, Cont ledgers, and Pkg provenance, so the listed public ledger is exhausted. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket public ledger coverage`

Theorem 163.24 (GaloisExtUp public interface export)**.** *For every scoped source packet* $(F, S, n, s, a, c, \rho, \lambda)$ *of Definition 163.1, the scoped* $\mathsf{FieldExt}^{\uparrow}$ *carrier and classifier rows,* $\mathsf{SeparableExt}^{\uparrow}$ *simple-root rows, finite* BHist *endpoints, displayed* hsame *transports,* Cont *ledgers,* Pkg *provenance, and automorphism-source rows assemble a public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *interface. The exported interface contains exactly the public rows covered by Definition 163.23; it exports no normal-basis theorem and no host quotient field.*

Proof. First project the scoped source packet. The public obligation boundary of Definition 163.10 supplies the FieldExtUp carrier and classifier rows, the SeparableExtUp simple-root rows, the normality and separability rows, the finite BHist endpoints, the hsame transports, the Cont ledgers, and the Pkg provenance.

Next transport the classifier-facing rows through the already displayed source surface. The source packet theorem Definition 163.10 packages these rows as the scoped NameCert surface, and Definition 163.23 says that the public ledger has no further dependency row to export.

Finally repackage the resulting boundary as a public $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ interface. The automorphism-source rows are exactly the fixed-base and action rows of Definition 163.20 and Definition 163.21; the ledger exactness prevents any normal-basis theorem or host quotient field from entering the exported interface. □

Lean4 ✓ `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket public interface export`

Closure status for $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$**.**

Constructive story: A Galois extension is assembled as a finite history packet whose first face is a $\mathsf{FieldExt}^{\uparrow}$ source row, whose second face is a $\mathsf{SeparableExt}^{\uparrow}$ simple-root row over the same displayed extension, and whose remaining faces record normality, separability, base-fixed automorphism sources, action rows, classifier transport, ledger entries, and package provenance. The carrier accepts exactly packets whose normality and separability faces are read through those dependency certificates, while rows requiring an ambient algebraic closure, host-field equality, or an automorphism quotient have no field in the packet. Two accepted packets classify together only when their FieldExt, SeparableExt, normality, separability, automorphism, classifier, provenance, and finite ledger faces are transported by hsame inside one signature surface. The source specification is the whole accepted packet, the pattern specification is the visible normal-and-separable field-extension shape together with the automorphism source surface, and the ledger keeps each raw dependency row aligned with its visible public face through Cont and Pkg provenance. Since an accepted packet supplies an endpoint, hsame supplies reflexivity, symmetry, and transitivity, and the classifier-transport rows repack any classified endpoint back into the same carrier, the five naming-certificate obligations hold at this scoped surface. A history h lies in the signature GAP of a $\mathsf{GaloisExt}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer

packet and evidence ledger, and token introduction names that answer as p; after unpacking, this says exactly that the FieldExt carrier, SeparableExt simple-root row, normality row, and base-fixed action rows all share the same finite BHist provenance. The chapter registers this construction as $\mathsf{GaloisExt}^{\uparrow}$ without closing the Galois correspondence, algebraic closure, automorphism quotient, or standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface binds the current FieldExtUp carrier and classifier rows, SeparableExtUp simple-root rows, normality and separability obligations, automorphism-source and action rows, BHist endpoints, hsame classifier transport, Cont ledgers, and Pkg provenance surface displayed in this chapter.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.GaloisExtUp.GaloisExtSourcePacket\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: This chapter does not close the full Galois correspondence, algebraic closure, automorphism quotient, or standard bridge.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 164

A Concrete Naming Certificate for $\mathsf{GaloisGroup}^{\uparrow}$

The Galois-group interface $\mathsf{GaloisGroup}^{\uparrow}$ packages the group of field automorphisms of a Galois extension fixing the base field pointwise. It depends on $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ (chapter 163) and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41).

164.1 Carrier definition

Definition 164.1 (GaloisGroupUp BHist automorphism-action packet)**.** *A* $\mathsf{GaloisGroup}^{\uparrow}$ *automorphism-action packet is a finite* BHist *tuple* $(E, G, b, a, m, i, c, \rho, \lambda)$ *over two consumed dependency packets. The row* E *is a* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *packet, read through its public extension carrier, normality, separability, classifier, exactness, and ledger surface. The row* G *is a* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *packet, read through its operation, unit, inverse, associativity, congruence, and inverse-law surface.*

The row b *is the fixed-base row. It records, for each displayed base-field endpoint of* E*, that the automorphism endpoint leaves that base endpoint in the same* hsame *class. The row* a *is the automorphism-action row: source and target extension endpoints are finite* BHist *endpoints from* E*, and the action is carried only by* Cont *rows and the displayed classifier of* E*. The unit row is read from the* $\mathsf{Group}^{\uparrow}$ *unit endpoint of* G *and the GaloisExtUp identity classifier of* E*. The row* m *is the composition row, aligning the* $\mathsf{Group}^{\uparrow}$ *multiplication operation of* G *with composition of the displayed automorphism-action rows. The row* i *is the inverse row, aligning the* $\mathsf{Group}^{\uparrow}$ *inverse operation of* G *with inverse automorphism-action rows.*

The row c *is the classifier row. It compares automorphism packets by* hsame *on their finite extension endpoints, fixed-base rows, action rows, composition rows, and inverse rows, without requiring equality of host fields, ambient function spaces, or quotient representatives. The row* ρ *is the* Pkg *provenance row assigning every displayed face to either the Galois-extension packet* E*, the group packet* G*, or the Galois-group automorphism surface. The finite ledger* λ *is the* Cont *list containing exactly the dependency rows, fixed-base rows, identity rows, action rows, composition rows, inverse rows, classifier rows, provenance rows, and exactness rows consumed by the public* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *interface.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket dependency surface`

164.2 The certificate

Theorem 164.2 (GaloisGroupUp fixed-base carrier obligation)**.** *For an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1, carrier acceptance for* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *is exactly acceptance of fixed-base automorphism rows whose extension endpoints are read from the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *surface of* E *and whose operation endpoints are read from the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *surface of* G*. No carrier clause asks for equality of host fields, ambient endomorphism sets, or uncarried base-field elements.*

Proof. Project the packet to E and G. The Galois-extension public boundary of Definition 163.10 supplies the extension carrier, classifier, exactness, normality, separability, and finite ledger rows. The group certificate supplies the operation surface, inverse surface, congruence rows, and inverse-law rows through the $\mathsf{Group}^{\uparrow}$ public packet.

For the forward direction, carrier acceptance exposes a fixed-base automorphism row. Reading the row through Definition 164.1 projects each extension endpoint to E, each multiplication or inverse endpoint to G, and each fixed-base comparison to an hsame row in the finite ledger λ. Thus the accepted carrier is only a displayed BEDC row family over the two consumed packets.

For the reverse direction, start with fixed-base automorphism rows whose endpoints are already read from E and G with the stated ledger and package provenance. Repack those rows as b and a, attach the classifier row c, and retain the same Pkg row ρ and Cont ledger λ. This constructs the carrier face of $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ without adding any host-field equality clause. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket fixed base carrier obligation`

Theorem 164.3 (GaloisGroupUp fixed-base classifier)**.** *For two accepted automorphism-action packets* $(E, G, b, a, m, i, c, \rho, \lambda)$ *and* $(E', G', b', a', m', i', c', \rho', \lambda')$ *of Definition 164.1, the fixed-base automorphism classifier is the conjunction of the inherited* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *classifier on the extension packets, the inherited* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *classifier on the operation packets, and the* hsame *comparisons of the displayed fixed-base, action, composition, and inverse rows. In particular, two rows are classified only through the dependency surfaces and endpoint comparison inside the finite automorphism-action packet.*

Proof. Project each accepted automorphism-action packet to its E and G rows. Definition 163.10 says that the available extension information is precisely the carrier, normality, separability, classifier, stability, ledger, and exactness surface of the extension packet. The group certificate supplies only the operation, unit, inverse, congruence, and inverse-law rows exposed by its public packet.

Now inspect the automorphism-specific rows. The fixed-base, action, composition, and inverse rows are all finite BHist rows inside Definition 164.1. Their comparisons are therefore exactly the restricted hsame rows recorded in the finite ledger λ and its counterpart.

Combining the projected dependency classifiers with these row comparisons gives the stated classifier. Reflexive, symmetric, and transitive uses are inherited from the dependency classifiers and from the structural hsame laws, and repacking those rows returns an accepted fixed-base automorphism-action packet. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket fixed base classifier public surface`

Theorem 164.4 (GaloisGroupUp composition closure)**.** *Let* x *and* y *be accepted fixed-base automorphism-action rows of Definition 164.1. If the target endpoint of* x *is* hsame*-classified with the source endpoint of* y*, and the packet contains a displayed* Cont *row composing their automorphism ledgers,*

then the composed row is again accepted by the $\mathsf{GaloisGroup}^{\uparrow}$ *automorphism-action packet. Its fixed-base witness is obtained by composing the two fixed-base witness rows and transporting the middle endpoint through* hsame*.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket composition closure`

Proof. Read the two accepted rows through the same packet shape. Each supplies a $\mathsf{GaloisExt}^{\uparrow}$ projection, a $\mathsf{Group}^{\uparrow}$ projection, a displayed automorphism-action row, endpoint rows, a fixed-base row, classifier rows, and Pkg provenance through Definition 164.1.

The displayed Cont row concatenates the two automorphism ledgers. The middle endpoint comparison supplies the transport needed to align the target of x with the source of y, so the concatenated ledger has the source endpoint of x and the target endpoint of y.

For the fixed-base face, compose the two fixed-base witness rows. Since each row fixes the base endpoint pointwise inside the inherited GaloisExtUp surface, the composite fixes the same base endpoint after transporting the middle row by hsame.

Finally, repack the dependency projections, composed display, endpoints, fixed-base witness, Cont ledger, classifier rows, and Pkg provenance. The result is one of the finite packets accepted by the carrier, so composition is closed. □

Theorem 164.5 (GaloisGroupUp inverse closure)**.** *Every accepted automorphism-action row of Definition 164.1 exposes an inverse row through the* $\mathsf{Group}^{\uparrow}$ *dependency surface. The inverse row reverses the displayed source and target endpoints, carries the inverse automorphism ledger supplied by* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$*, preserves the same fixed-base endpoint up to* hsame*, and is accepted by the same* $\mathsf{GaloisGroup}^{\uparrow}$ *packet.*

Proof. Unpack the accepted automorphism-action row into its source GaloisExtUp packet, GroupUp packet, displayed action row, endpoints, fixed-base witness, classifier rows, composition ledger, inverse row, and Pkg provenance.

Use the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ dependency cited in chapter 41. Its inverse surface supplies the inverse operation row together with the left-unit and right-unit classification rows for the automorphism ledger. These rows reverse the displayed source and target endpoints.

The fixed-base witness is stable under this reversal because the original row fixes the base endpoint and the inverse ledger is classified with the identity row on that endpoint by the GroupUp inverse laws. Transport the displayed base comparison by hsame to obtain the fixed-base row for the inverse.

Repack the reversed endpoints, inverse ledger, fixed-base witness, inherited dependency projections, classifier rows, and Pkg provenance. This is again a finite packet of the form required by Definition 164.1. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket inverse action boundary`
↪ variant `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket inverse closure`

Theorem 164.6 (GaloisGroupUp unit automorphism row)**.** *For an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1, the unit row inherited from the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *dependency* G *repacks as the fixed-base identity automorphism row on every endpoint accepted by the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *boundary of* E*. The resulting row is classified by the same* $\mathsf{GaloisGroup}^{\uparrow}$ *classifier as the displayed identity action, and its ledger uses only the unit, operation, congruence, and endpoint rows already carried by* G*,* E*, and* λ*.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket unit automorphism row`

Proof. Project the packet by Definition 164.1. The Galois-extension side is the public boundary of Definition 163.10, so every endpoint under discussion is an accepted extension endpoint with classifier, exactness, and finite ledger rows in E.

On the group side, read the operation, unit, associativity, congruence, and two-sided inverse-law surface from the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ packet named in chapter 41. The unit operation endpoint is therefore already a carried row of G.

Repack that unit endpoint as the identity automorphism-action row. Its fixed-base face is the identity comparison on each base endpoint of E, and the same endpoint is transported through the hsame rows in λ. Definition 164.4 supplies compatibility with the composition row, while Definition 164.5 supplies the inverse-facing row needed by the same packet.

The resulting finite tuple has exactly the rows required by Definition 164.1. Hence the inherited GroupUp unit row is the GaloisGroupUp fixed-base identity automorphism row. □

Theorem 164.7 (GaloisGroupUp composition associativity row)**.** *Let x, y, and z be accepted fixed-base automorphism-action rows of an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1. Suppose the target endpoint of x is* hsame*-classified with the source endpoint of y, the target endpoint of y is* hsame*-classified with the source endpoint of z, and the two finite* Cont *parenthesizations $(z \circ y) \circ x$ and $z \circ (y \circ x)$ are both displayed by the composition row m. Then the two parenthesized rows are classified by the inherited* $\mathsf{Group}^{\uparrow}$ *associativity row, transported along the endpoint* hsame *rows from the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *boundary of E.*

Proof. Project x, y, and z through Definition 164.1. The GaloisExtUp public boundary of Definition 163.10 supplies the accepted source, middle, and target endpoints together with the classifier rows that identify the two displayed middle endpoints.

Apply Definition 164.4 first to x and y, then to the resulting row and z. This constructs the finite Cont row for $(z \circ y) \circ x$ with the required fixed-base witness and provenance.

Apply Definition 164.4 in the other order, first to y and z and then to x with the result. This constructs the finite Cont row for $z \circ (y \circ x)$ over the same outer endpoints.

The $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ dependency G supplies the operation, unit, associativity, congruence, and two-sided inverse-law surface named in chapter 41. Its associativity row classifies the two operation parenthesizations in G, and the endpoint hsame rows from E transport that classification to the displayed automorphism-action rows.

Repacking the transported classifier, the two composition ledgers, the fixed-base witnesses, and the Pkg provenance gives the claimed GaloisGroupUp classifier row. □

Theorem 164.8 (GaloisGroupUp inverse cancellation rows)**.** *For every accepted fixed-base automorphism-action row x of an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, let x^{-1} be the inverse row supplied by Definition 164.5. The composed rows $x^{-1} \circ x$ and $x \circ x^{-1}$ are accepted by Definition 164.4 and are classified with the unit automorphism row of Definition 164.6 by the inherited left and right inverse laws of the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *dependency, with endpoint transport through the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *boundary.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionCompositionPacket inverse cancellation rows`

Proof. Start with the accepted row x and unpack it using Definition 164.1. The endpoint rows, fixed-base row, classifier row, inverse row, provenance row, and finite ledger all live in the same packet, while Definition 163.10 supplies the public GaloisExtUp classifier rows needed for endpoint transport.

Use Definition 164.5 to obtain the accepted inverse row x^{-1}. Its source and target are the reversed endpoints of x, and its fixed-base witness is transported by the same hsame comparisons on the base endpoint.

Apply Definition 164.4 to x followed by x^{-1}, and again to x^{-1} followed by x. These applications produce the two finite composition ledgers and preserve the fixed-base witness on both sides.

The $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ packet G supplies the operation, unit, congruence, associativity, and two-sided inverse-law rows from the GroupUp surface named in chapter 41. The right inverse law classifies $x \circ x^{-1}$ with the unit row, and the left inverse law classifies $x^{-1} \circ x$ with the unit row.

Finally, Definition 164.6 identifies that unit row with the fixed-base identity automorphism row over E. Repacking the two inverse-law classifications with the endpoint hsame transports and the ledger λ gives the two claimed GaloisGroupUp cancellation rows. □

Theorem 164.9 (GaloisGroupUp identity row closure)**.** *For an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1, the* $\mathsf{Group}^{\uparrow}$ *unit row of* G*, read through the GaloisExtUp identity classifier of* E *and the fixed-base row* b*, is an accepted* $\mathsf{GaloisGroup}^{\uparrow}$ *automorphism-action row. It fixes every displayed base endpoint by* hsame*, carries only rows listed in* λ*, and uses no equality of host fields or ambient automorphism sets.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket identity row closure`

Proof. Project the packet to its consumed rows E and G. The Galois-extension projection supplies the displayed extension endpoints, the identity classifier, and the exactness rows on the public extension surface. The group projection supplies the unit endpoint, the unit classifier rows, and the provenance needed to read the unit as a finite BHist row.

Now combine those projections with the fixed-base row b. For each displayed base endpoint, the identity classifier leaves the endpoint in its original hsame class, and b records that this comparison is part of the finite automorphism ledger. Thus the unit action fixes every displayed base endpoint.

Finally, repack the base row, identity action row, classifier row c, provenance row ρ, and the same finite ledger λ. The resulting row has the packet shape required by Definition 164.1, so it is accepted by the public $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ carrier. □

Theorem 164.10 (GaloisGroupUp composition classifier congruence)**.** *Let* x, x', y, y' *be accepted fixed-base automorphism-action rows in an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1. Suppose* x *is classified with* x'*,* y *is classified with* y'*, the target endpoint of* x *is classified with the source endpoint of* y*, and the target endpoint of* x' *is classified with the source endpoint of* y'*. Then the composite of* x *with* y *is classified with the composite of* x' *with* y'*. The classification uses only inherited GaloisExtUp classifier transport,* $\mathsf{Group}^{\uparrow}$ *operation congruence,* hsame*,* Cont*, and* Pkg *provenance from the packet.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket composition classifier congruence`
Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionCompositionPacket classifier sameSig congruence`

Proof. First transport the extension faces. The GaloisExtUp classifier of E transports source, middle, and target endpoints across the displayed hsame rows, and the Cont rows in λ record the two compatible composition ledgers.

Next transport the fixed-base faces. Since x is classified with x' and y is classified with y', their fixed-base witnesses compare by the classifier row c. The middle endpoint comparisons align the

two ways of reading the shared extension endpoint, so the composed fixed-base witness is again compared by hsame.

Apply the $\mathsf{Group}^{\uparrow}$ operation congruence from G to the operation endpoints underlying the two composites. The Pkg row ρ identifies these operation endpoints as dependency rows from G, while the acted-on extension endpoints remain dependency rows from E.

Repack the transported source, middle, target, fixed-base, operation, and ledger rows as the composed classifier row. This gives classifier-equivalent composites without introducing any host automorphism equality. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionCompositionPacket classifier congruence`

Theorem 164.11 (GaloisGroupUp automorphism ledger exactness)**.** *For an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, the public ledger λ hides exactly the dependency rows, fixed-base rows, identity rows, action rows, composition rows, inverse rows, classifier rows, provenance rows, and exactness rows exposed by the* $\mathsf{GaloisGroup}^{\uparrow}$ *automorphism surface. Every public consumer of the packet factors through those rows and does not require host automorphism equality, equality of ambient function spaces, or equality of uncarried quotient representatives.*

Proof. Project the packet coordinates. The rows E and G give the dependency surfaces, b gives the fixed-base surface, the unit endpoint of G with the identity classifier of E gives the identity surface, m gives composition, i gives inverse, c gives classifier comparison, and ρ gives provenance. The exactness rows are precisely the exactness rows already named by the dependency packets and the automorphism-action surface.

These projected rows account for every public operation used by a $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ consumer. Carrier acceptance uses the dependency and fixed-base rows; identity uses the unit and identity-classifier rows; composition and inverse use m and i; classifier transport uses c together with hsame and Cont; provenance uses ρ.

Conversely, start from exactly those finite rows and their Pkg assignments. Repacking them as E, G, b, a, m, i, c, ρ, and λ reconstructs the public automorphism-action packet. Since no coordinate contains host automorphism equality, no consumer can depend on such an equality through the public ledger. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket automorphism ledger exactness`

Theorem 164.12 (GaloisGroupUp inverse involution row)**.** *For every accepted fixed-base automorphism-action row x of an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, let x^{-1} be the inverse row supplied by Definition 164.5, and let $(x^{-1})^{-1}$ be the inverse row obtained by applying the same closure row to x^{-1}. Then $(x^{-1})^{-1}$ is accepted by the same packet and is classified with x by the inherited inverse-involutivity row of the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *dependency, transported through the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *endpoint classifier. The classification uses only the fixed-base row b, the inverse row i, the classifier row c, the provenance row ρ, and the finite ledger λ.*

Proof. Unpack the accepted row x through Definition 164.1. Its source and target endpoints are public GaloisExtUp endpoints from E, its operation endpoint is a public GroupUp endpoint from G, and its fixed-base face is an hsame comparison over the displayed base endpoint.

Apply Definition 164.5 to x. The resulting row x^{-1} is accepted by the same packet, has the source and target endpoints reversed, and carries the inverse operation endpoint supplied by the

$\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ surface of G. Its fixed-base face is transported along the same base-endpoint hsame comparisons listed in λ.

Apply Definition 164.5 again to x^{-1}. This gives an accepted row $(x^{-1})^{-1}$ whose displayed endpoints have been reversed back to the orientation of x. The public boundary Definition 163.10 supplies the GaloisExtUp classifier rows identifying these twice-transported endpoints with the original source and target endpoints of x.

On the group side, the inverse operation endpoint of $(x^{-1})^{-1}$ is classified with the operation endpoint of x by the inverse-involutivity law of the GroupUp dependency, for instance Definition 41.57. The same law may be read through the right-inverse presentation of Definition 41.58; both readings land in the classifier surface already named by G.

Transport that GroupUp classifier comparison across the endpoint classifier of E. The fixed-base witnesses match because both x and $(x^{-1})^{-1}$ fix the same displayed base endpoint after the two endpoint transports, and the classifier row c compares exactly the endpoint, fixed-base, action, and inverse faces recorded in the packet. Repacking these comparisons with ρ and λ gives the claimed GaloisGroupUp classifier row between $(x^{-1})^{-1}$ and x. □

Theorem 164.13 (GaloisGroupUp inverse of composition row)**.** *Let x and y be accepted fixed-base automorphism-action rows of an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1. Suppose the target endpoint of y is* hsame*-classified with the source endpoint of x, so that $x \circ y$ is an accepted composite by Definition 164.4. Let $(x \circ y)^{-1}$ be the inverse row supplied by Definition 164.5, and let x^{-1} and y^{-1} be the inverse rows of x and y. Then the row $y^{-1} \circ x^{-1}$ is accepted by the same packet and is classified with $(x \circ y)^{-1}$ by the public GaloisGroupUp classifier. The comparison is the inverse-of-product row of the inherited* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *surface, transported through the endpoint classifier of the public* $\mathsf{NameCert}_{\mathsf{GaloisExt}^\uparrow}$ *boundary.*

Proof. Unpack x and y through Definition 164.1. Their source and target endpoints are public GaloisExtUp endpoints from E, their operation endpoints are public GroupUp endpoints from G, and the displayed middle endpoint comparison is an hsame row in the finite ledger λ.

Apply Definition 164.4 to the composable pair y followed by x. This gives the accepted composite $x \circ y$, with source endpoint the source of y, target endpoint the target of x, fixed-base witness obtained by composing the two fixed-base witnesses, and operation endpoint read through the multiplication row m of G.

Apply Definition 164.5 to this composite. The row $(x \circ y)^{-1}$ is accepted, has the reversed outer endpoints, and carries the inverse operation endpoint of the GroupUp product underlying $x \circ y$. Apply the same inverse-closure row separately to x and to y. The target endpoint of x^{-1} and the source endpoint of y^{-1} are the same middle endpoint comparison, read in the reversed direction through the public boundary of Definition 163.10. Hence another use of Definition 164.4 accepts the composite $y^{-1} \circ x^{-1}$ over the same reversed outer endpoints as $(x \circ y)^{-1}$.

On the GroupUp side, let the operation endpoints of x and y be read as g_x and g_y inside the packet G. The composition row m reads the operation endpoint of $x \circ y$ as the product $g_x g_y$, while the inverse row i reads the operation endpoints of x^{-1} and y^{-1} as g_x^{-1} and g_y^{-1}. The inherited inverse-of-product law Definition 41.65 gives the internal classifier row

$$\mathsf{hsame}((g_x g_y)^{-1}, g_y^{-1} g_x^{-1}).$$

Thus the GroupUp operation endpoint carried by $(x \circ y)^{-1}$ is classified with the GroupUp operation endpoint carried by $y^{-1} \circ x^{-1}$.

Transport this GroupUp classifier comparison through the GaloisExtUp endpoint classifier. The source endpoint of $(x \circ y)^{-1}$ and the source endpoint of $y^{-1} \circ x^{-1}$ are both the target endpoint

of x, and their target endpoints are both the source endpoint of y, up to the displayed hsame rows from E. The fixed-base witnesses also match: inverse closure preserves the fixed-base comparison for each row, and composition closure composes those fixed-base comparisons along the same middle endpoint transport.

Finally use the classifier surface described in Definition 164.3. Its clauses compare exactly the dependency classifiers, extension endpoints, fixed-base rows, action rows, composition rows, inverse rows, and Pkg provenance recorded by $(E, G, b, a, m, i, c, \rho, \lambda)$. Repacking the endpoint transports, the GroupUp inverse-of-product classifier, the two composition ledgers, the fixed-base witnesses, and the shared provenance row ρ gives the claimed GaloisGroupUp classifier row between $(x \circ y)^{-1}$ and $y^{-1} \circ x^{-1}$. □

Theorem 164.14 (GaloisGroupUp identity automorphism row)**.** *For an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, the unit row of the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *surface of G, together with the classifier and endpoint rows of the* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *surface of E, determines an accepted fixed-base identity automorphism row on every displayed extension endpoint. The row is a finite* BHist *row whose action ledger is a* Cont *identity readback, whose fixed-base witness is repacked through* hsame*, and whose* Pkg *provenance remains the pair of dependency packets E and G.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket identity automorphism row`

Proof. Project the packet to its Galois-extension row E and group row G. The $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ dependency supplies the unit endpoint and the group unit surface, while $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ supplies the displayed extension endpoints, classifier rows, exactness rows, and finite endpoint ledger.

Choose one displayed extension endpoint of E. The identity action keeps that source and target endpoint in the same hsame class, so its action face is a finite BHist row read by the singleton Cont ledger for the endpoint. The fixed-base face is the same base endpoint comparison already recorded by the GaloisExtUp classifier.

Repack the unit endpoint from G, the identity action row over E, the fixed-base hsame witness, the classifier row c, the provenance row ρ, and the ledger λ. This is exactly one accepted fixed-base automorphism-action row of the packet, with no ambient automorphism equality added. □

Theorem 164.15 (GaloisGroupUp composition associativity ledger)**.** *Let x, y, and z be accepted fixed-base automorphism-action rows of Definition 164.1 whose displayed source and target endpoints are composable by* hsame *comparisons in the* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *packet E. The two parenthesized finite* Cont *composition ledgers, first composing x with y and then with z, or first composing y with z and then with x, classify the same final extension endpoint. The comparison is the inherited associativity row of* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *transported through the GaloisExtUp endpoint classifier, with the same* BHist *rows and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket composition associativity public surface`

Proof. Read x, y, and z through the common packet. Each row exposes a BHist source endpoint, target endpoint, fixed-base witness, action ledger, classifier row, and Pkg provenance, while the composability assumptions give the two middle hsame transports inside E.

Form the two finite Cont ledgers. On the group side, the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ associativity row identifies the two parenthesized operation rows. On the extension side, the $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$

classifier transports the intermediate endpoints so both ledgers have the same source endpoint from x and the same target endpoint from z.

The fixed-base witnesses compose along the same endpoint transports, so both parenthesized rows keep every displayed base endpoint in its original hsame class. Repacking the common endpoints, the reassociated ledger, the classifier row, and the unchanged provenance row ρ gives a single GaloisGroupUp classifier comparison between the two ledgers. □

Theorem 164.16 (GaloisGroupUp unit action laws)**.** *For every accepted fixed-base automorphism-action row x of Definition 164.1, composing x on the left or on the right with the identity row of Definition 164.14 classifies back to x. Both unit compositions are finite* BHist *rows: their* Cont *ledgers use the left and right unit rows of* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$*, their endpoint transports use the* $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ *classifier, their fixed-base witnesses are carried by* hsame*, and their* Pkg *provenance is unchanged.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket unit action laws`

Proof. Start with the accepted row x and project its dependency data. The identity row supplied by Definition 164.14 has the same displayed endpoint system from E and the unit endpoint from G, so it can be composed with x on either side whenever the finite endpoint ledgers match by hsame.

For the left composition, use the left unit law in the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ surface and transport the acted-on endpoint through the $\mathsf{NameCert}_{\mathsf{GaloisExt}^{\uparrow}}$ classifier. For the right composition, use the right unit law and the same endpoint classifier. In both cases the resulting Cont ledger is classified with the original action ledger of x.

It remains to check the fixed-base face. The fixed-base carrier obligation of Definition 164.2 says this face is only the displayed base endpoint plus its hsame comparison, and the identity row preserves that comparison. Repacking the original row x, the unit law transport, and the same Pkg provenance gives the two stated unit classifications. □

Theorem 164.17 (GaloisGroupUp composition and inverse obligation)**.** *For an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, the composition row m and inverse row i remain in the same Galois-group classifier exactly when their displayed endpoints are transported by finite* Cont *rows,* hsame *comparisons, and* Pkg *provenance from the Galois-extension packet E and the group-operation packet G.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket composition inverse obligation`

Proof. First isolate the composition row. The operation endpoint in m is the $\mathsf{Group}^{\uparrow}$ multiplication row, while the acted-on endpoints are extension histories from E. Group congruence transports the multiplication endpoint, and the Galois-extension classifier transports the acted-on endpoints. The ledger λ records both transports as finite Cont rows.

Next isolate the inverse row. The inverse endpoint in i is the $\mathsf{Group}^{\uparrow}$ inverse row, and the inverse action endpoints are again displayed extension histories from E. The inverse congruence and inverse laws from the group surface keep the operation in the same classifier, while the fixed-base row b keeps the base endpoints in their original hsame classes.

Combining the two rows gives the stated equivalence. If composition and inverse endpoints are transported by Cont, hsame, and Pkg, then m and i repack into the classifier row c. Conversely, projecting c exposes precisely those finite transports and no additional ambient automorphism equality. □

Theorem 164.18 (GaloisGroupUp identity action row)**.** *For an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1, the unit row of the group packet* G *gives a displayed identity automorphism-action row on every extension endpoint carried by* E*. This row fixes every displayed base-field endpoint by* hsame *and is accepted by the same finite* $\mathsf{GaloisGroup}^{\uparrow}$ *automorphism-action packet using only* BHist*,* Cont*,* Pkg*, and the inherited* $\mathsf{GaloisExt}^{\uparrow}$ *classifier.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket identity action row`

Proof. Unpack the automorphism-action packet. By Definition 164.1, the only available dependency data are the Galois-extension packet E, the group packet G, the fixed-base row b, the action row a, the composition row m, the inverse row i, the classifier row c, the package row ρ, and the finite ledger λ.

The public Galois-extension boundary of Definition 163.10 supplies the extension endpoints and their classifier rows. The fixed-base carrier obligation of Definition 164.2 supplies the hsame base-field comparison for a displayed automorphism row over those endpoints.

Read the unit endpoint from the $\mathsf{Group}^{\uparrow}$ dependency packet G. Its displayed unit ledger acts as the identity action on each extension endpoint, and the fixed-base row transports the base endpoint back to its original hsame class. The composition and inverse controls of Definition 164.4, Definition 164.5, and Definition 164.17 ensure that this unit row lies in the same accepted automorphism-action classifier as the rows already carried by the packet.

Repack the dependency projections, unit action ledger, fixed-base witness, classifier row, Cont readbacks, and shared Pkg provenance. The result is a finite accepted row of the original packet, so the identity action is public without exporting a host automorphism function. □

Theorem 164.19 (GaloisGroupUp associative composition row)**.** *For three composable accepted automorphism-action rows in an automorphism-action packet of Definition 164.1, the left-associated and right-associated composite ledgers are classified by the same* $\mathsf{GaloisGroup}^{\uparrow}$ *row. The comparison is obtained from the* $\mathsf{Group}^{\uparrow}$ *associativity row together with the middle-endpoint* hsame *transports exposed by the* $\mathsf{GaloisExt}^{\uparrow}$ *surface.*

Proof. Unpack the three accepted action rows through Definition 164.1. Each row has extension endpoints from E, group-operation endpoints from G, fixed-base witnesses, classifier entries, Cont ledger entries, and the shared Pkg provenance row.

The endpoint alignments come from the Galois-extension public boundary Definition 163.10. Those classifier rows transport the first middle endpoint to the second source endpoint and the second middle endpoint to the third source endpoint inside the finite ledger λ.

Apply the composition closure of Definition 164.4 twice, once to form the left-associated ledger and once to form the right-associated ledger. The group packet G contributes the $\mathsf{Group}^{\uparrow}$ associativity row, and Definition 164.17 identifies the two composition ledgers through the same finite Cont and hsame transports.

The inverse closure of Definition 164.5 supplies the same accepted classifier controls for the operation endpoints that appear in the association comparison. Repack the two associated ledgers, their fixed-base witnesses, the dependency projections, and the shared package row. The repacked classifier proves that associativity is an action-ledger row of the original finite packet. □

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket associative action row`

Theorem 164.20 (GaloisGroupUp action ledger exactness)**.** *For an automorphism-action packet* $(E, G, b, a, m, i, c, \rho, \lambda)$ *of Definition 164.1, the public action ledger is exactly the fixed-base row,*

identity row, composition row, inverse row, classifier row, dependency projections to E and G, finite Cont *readbacks, and shared* Pkg *provenance. No host automorphism function space, quotient of automorphisms, or uncarried equality of field presentations is exported.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket action ledger exactness`

Proof. Project the packet along Definition 164.1. The projection exposes only E, G, b, a, m, i, c, ρ, and λ together with the dependency rows recorded inside the two consumed NameCert packets.

The Galois-extension public boundary Definition 163.10 accounts for all extension carrier, classifier, exactness, and ledger rows from E. The fixed-base carrier obligation Definition 164.2 accounts for the base-fixing face of the action ledger.

The identity row is the unit action row supplied above. The composition and inverse faces are exactly the rows controlled by Definition 164.4, Definition 164.5, and Definition 164.17. These references exhaust the accepted action, association, and reversal data available in the finite packet.

Conversely, every listed row is a displayed packet row or a dependency projection already carried by λ and tagged by ρ. Repacking those rows gives the same public $\mathsf{GaloisGroup}^{\uparrow}$ automorphism-action packet, so the ledger is exact and has no additional ambient automorphism object behind it. □

Theorem 164.21 (GaloisGroupUp public NameCert obligation boundary)**.** *For an automorphism-action packet $(E, G, b, a, m, i, c, \rho, \lambda)$ of Definition 164.1, the public $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ obligation surface is exactly the following finite row family: the Galois-extension dependency packet E, the group dependency packet G, the fixed-base row b, the automorphism-action row a, the identity row read from the unit of G, the composition row m, the inverse row i, the classifier row c, the* Pkg *provenance row ρ, the finite* Cont *ledger λ, and the exactness rows named by those packets. This is the public obligation boundary consumed by downstream Galois and representation-facing chapters.*

Lean4 ✓ `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket semantic name certificate`

Proof. Project the packet to its dependency surfaces. The Galois-extension side is the public boundary of Definition 163.10; the group side is the operation and inverse surface named by the $\mathsf{Group}^{\uparrow}$ certificate. These two dependency projections account for the extension carrier, group operation, classifier, stability, ledger, and exactness rows available to the Galois-group packet.

The fixed-base carrier obligation is supplied by Definition 164.2. The identity row is supplied by Definition 164.9; classifier-stable composition is supplied by Definition 164.10; and the composition and inverse obligation is supplied by Definition 164.17. Therefore every public row is a projection of E, G, b, a, the identity row, m, i, c, ρ, or λ.

Conversely, each listed row is either a coordinate of Definition 164.1 or a projected row read from those coordinates. Repacking those rows gives the carrier, identity, operation, inverse, classifier, provenance, ledger, and exactness surface needed by downstream Galois and representation-facing uses, so no hidden host automorphism datum is part of the public boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$**.**

Constructive story: A Galois group here is not a host automorphism set; it is a finite automorphism-action packet built from a $\mathsf{GaloisExt}^{\uparrow}$ source row, a $\mathsf{Group}^{\uparrow}$ law row, fixed-base rows, action rows, composition and inverse rows, and the continuation ledgers that concatenate these rows to a public endpoint. The carrier accepts exactly those packets whose extension, group, fixed-base, action, composition, and inverse faces are unary histories tied by Cont to provenance, classifier, ledger, and endpoint rows, while quotient automorphism carriers and arbitrary ambient groups are outside the packet. Two accepted action packets classify together when the fixed-base row, action row, composition row, inverse row, provenance row, and endpoint row move by hsame through the same finite readback ledgers. The source specification is the accepted automorphism-action packet, the pattern specification records base-fixing, action, composition, inverse,

identity, and group-law rows inherited from GaloisExt$^{\uparrow}$ and Group$^{\uparrow}$, and the ledger keeps the raw action data visible as the same provenance and law endpoints. The five naming-certificate obligations come from the displayed packet endpoint for inhabitedness, the equivalence laws of hsame, and the transport theorems that rebuild a carrier packet after componentwise classifier movement. A history h lies in the signature GAP of a GaloisGroup$^{\uparrow}$ token p when the source accepts h, the signature relation pairs it to an answer action packet and evidence ledger, and token introduction identifies that answer with p; concretely, h must be the endpoint produced by the extension-plus-group provenance row and the composition-plus-inverse ledger for the same base-fixed action surface. The chapter registers this construction as GaloisGroup$^{\uparrow}$ without supplying a host automorphism group, an automorphism quotient, arbitrary Galois-group carriers, or a standard bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{GaloisGroup}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scoped surface is the four-file GaloisGroupUp obligation package: the automorphism action carrier, fixed-base classifier, group-law rows, inverse rows, and ledger exactness are all bound to the GaloisExtUp and GroupUp source certificates.

Formal verification: FormalStatus(NameCert$_{\mathsf{GaloisGroup}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.GaloisGroupUp.GaloisGroupAutomorphismActionPacket\_semantic\_name\_certificate`

Bridge status: none

Not claimed: The chapter does not close host automorphism groups, quotient automorphism carriers, arbitrary Galois groups, or a standard bridge.

Upgrade path: No higher paper-closure grade remains for this chapter; standard bridge status remains separately reported by `\bridgestatus`.

Chapter 165

A Concrete Naming Certificate for $\mathsf{SplittingField}^{\uparrow}$

The splitting-field interface $\mathsf{SplittingField}^{\uparrow}$ packages the smallest field extension over which a given polynomial factors into linear terms. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

165.1 Carrier definition

Definition 165.1 (SplittingFieldUp root carrier packet)**.** *A* $\mathsf{SplittingField}^{\uparrow}$ *root carrier packet is a finite* BHist *packet*

$$\mathcal{S} = (E, P, R, F, C, H, \Pi).$$

The row E is the consumed $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *source row. The row P is the consumed* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *polynomial row over that source. The row R records the displayed root endpoints for the carried polynomial, and the row F records the displayed factor rows whose product is the polynomial row P inside the carried extension.*

The finite ledger C is the Cont *factorization ledger. The row H records the* hsame *transport witnesses for the field-extension source, polynomial row, root endpoints, and factor rows. The row Π is the* Pkg *provenance packet recording exactly the consumed FieldExtUp source, PolynomialUp source, endpoint, factorization, continuation, and transport rows.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket provenance transport`

165.2 The certificate

Theorem 165.2 (SplittingFieldUp root classifier obligation)**.** *For a root carrier packet $\mathcal{S} = (E, P, R, F, C, H, \Pi)$ of Definition 165.1, the public classifier is determined by the FieldExtUp source row E, the PolynomialUp factor row P, the displayed root endpoints R, the factor rows F, and the* hsame *transport witnesses H. It does not classify quotient fields, ambient algebraic closures, or host polynomial roots not present in the carried ledger.*

Proof. Project the packet to E and P. The source of the classifier is the consumed field-extension certificate together with the consumed polynomial certificate, so every public read begins from those two BHist rows.

Project next to the root and factorization part. The rows R and F are the only endpoint and factor rows carried by the packet, and H is the only transport datum allowed to compare such rows.

The reverse direction repacks the same E, P, R, F, H rows into the packet classifier. Since no carrier field names a quotient field, algebraic closure, or host root outside R, those objects cannot be public classifier data. □

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket classifier obligation`

Theorem 165.3 (SplittingFieldUp root ledger obligation)**.** *Every public ledger read of a* $\mathsf{SplittingField}^{\uparrow}$ *root carrier packet is a row of the factorization continuation ledger C or the provenance packet Π attached to E, P, R, F, H. Conversely, every listed continuation or provenance row repacks into the same public splitting-field packet.*

Proof. Project the Cont component C. It records finite factorization reads for the polynomial row P, the root endpoints R, the factor rows F, and the transport witnesses H.

Project the Pkg component Π. Its provenance entries are exactly the consumed FieldExtUp row, the consumed PolynomialUp row, the endpoint rows, the factor rows, the continuation rows, and the transport rows named in the carrier.

For the converse, take any row on that finite list. The carrier packet Definition 165.1 has a field for it, so it reconstructs the same public splitting-field ledger without adding quotient fields, algebraic closures, or host polynomial roots. □

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket root ledger obligation`
↪ variant `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket ledger obligation`

Theorem 165.4 (SplittingFieldUp root NameCert surface)**.** *The* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *public surface for the root packet is the finite packet consisting of the FieldExtUp source row, PolynomialUp factor row, root endpoint rows, factorization rows,* Cont *factorization ledger,* hsame *transport witnesses, and* Pkg *provenance rows of Definition 165.1. This surface exports no quotient-field carrier, algebraic-closure carrier, or host-level root set.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket root namecert surface`

Proof. Use Definition 165.2 to fix the classifier from E, P, R, F, H. These are the only source, polynomial, endpoint, factorization, and transport rows available to the public surface.

Use Definition 165.3 to fix the ledger from C and Π. The continuation and provenance rows exhaust all public factorization reads attached to the classifier rows.

Repack the classifier and ledger rows through Definition 165.1. The result is exactly the public $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ surface, and all host-level splitting objects are excluded because the packet has no field for them. □

Theorem 165.5 (SplittingFieldUp root downstream threshold)**.** *Downstream CyclotomicUp and algebraic-field consumers of* $\mathsf{SplittingField}^{\uparrow}$ *may read exactly the root NameCert surface of Definition 165.4: the FieldExtUp source, PolynomialUp polynomial row, root endpoints, factor rows, continuation ledger, transport witnesses, and provenance packet. No downstream consumer receives a quotient field, algebraic closure, or host polynomial-root object unless it is represented by one of those carried rows.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket root downstream threshold`

Proof. Begin with Definition 165.4. It packages the classifier and ledger rows into the public splitting-field surface seen by consumers.

For a CyclotomicUp consumer, the polynomial row and root endpoint rows are read through P and R, while the factorization requirement is read through F and C. For an algebraic-field consumer, the field-extension source and provenance rows are read through E and Π.

The two consumer paths therefore share the same finite packet. Since Definition 165.2 and Definition 165.3 exclude quotient fields, algebraic closures, and host roots outside the packet, the downstream threshold is exactly the carried root surface. □

Theorem 165.6 (SplittingFieldUp root classifier transport)**.** *For a* $\mathsf{SplittingField}^{\uparrow}$ *root carrier packet*

$$\mathcal{S} = (E, P, R, F, C, H, \Pi),$$

the root classifier transports exactly the displayed FieldExtUp source row E, PolynomialUp row P, root endpoint rows R, factor rows F, and transport row H along hsame*. The transported classifier keeps the same factorization ledger C and the same provenance packet Π, and it exports no quotient field, algebraic closure, or host polynomial-root object.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket root classifier transport`

Proof. Project the classifier through Definition 165.2. Its public data are the FieldExtUp source row, the PolynomialUp row, the displayed roots, the displayed factors, and the hsame transport witnesses.

The carrier packet of Definition 165.1 keeps C and Π attached to those same rows. Transport therefore changes only the displayed endpoints along H and leaves the finite continuation ledger and provenance packet in place.

Repack the transported E, P, R, F, H rows with the same C and Π. Because the classifier obligation has no field for a quotient field, algebraic closure, or host root set, no such object is transported. □

Theorem 165.7 (SplittingFieldUp root factor-ledger exhaustion)**.** *Every public factorization read from a* $\mathsf{SplittingField}^{\uparrow}$ *root packet $\mathcal{S} = (E, P, R, F, C, H, \Pi)$ is exhausted by the finite* Cont *ledger C and the provenance packet Π. Conversely, every factor row listed in F with its root endpoint in R, transport row in H, continuation entry in C, and provenance entry in Π repacks as an accepted public factorization read of the same packet.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket factor ledger exhaustion`

Proof. Read the ledger obligation Definition 165.3. It says that public ledger reads are rows of C or provenance rows of Π attached to the displayed source, polynomial, root, factor, and transport data.

Induct over the finite factor rows F. In the empty case, C and Π have no factor row to bind, so no public factorization read can be projected.

In the cons case, the head factor is tied to the polynomial row P, a root endpoint in R, a transport witness in H, a continuation entry in C, and a provenance entry in Π. The induction hypothesis exhausts the tail factors through the same finite ledgers.

For the converse, attach each listed factor row to its displayed endpoint, transport, continuation, and provenance entries, then repack through Definition 165.1. The result is the same public factorization packet and adds no host-level factor source. □

Theorem 165.8 (SplittingFieldUp Cyclotomic consumer source boundary)**.** *A* $\mathsf{Cyclotomic}^{\uparrow}$ *consumer reading from* $\mathsf{SplittingField}^{\uparrow}$ *may consume exactly the FieldExtUp source row* E*, PolynomialUp row* P*, root endpoint rows* R*, factor rows* F*, finite factorization ledger* C*,* hsame *transport row* H*, and* Pkg *provenance packet* Π *of a carried packet* $\mathcal{S} = (E, P, R, F, C, H, \Pi)$*. These are the only root, factor, polynomial, FieldExtUp,* Cont*,* hsame*, and* Pkg *rows available at the consumer boundary.*

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket cyclotomic consumer source boundary`

Proof. Begin with Definition 165.5. It already restricts downstream consumers to the root NameCert surface consisting of the FieldExtUp, PolynomialUp, root, factor, continuation, transport, and provenance rows.

Apply Definition 165.6. This fixes the consumer's transport reads to the displayed E, P, R, F, H classifier packet, with the same C and Π still attached.

Apply Definition 165.7. This exhausts the factor side by the finite continuation ledger C and provenance packet Π, so every factor read consumed by $\mathsf{Cyclotomic}^{\uparrow}$ is already a row of the carried packet.

Combining these projections gives the exact consumer boundary. No quotient field, algebraic closure, host root set, or host factorization source is available unless it is represented by one of E, P, R, F, C, H, Π. □

Theorem 165.9 (SplittingFieldUp standard bridge boundary)**.** *The public root packet* $\mathcal{S} = (E, P, R, F, C, H, \Pi)$ *described by the* $\mathsf{SplittingField}^{\uparrow}$ *carrier gives the BEDC-side boundary of the standard splitting-field reading. Roots and linear factors are read only from the displayed* $\mathsf{FieldExt}^{\uparrow}$*,* $\mathsf{Poly}^{\uparrow}$*, root endpoint, factor,* Cont*,* hsame*, and* Pkg *rows of that packet. The bridge introduces no quotient fields, algebraic-closure carrier, host root set, or external factorization.*

Proof. Start from the root NameCert surface of Definition 165.4. It exposes the accepted packet as the displayed E, P, R, F, C, H, Π rows and no additional field, polynomial, root, or factor carrier.

Apply Definition 165.7. Every factor read in the standard interpretation is forced through the finite continuation ledger C and the package provenance Π, so the factor side is already exhausted by displayed packet data.

Use the downstream threshold of Definition 165.5 together with the consumer boundary of Definition 165.8. These project every standard root, linear-factor, transport, and provenance read to one of the displayed rows.

Finally invert the carrier of Definition 165.1. Since the carrier has no coordinate for quotient fields, algebraic closures, host root sets, or external factorization procedures, those data cannot be introduced by the BEDC-side bridge boundary. □

Lean4 ✓ `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket standard bridge boundary`

Closure status for $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$.

Constructive story: A splitting field is presented as a root carrier packet whose entries are a $\mathsf{FieldExt}^{\uparrow}$ source row, a $\mathsf{Poly}^{\uparrow}$ row over that source, displayed root endpoints, displayed factor rows, a finite factorization ledger, transport witnesses, and package provenance. The carrier accepts only packets where those rows are unary histories tied by the stated Cont displays, so quotient-field carriers, algebraic-closure carriers, and host root sets never become accepted inputs. Its classifier is the transported agreement of the field-extension row, polynomial row, root endpoints, factor rows, and transport row along hsame, with the same factorization ledger and provenance kept attached. The source specification is the whole root packet, the pattern specification is the visible factorization of the carried polynomial into the listed linear factors and roots, and the ledger records exactly the continuation and provenance rows that make each raw factor read visible. At this obligation boundary, inhabitedness is supplied by an accepted packet when one is displayed, reflexivity,

symmetry, and transitivity are the hsame rows demanded of the classifier, and carrier closure is the transport obligation that repacks the same E, P, R, F, C, H, Π data after classification. A history h lies in the signature GAP of a SplittingField$^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer root packet and evidence ledger, and token introduction names that answer as p; here this contracts to the claim that h is exactly the endpoint whose FieldExt row, Polynomial row, roots, factors, Cont ledger, hsame transport, and Pkg provenance are the carried packet rows. The chapter registers this construction as SplittingField$^{\uparrow}$ without adding a quotient field, an algebraic-closure object, a host-level root set, or a standard bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{SplittingField}^{\uparrow}}$, maturePackageClosed)

Scope closed: The exported public interface is exactly the root NameCert surface of Definition 165.4 together with the downstream threshold of Definition 165.5: the FieldExtUp source row, PolynomialUp row, root endpoints, factor rows, Cont factorization ledger, hsame transport, Pkg provenance, and the Cyclotomic and algebraic-field consumer boundary.

Formal verification: FormalStatus(NameCert$_{\mathsf{SplittingField}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SplittingFieldUp.SplittingFieldRootCarrierPacket\_standard\_bridge\_boundary`

Bridge status: none

Not claimed: No quotient-field carrier, algebraic-closure carrier, host root set, or `bridgeCheckedV` formal status is claimed.

Upgrade path: No further paper theory-axis step is recorded for this chapter; bridge verification remains on the separate formal axis.

Chapter 166

A Concrete Naming Certificate for $\mathsf{SeparableExt}^{\uparrow}$

The separable-extension interface $\mathsf{SeparableExt}^{\uparrow}$ packages a field extension whose minimal polynomials all have simple roots. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

166.1 Carrier definition

166.2 The certificate

Theorem 166.1 (Separable-extension FieldExt and Polynomial source surface)**.** *A* $\mathsf{SeparableExt}^{\uparrow}$ *source row is the joint BEDC source consisting of a* $\mathsf{FieldExt}^{\uparrow}$ *extension packet, a* $\mathsf{Poly}^{\uparrow}$ *minimal-polynomial packet over that extension, and shared provenance rows in* BHist *and* Pkg*. The two dependency witnesses are scoped by* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*, and the shared provenance requires the displayed base-field, extension-field, generator, and minimal-polynomial histories to be compared by* hsame *inside the same package ledger.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceRow fieldext polynomial source`

Proof. Project the $\mathsf{FieldExt}^{\uparrow}$ dependency certificate to obtain the base row, extension row, extension classifier, and package provenance. Project the $\mathsf{Poly}^{\uparrow}$ dependency certificate to obtain the polynomial carrier, coefficient ledger, and polynomial classifier over the displayed extension row.

The source row for $\mathsf{SeparableExt}^{\uparrow}$ is then the common pullback of these two projections over BHist and Pkg. The hsame rows identify the base and extension histories seen by the polynomial packet with the histories supplied by the field-extension packet, so the two dependencies describe one BEDC source rather than two unrelated presentations. □

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtJointSource fieldext polynomial source`
Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface dependency ledger closure`
Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceRow classifier stability`

Theorem 166.2 (Separable-extension carrier and classifier surface)**.** *The carrier surface for separable-extension histories consists of the joint source row of Definition 166.1 together with the displayed generator and minimal-polynomial histories. Two such carrier rows are classified by the inherited*

FieldExt$^{\uparrow}$ *classifier on the extension packet and by the* Poly$^{\uparrow}$ *equality classifier on the displayed minimal-polynomial rows, with the shared* BHist *and* Pkg *provenance transported along* hsame*.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceRow carrier classifier surface`
Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtJointSource carrier classifier surface`

Proof. Unpack a carried row into its extension packet, polynomial packet, generator history, minimal-polynomial history, and package ledger. The field-extension component supplies the comparison of base and extension histories, while the polynomial component supplies comparison of coefficient and polynomial rows.

For classification, compare the extension projections using the FieldExt$^{\uparrow}$ classifier and compare the minimal-polynomial projections using the Poly$^{\uparrow}$ equality classifier. The remaining carrier fields are provenance fields, so they move by the hsame transports recorded in the joint package ledger. □

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface carrier classifier surface`

Theorem 166.3 (Separable-extension simple-root obligation)**.** *The separability row for* SeparableExt$^{\uparrow}$ *is a displayed* Poly$^{\uparrow}$ *witness that the minimal-polynomial row has only simple roots. Concretely, the row records a derivative or gcd-style witness in* BHist*, continuation evidence in* Cont*, classifier transports in* hsame*, and package provenance in* Pkg*; it does not assert an uncarried host-algebra separability predicate.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSimpleRoot obligation`

Proof. Start from the minimal-polynomial packet supplied by Definition 166.1. Its Poly$^{\uparrow}$ ledger exposes the polynomial row, the derivative row or equivalent gcd-style comparison row, and the coefficient histories over the same extension packet.

The simple-root obligation is the package row that stores these displayed histories together with the Cont evidence computing the derivative or gcd comparison. Soundness is only a BEDC soundness statement: every accepted separability row is one of these displayed polynomial ledgers, transported by hsame and scoped by the shared Pkg provenance. □
