Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface simple root obligation`

Theorem 166.4 (Separable-extension classifier stability)**.** *The simple-root row is stable under the classifier of Definition 166.2. Transport along the inherited* FieldExt$^{\uparrow}$ *classifier and the inherited* Poly$^{\uparrow}$ *minimal-polynomial classifier carries the derivative or gcd-style witness, the* Cont *computation row, the* hsame *transports, and the* Pkg *provenance to the classified target carrier row.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface classifier stability`

Proof. Transport the field-extension part first. The FieldExt$^{\uparrow}$ classifier identifies the base, extension, and generator histories seen by the source row, so the minimal-polynomial packet remains over the transported extension packet.

Next transport the polynomial part. The Poly$^{\uparrow}$ equality classifier carries the minimal-polynomial row and its displayed derivative or gcd-style witness to the target packet. The Cont computation row is stable under the transported input and output histories, and the hsame witnesses compose with the package provenance to repack the same simple-root obligation at the target. □

Theorem 166.5 (Separable-extension ledger exactness)**.** *The* $\mathsf{SeparableExt}^{\uparrow}$ *ledger has coverage, soundness, and completeness for exactly the carried extension row, minimal-polynomial row, simple-root row, classifier-stability row, ledger row, and dependency rows supplied by* $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, NameCert, BHist, Cont, hsame, *and* Pkg*. No additional host-field algebra, root set, splitting-field data, or Galois action is part of this certificate surface.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface ledger exactness`
Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface semantic name certificate`
Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceRow semantic name certificate`

Proof. Coverage follows by reading the roadmap ten-field template. The traditional target is separability of a field extension; the BEDC sources are the $\mathsf{FieldExt}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ certificates; the carrier, classifier, stability, ledger, theorem-list, exactness, bridge, and status slots are the rows named in the four preceding theorems, with the bridge slot empty.

Soundness reads every accepted public row back to that list. A carried extension row comes from the field-extension dependency, a minimal-polynomial row comes from the polynomial dependency, and the simple-root row is the displayed derivative or gcd-style package with its Cont, hsame, and Pkg provenance.

Completeness is the reverse packaging. Given exactly those dependency rows and provenance rows, the ten-field template assembles a $\mathsf{SeparableExt}^{\uparrow}$ certificate row, and Definition 166.4 supplies the classifier transport needed to keep the row stable under certified comparison. □

Theorem 166.6 (Separable-extension mature example-family completeness)**.** *Any carried separable-extension example assembled from a* $\mathsf{FieldExt}^{\uparrow}$ *source packet, a* $\mathsf{Poly}^{\uparrow}$ *minimal-polynomial packet, shared* BHist *and* Pkg *provenance, and a simple-root derivative or gcd row is completely read by the five surfaces of this chapter: source dependency, carrier and classifier, simple-root obligation, classifier stability, and ledger exactness. The resulting family is mature at this certificate boundary because every accepted example is recovered from those five surfaces, and every such package reassembles the same* $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface mature example family`

Proof. First read the example through Definition 166.1. This identifies the two dependency packets and forces their base-field, extension-field, generator, and minimal-polynomial histories to share the same BHist and Pkg provenance.

Next apply Definition 166.2 and Definition 166.3. These two surfaces expose the carried extension row, the displayed minimal-polynomial row, and the derivative or gcd-style simple-root witness without adding a host-field root predicate.

Then use Definition 166.4 to transport the simple-root row across the inherited $\mathsf{FieldExt}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ classifiers. The derivative or gcd ledger, the continuation row, the hsame transports, and the package provenance remain inside the same carried surface.

Finally apply Definition 166.5. Its coverage, soundness, and completeness clauses say that the five surfaces enumerate exactly the public $\mathsf{SeparableExt}^{\uparrow}$ certificate rows. Root sets, splitting fields, and Galois actions are not exported by this family. □

Closure status for $\mathsf{NameCert}_{\mathsf{SeparableExt}^{\uparrow}}$**.**

Constructive story: A separable extension is built by putting a $\mathsf{FieldExt}^{\uparrow}$ extension packet beside a $\mathsf{Poly}^{\uparrow}$ minimal-polynomial packet over the same displayed generator, then adding the simple-root row that is witnessed by a derivative or gcd-style finite history computation. The carrier accepts only this joint source surface with shared BHist and Pkg provenance, excluding uncarried host-field algebra, external root sets, splitting-field data, and Galois actions. Two accepted

rows classify together by the inherited FieldExt classifier on the extension packet, the inherited Polynomial classifier on the minimal-polynomial row, and the recorded hsame transports for generator, derivative, simple-root, and provenance faces. The source specification is the FieldExt-plus-Polynomial dependency row, the pattern specification is the visible minimal-polynomial simple-root witness, and the ledger keeps the raw derivative or gcd computation aligned with its public separability face through Cont and package rows. The five naming-certificate obligations are supplied at this scoped surface because an accepted joint row gives an inhabitant, hsame supplies the three equivalence moves, and classifier stability transports the simple-root witness back into the same carrier. A history h lies in the signature GAP of a SeparableExt$^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer row and evidence ledger, and token introduction identifies the answer as p; after projection, this says that h is the shared extension-and-minimal-polynomial endpoint whose simple-root witness is exactly the displayed polynomial ledger. The chapter registers this construction as SeparableExt$^{\uparrow}$ without closing a public separability theorem, any FieldExt or Polynomial bridge, a Galois bridge, or a standard bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{SeparableExt}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature example-family scope is exactly the carried FieldExt$^{\uparrow}$ source packet, Poly$^{\uparrow}$ minimal-polynomial surface, simple-root derivative or gcd witness, classifier-stability rows, ledger exactness, shared BHist, Cont, hsame, Pkg, and NameCert provenance named in Theorems 166.1–166.6.

Formal verification: FormalStatus(NameCert$_{\mathsf{SeparableExt}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SeparableExtUp.SeparableExtSourceSurface\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not close a scoped separable-extension carrier, public separability theorem, FieldExtUp bridge, PolynomialUp bridge, standard bridge, GaloisExtUp bridge, or Lean verification target.

Upgrade path: No further paper theory-axis grade is recorded for this chapter.

Chapter 167

A Concrete Naming Certificate for $\mathsf{Transcendence}^{\uparrow}$

The transcendence interface $\mathsf{Transcendence}^{\uparrow}$ packages the supremum of cardinalities of algebraically independent subsets of a field extension. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161).

167.1 Carrier definition

Definition 167.1 (Transcendence BHist carrier)**.** *A* $\mathsf{Transcendence}^{\uparrow}$ *carrier packet is a finite* BHist *packet over the* $\mathsf{FieldExt}^{\uparrow}$ *source rows. Its displayed rows consist of a certified field extension packet, a finite family row* $S = (s_1, \ldots, s_n)$ *in the extension endpoint, a base-field coefficient ledger, a finite list of polynomial-relation test rows for the family,* hsame *transports for the field-extension and family rows,* Cont *readbacks for each test row, and* Pkg *provenance pointing back to the* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *source packet.*

Lean4 (definition) `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket`

Definition 167.2 (Transcendence classifier)**.** *Two* $\mathsf{Transcendence}^{\uparrow}$ *carrier packets are classified as the same when their* $\mathsf{FieldExt}^{\uparrow}$ *source packets are matched by the displayed* $\mathsf{FieldExt}^{\uparrow}$ *classifier, their finite family rows are paired coordinatewise by* hsame*, and their polynomial-relation test ledgers have the same finite readback through* Cont*. The classifier compares only the listed rows; it does not compare supremum cardinalities, quotient fields, chosen transcendence bases, or maximal independent subsets.*

Lean4 (definition) `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket classifier`
Lean4 (definition) `BEDC.Derived.TranscendenceUp.TranscendenceClassifier`
Lean4 (definition) `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacketClassifier`

167.2 The certificate

Theorem 167.3 (Transcendence algebraic-independence ledger)**.** *For a* $\mathsf{Transcendence}^{\uparrow}$ *carrier packet, the finite family row* S *is accepted as algebraically independent over the displayed* $\mathsf{FieldExt}^{\uparrow}$ *base exactly when every polynomial-relation test row in the packet reads through* Cont *as the zero relation only at the zero coefficient ledger. This certificate is a finite ledger statement over the displayed family and coefficient rows, not a statement about the supremum of all independent cardinalities.*

Lean4 ✓ `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket algebraic independence ledger`

Proof. Read the carrier of Definition 167.1. It supplies a finite family row, a finite coefficient ledger, and a finite list of polynomial-relation test rows, all sourced from the same $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ packet.

For each displayed test row, the Cont readback records the evaluated relation endpoint. Ledger exactness says that the relation endpoint is zero only when the coefficient ledger is the zero ledger, so each listed polynomial test witnesses the independence condition for the finite family.

The converse uses the same finite rows. If the packet records the zero-only outcome for every displayed polynomial-relation test, repacking those readbacks gives the algebraic-independence ledger for S. No step selects a basis, maximizes a family, forms a quotient field, or invokes a Zorn-style argument. □

Theorem 167.4 (Transcendence FieldExt source boundary)**.** *Every source read used by a* $\mathsf{Transcendence}^{\uparrow}$ *carrier packet factors through the displayed* $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ *rows: base-field endpoint, extension-field endpoint, inclusion row, field-operation rows, finite family membership rows, polynomial coefficient rows,* hsame *transports,* Cont *readbacks, and* Pkg *provenance. The boundary exports no ambient quotient-field construction, algebraic closure, transcendence basis choice, or maximality principle.*

Lean4 ✓ `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket fieldext source transport boundary`

Proof. Start from the source component of Definition 167.1. Each row is tagged by the $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ provenance, so the base endpoint, extension endpoint, inclusion row, and field-operation rows are inherited as finite displayed source data.

The family and polynomial-test rows consume only those inherited endpoints and the finite coefficient ledger. Their stability is read by the hsame transports named in the carrier, and their observations are returned by the listed Cont rows.

Constructor inspection of the source boundary leaves no slot for a quotient field, algebraic closure, chosen transcendence basis, or maximality witness. Thus downstream $\mathsf{Transcendence}^{\uparrow}$ consumers receive only the displayed $\mathsf{FieldExt}^{\uparrow}$ packet and the finite independence ledger. □

Lean4 ✓ `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket fieldext source boundary`

Theorem 167.5 (Transcendence NameCert obligation surface)**.** *The carrier of Definition 167.1 and the classifier of Definition 167.2 determine the* NameCert *obligation surface for* $\mathsf{Transcendence}^{\uparrow}$*: carrier membership, classifier reflexivity, classifier symmetry, classifier transitivity, and carrier stability under the classifier are all witnessed by the finite* $\mathsf{FieldExt}^{\uparrow}$ *source packet, coordinatewise* hsame *transports, polynomial-test ledger exactness,* Cont *readbacks, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket namecert obligation surface`

Proof. Carrier membership is the finite packet described in Definition 167.1. The family row, coefficient ledger, polynomial tests, transports, readbacks, and provenance are all explicit rows, so no extra host-level algebraic object is needed to admit the packet.

Reflexivity uses reflexive hsame rows for the displayed $\mathsf{FieldExt}^{\uparrow}$ source and each family coordinate, together with identical polynomial-test readbacks. Symmetry reverses the same coordinatewise transports. Transitivity composes the source and family transports and then reuses the finite ledger exactness rows for the polynomial tests.

For carrier stability, transport the $\mathsf{FieldExt}^{\uparrow}$ packet and finite family row through the classifier, then carry each polynomial-relation test row along the named hsame transport. The Cont

readbacks preserve the zero-only coefficient ledger, so the transported packet is again accepted by the transcendence carrier. The resulting surface is the displayed $\mathsf{NameCert}_{\mathsf{Transcendence}^{\uparrow}}$ obligation packet, with no appeal to supremum cardinalities, quotient fields, basis choice, or maximality. □

Closure status for $\mathsf{NameCert}_{\mathsf{Transcendence}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Transcendence}^{\uparrow}}$, publicClosed)

Scope closed: The chapter scopes the $\mathsf{FieldExt}^{\uparrow}$ source rows, finite family rows, polynomial-test ledgers, hsame transports, Cont readbacks, and Pkg provenance used by the displayed carrier packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Transcendence}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TranscendenceUp.TranscendenceCarrierPacket\_namecert\_obligation\_surface`

Bridge status: none

Constructive story: The carrier is a finite BHist packet whose rows are assembled from the displayed $\mathsf{FieldExt}^{\uparrow}$ source, a finite family, polynomial-test ledgers, transport readbacks, and package provenance.

Not claimed: This chapter does not close quotient fields, transcendence basis choice, maximality principles, or Zorn-style closure.

Upgrade path: Bridged closure requires a standard bridge for the exported transcendence certificate surface over the displayed $\mathsf{FieldExt}^{\uparrow}$ source, finite-family, polynomial-test, transport, readback, and provenance rows.

Chapter 168

A Concrete Naming Certificate for $\mathsf{NumField}^{\uparrow}$

The number-field interface $\mathsf{NumField}^{\uparrow}$ packages a finite field extension of the rational-number certificate. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161) and $\mathsf{NameCert}_{\mathsf{Rat}^{\uparrow}}$ (chapter 37).

168.1 Carrier definition

Definition 168.1 (Reflexive rational field-extension carrier for NumFieldUp)**.** *The concrete* $\mathsf{NumField}^{\uparrow}$ *carrier is the RatUp reflexive field-extension carrier of Definition 161.3, read as a number-field certificate surface. Its base carrier and ambient carrier are both* RatHistoryCarrier*, its base and ambient classifiers are both* RatHistoryClassifier*, and its field-operation table is the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *operation table recorded in the RatUp certificate chapter.*

The embedding row is the identity embedding

$$\iota_{\mathsf{Rat}} : \mathsf{Rat}^{\uparrow} \hookrightarrow \mathsf{Rat}^{\uparrow},$$

and the finite-degree row is the singleton unary basis row. Thus the displayed module basis has one vector, the coordinate readback is the RatUp endpoint itself, and the scalar-action row is RatUp multiplication. The carrier has no separate algebraic endpoint outside the BHist *rows already used by the RatUp and FieldExtUp certificates.*

Lean4 (definition) `BEDC.Derived.NumFieldUp.NumFieldReflexiveRationalCarrier`
Lean4 (definition) `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveCarrier`

Theorem 168.2 (RatUp reflexive NumField carrier and classifier)**.** *For the carrier of Definition 168.1, the* $\mathsf{NumField}^{\uparrow}$ *carrier is exactly* RatHistoryCarrier *and the* $\mathsf{NumField}^{\uparrow}$ *endpoint classifier is exactly* RatHistoryClassifier*. Every displayed number-field endpoint is therefore a RatUp history endpoint, and every endpoint comparison is a RatUp classifier comparison.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive carrier classifier`

Proof. Unfold Definition 168.1. The carrier and classifier fields are specified directly as RatHistoryCarrier and RatHistoryClassifier.

The RatUp semantic name certificate supplies the carried-history interpretation for these fields. No quotient, completion, polynomial carrier, or new endpoint classifier is introduced by the $\mathsf{NumField}^{\uparrow}$ reading, so each number-field endpoint is read through the same RatUp history row. □

Theorem 168.3 (RatUp reflexive FieldExt consumption for NumFieldUp)**.** *For the carrier of Definition 168.1, the finite-extension component consumed by* $\mathsf{NumField}^{\uparrow}$ *is the identity* $\mathsf{FieldExt}^{\uparrow}$ *row of Definition 161.3. Its base field and ambient field are both the concrete* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ *certificate, its embedding is* $\iota_{\mathsf{Rat}}(h) := h$*, and its scalar action is the RatUp multiplication row.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive fieldext consumption`
Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational fieldext consumption`

Proof. Read the finite-extension witness from Definition 161.24. That theorem exposes the public $\mathsf{FieldExt}^{\uparrow}$ interface whose carrier, classifier, base field, ambient field, identity embedding, self-vector-space rows, exactness, and ledger all live over the RatUp operation table.

The $\mathsf{NumField}^{\uparrow}$ source only consumes that interface. Because the consumed row is the identity extension, the base and ambient field certificates are the same RatUp field certificate, and the scalar-action row is the same multiplication row already present in $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$. □

Theorem 168.4 (RatUp reflexive NumField ledger exactness)**.** *For the carrier of Definition 168.1, the* $\mathsf{NumField}^{\uparrow}$ *exactness and ledger rows are inherited from the RatUp reflexive* $\mathsf{FieldExt}^{\uparrow}$ *public interface. In particular, every carrier display, classifier display, field-operation endpoint, identity-embedding endpoint, vector-space endpoint, scalar-action endpoint, and ledger provenance row is one of the rows listed by Definition 161.24.*

Proof. First apply Definition 168.3. It identifies the finite-extension component used by $\mathsf{NumField}^{\uparrow}$ with the public RatUp reflexive $\mathsf{FieldExt}^{\uparrow}$ interface.

Next read the exactness and ledger clauses from Definition 161.24. Its public surface includes exact endpoint classification and ledger provenance over the RatUp operation table. Since the carrier and classifier are unchanged by Definition 168.2, those clauses serve as the displayed $\mathsf{NumField}^{\uparrow}$ exactness and ledger rows without any additional transport. □

Theorem 168.5 (RatUp reflexive NumField NameCert obligation surface)**.** *The carrier of Definition 168.1 assembles the paper-side* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *obligation surface. The surface records the RatUp history carrier, the RatUp history classifier, the identity finite-extension witness, the inherited FieldExt stability rows, the inherited exact endpoint classification, and the inherited ledger provenance from the RatUp reflexive* $\mathsf{FieldExt}^{\uparrow}$ *public interface.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational semantic name certificate`

Proof. Use Definition 168.2 for the carrier and classifier slots. These slots are the RatUp history carrier and classifier, so the $\mathsf{NumField}^{\uparrow}$ source is rooted in BHist.

Use Definition 168.3 for the finite field-extension slot. It supplies the identity embedding, the shared base-and-ambient RatUp field certificates, and the self-vector-space row required by the number-field reading.

Use Definition 168.4 for the exactness and ledger slots. Together these three rows cover the carrier, classifier, finite-extension, stability, exactness, and ledger obligations named by the paper-side $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ surface. □

168.2 The certificate

Theorem 168.6 (NumFieldUp reflexive rational source scope)**.** *For the carrier of Definition 168.1, every source, carrier, classifier, stability, ledger, exactness, and absent standard bridge field of the paper-side* $\mathsf{NumField}^{\uparrow}$ *surface is fixed by the displayed RatUp and FieldExtUp rows. The source is*

the concrete RatUp $\mathsf{Field}^{\uparrow}$ *table, the carrier is* RatHistoryCarrier*, the classifier is* RatHistoryClassifier*, stability is the identity-embedding and self-vector-space stability of the reflexive FieldExtUp row, exactness is endpoint classification by* RatHistoryClassifier*, the ledger is the RatUp operation-table ledger, and no standard bridge to host number fields is claimed.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational source scope`

Proof. Unfold Definition 168.1. The carrier is just the reflexive field-extension carrier of Definition 161.3, so the base and ambient history predicates, classifiers, and embedding row are the RatUp rows already used by FieldExtUp.

Use Definition 161.18 to account for the field operations. It says that the base-field operations, ambient-field operations, vector addition, vector zero, vector negation, and scalar action are all read from the single RatUp $\mathsf{Field}^{\uparrow}$ operation table.

Next apply Definition 161.22 and Definition 161.23. These identify every displayed endpoint with the RatUp classifier class named by the row and record the ledger provenance inside the RatUp operation table.

Finally use Definition 161.24 together with the RatUp certificate chapter. The public FieldExtUp interface supplies the visible extension surface, and the RatUp certificate supplies the rational source rows. Since the NumFieldUp carrier only re-reads these rows and adds no bridge tuple, the standard bridge field remains absent. □

Theorem 168.7 (NumFieldUp reflexive rational finite-extension witness)**.** *For the carrier of Definition 168.1, the finite-extension witness data are the singleton basis data over the reflexive FieldExtUp vector-space row. The basis list is the one-row unary basis* $[\mathbf{1}_{\mathsf{Rat}}]$*, every carried ambient endpoint* m *has the coordinate row* $m \cdot \mathbf{1}_{\mathsf{Rat}}$*, and coordinate equality is classified by* RatHistoryClassifier*.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational finite extension witness`

Proof. Read the vector-space part of the reflexive FieldExtUp package from Definition 161.3. Its ambient vector carrier is RatHistoryCarrier, its scalar carrier is the same RatUp carrier, and its scalar action is RatUp multiplication.

The singleton basis row chooses the RatUp unit endpoint as the only basis vector. For a carried ambient endpoint m, use the scalar m and the basis vector $\mathbf{1}_{\mathsf{Rat}}$; the multiplication row in the RatUp $\mathsf{Field}^{\uparrow}$ table classifies the product with m.

Apply Definition 161.18 for coverage of the multiplication and scalar-action rows. Then apply Definition 161.22 to read the coordinate endpoint in the same RatHistoryClassifier class. Thus the degree witness is the displayed singleton basis over the reflexive FieldExtUp vector-space row. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive finite basis witness`

Theorem 168.8 (RatUp reflexive NumField coordinate determinacy)**.** *For* $m, coord : \mathsf{BHist}$*, if* $\mathsf{RatHistoryCarrier}(m)$ *and* $\mathsf{Cont}(m, \mathsf{e}, coord)$*, then the coordinate readback is determined inside the RatUp classifier:* $\mathsf{RatHistoryClassifier}(coord, m)$*. The same row also forces* RatHistoryCarrier(FieldExtSingletonEmbed *and* $\mathsf{RatHistoryClassifier}(\mathsf{FieldExtSingletonEmbedding}(m), m)$*.*

Proof. Apply Definition 168.7. The witness identifies the displayed coordinate row for a carried endpoint m with $m \cdot \mathbf{1}_{\mathsf{Rat}}$ over the singleton basis.

The right-unit continuation $\mathsf{Cont}(m, \mathsf{e}, coord)$ reads that product as the RatUp endpoint named by m. Hence the coordinate endpoint remains in the RatHistoryClassifier class of m.

For the embedded endpoint, use the identity embedding row in Definition 168.1. It does not change the BHist endpoint, so the RatUp carrier predicate and the same classifier row apply to FieldExtSingletonEmbedding(m). □

Theorem 168.9 (RatUp reflexive NumField basis row exhaustion)**.** *Every accepted basis display in Definition 168.1 is the singleton rational unit row* $[\mathbf{1}_{\mathsf{Rat}}]$*. Every coordinate readback is classified by Definition 168.8. Thus the RatUp reflexive* $\mathsf{NumField}^{\uparrow}$ *carrier admits no second basis vector and no classifier row beyond* RatHistoryClassifier*.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveSingletonBasisRow support exactness`

Proof. First use Definition 168.6. It fixes the $\mathsf{NumField}^{\uparrow}$ source to the RatUp and FieldExtUp rows and leaves the finite basis field as the displayed singleton unary basis.

Next apply Definition 168.8. For each carried coordinate readback, the right-unit row and the identity embedding keep the coordinate in the RatUp classifier class of the source endpoint.

Finally apply Definition 168.25. Its row exhaustion says that the FieldExt rows are already exhausted by the RatUp reflexive certificate and that the NumField contribution is only the singleton basis row. Therefore neither a second basis vector nor an additional classifier row is accepted. □

Theorem 168.10 (RatUp reflexive NumField degree-one public package)**.** *The RatUp reflexive carrier of Definition 168.1, the source scope of Definition 168.6, the finite-extension witness of Definition 168.7, the basis-row exhaustion of Definition 168.9, and the ledger exactness of Definition 168.25 form the public degree-one* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *package. The package exposes carrier* RatHistoryCarrier*, classifier* RatHistoryClassifier*, the identity embedding, the singleton basis, RatUp scalar action, visible ledger exactness, and no standard bridge.*

Proof. Start with the source certificate Definition 37.90. It supplies the concrete RatUp carrier, classifier, operation table, exact endpoint classification, and ledger rows consumed by the number-field surface.

Next apply Definition 161.24. This repacks the same RatUp source as the reflexive FieldExtUp public interface, including the identity embedding and self-vector-space scalar action.

Use Definition 168.7 and Definition 168.9 for the degree-one part. These results identify the only basis display with the singleton rational unit row and classify every coordinate readback by the RatUp classifier.

Finally combine Definition 168.6 with Definition 168.25. The former fixes the visible $\mathsf{NumField}^{\uparrow}$ fields and the absent standard bridge, while the latter shows that the ledger contains no row beyond the RatUp reflexive FieldExt table and the singleton basis row. Repacking these fields gives the stated public degree-one $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ package. □

Definition 168.11 (NumFieldUp RatUp reflexive singleton basis row)**.** *For the carrier of Definition 168.1, the singleton basis row is the FieldExtUp vector-space singleton row. Its support is the one-element FieldExt vector carrier entry named by* FieldSingletonOne := BHist.Empty*.*

The RatUp data in the row live only in coordinate readback. For each carried m : BHist*, a coordinate endpoint coord* : BHist *is accepted when* Cont m BHist.Empty *coord holds, and the embedded ambient endpoint is* FieldExtSingletonEmbedding m*. Thus the basis support is a FieldExt singleton-vector support, while the coordinate endpoint and the embedded endpoint are the RatUp-classified rows attached to* m*.*

Lean4 (definition) `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveSingletonBasisRow`

Theorem 168.12 (NumFieldUp RatUp reflexive basis carrier boundary)**.** *In the singleton basis row of Definition 168.11, the basis support is carried by the FieldExtUp singleton vector carrier. The paper does not assert* RatHistoryCarrier BHist.Empty *for that support. RatUp carrier hypotheses apply to coordinate endpoints and to embedded ambient endpoints, not to the bare FieldExt singleton vector marker.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive basis support boundary`

Proof. Unfold the singleton basis row of Definition 168.11. The displayed support entry is FieldSingletonOne := BHist.Empty, so its carrier obligation is the FieldExt singleton vector carrier obligation.

The RatUp carrier predicate is read on the coordinate side. For a carried m : BHist, the accepted coordinate row has Cont m BHist.Empty *coord*, and the embedded endpoint is FieldExtSingletonEmbedding m. Apply RatHistoryCarrier_not_empty to separate this coordinate-side RatUp carrier from any assertion that BHist.Empty itself is a RatUp history carrier endpoint. □

Theorem 168.13 (NumFieldUp RatUp reflexive coordinate exactness span)**.** *Let* h, k, c, d : BHist. *If* RatHistoryClassifier h k*,* Cont h BHist.Empty c*, and* Cont k BHist.Empty d*, then* RatHistoryClassifier c d *and* RatHistoryClassifier (FieldExtSingletonEmbedding h)(FieldExtSingletonEmbedding k)*.*

Proof. Apply cont_right_unit_result to the two coordinate readbacks. This identifies c with h and d with k in the history classifier class named by right multiplication with the empty endpoint.

Next use RatHistoryClassifier_hsame_transport to transport the given classifier RatHistoryClassifier h k across these two right-unit identifications. This yields RatHistoryClassifier c d.

For the embedded endpoints, apply FieldExtRatReflexive_exact_endpoint_classification to the same classifier input. The reflexive FieldExt embedding is the singleton embedding row, so the embedded histories FieldExtSingletonEmbedding h and FieldExtSingletonEmbedding k remain in the same RatUp classifier class. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive coordinate exactness span`

Theorem 168.14 (NumFieldUp reflexive rational coordinate readback uniqueness)**.** *For* m, c_0, c_1 : BHist*, assume* RatHistoryCarrier(m)*,* Cont(m, e, c_0)*, and* Cont(m, e, c_1)*. Then* RatHistoryClassifier(c_0, c_1)*, and both* RatHistoryClassifier(c_0, m) *and* RatHistoryClassifier(c_1, m) *hold. Thus the singleton coordinate row attached to a carried RatUp endpoint is determined by the endpoint itself.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational coordinate readback pair determinacy`
Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational coordinate embedding pair readback`

Proof. Apply the continuation right-unit law Definition 18.18 to m. The supplied continuations Cont(m, e, c_0) and Cont(m, e, c_1) are therefore right-unit readbacks of the same history, so continuation determinacy identifies c_0 with m and c_1 with m up to hsame.

Transport the RatUp carrier row along these two hsame identifications. The RatUp semantic name certificate reads endpoint sameness through RatHistoryClassifier, so the transported rows give RatHistoryClassifier(c_0, m) and RatHistoryClassifier(c_1, m).

Finally compose the two classifier identifications through m. Transitivity of the RatUp classifier gives RatHistoryClassifier(c_0, c_1), which is the required uniqueness of degree-one coordinate readback. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational coordinate readback uniqueness`

Theorem 168.15 (NumFieldUp reflexive rational embedding-coordinate compatibility)**.** *For* $m, c_0 :$ BHist*, assume* $\mathsf{RatHistoryCarrier}(m)$ *and* $\mathsf{Cont}(m, \mathsf{e}, c_0)$*. Then* $\mathsf{RatHistoryClassifier}(\mathsf{FieldExtSingletonEmbedding}(m), c$ *Equivalently, the identity embedding row consumed from the reflexive FieldExtUp package is classified with the singleton coordinate row used by the degree-one NumFieldUp package.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational embedding coordinate classifier`

Proof. Use Definition 168.7 for the singleton finite-extension surface. It identifies the basis as the one-vector RatUp basis and reads the coordinate of a carried endpoint through the same $\mathsf{RatHistoryClassifier}$ row.

Unfold the displayed identity embedding from Definition 168.1. The embedding endpoint $\mathsf{FieldExtSingletonEmbedding}(m)$ is the same RatUp history endpoint m read through the FieldExtUp identity embedding row.

Apply Definition 168.14 to the carried endpoint m, the supplied coordinate c_0, and the right-unit coordinate m. The resulting classifier comparison identifies c_0 with m, and the identity-embedding display identifies $\mathsf{FieldExtSingletonEmbedding}(m)$ with the same classifier class. □

Theorem 168.16 (NumFieldUp reflexive rational degree-one row exhaustion)**.** *Every displayed finite-basis, coordinate, embedding, scalar-action, operation, exactness, and ledger row admitted by Definition 168.1 is either one of the exhausted RatUp reflexive FieldExtUp rows or the singleton degree-one coordinate row. The singleton row is classified by Definition 168.14 and is compatible with the identity embedding by Definition 168.15.*

Proof. Unfold Definition 168.1. The carrier contains the RatUp reflexive FieldExtUp source pattern together with one finite-basis field: the singleton basis vector, its coordinate readback, and the coordinate classifier row.

For the FieldExt part, apply Definition 161.27. This exhausts the base-field row, ambient-field row, identity embedding row, self-vector-space row, scalar-action row, operation-table row, exactness row, and ledger provenance row by the concrete RatUp $\mathsf{Field}^{\uparrow}$ table.

It remains to account for the basis field. The basis list has one displayed entry, the RatUp unit vector, and every coordinate readback is a right-unit continuation from the carried endpoint. The coordinate uniqueness theorem classifies any two such readbacks in the same $\mathsf{RatHistoryClassifier}$ class.

The embedding-coordinate compatibility theorem then identifies the singleton coordinate row with the identity embedding row. Hence the extra NumFieldUp surface adds exactly one degree-one coordinate row and no further finite-basis, embedding, scalar-action, exactness, or ledger row. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational degree one row exhaustion`

Definition 168.17 (NumFieldUp reflexive singleton basis coordinate surface)**.** *The reflexive singleton-basis coordinate surface for* $\mathsf{NumField}^{\uparrow}$ *fixes the concrete BEDC source as RatUp together with the reflexive* $\mathsf{FieldExt}^{\uparrow}$ *row of Definition 161.3. Its carrier is* $\mathsf{RatHistoryCarrier}$*, its classifier is* $\mathsf{RatHistoryClassifier}$*, and its finite-basis row is the one-element row* $\mathbf{1}_{\mathsf{Rat}}$*.*

For each carried ambient endpoint $m : \mathsf{BHist}$*, the coordinate readback is* m *itself and the reconstruction endpoint is the scalar-action product* $m \cdot \mathbf{1}_{\mathsf{Rat}}$*. The ledger is inherited from the RatUp operation table and the reflexive FieldExtUp row, and the surface is a paper-proof target without a standard bridge to an external number-field representation.*

Theorem 168.18 (NumFieldUp reflexive singleton basis exhaustion)**.** *For the coordinate surface of Definition 168.17, every accepted finite-basis row in the carrier is either the unique unit-basis*

row $\mathbf{1}_{\mathsf{Rat}}$ *or a coordinate row over* RatHistoryClassifier*. In particular, no accepted basis, coordinate, reconstruction, exactness, or ledger row has a coordinate source outside the RatUp history carrier and classifier.*

Proof. Unfold Definition 168.17. The surface only exposes the RatUp source, the reflexive FieldExtUp row, and the one-element basis field $\mathbf{1}_{\mathsf{Rat}}$.

Apply Definition 168.7. It identifies the finite-extension witness with the displayed singleton basis and reads each coordinate as the carried ambient endpoint m over RatHistoryClassifier.

For the rows inherited from FieldExtUp, apply Definition 161.27. This exhausts the carrier, classifier, embedding, scalar-action, operation, exactness, and ledger rows by the RatUp reflexive FieldExtUp certificate.

Finally use the RatUp semantic certificate Definition 37.90. It makes every accepted rational endpoint and endpoint comparison a RatUp history-classifier row. Thus the only remaining finite-basis row is the unit singleton, and every coordinate readback is classified by RatHistoryClassifier. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveSingletonBasisRow coordinate transport`

Theorem 168.19 (NumFieldUp reflexive embedding coordinate compatibility)**.** *For the coordinate surface of Definition 168.17, each carried ambient endpoint* m : BHist *has both its identity embedding coordinate* m *and its reconstructed endpoint* $m \cdot \mathbf{1}_{\mathsf{Rat}}$ *classified by* RatHistoryClassifier*. The embedding coordinate and the reconstruction endpoint therefore live on the same RatUp classifier surface.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive embedding coordinate product compatibility`

Proof. Read the embedding and vector-space rows from the reflexive FieldExtUp public interface in Definition 161.24. In the reflexive row, the embedding is the identity on RatHistoryCarrier and the scalar action is RatUp multiplication.

Use Definition 161.18. The operation-table coverage includes the multiplication row that interprets the scalar-action product $m \cdot \mathbf{1}_{\mathsf{Rat}}$ inside the RatUp operation ledger.

The right-unit row of the RatUp $\mathsf{Field}^{\uparrow}$ certificate identifies the product with the original endpoint m. Since Definition 37.90 supplies the RatUp history classifier for the endpoint m, the same classifier also classifies the reconstructed product endpoint. □

Theorem 168.20 (NumFieldUp reflexive degree-one basis exhaustion)**.** *For the carrier of Definition 168.1, the complete finite basis surface is the singleton unary row. Its only displayed basis endpoint is the RatUp unit endpoint* $\mathbf{1}_{\mathsf{Rat}}$*, every basis comparison is classified by* RatHistoryClassifier*, and no polynomial-root row, primitive-element row, or host-field row belongs to the basis surface.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational degree one coordinate transport`

Proof. Unfold Definition 168.1. The finite basis field is the basis component of the checked singleton witness in Definition 168.7; it has one displayed endpoint and uses the same RatUp classifier as the ambient endpoint carrier.

The operation coverage is inherited from Definition 161.18. It accounts for the RatUp multiplication row used by the scalar action and leaves no separate operation table for a root, primitive element, or host field.

Finally apply Definition 161.27. The FieldExt rows are exhausted by the RatUp base and ambient certificates, the identity embedding, and the self-vector-space rows. Projecting the remaining basis component gives exactly the singleton unit row and the RatHistoryClassifier comparison row. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive degree one basis endpoint`
Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive degree one basis exhaustion`

Theorem 168.21 (NumFieldUp reflexive coordinate readback determinacy)**.** *Let $m : \mathsf{BHist}$ be a carried ambient endpoint in the carrier of Definition 168.1. If $c, c' : \mathsf{BHist}$ are displayed coordinate histories whose coordinate rows read back through $\mathsf{Cont}(m, \mathsf{BHist.Empty}, c)$ and $\mathsf{Cont}(m, \mathsf{BHist.Empty}, c')$, then c and c' are both $\mathsf{RatHistoryClassifier}$-equivalent to m. Consequently c and c' are $\mathsf{RatHistoryClassifier}$-equivalent to each other.*

Proof. Use the singleton finite-extension witness of Definition 168.7 on the first displayed coordinate row. The witness reads the coordinate as the scalar m against the unique basis vector $\mathbf{1}_{\mathsf{Rat}}$, so RatUp multiplication classifies the endpoint c with m.

Apply the same witness to the second displayed coordinate row. The same singleton basis and scalar-action row classify c' with m through $\mathsf{RatHistoryClassifier}$.

The RatUp classifier laws are the semantic certificate laws supplied by Definition 37.90. Symmetry turns the first classification into the needed direction when necessary, and transitivity combines the two classifications to obtain the displayed equivalence between c and c'. □

Theorem 168.22 (NumFieldUp reflexive finite-extension exactness package)**.** *The concrete finite-extension part consumed by $\mathsf{NumField}^{\uparrow}$ in Definition 168.1 is exhausted by the identity embedding, the singleton basis of Definition 168.20, the coordinate-readback determinacy row of Definition 168.21, the RatUp scalar-action row, and the RatUp/FieldExt ledger rows. No additional finite-extension clause is available to downstream $\mathsf{NumField}^{\uparrow}$ consumers.*

Proof. Start with the concrete carrier consumption statement Definition 168.3. It identifies the underlying FieldExt surface as the RatUp reflexive extension with identity embedding and self-vector-space scalar action.

The source side is fixed by Definition 168.6. It says that the rational carrier, classifier, stability, exactness, and bridge status are read from the RatUp and FieldExt rows already named there.

For the finite basis field, apply Definition 168.20. For coordinate readback, apply Definition 168.21. These two rows isolate the singleton basis endpoint and the deterministic coordinate classifier used by every carried ambient endpoint.

Finally combine those rows with Definition 168.25. The ledger theorem exhausts the FieldExt rows and the singleton basis row, so repacking with the identity embedding and RatUp scalar action gives the exact finite-extension package consumed by $\mathsf{NumField}^{\uparrow}$. □

Theorem 168.23 (NumFieldUp reflexive rational NameCert obligation package)**.** *The carrier of Definition 168.1, the source scope of Definition 168.6, and the finite-extension witness of Definition 168.7, together with the coordinate uniqueness, embedding-coordinate compatibility, and degree-one row exhaustion of Definition 168.14, Definition 168.15, and Definition 168.16, assemble the paper-side $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ obligation package. The package consists of the RatUp rational source, the reflexive FieldExtUp extension carrier, the identity embedding, the singleton finite basis, the RatUp classifier exactness row, the RatUp operation-table ledger, and an absent standard-bridge field.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational namecert obligation package`

Proof. Use Definition 168.1 for the public carrier field. It names the same BHist carrier and classifier as RatUp and imports the reflexive FieldExtUp embedding and vector-space rows.

Use Definition 168.6 for source, classifier, stability, exactness, ledger, and standard-bridge status. Its rows are precisely the RatUp and FieldExtUp rows cited there.

Use Definition 168.7 for the finite-extension field. The singleton basis supplies a concrete degree witness and the coordinate exactness remains RatUp classifier exactness.

Use Definition 168.14, Definition 168.15, and Definition 168.16 for the reusable degree-one surface. These clauses show that right-unit coordinate readback is unique, the identity embedding sits in the same RatUp classifier class as the singleton coordinate, and the displayed rows are exhausted by the FieldExt table plus that singleton coordinate row.

The public NameCert interface of Definition 161.24 packages the underlying extension surface, while the RatUp certificate chapter supplies the rational source certificate. Repacking those rows with the singleton basis gives the displayed paper-side $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ obligation package and introduces no parameter-transport schema. □

Theorem 168.24 (RatUp reflexive NumField classifier transport)**.** *For accepted package histories P, Q : BHist in the carrier of Definition 168.1, if the displayed package rows of P and Q are componentwise related by* hsame*, then the* $\mathsf{NumField}^{\uparrow}$ *classifier transports the carrier of P to the carrier of Q. The transported rows are exactly the RatUp carrier row, the RatUp FieldUp base row, the RatUp FieldUp ambient row, the identity embedding row, the singleton basis row, and the scalar-action row.*

Proof. Unfold Definition 168.1. The source pattern is the RatUp reflexive $\mathsf{FieldExt}^{\uparrow}$ pattern with a singleton basis field, so the carrier rows of P and Q have the same visible components.

Apply Definition 161.25. It fixes the base carrier, ambient carrier, vector carrier, classifiers, identity embedding, and scalar action to the concrete RatUp data already certified by the $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ source.

The RatUp classifier component is read from Definition 37.90. Thus componentwise hsame transports the rational endpoint rows, and the identity embedding does not alter either endpoint.

It remains to transport the singleton basis row. The row has one displayed unit vector and one coordinate classifier, both over the same $\mathsf{RatHistoryCarrier}$ and $\mathsf{RatHistoryClassifier}$. Projection from the componentwise hsame hypothesis therefore gives the transported basis row, and repacking the transported FieldExt rows with this basis row gives the claimed $\mathsf{NumField}^{\uparrow}$ carrier transport. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveSingletonBasis scalar transport`
Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive classifier transport`

Theorem 168.25 (RatUp reflexive NumField ledger exactness)**.** *Every accepted* $\mathsf{NumField}^{\uparrow}$ *carrier row, embedding row, basis row, scalar-action row, operation row, exactness row, and ledger row in Definition 168.1 is one of the displayed rows of the RatUp reflexive* $\mathsf{FieldExt}^{\uparrow}$ *certificate, together with the singleton basis row. In particular, the FieldExt rows are exhausted by Definition 161.27, and the basis row adds only the unit vector over* $\mathsf{RatHistoryCarrier}$ *with coordinate classifier* $\mathsf{RatHistoryClassifier}$*.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive ledger exactness`

Proof. Begin with an accepted $\mathsf{NumField}^{\uparrow}$ row and unfold Definition 168.1. The definition admits only rows belonging to the RatUp reflexive $\mathsf{FieldExt}^{\uparrow}$ source pattern and the singleton basis field.

For carrier, classifier, embedding, scalar-action, operation, exactness, and ledger rows, apply Definition 161.27. It says that the FieldExt part is covered by the two reads of the $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ endpoint certificate, the identity embedding row, and the self-vector-space row whose scalar action is RatUp multiplication.

The remaining row is the singleton basis field. Its support has one basis entry, the rational unit history, and its coordinate comparison is the same RatUp classifier. The basis ledger therefore records no operation endpoint beyond the unit row already present in the RatUp FieldUp table and no classifier beyond RatHistoryClassifier.

Combining these projections gives row exactness for the complete $\mathsf{NumField}^{\uparrow}$ carrier: every accepted row is either one of the exhausted FieldExt rows or the displayed singleton basis row. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexiveSingletonBasis ledger exactness`
↪ variant `BEDC.Derived.NumFieldUp.NumFieldRatReflexive ledger exactness`

Theorem 168.26 (RatUp reflexive NumField scoped NameCert certificate)**.** *The RatUp reflexive* $\mathsf{NumField}^{\uparrow}$ *construction carries a scoped* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *certificate with the following ten fields.*

1. *The traditional target is the finite field extension of RatUp presented by the reflexive identity extension and the singleton rational basis.*
2. *The BEDC source is RatUp together with the reflexive* $\mathsf{FieldExt}^{\uparrow}$ *extension over* BHist*.*
3. *The public carrier is Definition 168.1.*
4. *The classifier is* RatHistoryClassifier *on the RatUp endpoint histories.*
5. *The classifier-stability field is supplied by Definition 168.24.*
6. *The exactness field is supplied by Definition 168.25.*
7. *The ledger field is the RatUp operation-table ledger together with the singleton basis row, as exhausted by Definition 168.25.*
8. *The core witness list is Definition 168.7 together with Definition 168.23.*
9. *The standard-bridge field is absent.*
10. *The formalization target is the* BEDC.Derived.NumFieldUp *RatUp reflexive certificate surface.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive scoped namecert certificate`

Proof. The carrier and classifier fields are projections of Definition 168.1. That carrier is already a package over BHist whose visible endpoint classifier is RatHistoryClassifier.

The stability field is Definition 168.24. The exactness and ledger fields are the two projections of Definition 168.25: one projection says that accepted rows are exactly the displayed RatUp reflexive FieldExt rows, and the other isolates the singleton basis row.

The finite-extension witness is Definition 168.7, and the assembled NameCert obligations are Definition 168.23. Repacking these named fields gives the scoped certificate. No additional bridge row is constructed, so the standard-bridge field remains absent. □

Theorem 168.27 (RatUp reflexive NumField public NameCert interface)**.** *The scoped certificate of Definition 168.26 exports the public* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *surface whose data are the RatUp carrier,* RatHistoryClassifier*, the identity embedding, the singleton finite basis, scalar action by RatUp multiplication, exact endpoint classification, and the RatUp operation-table ledger.*

Proof. Project the scoped certificate along its carrier and classifier fields. These are the RatUp history carrier and RatHistoryClassifier because Definition 168.1 is built from the RatUp reflexive FieldExt carrier.

Project the extension fields from Definition 161.24. They give the identity embedding, the self-vector-space row, and scalar action by RatUp multiplication.

Project the finite-basis field from Definition 168.7. Its basis has exactly the rational unit vector, and its coordinate classifier is the RatUp endpoint classifier.

Finally project exactness and ledger provenance from Definition 168.25. Repacking these projections yields the displayed public $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ interface. □

Theorem 168.28 (RatUp reflexive NumField standard-bridge boundary)**.** *The certificate of Definition 168.26 claims no host number-field bridge. Any standard bridge for this surface must separately interpret the RatUp identity field extension and singleton basis. The public BEDC surface established here remains entirely within RatUp,* $\mathsf{FieldExt}^{\uparrow}$*,* hsame*, and the displayed* BHist *rows.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldUp StdBridge`

Proof. Read the bridge field of the scoped certificate. It is explicitly absent, so the certificate exports only BEDC package data and no host interpretation.

The exported BEDC data are still concrete: the RatUp source certificate, the reflexive FieldExt carrier, identity embedding, singleton basis, classifier transport, exact endpoint classification, and operation-table ledger. These are precisely the fields cited in Definition 168.27.

Therefore any host number-field bridge has to add an interpretation of the RatUp identity extension and its singleton basis as a separate construction. The present certificate stops at the public BEDC interface and does not claim a standard bridge. □

Theorem 168.29 (NumFieldUp reflexive rational FieldExt scope)**.** *The NumFieldUp source over Definition 168.1 consumes exactly the RatUp reflexive* $\mathsf{FieldExt}^{\uparrow}$ *public interface. Its base field and ambient field are both* $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$*, its embedding is the identity row, its vector carrier is* RatHistoryCarrier*, its scalar action is RatUp multiplication, and it introduces no additional* BHist *endpoint or classifier beyond the RatUp reflexive source.*

Proof. Read the public extension surface from Definition 161.24. The interface lists the two $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$ endpoint certificates, the identity embedding, and the self-vector-space carrier over RatHistoryCarrier.

Apply Definition 161.18 to the vector and scalar rows. It identifies vector addition, vector zero, vector negation, and scalar action with rows of the RatUp operation table, so the scalar action is RatUp multiplication.

The carrier of Definition 168.1 only repacks this public $\mathsf{FieldExt}^{\uparrow}$ surface with the singleton basis field. Therefore the NumFieldUp source has no separate endpoint, classifier, or operation row outside the RatUp reflexive FieldExt scope. □

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldRatReflexive fieldext scope`

Theorem 168.30 (NumFieldUp reflexive rational singleton-basis exhaustion)**.** *Every finite-basis row admitted by the carrier of Definition 168.1 is the singleton rational unit basis row. Its only basis endpoint is the RatUp unit history, and every coordinate comparison is classified by* RatHistoryClassifier*.*

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational singleton basis transport`

Proof. Use Definition 168.7. The finite-extension witness has basis list $[\mathbf{1}_{\mathsf{Rat}}]$ and represents each carried ambient endpoint by the coordinate row $m \cdot \mathbf{1}_{\mathsf{Rat}}$.

Apply Definition 168.25. It exhausts every accepted NumField row by the RatUp reflexive FieldExt rows together with the displayed singleton basis row.

Since there is no second basis field in Definition 168.1, any admitted finite-basis row is that singleton row. The coordinate classifier is the RatUp classifier already named by the finite-extension witness, namely RatHistoryClassifier. □

Theorem 168.31 (NumFieldUp reflexive rational exactness package)**.** *The carrier, classifier, FieldExt scope, singleton basis, stability, endpoint exactness, and ledger rows of Definition 168.1 assemble a concrete paper-side exactness package for* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *over* BHist.

Lean4 ✓ `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational exactness package`

Proof. Start with the carrier and classifier fields from Definition 168.24. They place the RatUp reflexive package rows in BHist and transport accepted packages componentwise by hsame.

Use Definition 168.29 for the extension surface. It fixes the base and ambient fields to $\mathsf{Field}^{\uparrow}(\mathsf{Rat}^{\uparrow})$, the embedding to the identity row, the vector carrier to RatHistoryCarrier, and scalar action to RatUp multiplication.

Use Definition 168.30 for the finite-basis clause. It shows that the only basis row is the rational unit row and that coordinate comparisons are read by RatHistoryClassifier.

Finally combine Definition 168.25 with Definition 37.90. The former exhausts the ledger and exactness rows by the RatUp FieldExt table plus the singleton basis, while the latter supplies the RatUp endpoint certificate. These rows are exactly the carrier, classifier, stability, endpoint exactness, and ledger fields required for the paper-side $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ exactness package. □

Theorem 168.32 (NumField reflexive dependency lattice)**.** *Every accepted reflexive* $\mathsf{NumField}^{\uparrow}$ *carrier read consumes the* $\mathsf{Rat}^{\uparrow}$ *carrier and classifier rows of chapter 37 and the identity-extension rows of chapter 161 before it exposes the singleton-basis number-field row. In particular, the reflexive number-field packet is not an isolated carrier: its public read factors through the displayed rational source, the RatUp field table, the* $\mathsf{FieldExt}^{\uparrow}$ *identity embedding, the inherited vector-space rows, and the local* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Proof. Start with the reflexive carrier rows displayed earlier in this chapter. The base field, ambient field, endpoint classifier, and scalar-action rows are all inherited from the rational certificate and the identity $\mathsf{FieldExt}^{\uparrow}$ packet.

The singleton-basis row is exposed only after that inherited lattice has been read. The $\mathsf{Rat}^{\uparrow}$ rows supply the carrier and classifier surface, while the $\mathsf{FieldExt}^{\uparrow}$ rows supply the identity embedding and vector-space package.

The local $\mathsf{NumField}^{\uparrow}$ naming row repackages those displayed dependencies through its own transport, continuation, package, and certificate rows. Since no independent number-field carrier is present before the rational and identity-extension rows are consumed, every public reflexive read factors through the two sibling certificates. □

Theorem 168.33 (NumFieldUp mature reflexive coverage)**.** *The degree-one RatUp reflexive* $\mathsf{NumField}^{\uparrow}$ *package exhausts the paper-side mature treatment currently claimed for this chapter. Its visible surface is exactly the carrier and classifier row, FieldExt consumption row, finite-extension witness, singleton basis, coordinate readback, ledger exactness rows, public interface, and exactness package for the reflexive rational package. Nontrivial number fields and algebraic-integer theory remain outside this claim.*

Proof. Read the carrier and classifier from Definition 168.2, and read the FieldExt consumption row from Definition 168.3.

The finite-extension witness and singleton basis are supplied by Definition 168.7 and Definition 168.30. Coordinate readback is then fixed by the coordinate exactness, readback, and degree-one exhaustion rows in the reflexive certificate file.

Finally apply the ledger exactness rows, the public-interface row, and Definition 168.31. These rows repack the displayed reflexive rational package without adding a nontrivial extension, integral basis, class group, or algebraic-integer field. □

Closure status for $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$.

Constructive story: The number-field surface closed here is the reflexive rational extension: start with a $\mathsf{Rat}^\uparrow$ history endpoint, use the same $\mathsf{Rat}^\uparrow$ carrier and classifier for both the base and ambient fields, and consume the identity $\mathsf{FieldExt}^\uparrow$ row whose embedding sends each rational endpoint to itself. A history is admitted exactly when it is already a RatUp carrier history in this degree-one extension; no polynomial root, second basis vector, algebraic-integer endpoint, or separate ambient carrier is accepted. The classifier is simply the RatUp history classifier, transported through the identity embedding and the right-unit coordinate readback, so two displayed number-field endpoints are the same precisely when the underlying rational histories are classified as the same rational. The source specification is the RatUp field-operation table together with the reflexive $\mathsf{FieldExt}^\uparrow$ interface, the pattern specification is identity embedding, singleton unary basis, scalar action by RatUp multiplication, coordinate readback, basis exhaustion, and exact endpoint classification, and the ledger keeps the carrier, operation-table, finite-extension, basis, coordinate, embedding, scalar-action, and provenance rows visible. The five name-certificate obligations are inherited from RatUp and FieldExtUp: an accepted rational endpoint inhabits the carrier, the RatUp classifier supplies reflexivity, symmetry, and transitivity, and identity transport keeps every accepted endpoint inside the same degree-one package. A history h lies in the signature gap of a $\mathsf{NumField}^\uparrow$ token p when the source-domain accepts h as a rational endpoint in this reflexive extension, the signature relation pairs it with an answer endpoint and the singleton-basis evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is the rational coordinate encoded by p and its embedding coordinate is the same RatUp endpoint. The chapter registers this degree-one reflexive construction under the name $\mathsf{NumField}^\uparrow$; it introduces no nontrivial number field, Galois structure, algebraic-integer theory, public-object closure, or standard bridge.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 168.28 is the paper-side bridge boundary for the RatUp reflexive NumFieldUp interface over FieldExtUp: BHist, RatHistoryCarrier, RatHistoryClassifier, the reflexive degree-one carrier, finite-extension witness, coordinate readback, singleton-basis exhaustion, ledger exactness, the NameCert obligation package, and the exactness package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.NumFieldUp.NumFieldReflexiveRational\_exactness\_package`

Bridge status: bridgeChecked

Not claimed: Nontrivial number fields, algebraic integer theory, Galois structure, public-object closure, and standard bridges are not claimed here.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 169

A Concrete Naming Certificate for $\mathsf{RingOfIntegers}^{\uparrow}$

The ring-of-integers interface $\mathsf{RingOfIntegers}^{\uparrow}$ packages the integral closure of $\mathsf{Int}^{\uparrow}$ inside a number-field carrier. It depends on $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168) and $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$ (chapter 31).

169.1 Carrier definition

Definition 169.1 (RingOfIntegers Dedekind-source carrier)**.** *A* $\mathsf{RingOfIntegers}^{\uparrow}$ *Dedekind-source carrier is a finite displayed* BHist *packet*

$$\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho)$$

over $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$*. The row* $\mathcal{N}$ *is the accepted number-field carrier row, and* $\mathcal{Z}$ *is the accepted embedded integer row read through* $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$ *inside the same field-operation boundary. The row* η *records the displayed embedding provenance from the integer source into the number-field source.*

The finite ledger E *lists integral-equation rows over the visible field addition, multiplication, zero, one, and negation operations supplied by* $\mathcal{N}$*, with coefficients read from* $\mathcal{Z}$*. The classifier row* κ *records the* hsame *transports for the number-field carrier, embedded integer rows, field-operation endpoints, and every equation row in* E*. The row* τ *is the finite* Cont *provenance tying the equation ledger to the two dependency certificates, and* ρ *is the shared* Pkg *provenance. No host quotient of algebraic integers, host polynomial equality, or ambient choice of a number-field model is a field of the carrier.*

Lean4 (definition) `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier`

169.2 The certificate

Theorem 169.2 (RingOfIntegers integral-closure obligation surface)**.** *The* $\mathsf{RingOfIntegers}^{\uparrow}$ *root obligation surface consists of the Dedekind-source carrier of Definition 169.1, its classifier* κ*, the finite integral-equation ledger* E*, the transport rows for* $\mathcal{N}$*,* $\mathcal{Z}$*,* η*, and* E*, and the no-host-quotient ledger recording that integral closure is read only from displayed* BHist*,* hsame*,* Cont*, and* Pkg *data. These rows form the root* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *obligation surface over* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$*.*

Every accepted root row projects to the number-field carrier row, the embedded integer row, the integral-equation ledger, classifier transport, continuation provenance, and package provenance listed above. Conversely, any finite row family with exactly these fields repacks as a $\mathsf{RingOfIntegers}^{\uparrow}$ *obligation surface.*

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier integral closure obligation surface`

Proof. Read the two dependency certificates first. The $\mathsf{NumField}^{\uparrow}$ certificate supplies the visible field carrier and operation endpoints used by $\mathcal{N}$, while the $\mathsf{Int}^{\uparrow}$ certificate supplies the embedded integer row and the coefficient rows used by $\mathcal{Z}$ and η.

Project the carrier of Definition 169.1. Its visible fields are precisely $\mathcal{N}$, $\mathcal{Z}$, η, the integral-equation ledger E, the classifier row κ, the continuation row τ, and the package row ρ. The no-host-quotient clause in the definition excludes any additional ambient quotient or host polynomial-equality witness.

It remains to check the equation ledger. Induct over the finite ledger E. The empty ledger contributes no integral equation and leaves only the dependency, classifier, continuation, and package rows. In the cons step, the head equation is projected to its displayed field-operation endpoints and integer-coefficient rows, while the induction hypothesis projects the tail ledger.

The same induction gives the reverse packaging. Given the listed rows, rebuild the empty ledger immediately, and in the cons case attach the displayed head equation to the carrier already rebuilt for the tail. The transport rows for $\mathcal{N}$, $\mathcal{Z}$, η, and E supply exactly the classifier stability required by κ.

Collecting these fields yields the stated $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ obligation surface. Since every field has been projected from, or repacked into, the displayed finite packet, the surface has no hidden host quotient or detached integral-closure carrier. □

Theorem 169.3 (RingOfIntegers dependency projection boundary)**.** *Every accepted* $\mathsf{RingOfIntegers}^{\uparrow}$ *Dedekind-source carrier*

$$\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho)$$

projects exactly to the $\mathsf{NumField}^{\uparrow}$ *carrier and operation rows carried by* $\mathcal{N}$*, the embedded* $\mathsf{Int}^{\uparrow}$ *rows carried by* $\mathcal{Z}$ *and* η*, the displayed* Cont *provenance* τ*, the* hsame *classifier row* κ*, and the* Pkg *provenance* ρ*. The dependency projection has no host polynomial-equality row, host integral-closure carrier, or quotient carrier.*

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier dependency projection boundary`

Proof. Unpack the carrier of Definition 169.1. Its dependency fields are precisely the number-field row $\mathcal{N}$, embedded integer row $\mathcal{Z}$, embedding provenance η, classifier κ, continuation row τ, and package row ρ.

Apply Definition 169.2. The obligation surface projects accepted rows to those displayed dependency rows and to the finite equation ledger E, with no hidden host carrier.

Finally drop the equation entries and retain only the rows that describe the dependency boundary. Because the carrier definition has no field for host polynomial equality, a quotient carrier, or a detached integral-closure object, the projection is exhausted by the listed $\mathsf{NumField}^{\uparrow}$, $\mathsf{Int}^{\uparrow}$, Cont, hsame, and Pkg rows. □

Theorem 169.4 (RingOfIntegers equation-ledger transport closure)**.** *For an accepted* $\mathsf{RingOfIntegers}^{\uparrow}$ *Dedekind-source carrier*

$$\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho),$$

transport the finite integral-equation ledger E *by the displayed classifier row* κ*. The transported ledger, together with the same* $\mathsf{NumField}^{\uparrow}$ *carrier row, embedded* $\mathsf{Int}^{\uparrow}$ *rows,* Cont *provenance, and* Pkg *provenance, repacks as the same accepted* $\mathsf{RingOfIntegers}^{\uparrow}$ *obligation surface. No host polynomial-equality row, quotient carrier, or detached integral-closure carrier is introduced by the transport.*

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier equation ledger transport closure`

Proof. Unpack Definition 169.1. The classifier row κ contains the hsame transports for the number-field carrier, embedded integer rows, field-operation endpoints, and every integral-equation row in E.

Induct over the finite ledger E, following the ledger argument in Definition 169.2. In the empty case, transport preserves only the dependency, classifier, continuation, and package rows, so the obligation surface repacks immediately.

In the cons case, the head equation is transported through the displayed field-operation endpoints and integer-coefficient rows recorded by κ. The induction hypothesis transports the tail ledger and repacks it over the same $\mathcal{N}$, $\mathcal{Z}$, η, τ, and ρ rows.

Attach the transported head equation to the transported tail and repack through the obligation surface. Since every transported equation row remains a row of the displayed finite ledger and the carrier has no host polynomial-equality or quotient field, the accepted surface is unchanged. □

Theorem 169.5 (RingOfIntegers root classifier transport)**.** *For a* $\mathsf{RingOfIntegers}^{\uparrow}$ *Dedekind-source carrier*

$$\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho),$$

the root classifier transports exactly the displayed packet fields $\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho$ *along* hsame*. A transported accepted row has the same number-field source row, embedded integer row, embedding-provenance row, finite integral-equation ledger, classifier row,* Cont *provenance row, and* Pkg *provenance row. No host integral-closure carrier, quotient object, or detached polynomial-equality row is transported.*

Proof. Project the carrier through Definition 169.1. Its named fields are exactly $\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho$, and the classifier row κ records the allowed hsame transports for these fields.

Apply the obligation surface of Definition 169.2. It says that accepted root rows project only to the number-field source, embedded integer source, embedding provenance, integral-equation ledger, classifier transport, continuation provenance, and package provenance.

Repack the transported projections with the same finite ledger and provenance rows. Since neither the carrier definition nor the obligation surface has a field for a host integral-closure carrier, quotient object, or detached polynomial-equality row, transport is exhausted by the displayed packet fields. □

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier classifier transport`

Theorem 169.6 (RingOfIntegers integral-equation ledger exhaustion)**.** *Every integral-equation read accepted by a* $\mathsf{RingOfIntegers}^{\uparrow}$ *root surface is one of the finite ledger rows in* E *of the Dedekind-source carrier* $\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho)$*. Conversely, every row of* E*, together with its* hsame *classifier entry in* κ*, its finite* Cont *provenance in* τ*, and the shared* Pkg *row* ρ*, repacks as an accepted integral-equation read of the same root surface.*

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersEquationLedgerCarrier finite ledger readback`

Proof. Induct on the finite ledger E. In the empty case, the carrier still exposes the dependency rows, classifier row, continuation row, and package row, but it exposes no integral-equation read.

In the cons case, project the head equation to its displayed field-operation endpoints and integer-coefficient rows. The classifier component of κ and the continuation component of τ are the only rows that bind this head equation to the root packet.

Apply the induction hypothesis to the tail ledger. It exhausts all remaining integral-equation reads through the same $\mathcal{N}, \mathcal{Z}, \eta$ source rows and the same shared package provenance.

The reverse direction uses the same induction. The empty ledger repacks immediately, and the cons step attaches the displayed head equation before repacking the tail. Thus the accepted equation reads are exactly the finite rows of E, with no host integral-closure or quotient source. □

Theorem 169.7 (RingOfIntegers DirichletUnit source readback)**.** *A downstream* $\mathsf{DirichletUnit}^{\uparrow}$ *consumer reading from* $\mathsf{RingOfIntegers}^{\uparrow}$ *may read only the embedded integer row* $\mathcal{Z}$*, the integral-equation ledger* E*, the classifier row* κ*, the finite* Cont *provenance row* τ*, and the shared* Pkg *provenance row* ρ *carried by the accepted Dedekind-source packet* $\mathcal{O} = (\mathcal{N}, \mathcal{Z}, \eta, E, \kappa, \tau, \rho)$*. The consumer may also retain the number-field source row* $\mathcal{N}$ *and embedding provenance* η *as dependency scope, but it receives no host integral-closure carrier, quotient object, or analytic unit datum from* $\mathsf{RingOfIntegers}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier dirichletunit source readback`

Proof. Project the $\mathsf{RingOfIntegers}^{\uparrow}$ source through Definition 169.2. The dependency rows available to any consumer are the number-field row, embedded integer row, embedding provenance, integral-equation ledger, classifier, continuation provenance, and package provenance.

Use Definition 169.5 to identify the transported classifier data. A $\mathsf{DirichletUnit}^{\uparrow}$ reader may compare accepted integer and equation rows only through the displayed hsame entries of κ.

Use Definition 169.6 to exhaust the equation side. Every equation read is a member of E and is tied to the same finite continuation and package rows.

Therefore the downstream readback surface is exactly the embedded integer, equation-ledger, classifier, Cont, and Pkg rows, with $\mathcal{N}$ and η serving only as dependency scope. No additional host integral-closure, quotient, or analytic unit row is available to the consumer. □

Theorem 169.8 (RingOfIntegers scoped dependency package)**.** *The* $\mathsf{RingOfIntegers}^{\uparrow}$ *carrier, integral-equation ledger, dependency projection, classifier transport, ledger exhaustion, and* $\mathsf{DirichletUnit}^{\uparrow}$ *readback rows of this chapter are exhausted by the scoped primitive package consisting of* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$*.*

No public read of the chapter uses a host integral-closure predicate, quotient integer object, analytic unit datum, or extra dependency beyond those primitive rows and the displayed source certificates.

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier scoped dependency package`

Proof. First use Definition 169.2. It lists the carrier and integral-equation ledger rows available to the chapter and ties them to the number-field and integer source certificates.

Next apply Definition 169.3 and Definition 169.5. These identify the dependency projection and classifier transport as rows over BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$.

Finally use Definition 169.6 together with Definition 169.7. The ledger exhaustion and downstream readback clauses show that every consumer row is one of the displayed primitive rows, so the obligation surface is a scoped dependency package. □

Theorem 169.9 (RingOfIntegers scoped BHist source binding)**.** *The Dedekind-source carrier, dependency projection boundary, equation-ledger transport closure, root classifier transport, integral-equation ledger exhaustion, and* $\mathsf{DirichletUnit}^{\uparrow}$ *source readback bind the* $\mathsf{RingOfIntegers}^{\uparrow}$ *obligation surface entirely to* BHist, hsame, Cont, $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$, *and* Pkg *rows.*

No host polynomial equality, quotient object, detached integral-closure carrier, analytic unit datum, or standard bridge row is in scope for this binding.

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersClassifierTransportCarrier scoped bhist source binding`

Proof. First project the carrier and obligation rows through Definition 169.1 and Definition 169.2. These two blocks identify the accepted surface with the displayed number-field source, embedded integer source, integral-equation ledger, classifier, continuation, and package provenance.

Next bind the dependency and transport faces. Apply Definition 169.3, Definition 169.4, and Definition 169.5. They restrict all dependency projections, equation transport, and root classifier movement to the same BHist, hsame, Cont, $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$, and Pkg rows.

Finally use Definition 169.6 and Definition 169.7. The equation ledger is exhausted by the finite displayed rows, and the downstream $\mathsf{DirichletUnit}^{\uparrow}$ readback receives only the embedded integer, equation ledger, classifier, continuation, package, and dependency-scope rows already listed.

Repacking these projections gives the scoped source binding. Since none of the cited blocks exports a field for host polynomial equality, a quotient object, a detached integral-closure carrier, an analytic unit datum, or a standard bridge, those rows are outside the $\mathsf{RingOfIntegers}^{\uparrow}$ obligation surface. □

Lean4 ✓ `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier scoped bhist source binding`

Closure status for $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$**.**

Constructive story: A ring of integers is presented as a Dedekind-source packet over a $\mathsf{NumField}^{\uparrow}$ carrier and an embedded $\mathsf{Int}^{\uparrow}$ row, with the embedding provenance followed by a finite ledger of integral equations written in the visible field operations. The carrier accepts exactly the number-field row, embedded-integer row, embedding row, integral-equation ledger, classifier row, continuation provenance, and package provenance displayed in that packet, while host polynomial equality, quotient algebraic-integer objects, and detached integral-closure carriers have no slot. Its classifier transports the number-field carrier, embedded integer rows, operation endpoints, and every equation row by hsame, then repacks the same finite ledger with the same Cont and Pkg provenance. The source specification is the combined NumField and Int dependency surface, the pattern specification is the displayed integral-equation witness family, and the ledger keeps each raw equation row visible as one of the finite rows tied to the dependency certificates. The five naming-certificate obligations are represented by the displayed dependency package: an accepted packet provides a carrier endpoint, hsame gives reflexive, symmetric, and transitive comparison, and the equation-ledger transport theorem supplies closure under classified replacement. A history h lies in the signature GAP of a $\mathsf{RingOfIntegers}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it to an answer packet and evidence ledger, and token introduction names that answer as p; in this chapter, that means h is the endpoint whose number-field source, embedded integer source, integral-equation ledger, classifier, continuation row, and package provenance are exactly the carried rows. The chapter registers this construction as $\mathsf{RingOfIntegers}^{\uparrow}$ without closing full algebraic-integer theory, class-group structure, analytic units, or a standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature package consists of the displayed Dedekind-source carrier, integral-equation ledger, classifier transport, ledger exhaustion, and DirichletUnit readback rows over BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{Int}^{\uparrow}}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RingOfIntegersUp.RingOfIntegersDedekindSourceCarrier\_scoped\_bhist\_source\_binding`

Bridge status: none

Not claimed: It does not close full algebraic-integer theory, class-group structure, analytic units, or standard bridge rows.

Upgrade path: No further paper theory-axis strengthening is recorded for the displayed mature package; any standard bridge remains a separate bridge-axis matter.

Chapter 170

A Concrete Naming Certificate for $\mathsf{IdealClass}^{\uparrow}$

The ideal-class interface $\mathsf{IdealClass}^{\uparrow}$ packages the quotient group of fractional ideals modulo principal ideals in a Dedekind domain. It depends on $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ (chapter 172) and $\mathsf{NameCert}_{\mathsf{QuotientGroup}^{\uparrow}}$ (chapter 82).

170.1 Carrier definition

Theorem 170.1 (IdealClass fractional-ideal carrier obligation)**.** *An* $\mathsf{IdealClass}^{\uparrow}$ *carrier endpoint is a* BHist *row carrying the* $\mathsf{Dedekind}^{\uparrow}$ *fractional-ideal source, the nonzero and invertible fractional-ideal ledger, and the* $\mathsf{QuotientGroup}^{\uparrow}$ *source boundary. The endpoint is admitted only when its* BHist*,* NameCert*,* hsame*, and* Pkg *rows identify the same Dedekind carrier and the same quotient-group boundary.*

Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassFractionalIdealCarrier obligation`
Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassFractionalCarrier source obligation`

Proof. Start from the opening dependencies on $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{QuotientGroup}^{\uparrow}}$. The carrier obligation reads the Dedekind fractional-ideal source as the BEDC source field, chooses BHist rows as the carrier, and records nonzero and invertible fractional-ideal evidence in the ledger before any quotient is formed.

The ten-field fit is: traditional target ideal classes of a Dedekind domain; BEDC source the cited $\mathsf{Dedekind}^{\uparrow}$ certificate together with the $\mathsf{QuotientGroup}^{\uparrow}$ source boundary; carrier BHist rows for fractional ideals; classifier pending principal-ideal equivalence; stability pending quotient transport; ledger the Dedekind source plus nonzero and invertible evidence; core theorem carrier endpoint admission; exactness exclusion of detached fractional-ideal representatives; standard bridge none; status ProofTarget. □

Theorem 170.2 (IdealClass principal classifier obligation)**.** *The* $\mathsf{IdealClass}^{\uparrow}$ *classifier relates two carried fractional-ideal endpoints exactly when their quotient product is principal. Reflexivity, symmetry, transitivity, and carrier transport are inherited from the* $\mathsf{Dedekind}^{\uparrow}$ *fractional-ideal rows and the* $\mathsf{QuotientGroup}^{\uparrow}$ *classifier boundary, so the classifier is a carried BEDC relation rather than a host quotient relation.*

Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassPrincipalClassifier semanticNameCert`

Proof. Use the fractional-ideal carrier fixed by Definition 170.1. The classifier row is the principal quotient-product witness relation over the same Dedekind source, so equality of endpoints is certified by a visible principal ideal and not by eliminating a quotient type.

The ten-field fit is: traditional target ideal-class equality; BEDC source $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ with the $\mathsf{QuotientGroup}^{\uparrow}$ source boundary; carrier carried fractional-ideal endpoints; classifier principal quotient-product equivalence; stability reflexivity, symmetry, transitivity, and carrier transport; ledger the two endpoints and the principal witness; core theorem classifier admission and equivalence laws; exactness absence of host quotient soundness; standard bridge none; status ProofTarget. □

Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassPrincipalClassifier empty boundary laws`

Theorem 170.3 (IdealClass quotient operation exactness obligation)**.** *Fractional-ideal multiplication descends through the principal-class classifier of Definition 170.2. The* $\mathsf{IdealClass}^{\uparrow}$ *ledger hides only the principal witness while preserving the* BHist*,* NameCert*,* hsame*, and* Pkg *provenance rows for the Dedekind source, the carried representatives, and the* $\mathsf{QuotientGroup}^{\uparrow}$ *operation boundary.*

Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassQuotientOperation exactness obligation`
Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassQuotientOperation empty product exactness`

Proof. First apply Definition 170.1 and Definition 170.2 to fix the carried representatives and the principal classifier. Multiplication is then read as a $\mathsf{QuotientGroup}^{\uparrow}$ operation row over that classifier, with identity and inverse data transported through the same source boundary.

The ten-field fit is: traditional target the ideal-class group operation; BEDC source the shared $\mathsf{Dedekind}^{\uparrow}$ fractional-ideal source and $\mathsf{NameCert}_{\mathsf{QuotientGroup}^{\uparrow}}$; carrier carried fractional-ideal endpoints; classifier principal quotient-product equivalence; stability multiplication descent, identity descent, inverse descent, and representative independence; ledger preserved BHist, NameCert, hsame, and Pkg provenance with only the principal witness hidden; core theorem quotient operation exactness; exactness no detached quotient and no lost provenance row; standard bridge none; status ProofTarget. □

170.2 The certificate

Theorem 170.4 (IdealClass scoped source certificate)**.** *The carrier obligation of Definition 170.1, the principal classifier obligation of Definition 170.2, and the quotient operation exactness obligation of Definition 170.3 jointly determine the scoped* $\mathsf{IdealClass}^{\uparrow}$ *source certificate over the cited* $\mathsf{Dedekind}^{\uparrow}$ *and* $\mathsf{QuotientGroup}^{\uparrow}$ *sources. Its carrier endpoints are* BHist *rows with Dedekind fractional-ideal provenance and quotient boundary provenance; its classifier equality is the principal quotient-product witness relation; its multiplication, identity, and inverse descent are read through the* $\mathsf{QuotientGroup}^{\uparrow}$ *operation boundary; and its ledger hides only the principal witness while preserving* BHist*,* NameCert*,* hsame*, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.IdealClassUp.IdealClassScoped source certificate`

Proof. Repack the carrier site as the carrier and ledger source of the certificate. The admitted endpoints are the BHist rows already tied to the $\mathsf{Dedekind}^{\uparrow}$ fractional-ideal source and the $\mathsf{QuotientGroup}^{\uparrow}$ boundary, with NameCert, hsame, and Pkg rows kept in the same source scope.

Repack the classifier site as the equality field. The relation is not a host quotient equality: it is the principal quotient-product witness relation on the carried endpoints, and its equivalence behavior is the one transported through the named Dedekind and quotient-group sources.

Repack the operation site as the stability and exactness fields. Multiplication, identity, and inverse descent are read through the $\mathsf{QuotientGroup}^{\uparrow}$ operation boundary, and the exactness ledger hides only the principal witness while retaining the visible BHist, NameCert, hsame, and Pkg provenance rows.

These three repackings fill the roadmap ten-field template for $\mathsf{IdealClass}^{\uparrow}$: traditional target, BEDC source, carrier, classifier, stability, ledger, core theorem surface, exactness exclusion, standard bridge status, and verification status. Thus the scoped source certificate is determined within exactly the $\mathsf{Dedekind}^{\uparrow}$, $\mathsf{QuotientGroup}^{\uparrow}$, BHist, NameCert, hsame, and Pkg scope recorded above. □

Closure status for $\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$.

Constructive story: An ideal class is built from carried fractional-ideal endpoints over the displayed $\mathsf{Dedekind}^{\uparrow}$ source and the $\mathsf{QuotientGroup}^{\uparrow}$ boundary, with nonzero, invertible, and quotient-operation evidence kept as certificate rows before any quotient object is formed. The carrier accepts exactly those BHist rows whose Dedekind provenance and quotient-group provenance identify the same fractional-ideal boundary, while detached representatives and host quotient types are left outside the source. Two accepted endpoints classify together when the quotient product between them is witnessed as principal inside the same carried Dedekind and QuotientGroup rows, so equality of ideal classes is a visible principal-witness relation rather than elimination into a quotient set. The source specification is the paired Dedekind and QuotientGroup surface, the pattern specification is fractional-ideal multiplication with identity and inverse descent through principal witnesses, and the ledger hides only the principal witness while retaining the endpoint, classifier, hsame, and Pkg provenance rows. The five naming-certificate obligations are supplied by the scoped source certificate: an accepted fractional-ideal endpoint inhabits the carrier, the principal classifier inherits reflexivity, symmetry, and transitivity from the quotient boundary, and carrier transport follows from the same Dedekind and QuotientGroup source rows. A history h lies in the signature GAP of an $\mathsf{IdealClass}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer fractional-ideal row and evidence ledger, and token introduction names that answer as p; concretely, h must carry the Dedekind fractional-ideal provenance, the quotient boundary, and the principal-witness ledger that identifies its class. The chapter registers this construction as $\mathsf{IdealClass}^{\uparrow}$ without closing a public NameCert surface, a standard bridge, or a separate Lean theorem for the full ideal-class interface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridged paper surface is the $\mathsf{Dedekind}^{\uparrow}$ fractional-ideal endpoint, $\mathsf{QuotientGroup}^{\uparrow}$ principal-classifier boundary, quotient-operation descent, and visible BHist, NameCert, hsame, and Pkg provenance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.IdealClassUp.IdealClassScoped\_source\_certificate`

Bridge status: none

Not claimed: This chapter does not close a standard bridge or a separate host quotient model for IdealClassUp.

Upgrade path: No paper-side theory-grade obligation remains before a separate standard bridge is supplied; bridge verification is not claimed here.

Chapter 171

A Concrete Naming Certificate for $\mathsf{DirichletUnit}^{\uparrow}$

The Dirichlet-unit interface $\mathsf{DirichletUnit}^{\uparrow}$ packages the structure of the unit group of a ring of integers as a finitely generated abelian group of rank r_1+r_2-1. It depends on $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ (chapter 169) and $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ (chapter 42).

171.1 Carrier definition

Definition 171.1 (DirichletUnit carrier packet)**.** *A* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packet is a displayed* BHist *tuple*

$$\mathcal{D} = (\mathcal{O}, \mathcal{A}, u, \iota, \nu, \beta, \rho)$$

whose entries are read as follows. The row $\mathcal{O}$ *is the dependency* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$*, the row* $\mathcal{A}$ *is the dependency* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$*, the row* u *is a visible unit row over* $\mathcal{O}$*, the row* ι *records the inverse and unit-product witnesses for* u*, the row* ν *is a unary free-rank witness, the row* β *is the finite basis and logarithmic ledger row, and the row* ρ *is the* Pkg *provenance tying these entries to the two dependency certificates. The packet also carries the finite* Cont *readbacks from* $\mathcal{O}$ *to* u *and* ι*, from* $\mathcal{A}$ *to the public abelian-group law rows, and from* ρ *to every exported dependency slot.*

The packet is a history-facing carrier. It exposes no host-level unit type, no analytic logarithm equality, no determinant, and no standard bridge; it exposes only the named rows, their readback ledgers, and their package provenance.

Lean4 (definition) `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier`

Theorem 171.2 (DirichletUnit visible unit row obligation)**.** *Every accepted* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packet exposes the visible unit row* u *and the inverse/unit-product row* ι *as carried* BHist *rows over the dependency certificate* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$*. These rows are exported only through the finite* Cont *readback and* Pkg *provenance of Definition 171.1; they are not host units and do not assert host-level multiplication outside the displayed history.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier visible unit rows`

Proof. Project an accepted packet to its tuple entries. The rows $\mathcal{O}$, u, and ι are named components of the same displayed BHist packet, and the carrier definition includes the Cont readback from $\mathcal{O}$ to the two unit-facing rows.

The provenance row ρ records that the readback is part of the same package. Repacking these projections gives exactly the exported unit and inverse surface, with no additional host carrier available to inspect. □

Theorem 171.3 (DirichletUnit classifier obligation)**.** *Classifier transport for* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packets is componentwise* hsame *together with dependency provenance transport. If packets* $\mathcal{D}$ *and* $\mathcal{D}'$ *are classified, then* hsame *transports the visible unit rows, inverse/unit-product rows, rank witness rows, finite basis/log-ledger rows, and package provenance rows, while the dependency slots remain tied to* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *by their displayed* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier classifier transport`

Proof. Unpack the classifier as comparisons between the corresponding displayed rows of $\mathcal{D}$ and $\mathcal{D}'$. Each comparison is an hsame witness at a named projection of the carrier packet.

Transport the unit and inverse rows through the $\mathsf{RingOfIntegers}^{\uparrow}$ readback, then transport the rank and basis/log-ledger rows through their own packet projections. The package row transports the dependency provenance at the same time.

Repack the transported rows with the target packet's readback ledgers. The result is componentwise classifier transport for the whole Dirichlet-unit surface. □

Theorem 171.4 (DirichletUnit free-rank witness ledger)**.** *The free-rank witness* ν *and the finite basis/logarithmic ledger row* β *of a* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packet are visible ledger rows. Their stability under accepted carrier comparison is carried by* Cont*,* hsame*, and* Pkg *provenance, and does not assert equality of analytic logarithms or equality of regulator values.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier free rank witness ledger`

Proof. Project the rank and basis/log-ledger entries from the carrier packet. They are listed as displayed BHist rows, so their visibility is part of the packet rather than a theorem about an external analytic object.

For a classified pair, apply componentwise hsame to the rank row and to the ledger row. The Cont entries preserve the finite readback pattern, and ρ supplies the package provenance tying those rows to the same dependency boundary.

The proof stops at the ledger boundary. Since no analytic logarithm map or determinant row is a component of the packet, no such equality can be projected from this obligation. □

Theorem 171.5 (DirichletUnit abelian-group dependency obligation)**.** *The public abelian-group laws used by* $\mathsf{DirichletUnit}^{\uparrow}$ *are inherited through the dependency certificate* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *and are restricted to unit rows accepted by the* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *dependency. Thus the group-law surface is available only where the ring-of-integers certificate supplies the visible unit and inverse rows of Definition 171.1.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier abgroup dependency obligation`

Proof. Project the dependency row $\mathcal{A}$ and its Cont readback from the carrier packet. This is the only source of the public abelian-group law rows.

Project the ring-of-integers row $\mathcal{O}$ together with u and ι. The law rows from $\mathcal{A}$ are paired with these unit-facing rows by the same package provenance row ρ.

Repack the dependency projections. The inherited law surface is therefore confined to accepted unit rows over $\mathcal{O}$, rather than a free-standing group law on an ambient host type. □

Theorem 171.6 (DirichletUnit NameCert surface obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{DirichletUnit}^\uparrow}$ *surface is assembled from the carrier packet of Definition 171.1, the componentwise classifier of Definition 171.3, the dependency certificates* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{AbGroup}^\uparrow}$*, the visible unit and inverse rows, the rank and finite basis/log-ledger rows, the* Cont *stability rows, the* Pkg *provenance rows, and the exactness claim that every exported Dirichlet-unit row is one of these displayed packet entries.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier namecert obligation surface`

Proof. Start with an accepted carrier packet. Its displayed entries give the carrier, dependency, unit, inverse, rank, ledger, and provenance rows.

Use the classifier obligation to supply transport for comparisons between accepted packets. Use the visible-unit obligation and the abelian-group dependency obligation to bind the unit-facing rows to $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^\uparrow}$ and the law-facing rows to $\mathsf{NameCert}_{\mathsf{AbGroup}^\uparrow}$.

The exactness statement is obtained by projection and repacking. Any exported certificate row must be one of the packet entries or one of the finite readbacks named in the packet, and those entries repack as the public $\mathsf{NameCert}_{\mathsf{DirichletUnit}^\uparrow}$ surface. □

Theorem 171.7 (DirichletUnit Regulator consumer boundary)**.** *A downstream* $\mathsf{Regulator}^\uparrow$ *certificate may consume from* $\mathsf{DirichletUnit}^\uparrow$ *only the visible unit rows, inverse/unit-product rows, unary rank witness, finite basis/logarithmic ledger rows, dependency rows,* Cont *readbacks, and* Pkg *provenance rows described above. It may not read a determinant, an analytic regulator value, or a standard bridge from* $\mathsf{DirichletUnit}^\uparrow$ *alone.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier regulator consumer boundary`

Proof. Project the public $\mathsf{NameCert}_{\mathsf{DirichletUnit}^\uparrow}$ surface from Definition 171.6. The listed consumer inputs are exactly the rows present in that surface.

Inspect the carrier packet: determinant rows, analytic regulator values, and standard bridge rows are not entries of $\mathcal{D}$, nor are they reachable by the finite Cont readbacks named by the packet.

Therefore a $\mathsf{Regulator}^\uparrow$ construction can cite the unit, inverse, rank, ledger, dependency, readback, and provenance rows. Any determinant or analytic regulator row must come from a separate regulator-side construction. □

Theorem 171.8 (DirichletUnit Regulator unit-row source exhaustion)**.** *Every* $\mathsf{Regulator}^\uparrow$ *consumer read of a* $\mathsf{DirichletUnit}^\uparrow$ *unit row or inverse row factors through the visible unit row* u*, the inverse/unit-product row* ι*, the ring-of-integers dependency row* $\mathcal{O}$*, the finite* Cont *readback, and the* Pkg *provenance of Definition 171.1. No other unit-facing source is exported by the carrier packet.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier regulator unit row source exhaustion`

Proof. Project the accepted packet through Definition 171.1. The only unit-facing entries are u and ι, and their source dependency is the displayed row $\mathcal{O}$.

Apply Definition 171.6 to pass from packet entries to public certificate rows. Then apply Definition 171.12 where the read asks for the inherited inverse or product law row.

The finite Cont readback and the provenance row ρ are the remaining packet entries tying these unit-facing rows to the exported surface. Repacking these projections gives the stated source exhaustion for every $\mathsf{Regulator}^\uparrow$ unit-row read. □

Theorem 171.9 (DirichletUnit Regulator rank-ledger source)**.** *Every* $\mathsf{Regulator}^{\uparrow}$ *read of a* $\mathsf{DirichletUnit}^{\uparrow}$ *rank row, basis row, or logarithmic-ledger row factors through the unary rank witness* ν *and the finite ledger row* β *of Definition 171.1. The factorization asserts no determinant, analytic logarithm equality, or regulator value.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier regulator rank ledger source`

Proof. Project the carrier packet. Its rank-facing component is the unary witness ν, and its basis or logarithm-facing component is the finite ledger row β.

Apply Definition 171.11. This identifies the rank row as a $\mathsf{UnaryHistory}$ ledger and keeps the visible expression inside finite readback.

Finally apply Definition 171.6 to read these two rows as public $\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$ entries. Since Definition 171.1 contains no determinant or analytic logarithm equality row, the consumer read cannot project either one from $\mathsf{DirichletUnit}^{\uparrow}$ alone. □

Theorem 171.10 (DirichletUnit Regulator consumer threshold package)**.** *The exact* $\mathsf{DirichletUnit}^{\uparrow}$ *threshold package available to* $\mathsf{Regulator}^{\uparrow}$ *consists of the unit-row source surface of Definition 171.8, the rank-ledger source surface of Definition 171.9, and the exclusion boundary of Definition 171.7. Thus a* $\mathsf{Regulator}^{\uparrow}$ *construction may consume visible unit and inverse rows, the unary rank witness, finite basis/logarithmic ledger rows, dependency rows,* Cont *readbacks, and* Pkg *provenance, but not determinant, analytic regulator, or standard-bridge rows from* $\mathsf{DirichletUnit}^{\uparrow}$ *alone.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier regulator consumer threshold package`

Proof. First project the unit-facing surface. Apply Definition 171.8; this gives the rows u, ι, $\mathcal{O}$, their finite readback, and their package provenance.

Next project the rank-facing surface. Apply Definition 171.9; this gives the unary witness ν and the finite ledger row β, without analytic determinant or logarithm equality.

Finally apply Definition 171.7. It excludes every regulator-facing row not listed by the two source projections. Repacking the surviving rows gives exactly the threshold package stated above. □

Theorem 171.11 (Dirichlet-unit rank ledger)**.** *Every accepted carrier of Definition 171.1 contains a rank witness as a* $\mathsf{UnaryHistory}$ *row recording the visible ledger expression* $r_1 + r_2 - 1$*. This row is stable under the row classifier of Definition 171.3, and it asserts no host arithmetic beyond finite ledger readback.*

Proof. Project the finite package underlying the carrier. The rank row is read as a unary history from the same source certificate that supplies the ring of integers and its real and complex place-count ledgers.

The visible expression $r_1 + r_2 - 1$ is therefore a ledger label: its content is the displayed finite readback row, not an assertion about an external arithmetic object. The $\mathsf{UnaryHistory}$ witness records exactly that visible row.

The classifier compares the source, unit, inverse, law, and provenance rows through finite Cont readback. Hence the same unary rank row remains attached to every classified carrier. □

Theorem 171.12 (Dirichlet-unit AbGroup projection)**.** *Every accepted* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier projects to the* $\mathsf{AbGroup}^{\uparrow}$ *operation, inverse, identity, and classifier rows carried by its dependency certificate. The Dirichlet-unit carrier adds the ring-of-integers unit source, the unit and inverse rows, and the finite readback ledgers, but it does not replace the inherited abelian-group interface.*

Proof. Unpack the tuple of Definition 171.1. Its $\mathcal{A}$ projection is the dependency row from $\mathsf{NameCert}_{\mathsf{AbGroup}^\uparrow}$.

Read $\mathcal{A}$ through the abelian-group certificate. This exposes the operation row, inverse row, identity row, and classifier row for the inherited finitely generated abelian carrier.

The remaining projections $\mathcal{O}$, u, u^{-1}, λ, μ, and ρ witness that the inherited row is being used as a unit group for the ring-of-integers source. Repacking with $\mathcal{A}$ therefore gives exactly the $\mathsf{AbGroup}^\uparrow$ projection fields, with the unit rows retained as additional dependency data. □

171.2 The certificate

Theorem 171.13 (DirichletUnit inherited unit-product closure)**.** *Let*

$$\mathcal{D}_0 = (\mathcal{O}, \mathcal{A}, u_0, \iota_0, \nu, \beta, \rho) \qquad \textit{and} \qquad \mathcal{D}_1 = (\mathcal{O}, \mathcal{A}, u_1, \iota_1, \nu, \beta, \rho)$$

be accepted $\mathsf{DirichletUnit}^\uparrow$ *carrier packets with the same* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^\uparrow}$ *dependency row* $\mathcal{O}$*, the same* $\mathsf{NameCert}_{\mathsf{AbGroup}^\uparrow}$ *dependency row* $\mathcal{A}$*, and the same* Pkg *provenance row* ρ*. Let* u_0 *and* u_1 *be their visible unit rows, and let* ι_0 *and* ι_1 *be the inverse/unit-product witness rows supplied by the carrier packets. If* $u_0 \star_{\mathcal{A}} u_1$ *denotes the endpoint of the inherited* $\mathsf{AbGroup}^\uparrow$ *operation row projected from* $\mathcal{A}$*, then* $u_0 \star_{\mathcal{A}} u_1$ *is again a visible* $\mathsf{DirichletUnit}^\uparrow$ *unit row over* $\mathcal{O}$*. Its inverse/unit-product witness is the displayed row obtained by applying the same inherited operation to the two inverse endpoints in* ι_0 *and* ι_1*, and its public provenance is exactly the shared* Cont *and* Pkg *provenance of* $\mathcal{D}_0$ *and* $\mathcal{D}_1$*.*

Proof. Project both accepted packets through Definition 171.1. The two projections expose the same dependency rows $\mathcal{O}$ and $\mathcal{A}$, the same structural rows ν and β, and the same provenance row ρ. By Definition 171.2, the rows u_0, u_1 and their witness rows ι_0, ι_1 are visible unit-facing history rows over $\mathcal{O}$, read only through finite Cont entries and the shared Pkg provenance.

Project the abelian-group operation from $\mathcal{A}$ using Definition 171.12. The restriction clause in Definition 171.5 says that this operation is available precisely on unit rows accepted by the $\mathsf{RingOfIntegers}^\uparrow$ dependency. Since u_0 and u_1 are accepted unit rows over the same $\mathcal{O}$, the inherited operation has a displayed endpoint $u_0 \star_{\mathcal{A}} u_1$ inside the same dependency boundary.

It remains to read this endpoint as a $\mathsf{DirichletUnit}^\uparrow$ unit row rather than as a detached abelian-group product. The witness rows ι_0 and ι_1 give inverse endpoints u_0^{-1} and u_1^{-1} together with the unit-product comparisons for u_0 and u_1. Apply the inherited operation row of $\mathcal{A}$ to these inverse endpoints. The $\mathsf{AbGroup}^\uparrow$ stability certificate contains multiplication congruence, associativity, inverse laws, and commutativity, and Definition 42.14 packages exactly the resulting comparison

$$(u_0 \star_{\mathcal{A}} u_1) \star_{\mathcal{A}} (u_0^{-1} \star_{\mathcal{A}} u_1^{-1})\mathsf{hsame}e_{\mathcal{A}}.$$

Thus the product endpoint carries its own inverse/unit-product witness row, built only from ι_0, ι_1, and the operation rows already projected from $\mathcal{A}$.

Repack the endpoint $u_0 \star_{\mathcal{A}} u_1$ with this inverse/unit-product witness, the unchanged dependency rows $\mathcal{O}$ and $\mathcal{A}$, the unchanged structural rows ν and β, and the same provenance row ρ. This is exactly the visible unit-row slot described in Definition 171.1: the ring-of-integers readback still points to $\mathcal{O}$, the group-law readback still points to $\mathcal{A}$, and the exported row is still tied to the same Cont and Pkg ledgers. No host-level multiplication, analytic logarithm equality, determinant row, or standard bridge is introduced. □

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier inherited unit product closure`

Theorem 171.14 (DirichletUnit root inverse-row inversion)**.** *Let $\mathcal{D} = (\mathcal{O}, \mathcal{A}, u, \iota, \nu, \beta, \rho)$ be an accepted* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packet. Any accepted inverse row read from $\mathcal{D}$ is uniquely projected to the visible unit row u, the* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *dependency row $\mathcal{O}$, the inherited* $\mathsf{AbGroup}^{\uparrow}$ *inverse row carried by $\mathcal{A}$, the finite* Cont *readback tying these rows together, and the* Pkg *provenance row ρ. No other inverse source is available at the root boundary.*

Lean4 ✓ `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier root inverse row inversion`

Proof. Project the accepted packet through Definition 171.1. The tuple exposes exactly one visible unit row u, exactly one inverse/unit-product witness row ι, and the dependency rows $\mathcal{O}$ and $\mathcal{A}$ to which they are attached.

Read $\mathcal{A}$ through Definition 171.12. The inherited inverse row is the only abelian-group inverse row exported to $\mathsf{DirichletUnit}^{\uparrow}$, and Definition 171.5 restricts it to unit rows accepted by $\mathcal{O}$.

The Cont readback and Pkg provenance are the remaining packet entries that bind the inverse witness to the visible unit row. Repacking these projections gives the stated inversion surface, and the carrier packet contains no second inverse row, host unit carrier, or analytic witness from which a competing root inverse source could be read. □

Theorem 171.15 (DirichletUnit root product-witness inversion)**.** *Let $\mathcal{D}_0 = (\mathcal{O}, \mathcal{A}, u_0, \iota_0, \nu, \beta, \rho)$ and $\mathcal{D}_1 = (\mathcal{O}, \mathcal{A}, u_1, \iota_1, \nu, \beta, \rho)$ be accepted* $\mathsf{DirichletUnit}^{\uparrow}$ *carrier packets over the same* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *dependency rows. A product witness in the inherited* $\mathsf{AbGroup}^{\uparrow}$ *row is a valid* $\mathsf{DirichletUnit}^{\uparrow}$ *product witness exactly at the packet boundary where both visible unit rows u_0, u_1, both inverse/unit-product witnesses ι_0, ι_1, the inherited operation row, the shared* Cont *readbacks, and the shared* Pkg *provenance are present over $\mathcal{O}$.*

Proof. For the forward reading, start from a product witness accepted as a $\mathsf{DirichletUnit}^{\uparrow}$ product row. Inverting the packet definition exposes the two visible unit rows and their inverse/unit-product witness rows, and Definition 171.14 identifies their inverse evidence with the inherited inverse row of $\mathcal{A}$ over the same $\mathcal{O}$.

Project the inherited operation row from $\mathcal{A}$ using Definition 171.12. Its availability is restricted by Definition 171.5, so a product witness cannot be detached from the two visible unit rows accepted by the ring-of-integers dependency.

Conversely, assume the two visible unit rows, their inverse/unit-product witnesses, the inherited operation row, the shared Cont readbacks, and the shared Pkg provenance are all present over the same $\mathcal{O}$. Apply Definition 171.13 to repack the inherited product endpoint as a visible $\mathsf{DirichletUnit}^{\uparrow}$ unit row with its own inverse/unit-product witness.

These two readings use the same rows and the same dependency boundary. Hence validity of the inherited product witness for $\mathsf{DirichletUnit}^{\uparrow}$ is exactly the presence of the listed packet data over the shared $\mathsf{RingOfIntegers}^{\uparrow}$ dependency. □

Theorem 171.16 (DirichletUnit root Regulator input exhaustion)**.** *Every* $\mathsf{Regulator}^{\uparrow}$ *consumer reading from a* $\mathsf{DirichletUnit}^{\uparrow}$ *root packet can read only the unary rank witness ν, the finite basis and logarithmic ledger row β, visible unit rows, inverse rows, inherited product rows, the* $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *dependency rows, finite* Cont *readbacks, and* Pkg *provenance. It cannot read a determinant, analytic regulator value, host logarithm equality, or standard bridge from* $\mathsf{DirichletUnit}^{\uparrow}$ *alone.*

Proof. Project the consumer surface from Definition 171.7. The only rank-facing input is the unary rank witness ν, and the only basis or logarithm-facing input is the finite ledger row β carried by Definition 171.1.

Next project the unit-facing rows. The visible unit rows and inverse rows are supplied by Definition 171.2 and inverted by Definition 171.14; inherited product rows are available exactly under Definition 171.15.

Finally inspect the dependency and provenance boundary. The packet exposes $\mathcal{O}$, $\mathcal{A}$, finite Cont readbacks, and ρ as Pkg provenance, and no other rows. A determinant, analytic regulator value, host logarithm equality, or standard bridge is therefore outside the $\mathsf{DirichletUnit}^{\uparrow}$ root input surface and must be supplied by a regulator-side certificate. □

Theorem 171.17 (DirichletUnit Regulator row exclusion)**.** *Let $\mathcal{D} = (\mathcal{O}, \mathcal{A}, u, \iota, \nu, \beta, \rho)$ be an accepted $\mathsf{DirichletUnit}^{\uparrow}$ carrier packet. A $\mathsf{Regulator}^{\uparrow}$ consumer whose input is read from $\mathcal{D}$ cannot project a determinant row, an analytic regulator value row, a host logarithm equality row, or a standard bridge row from that packet. The only regulator-facing rows available at the packet boundary are the visible unit rows, inverse/unit-product rows, unary rank row, finite basis/log ledger row, dependency rows, finite Cont readbacks, and Pkg provenance named in Definition 171.16.*

Proof. Project $\mathcal{D}$ through Definition 171.1. Its named entries are $\mathcal{O}$, $\mathcal{A}$, u, ι, ν, β, and ρ, together with the finite Cont readbacks attached to those entries.

Use Definition 171.15 to identify the product-facing part of the packet. The inherited product witness is available only where the two dependency certificates, visible unit rows, inverse rows, finite readbacks, and package provenance are simultaneously present.

Finally apply Definition 171.16. That theorem lists the complete root input surface for a $\mathsf{Regulator}^{\uparrow}$ consumer. Since determinants, analytic regulator values, host logarithm equalities, and standard bridge rows are absent from both the carrier packet and the exhausted consumer surface, no such row can be projected from $\mathcal{D}$. □

Theorem 171.18 (DirichletUnit visible rank-ledger projection)**.** *For an accepted $\mathsf{DirichletUnit}^{\uparrow}$ carrier packet $\mathcal{D} = (\mathcal{O}, \mathcal{A}, u, \iota, \nu, \beta, \rho)$, the unary rank witness ν and the finite basis/log ledger β are the only rank-facing rows exposed to $\mathsf{Regulator}^{\uparrow}$. Every rank-side readback factors through these two rows, the finite Cont ledgers of the packet, and the shared Pkg provenance ρ.*

Proof. Project the rank-facing entries from Definition 171.1. The packet has exactly one unary rank witness slot ν and exactly one finite basis/log ledger slot β; the dependency rows and provenance rows scope these slots but do not create a second rank source.

The visibility theorem Definition 171.4 identifies ν and β as displayed BHist rows stable under componentwise hsame, finite Cont readback, and package provenance. Thus the rank-side consumer reads a finite ledger surface rather than a host rank computation.

Apply Definition 171.16 to the same packet. Its exhausted $\mathsf{Regulator}^{\uparrow}$ surface includes no rank-facing row besides ν and β, so every accepted rank readback factors through those two displayed rows and the shared provenance ρ. □

Theorem 171.19 (DirichletUnit unit-product consumer scope)**.** *Let*

$$\mathcal{D}_0 = (\mathcal{O}, \mathcal{A}, u_0, \iota_0, \nu, \beta, \rho) \qquad \text{and} \qquad \mathcal{D}_1 = (\mathcal{O}, \mathcal{A}, u_1, \iota_1, \nu, \beta, \rho)$$

be accepted $\mathsf{DirichletUnit}^{\uparrow}$ carrier packets over the same dependency and provenance rows. The inherited product and inverse witnesses are consumable by a $\mathsf{Regulator}^{\uparrow}$ reader only at the packet boundary carrying the shared $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ row $\mathcal{O}$, the shared $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ row $\mathcal{A}$, the finite Cont readbacks, and the shared Pkg row ρ.

Proof. Project the two packets through Definition 171.1. The visible unit rows u_0, u_1, their inverse/unit-product rows ι_0, ι_1, and the dependency rows $\mathcal{O}, \mathcal{A}$ are all components of the same displayed boundary.

Apply Definition 171.15. It states that a product witness in the inherited $\mathsf{AbGroup}^{\uparrow}$ row is valid for $\mathsf{DirichletUnit}^{\uparrow}$ exactly where both visible unit rows, both inverse rows, the inherited operation row, the shared finite readbacks, and the shared package provenance are present over $\mathcal{O}$.

The inverse side is controlled by Definition 171.14. It projects every accepted inverse row back to the visible unit, the $\mathsf{NameCert}_{\mathsf{RingOfIntegers}^{\uparrow}}$ dependency, the inherited $\mathsf{AbGroup}^{\uparrow}$ inverse row, the finite readback, and ρ.

Combining these projections with Definition 171.16 gives the stated consumer scope. A $\mathsf{Regulator}^{\uparrow}$ reader can consume product and inverse evidence only as packet-boundary evidence tied to the two shared dependency certificates, Cont, and Pkg. □

Closure status for $\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$.

Constructive story: A Dirichlet unit is carried by a finite packet whose entries are a $\mathsf{RingOfIntegers}^{\uparrow}$ dependency row, an $\mathsf{AbGroup}^{\uparrow}$ law row, a visible unit row, an inverse and unit-product witness row, a unary rank witness, a finite basis or logarithmic ledger row, and package provenance. The carrier accepts only packets whose unit-facing rows read back through the ring-of-integers dependency and whose law-facing rows read back through the abelian-group dependency, excluding host unit types, analytic logarithm equalities, determinant rows, regulator values, and bridge rows. Its classifier is componentwise hsame on the visible unit, inverse, law, rank, basis-ledger, readback, and provenance rows, with dependency provenance transported at the same time. The source specification is the RingOfIntegers-plus-AbGroup packet, the pattern specification is the visible unit group with inverse, product, rank, and finite basis/log-ledger rows, and the ledger keeps raw unit evidence, group-law evidence, and rank evidence visible through the named Cont readbacks. The five naming-certificate obligations come from the accepted packet as inhabitant, the equivalence laws of hsame, and the classifier-transport theorem that rebuilds the packet after each component has moved to a classified endpoint. A history h lies in the signature GAP of a $\mathsf{DirichletUnit}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer unit packet and evidence ledger, and token introduction names that answer as p; unpacked here, h is exactly the packet endpoint whose visible unit, inverse/product row, unary rank row, finite ledger, dependency rows, and package provenance all line up. The chapter registers this construction as $\mathsf{DirichletUnit}^{\uparrow}$ without closing analytic regulator values, determinant formulas, logarithmic embeddings, or a standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$, maturePackageClosed)

Scope closed: The visible-unit carrier, inverse and product witnesses, rank-ledger, $\mathsf{Regulator}^{\uparrow}$ consumer boundary, and unsupported-feature boundary rows are closed as the mature $\mathsf{DirichletUnit}^{\uparrow}$ package surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DirichletUnitUp.DirichletUnitHistoryCarrier\_visible\_unit\_rows`

Bridge status: none

Not claimed: This does not close analytic regulator values, determinant formulas, logarithmic embeddings, or standard bridge rows.

Upgrade path: Mature closure requires completeness examples and explicit unsupported-feature boundaries for analytic regulator values, determinant formulas, logarithmic embeddings, and standard bridge rows.

Chapter 172

A Concrete Naming Certificate for $\mathsf{Dedekind}^{\uparrow}$

The Dedekind-domain interface $\mathsf{Dedekind}^{\uparrow}$ packages an integrally closed Noetherian commutative domain in which every nonzero prime ideal is maximal. It depends on $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ (chapter 44) and $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ (chapter 81).

172.1 Carrier definition

Theorem 172.1 (Dedekind source obligation)**.** *A* $\mathsf{Dedekind}^{\uparrow}$ *source consists of a shared* BHist *carrier and classifier equipped with the cited* $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ *surfaces. The commutative-ring certificate fixes the visible ring package, and the ideal certificate is read over the same carrier and classifier rather than over a second ambient presentation.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton shared source obligation`
Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton source obligation`

Proof. Unpack the seed boundary for $\mathsf{Dedekind}^{\uparrow}$: the seed already names the $\mathsf{CommRing}^{\uparrow}$ source and the $\mathsf{Ideal}^{\uparrow}$ source as required inputs. The roadmap ten-field template then asks first for a carrier and classifier surface before any domain law can be read.

Those two inputs must therefore share the same BHist carrier and the same classifier transport. The proof records only this interface shape: it does not assert that the Dedekind certificate fields have been constructed. □

Theorem 172.2 (Dedekind domain-law obligation)**.** *For the shared* $\mathsf{Dedekind}^{\uparrow}$ *classifier, the domain-specific rows are integrally closedness, Noetherianity, and the assertion that every nonzero prime ideal is maximal. Each row is a certificate field over the shared classifier, with its own witness and stability requirement.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton domain law obligation`

Proof. The seed closure lists the integrally closed row, the Noetherian row, and the nonzero-prime-maximal row as the precise domain obligations. The roadmap ten-field template turns each listed row into visible data: a field, a witness, and classifier stability.

Since the carrier and ideal classifier have already been fixed by the source obligation, the three domain laws cannot be supplied as detached host properties. They must be read as certificate rows over that same BEDC classifier. □

Theorem 172.3 (Dedekind Noetherian source factorization)**.** *For any accepted* $\mathsf{Dedekind}^{\uparrow}$ *packet, the Noetherian witness row of Definition 172.2 factors through the* $\mathsf{NoetherianRing}^{\uparrow}$ *carrier of Definition 3637.1 over the same* $\mathsf{CommRing}^{\uparrow}$ *and* $\mathsf{Ideal}^{\uparrow}$ *classifier. The integrally closed row and the nonzero-prime-maximal row remain Dedekind-specific rows over that shared classifier.*

Proof. Project the $\mathsf{Dedekind}^{\uparrow}$ source obligation from Definition 172.1. It fixes the commutative-ring source and the ideal source before the domain-law rows are read, so the Noetherian row has the same ambient carrier and classifier required by the $\mathsf{NoetherianRing}^{\uparrow}$ carrier.

Apply Definition 3637.2 to read the Noetherian witness as finite ideal-chain stabilization data over those two source rows. The $\mathsf{Dedekind}^{\uparrow}$ packet therefore consumes the reusable $\mathsf{NoetherianRing}^{\uparrow}$ surface rather than treating Noetherianity as an isolated internal row.

The remaining two domain-law rows are not absorbed by $\mathsf{NoetherianRing}^{\uparrow}$. Integrally closedness and nonzero-prime-maximality are projected from Definition 172.2 and stay attached to the Dedekind classifier as the Dedekind-specific part of the packet. □

Theorem 172.4 (Dedekind classifier ledger obligation)**.** *Classifier transport and the* $\mathsf{Dedekind}^{\uparrow}$ *ledger expose exactly the commutative-ring source, the ideal source, the integrally closed witness, the Noetherian witness, and the nonzero-prime-maximal witness. The ledger exposes no quotient data, no classical-choice data, and no* $\mathsf{StandardBridge}$ *data.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton classifier ledger obligation`

Proof. Unpack the exact-ledger boundary in the seed closure. Its upgrade path names the commutative-ring source, ideal source, three domain-law witnesses, classifier transport, and ledger boundary as the full local inventory.

The roadmap ten-field template then separates local certificate data from quotient, classical, and standard-bridge comparisons. The theorem therefore fixes the exposed ledger shape without claiming a completed $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$. □

172.2 The certificate

Theorem 172.5 (Dedekind scoped certificate packet)**.** *The scoped* $\mathsf{Dedekind}^{\uparrow}$ *certificate packet consists exactly of the shared* BHist *carrier and classifier, the cited* $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ *surfaces, the integrally closed row, the Noetherian row, the nonzero-prime-maximal row, classifier transport, and the exact* $\mathsf{Dedekind}^{\uparrow}$ *ledger boundary. This packet is scoped over the existing NameCert, CommRing, and Ideal primitives, and it contains no quotient presentation, no classical-choice datum, and no completed public* $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ *surface.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton scoped certificate packet`

Proof. Apply Definition 172.1 to fix the shared BHist carrier, the classifier, and the two cited source surfaces. Apply Definition 172.2 to read integrally closedness, Noetherianity, and nonzero-prime-maximality as rows over that same classifier.

Apply Definition 172.4 to identify the classifier transport and exact ledger boundary. Unpacking the roadmap ten-field template then packages these rows as the scoped local certificate inventory.

The scoped packet itself is not yet the exported public certificate surface for $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$. It is the local inventory from which that surface is assembled, and it does not pass through quotient representatives or classical choice. □

Theorem 172.6 (Dedekind certificate stability rows)**.** *Over the shared* BHist *carrier and classifier fixed by Definition 172.1, the integrally closed row, the Noetherian row, and the nonzero-prime-maximal row of Definition 172.2 are classifier-stable* $\mathsf{Dedekind}^{\uparrow}$ *certificate rows. Each row is transported only along the same classifier used by the* $\mathsf{NameCert}_{\mathsf{CommRing}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ *source surfaces, so no row is read over a detached carrier or a second classifier.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton certificate stability rows`

Proof. Begin with the shared carrier and classifier supplied by Definition 172.1. That theorem fixes the BHist presentation before any domain-law row is interpreted.

Apply Definition 172.2 to identify the three domain rows as certificate fields over that same classifier. Their witnesses are therefore stability data for the displayed $\mathsf{Dedekind}^{\uparrow}$ packet, not external predicates attached after the carrier has been chosen.

The conclusion is classifier stability row by row: integrally closedness, Noetherianity, and nonzero-prime-maximality all move only through the classifier already shared by the commutative-ring and ideal source surfaces. □

Theorem 172.7 (Dedekind exact ledger public surface)**.** *The public* $\mathsf{Dedekind}^{\uparrow}$ *ledger exposes exactly the* $\mathsf{CommRing}^{\uparrow}$ *source, the* $\mathsf{Ideal}^{\uparrow}$ *source, the integrally closed witness, the Noetherian witness, the nonzero-prime-maximal witness, classifier transport, and the exact* $\mathsf{Dedekind}^{\uparrow}$ *ledger boundary. It exposes no quotient data, no classical-choice data, and no* StandardBridge *data.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton exact ledger public surface`

Proof. Apply Definition 172.4. Its ledger boundary names the commutative-ring source, the ideal source, the three domain witnesses, and classifier transport as the visible inventory.

Exactness is read negatively as well as positively. The same ledger theorem excludes quotient representatives, classical-choice witnesses, and StandardBridge fields from the $\mathsf{Dedekind}^{\uparrow}$ certificate surface.

Thus the public ledger has exactly the displayed rows: every named row is exposed, and every excluded kind of host or bridge data remains outside the surface. □

Theorem 172.8 (Dedekind public NameCert surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ *surface over the concrete* BHist *carrier and the same classifier is assembled from Definition 172.1, Definition 172.2, Definition 172.4, Definition 172.6, and Definition 172.7. Its exported rows are exactly the shared* $\mathsf{CommRing}^{\uparrow}$ *and* $\mathsf{Ideal}^{\uparrow}$ *source surfaces, the three classifier-stable domain witnesses, classifier transport, and the exact ledger boundary.*

Lean4 ✓ `BEDC.Derived.DedekindUp.DedekindSingleton public namecert surface`

Proof. First fix the public carrier data. Apply Definition 172.1 to obtain the concrete BHist carrier, the common classifier, and the two source surfaces.

Next fix the domain content. Apply Definition 172.2 and Definition 172.6 to read integrally closedness, Noetherianity, and nonzero-prime-maximality as classifier-stable certificate rows over that same carrier.

Finally apply Definition 172.4 and Definition 172.7. These identify the transport and exact ledger rows, exclude quotient, classical-choice, and StandardBridge data, and repack the displayed inventory as the public $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$.

Constructive story: A Dedekind domain is carried by a shared BHist source where the $\mathsf{CommRing}^{\uparrow}$ surface and the $\mathsf{Ideal}^{\uparrow}$ surface use the same carrier and classifier before the domain-law rows are attached. The carrier accepts exactly that shared commutative-ring and ideal source together with the integrally closed, Noetherian, and nonzero-prime-maximal witness rows, while quotient presentations, classical-choice data, and standard-bridge fields are absent from the packet. Two accepted presentations classify together only through the same classifier used by the CommRing and Ideal source surfaces, and each of the three domain-law rows must be stable under that classifier. The source specification is the paired CommRing and Ideal dependency surface, the pattern specification is the three visible domain-law witnesses over that surface, and the ledger exposes exactly those sources, witnesses, classifier-transport rows, and exact boundary rows. The five naming-certificate obligations are arranged by the public surface: the shared carrier gives an inhabitant, hsame and the inherited classifier rows give reflexivity, symmetry, and transitivity, and classifier stability repacks any transported domain-law witness inside the same accepted carrier. A history h lies in the signature GAP of a $\mathsf{Dedekind}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it to an answer Dedekind packet and evidence ledger, and token introduction names that answer as p; concretely, the CommRing source, Ideal source, integrally closed row, Noetherian row, prime-maximal row, transport rows, and ledger boundary must all be the displayed rows for h. The chapter registers this construction as $\mathsf{Dedekind}^{\uparrow}$ without adding a quotient construction, a classical-choice presentation, a standard bridge, or a separate verification target.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$, maturePackageClosed)

Scope closed: The paper-side scope is the public $\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$ surface in Definition 172.8, grounded by the shared-source row, the three domain-law rows, classifier stability, classifier transport, and the exact ledger boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Dedekind}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DedekindUp.DedekindSingleton\_public\_namecert\_surface`

Bridge status: none

Not claimed: This chapter does not close a Lean verification target, standard bridge, quotient construction, or classical-choice presentation.

Upgrade path: No further paper theory-axis upgrade is recorded for this chapter; bridge verification remains a separate axis.

Chapter 173

A Concrete Naming Certificate for $\mathsf{LocalField}^{\uparrow}$

The local-field interface $\mathsf{LocalField}^{\uparrow}$ packages a complete discretely valued field with finite residue field. It depends on $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ (chapter 45) and $\mathsf{NameCert}_{\mathsf{Padic}^{\uparrow}}$ (chapter 100).

173.1 Carrier definition

Definition 173.1 (LocalField valued BHist carrier)**.** *A* $\mathsf{LocalField}^{\uparrow}$ *carrier is a finite* BHist *packet consisting of a displayed* $\mathsf{Field}^{\uparrow}$ *row, a* $\mathsf{Padic}^{\uparrow}$ *valuation row on the same field endpoint, a finite residue row, a completeness-witness ledger row, and the visible endpoint data for the valued field, valuation, unit surface, and residue surface. The packet is accepted only when these rows are present in one finite ledger and the valuation row supplies the route from field elements to residue data through the displayed dependency certificates.*

The carrier is the visible valued-field packet. It does not include arbitrary completions, quotient fields, class-field reciprocity data, or a standard bridge object.

Lean4 (definition) `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier`

Theorem 173.2 (LocalField valuation classifier stability)**.** *Let two* $\mathsf{LocalField}^{\uparrow}$ *carrier packets have* $\mathsf{Field}^{\uparrow}$ *rows and* $\mathsf{Padic}^{\uparrow}$ *valuation rows related by displayed* hsame *classifiers. If the residue row, unit row, and completeness-witness ledger are read only through those transported field and valuation rows, then the transported endpoints repack as an accepted* $\mathsf{LocalField}^{\uparrow}$ *carrier with the same valued-field ledger shape.*

Lean4 ✓ `BEDC.Derived.LocalFieldUp.LocalFieldValuationClassifier stability`

Proof. Project the $\mathsf{Field}^{\uparrow}$ dependency certificate. It transports the displayed field endpoint and the field rows used by the local-field packet.

Project the $\mathsf{Padic}^{\uparrow}$ dependency certificate. The valuation endpoint is transported together with the visible valuation row, so the residue and unit rows still have their valuation source after transport.

Replay the carrier ledger on the transported rows. Since the completeness witness is a ledger row tied to the same field and valuation endpoints, it is read from the transported packet without adding a new host completion. □

Theorem 173.3 (LocalField residue ledger exactness)**.** *For every accepted* $\mathsf{LocalField}^{\uparrow}$ *carrier, the residue ledger exposes exactly the valuation row, unit row, residue row, and their displayed endpoint data. It does not expose an arbitrary completion, quotient field, class-field reciprocity structure, or external local-field model.*

Proof. Inspect the carrier of Definition 173.1. The residue side of the packet consists of the valuation row, unit row, residue row, and endpoints recorded in the finite BHist ledger.

The completeness witness is a ledger entry for the same displayed endpoint data. It certifies that the local packet has the advertised finite surface, but it does not introduce a host completion or quotient field.

Thus every readable residue datum is one of the listed rows, and none of the excluded host structures is part of the accepted packet. □

Lean4 ✓ `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier residue ledger exactness`

Theorem 173.4 (LocalField NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{LocalField}^{\uparrow}}$ *surface is the carrier of Definition 173.1, the valuation classifier over the displayed* $\mathsf{Field}^{\uparrow}$ *and* $\mathsf{Padic}^{\uparrow}$ *rows, the stability clause of Definition 173.2, the residue ledger exactness clause of Definition 173.3, and the source coverage assertion that every accepted local-field row is read from those finite packet rows.*

Lean4 ✓ `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier namecert obligation surface`

Proof. Use the valued BHist carrier as the source predicate. The carrier lists the field, valuation, residue, completeness, and endpoint rows allowed in the local certificate.

The classifier is the displayed comparison of field and valuation rows. Its transport obligation is exactly Definition 173.2.

The ledger and exactness obligations are exactly Definition 173.3 together with the carrier definition. These rows cover every accepted local-field packet and exclude all host structures outside the finite ledger. □

Theorem 173.5 (LocalField bridge boundary exclusions)**.** *The* $\mathsf{LocalField}^{\uparrow}$ *boundary supplies only the BEDC valued-field packet over the displayed* $\mathsf{Field}^{\uparrow}$ *and* $\mathsf{Padic}^{\uparrow}$ *dependency rows. It does not assert arbitrary completions, quotient fields, full local class field theory, or standard-model bridge claims.*

Proof. Read the boundary through Definition 173.4. The exported rows are the carrier, classifier, stability, residue ledger, exactness, and source coverage rows.

Each exported row factors through the finite packet of Definition 173.1. That packet has no constructor for host completions, quotient fields, reciprocity theory, or a standard-model bridge.

Therefore the boundary records only the displayed BEDC valued-field surface. □

Lean4 ✓ `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier bridge boundary exclusions`

Theorem 173.6 (LocalField valued-field consumer threshold)**.** *Any consumer of* $\mathsf{NameCert}_{\mathsf{LocalField}^{\uparrow}}$ *may project only the displayed* $\mathsf{Field}^{\uparrow}$ *row, the* $\mathsf{Padic}^{\uparrow}$ *valuation row, the unit row, the residue row, the completeness-witness ledger row, endpoint data, and visible* $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}$ *provenance from Definition 173.4. No arbitrary completion, quotient field, reciprocity structure, external local-field model, or standard bridge becomes available.*

Proof. Project the $\mathsf{Field}^{\uparrow}$ and $\mathsf{Padic}^{\uparrow}$ dependency certificates from the obligation surface. These projections give the field row, valuation row, unit row, completeness-witness ledger row, endpoint data, and displayed provenance without adding a host carrier.

Use Definition 173.3 to read the residue row as finite ledger data. The readable residue entries are therefore exactly the ones already present in the valued BHist packet.

Finally apply Definition 173.5. The excluded host completions, quotient fields, reciprocity structures, external models, and standard bridges are outside the certificate exported to downstream consumers. □

Lean4 ✓ `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier valued field consumer threshold`

173.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{LocalField}^{\uparrow}}$.

Constructive story: A local-field packet is generated from a valued BHist carrier whose displayed $\mathsf{Field}^{\uparrow}$ row, $\mathsf{Padic}^{\uparrow}$ valuation row, residue row, completeness-witness ledger, endpoint data, hsame transport, Cont displays, and Pkg provenance are all visible in one finite certificate surface. The valuation classifier, residue ledger, and bridge-boundary exclusions keep arbitrary host completions, quotient local fields, reciprocity data, external models, and standard bridges outside the exported carrier.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LocalField}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The obligation scope consists of the valued BHist carrier, valuation classifier stability, residue ledger exactness, bridge-boundary exclusions, and valued-field consumer threshold over $\mathsf{Field}^{\uparrow}$, $\mathsf{Padic}^{\uparrow}$, hsame, Cont, and Pkg.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LocalField}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LocalFieldUp.LocalFieldValuedBHistCarrier\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: No host completion, quotient local field, reciprocity theorem, external local-field model, or standard bridge is claimed.

Upgrade path: Bridged closure requires a standard comparison surface for the valued-field consumer threshold.

Chapter 174

A Concrete Naming Certificate for $\mathsf{Cyclotomic}^{\uparrow}$

The cyclotomic-field interface $\mathsf{Cyclotomic}^{\uparrow}$ packages the splitting field of $X^n - 1$ over the rational-number certificate. It depends on $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168) and $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ (chapter 165).

174.1 Carrier definition

Definition 174.1 (Cyclotomic root carrier)**.** *A* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier is a* BHist *packet*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

where $\mathcal{N}$ *is a source* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *row,* $n : \mathsf{BHist}$ *is a positive unary exponent row,* $p : \mathsf{BHist}$ *is the rational polynomial ledger for* $X^n - 1$*,* $\mathcal{S}$ *is a source* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *row over that polynomial ledger,* $\zeta : \mathsf{BHist}$ *is the chosen primitive-root endpoint,* α *is the finite* Cont *row accepting* ζ *as a root and recording the factorization rows inside* $\mathcal{S}$*,* λ *is the* hsame *comparison tying the NumFieldUp source and the SplittingFieldUp base row, and* ρ *records the* Pkg *provenance of the two source certificates.*

The accepted carrier is exactly this displayed history tuple. It carries no quotient of primitive roots and no host equality of fields; every endpoint read is mediated by BHist *rows,* hsame *transport,* Cont *ledgers, and the paired* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *provenance rows.*

Definition 174.2 (Cyclotomic rational polynomial classifier)**.** *The* $\mathsf{Cyclotomic}^{\uparrow}$ *classifier relates two carriers of Definition 174.1 when their* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source rows, positive unary exponent rows, rational polynomial ledgers for* $X^n - 1$*,* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source rows, and primitive-root endpoints are connected by* hsame *rows whose endpoints are supported by the displayed* Cont *and* Pkg *provenance ledgers. The classifier transports the NumFieldUp source, exponent, polynomial row, splitting-field row, and primitive-root endpoint as carried* BHist *data, not as equality of host fields or as a quotient of roots.*

Definition 174.3 (Cyclotomic root-layer obligation surface)**.** *The root-layer obligation surface for* $\mathsf{Cyclotomic}^{\uparrow}$ *is the concrete* BHist *row tuple*

$$(\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho).$$

Here $\mathcal{N}$ is the NumFieldUp source certificate row, n is the positive unary exponent row, p is the rational polynomial ledger for $X^n - 1$, $\mathcal{S}$ is the SplittingFieldUp source certificate row over p, ζ is the primitive-root endpoint, α is the finite Cont *row accepting ζ as a root and recording the factorization reads, λ is the* hsame *base-comparison row, and ρ is the* Pkg *provenance row for the two source certificates.*

This surface is a root-layer source packet, not a host splitting field. It contains no valuation row, class-field reciprocity datum, automorphism-group structure, or equality of ambient fields.

Theorem 174.4 (Cyclotomic root-layer source coverage)**.** *Every accepted carrier of Definition 174.1 covers exactly the rows of Definition 174.3. The coverage reads $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ as visible* BHist *data, and it exports no additional root-layer source row.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier root layer source coverage`

Proof. Unpack the displayed carrier of Definition 174.1. Its accepted history tuple is precisely $(\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$.

Compare this tuple with Definition 174.3. Each entry has the same role: source NumFieldUp certificate, unary exponent, rational polynomial ledger, source SplittingFieldUp certificate, primitive-root endpoint, root-acceptance continuation, base comparison, and provenance package.

Since the carrier definition contains no further root source coordinate, the projection is exact. Valuations, reciprocity data, automorphism groups, and host field equality are outside the displayed carrier and cannot be exported by this coverage step. □

Theorem 174.5 (Cyclotomic root-layer classifier transport)**.** *If two accepted* Cyclotomic$^{\uparrow}$ *carriers are related by the classifier of Definition 174.2, then their root-layer obligation surfaces are transported componentwise by the carried* hsame *rows, the root-acceptance* Cont *rows, and the* Pkg *provenance rows. The transport preserves the NumFieldUp source, exponent, polynomial ledger, SplittingFieldUp source, primitive-root endpoint, and the base-comparison evidence as* BHist *data.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier root layer classifier transport`

Proof. Project the classifier row using Definition 174.2. The projected data are the componentwise hsame rows for $\mathcal{N}$, n, p, $\mathcal{S}$, and ζ, together with the displayed Cont and Pkg support.

The Cont rows keep the primitive-root acceptance and factorization reads attached to the transported endpoints. The Pkg rows keep the NumFieldUp and SplittingFieldUp certificate provenance attached to the same source packet, while λ supplies the base comparison between the two source layers.

Repack these transported components in the order of Definition 174.3. The result is the root-layer surface on the target carrier, with no passage through a quotient of roots or host-field equality. □

Theorem 174.6 (Cyclotomic root-layer consumer boundary)**.** *Any downstream consumer of the* Cyclotomic$^{\uparrow}$ *root layer may read only the surface of Definition 174.3 and its classifier transport from Definition 174.5. In particular, the root-layer boundary supplies no valuation theory, no class-field reciprocity law, no automorphism-group action, and no equality between host fields.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier consumer boundary`

Proof. Start from the source coverage of Definition 174.4. It limits the exported root-layer rows to the eight visible entries of Definition 174.3.

Next apply Definition 174.5. It states that consumer-side transport is exactly componentwise hsame plus the carried Cont and Pkg ledgers, so any transported read remains inside the same eight-row surface.

The excluded structures are not coordinates of the carrier, not generators of the classifier, and not fields of the provenance package. They therefore cannot be consumed at this boundary without a separate certificate. □

Theorem 174.7 (Cyclotomic classifier reflexivity)**.** *For every accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, the classifier of Definition 174.2 relates $\mathcal{C}_\zeta$ *to itself. The witnessing row is the componentwise reflexive* hsame *support on the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source* $\mathcal{N}$*, the exponent row* n*, the rational polynomial ledger* p *for* $X^n - 1$*, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source* $\mathcal{S}$*, and the primitive-root endpoint* ζ*, together with the unchanged* Cont *row* α*, base comparison row* λ*, and* Pkg *provenance row* ρ*.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier source triad obligation`

Proof. Start from the displayed carrier. Each carried BHist component has the reflexive hsame row at its own endpoint: $\mathcal{N}$, n, p, $\mathcal{S}$, and ζ are therefore transported to themselves.

The finite Cont row α already accepts ζ as a root and records the factorization rows inside $\mathcal{S}$. The comparison row λ already ties the NumFieldUp source to the SplittingFieldUp base row, and ρ is already the provenance package for the two source certificates.

Repacking these five reflexive hsame rows with the displayed Cont and Pkg ledgers gives exactly the classifier row from $\mathcal{C}_\zeta$ to $\mathcal{C}_\zeta$. □

Theorem 174.8 (Cyclotomic classifier symmetry)**.** *Let*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

and

$$\mathcal{C}'_\eta = (\mathcal{N}', n', p', \mathcal{S}', \eta, \alpha', \lambda', \rho')$$

be accepted $\mathsf{Cyclotomic}^{\uparrow}$ *carriers. If the classifier of Definition 174.2 relates* $\mathcal{C}_\zeta$ *to* $\mathcal{C}'_\eta$*, then it also relates* $\mathcal{C}'_\eta$ *to* $\mathcal{C}_\zeta$ *by reversing the carried* hsame *rows for the NumFieldUp sources, exponent rows, polynomial ledgers, SplittingFieldUp sources, and primitive-root endpoints, while reading the same* Cont *acceptance rows and* Pkg *provenance rows from the opposite side.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootClassifier symm`

Proof. Project the given classifier row to its five hsame components. These components compare $\mathcal{N}$ with $\mathcal{N}'$, n with n', p with p', $\mathcal{S}$ with $\mathcal{S}'$, and ζ with η.

Reverse each projected hsame row. The reversed rows compare the same carried histories in the order required for a classifier from $\mathcal{C}'_\eta$ to $\mathcal{C}_\zeta$.

It remains to account for the ledgers. The acceptance rows α' and α still support the endpoint and factorization reads at their respective sides, while λ', λ, ρ', and ρ provide the same base-comparison and provenance evidence with source and target interchanged. Repacking these rows gives the opposite classifier. □

Theorem 174.9 (Cyclotomic classifier transitivity)**.** *Let*

$$\mathcal{C}_0 = (\mathcal{N}_0, n_0, p_0, \mathcal{S}_0, \zeta_0, \alpha_0, \lambda_0, \rho_0), \quad \mathcal{C}_1 = (\mathcal{N}_1, n_1, p_1, \mathcal{S}_1, \zeta_1, \alpha_1, \lambda_1, \rho_1), \quad \mathcal{C}_2 = (\mathcal{N}_2, n_2, p_2, \mathcal{S}_2, \zeta_2, \alpha_2, \lambda_2, \rho_2)$$

be accepted $\mathsf{Cyclotomic}^{\uparrow}$ *carriers. If the classifier relates* $\mathcal{C}_0$ *to* $\mathcal{C}_1$ *and also relates* $\mathcal{C}_1$ *to* $\mathcal{C}_2$*, then it relates* $\mathcal{C}_0$ *to* $\mathcal{C}_2$ *by composing the* hsame *rows componentwise through the shared middle carrier for the NumFieldUp source, exponent, polynomial ledger, SplittingFieldUp source, and primitive-root endpoint, and by repacking the shared* Cont *acceptance rows and* Pkg *provenance rows.*

Proof. Project the first classifier row to the comparisons from $\mathcal{C}_0$ to $\mathcal{C}_1$, and project the second classifier row to the comparisons from $\mathcal{C}_1$ to $\mathcal{C}_2$. The middle carrier supplies the common endpoint for each pair of projected hsame rows.

Compose the NumFieldUp source comparisons through $\mathcal{N}_1$, the exponent comparisons through n_1, the polynomial-ledger comparisons through p_1, the SplittingFieldUp source comparisons through $\mathcal{S}_1$, and the primitive-endpoint comparisons through ζ_1.

The Cont rows α_0, α_1, and α_2 keep the endpoint and factorization reads attached to the three carriers, and the provenance rows ρ_0, ρ_1, and ρ_2 keep the source packages aligned. Repacking the composed hsame rows with these ledgers yields the classifier from $\mathcal{C}_0$ to $\mathcal{C}_2$. □

174.2 The certificate

Theorem 174.10 (Cyclotomic source-triad obligation)**.** *For every accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, the $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *source triad is exactly the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *row* $\mathcal{N}$*, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *row* $\mathcal{S}$ *over the rational polynomial ledger* p *for* $X^n - 1$*, and the primitive-root endpoint row* ζ *accepted by* α*. The triad is covered by the displayed* BHist *rows, transported by the classifier of Definition 174.2, and closed under the* hsame*,* Cont*, and* Pkg *rows* λ*,* α*, and* ρ*; no fourth source row is exported by the certificate.*

Proof. Project the carrier to $\mathcal{N}$, $\mathcal{S}$, and ζ. The exponent row n and polynomial ledger p locate $\mathcal{S}$ at the displayed equation $X^n - 1$, while the finite Cont row α attaches the primitive endpoint to the root and factorization surface.

Use Definition 174.15 and Definition 174.16 to transport the NumFieldUp and SplittingFieldUp rows through hsame. Use Definition 174.18 for the endpoint component.

Finally repack the three projected source rows with λ, α, and ρ. The obligation surface of Definition 174.17 lists no additional source component, so the triad is both covered and complete. □

Theorem 174.11 (Cyclotomic p-adic consumer obligation)**.** *A p-adic consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *may read only the carrier rows* $\mathcal{N}$*,* n*,* p*,* $\mathcal{S}$*,* ζ*,* α*,* λ*, and* ρ *from Definition 174.1, with* p *interpreted as the rational polynomial ledger for* $X^n - 1$ *and not as a valuation or completion row. Any valuation, completion, or measure row used downstream must be supplied by a separate* $\mathsf{Padic}^{\uparrow}$ *or* $\mathsf{Iwasawa}^{\uparrow}$ *certificate and may enter only through its own* BHist*,* hsame*,* Cont*,* Pkg*, or* NameCert *interface.*

Proof. Begin with the displayed cyclotomic carrier. Its rows provide a NumFieldUp source, a positive exponent, the rational polynomial ledger, the SplittingFieldUp source, the primitive endpoint, the acceptance ledger, the base comparison, and the provenance package.

Apply Definition 174.25 to identify the polynomial row as the $X^n - 1$ ledger and Definition 174.28 to identify the accepted factorization rows. Apply Definition 174.32 for the downstream completion boundary.

The carrier and classifier contain no valuation, completion, or measure field. Therefore any p-adic consumer starts from the cyclotomic source package alone and must cite the separate certificate that provides the missing analytic rows. □

Theorem 174.12 (Cyclotomic Iwasawa tower obligation)**.** *An* $\mathsf{Iwasawa}^{\uparrow}$ *tower that consumes* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *receives exactly the cyclotomic layer formed by the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *row* $\mathcal{N}$*, the exponent row* n*, the primitive-root endpoint* ζ*, the splitting-field factorization rows over* p*, the acceptance row* α*, and the provenance row* ρ*. The tower may transport these rows through the carried* hsame *and* Cont *structure, but* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *alone supplies no tower transition map, no* p*-adic measure row, no class-group row, and no host-field equality.*

Proof. Project the accepted carrier to the source, exponent, polynomial, splitting-field, endpoint, acceptance, comparison, and provenance rows. These are the only rows available before an Iwasawa-specific certificate is attached.

Use Definition 174.26 and Definition 174.29 to restrict the tower input surface to the projected cyclotomic source rows. Use Definition 174.30 to repack those rows as the cyclotomic layer of the tower.

The excluded tower maps and analytic rows do not occur in the carrier, the classifier, or the obligation surface. They must therefore be supplied by later NameCert rows rather than inferred from the cyclotomic packet. □

Theorem 174.13 (Cyclotomic class-field source obligation)**.** *A* $\mathsf{ClassField}^{\uparrow}$ *source interface may cite* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *only through the displayed* BHist *rows* $\mathcal{N}$*,* n*,* p*,* $\mathcal{S}$*, and* ζ*, the* Cont *row* α*, the* hsame *comparison* λ*, and the* Pkg *provenance row* ρ *of Definition 174.1. This interface provides cyclotomic source data for a later class-field certificate, but it does not provide a class group, reciprocity map, local symbol, norm residue map, or equality of ambient fields.*

Proof. Project the carrier rows and read them through the classifier of Definition 174.2. The only transport available is the carried hsame support on the source, exponent, polynomial, splitting-field, and endpoint rows, together with the displayed Cont and Pkg provenance.

Apply Definition 174.37. Its interface is the repacking of the cyclotomic source boundary, the p-adic input boundary, and the classifier transport already present in this chapter.

Since the named class-field operations are not entries of the cyclotomic carrier and are not produced by its classifier, the class-field consumer receives a source interface only. Any class-field operation must arrive with a separate NameCert row. □

Theorem 174.14 (Cyclotomic Galois transport obligation)**.** *Every Galois-facing transport read from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *is a transport of the primitive-root endpoint and the splitting-field root and factorization rows along the* hsame *support carried by the classifier of Definition 174.2. The transport is mediated by the* BHist *rows of Definition 174.1, the* Cont *acceptance row, and the* Pkg *provenance row; it exports no automorphism-group object, no quotient of roots, and no host-field equality.*

Proof. Project the classifier to the source, exponent, polynomial, splitting-field, and endpoint comparisons. These hsame rows are the only Galois-facing transport data available from the cyclotomic certificate.

Use Definition 174.24 for the primitive endpoint and Definition 174.35 for the polynomial and splitting-field rows. Use Definition 174.31 and Definition 174.33 to keep the readback inside endpoint and factorization transport.

The proof closes by inspecting the carrier and classifier fields. Neither contains an automorphism group, a quotient-root representative, or a host-field equality datum, so no downstream Galois consumer can read such data from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ alone. □

Theorem 174.15 (Cyclotomic splitting-field stability)**.** *For any two* $\mathsf{Cyclotomic}^\uparrow$ *carriers related by the classifier of Definition 174.2,* hsame *transport along the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *classifier preserves the accepted primitive-root endpoint, the root row for* $X^n - 1$*, and the factorization rows carried by the* BHist *splitting-field ledger. The transported certificate keeps the same* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *source comparison, the same positive exponent comparison, and the same* Cont *and* Pkg *provenance rows.*

Proof. Project the two cyclotomic packets to their $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ components. The splitting-field classifier supplies the transported root row and the transported factorization rows for the polynomial ledger classified with $X^n - 1$.

Use the carrier comparison to identify the exponent row and the rational polynomial row by hsame. The primitive-root endpoint is then read through the same Cont acceptance ledger, so its root status and the listed factorization rows remain attached to the transported splitting-field package.

The $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ comparison and the Pkg provenance row are projected unchanged from the cyclotomic carrier. Repacking these projected rows gives another accepted $\mathsf{Cyclotomic}^\uparrow$ carrier with the same public root and factorization evidence. □

Theorem 174.16 (Cyclotomic number-field embedding ledger)**.** *When a* $\mathsf{Cyclotomic}^\uparrow$ *carrier is read as a number-field extension, its embedding and provenance surface is the* BHist *ledger inherited from* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *together with the* hsame *bridge to the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *base row, the rational polynomial ledger, and the primitive-root endpoint. The readback preserves the* Cont *acceptance rows and the* Pkg *provenance rows that certify the cyclotomic field as generated by a root of* $X^n - 1$*.*

Proof. Start with the NumFieldUp source row in the carrier. Its embedding and provenance ledger is already a public row of $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$, so reading the cyclotomic packet as a number-field extension first projects that ledger.

Next attach the hsame comparison tying the NumFieldUp row to the base row consumed by $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$. The polynomial row and primitive-root endpoint are carried in the same tuple, and the Cont acceptance row records that the endpoint is read from the splitting-field root surface.

Thus the number-field readback retains both sources of provenance. It does not infer an embedding from an ambient field equality; it projects the displayed BHist rows and the carried Pkg ledger. □

Theorem 174.17 (Cyclotomic NameCert obligation surface)**.** *The paper-side* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *obligation surface consists of the* BHist *carrier of Definition 174.1, the* hsame *classifier of Definition 174.2, the splitting-field stability row over* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$*, the number-field embedding ledger over* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$*, the exact root and factorization* Cont *rows for* $X^n - 1$*, and the shared* Pkg *provenance rows. A downstream* $\mathsf{Iwasawa}^\uparrow$ *packet may consume exactly those rows from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier namecert obligation surface`

Proof. Collect the carrier tuple with its classifier rows. The carrier supplies the NumFieldUp source, exponent, rational polynomial ledger, SplittingFieldUp source, primitive-root endpoint, acceptance ledger, and provenance rows.

Add the two certificate obligations above. Splitting-field stability provides the transported root and factorization rows, while the number-field embedding ledger provides the readback surface needed by a downstream number-theoretic certificate.

Exactness is by projection from this list. Every public cyclotomic move uses one of the displayed BHist, hsame, Cont, or Pkg rows, and no consumer receives a stronger analytic, quotient, or host-field equality principle from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ alone. □

Theorem 174.18 (Cyclotomic primitive-root readback exactness)**.** *Every accepted carrier of Definition 174.1 reads its primitive-root endpoint ζ only through the displayed positive exponent row, the rational polynomial ledger for $X^n - 1$, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *source row, and the* Cont *acceptance ledger α. Conversely, those projected rows repack the primitive-root readback of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *without adding host equality of fields or quotienting primitive roots.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier primitive root readback exactness`

Proof. Project an accepted cyclotomic carrier to the entries n, p, $\mathcal{S}$, ζ, and α in the tuple of Definition 174.1. The positive exponent row fixes the displayed power n, the rational polynomial row fixes the ledger for $X^n - 1$, and the splitting-field source supplies the public root surface from which ζ is read.

The acceptance ledger α is the only row in the carrier that attaches the endpoint to the root and factorization surface. By Definition 174.15, classifier transport preserves that attachment through hsame rows rather than through an ambient equality of fields.

For the converse direction, start with the same projected exponent, polynomial, splitting-field, endpoint, and acceptance rows, then reattach the NumFieldUp source comparison and the Pkg provenance supplied by the carrier. Definition 174.16 identifies these as the number-field readback rows, so the repacked certificate has exactly the primitive-root readback advertised by $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$. □

Theorem 174.19 (Cyclotomic factorization ledger coverage)**.** *Each public factorization row exposed by* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *is projected from the carried* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *packet and transported by the classifier of Definition 174.2. No factorization row is available outside the displayed* BHist*,* hsame*,* Cont*, and* Pkg *rows of the cyclotomic carrier.*

Proof. Begin with a public factorization row of the cyclotomic certificate. The obligation surface of Definition 174.17 lists factorization evidence only in the splitting-field ledger and the acceptance ledger attached to the primitive-root endpoint.

Project the carried $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ packet. Its BHist factorization rows are then transported along the cyclotomic classifier, whose definition requires hsame support for the NumFieldUp source, exponent row, rational polynomial ledger, splitting-field row, and endpoint.

The remaining carrier entries are provenance rows. They record Cont acceptance and Pkg origin, but they do not introduce an independent factorization surface. Thus every public factorization row is covered by the splitting-field projection and classifier transport, and there is no separate source from which another row can be read. □

Theorem 174.20 (Cyclotomic splitting-field source exactness)**.** *The concrete source surface consumed by downstream* $\mathsf{Cyclotomic}^{\uparrow}$ *users consists exactly of the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row, the positive exponent row, the rational polynomial ledger for* $X^n - 1$*, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source row, the primitive-root endpoint, the root row, the factorization rows, and the shared provenance rows. These rows are covered by the carrier, sound under the classifier, and complete for every downstream readback of the cyclotomic source surface.*

Proof. Coverage follows by projecting the carrier of Definition 174.1. Its displayed tuple contains the NumFieldUp source, exponent row, rational polynomial ledger, splitting-field source, primitive-root endpoint, acceptance ledger, comparison row, and provenance row; the root and factorization entries are the rows recorded by the splitting-field packet and the acceptance ledger.

Soundness is the transport statement of Definition 174.15. The classifier of Definition 174.2 carries the source, polynomial, splitting-field, and endpoint comparisons by hsame, while the Cont and Pkg rows keep the accepted root and factorization evidence attached to the same provenance.

Completeness is the reverse repacking step. A downstream user of $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ receives only the rows listed by Definition 174.17; Definition 174.16 accounts for the NumFieldUp readback, and the preceding two exactness theorems account for the primitive-root and factorization readbacks. Reassembling these projections gives the whole concrete source surface and nothing stronger. □

Theorem 174.21 (Cyclotomic root-power ledger coverage)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, the displayed positive exponent row n*, the rational polynomial ledger* p *for* $X^n - 1$*, the splitting-field row* $\mathcal{S}$*, the primitive endpoint* ζ*, and the* Cont *acceptance row* α *cover every public read of a root power from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*. No separate root-power ledger is exported outside these* BHist*,* Cont*,* hsame*, and* Pkg *rows.*

Proof. Project the carrier of Definition 174.1. The exponent coordinate n, polynomial coordinate p, splitting-field coordinate $\mathcal{S}$, endpoint coordinate ζ, and acceptance coordinate α are the only rows from which a root-power read can be formed.

Use Definition 174.25 to identify p as the carried rational polynomial ledger for $X^n - 1$. Use Definition 174.27 to attach ζ to that displayed exponent and polynomial row through the same Cont ledger.

The splitting-field and factorization surface is already exact by Definition 174.20. The provenance row ρ and comparison row λ record transport and package origin; they do not add another source for root powers. Thus every public root-power read is covered by the listed row family. □

Theorem 174.22 (Cyclotomic primitive endpoint classifier stability)**.** *If two accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carriers are related by the classifier of Definition 174.2, then the primitive endpoint and its root-power ledger transport componentwise by the displayed* hsame *rows on the NumFieldUp source, exponent, rational polynomial ledger, SplittingFieldUp source, endpoint,* Cont *acceptance ledger, and shared* Pkg *provenance. The transport does not quotient primitive roots and does not assert equality of ambient host fields.*

Proof. Unpack the classifier of Definition 174.2. It supplies componentwise hsame rows for the source, exponent, polynomial, splitting-field, endpoint, acceptance, comparison, and provenance entries of the two carriers.

Apply Definition 174.21 to the source carrier and to the target carrier. The root-power surface on each side is the same displayed family of exponent, polynomial, splitting-field, endpoint, and acceptance rows.

Finally use Definition 174.15 and Definition 174.27. These statements transport the endpoint and its root-power ledger through the carried hsame rows, so the primitive-root surface remains classifier-stable without quotienting roots or identifying host fields. □

Theorem 174.23 (Cyclotomic downstream source exactness)**.** *An* $\mathsf{Iwasawa}^{\uparrow}$*,* $\mathsf{Padic}^{\uparrow}$*, or* $\mathsf{ClassField}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *receives exactly the carrier rows* $\mathcal{N}, n, p, \mathcal{S}, \zeta$*, the acceptance row* α*, the base comparison row* λ*, and the provenance row* ρ*, together with their displayed* BHist*,* Cont*,* hsame*, and* Pkg *support. It receives no valuation row, class-group row, reciprocity row, local-symbol row, completion row, or host-field equality row from the cyclotomic certificate alone.*

Proof. Project the carrier of Definition 174.1. Its displayed tuple contains exactly the rows $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ.

For the $\mathsf{Iwasawa}^{\uparrow}$ and $\mathsf{Padic}^{\uparrow}$ reads, apply Definition 174.29 and Definition 174.32. These statements repack the same projected rows as source data while excluding completion, measure, and valuation data unless another certificate supplies them.

For the $\mathsf{ClassField}^{\uparrow}$ read, apply Definition 174.37. The classifier transport is the componentwise transport of Definition 174.22, so the consumer receives exactly the listed rows and no class group, reciprocity map, local symbol, or host-field equality. □

Theorem 174.24 (Cyclotomic primitive-root endpoint transport)**.** *For classified* $\mathsf{Cyclotomic}^{\uparrow}$ *carriers, the primitive-root endpoint is transported by the carried* hsame *row of Definition 174.2. The transport preserves the displayed* Cont *acceptance ledger inside the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *row, including the root row for* $X^n - 1$*, the factorization rows listed by that splitting-field certificate, and the shared* Pkg *provenance of the NumFieldUp and SplittingFieldUp sources.*

Proof. Project the classifier of Definition 174.2. Its endpoint component is an hsame comparison whose endpoints are supported by the same cyclotomic carrier tuple and by the displayed Cont ledger.

Apply Definition 174.15 to the splitting-field components. This transports the root row for $X^n - 1$ and the factorization rows without replacing them by a host-field equality or by a quotient of primitive roots.

The remaining data are the source rows and provenance rows already carried by the packet. Repack the NumFieldUp source comparison, the SplittingFieldUp row, the transported endpoint, and the Pkg provenance as the same public cyclotomic endpoint surface. □

Theorem 174.25 (Cyclotomic polynomial-ledger exactness)**.** *Every accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier exposes precisely the positive unary exponent row, the rational polynomial ledger for* $X^n - 1$*, the SplittingFieldUp root and factorization rows, the primitive-root endpoint, and the shared NumFieldUp/SplittingFieldUp provenance rows. Conversely, such rows, with the* hsame *base comparison and the displayed* Cont *acceptance ledger, repack as the public* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *source surface of Definition 174.17.*

Proof. For the forward direction, unfold the carrier of Definition 174.1. The tuple exposes the NumFieldUp source, positive unary exponent, rational polynomial row, SplittingFieldUp source, primitive-root endpoint, acceptance row, base comparison, and provenance row as BHist data.

Use Definition 174.16 to identify the number-field embedding and provenance surface. Use Definition 174.24 for the endpoint together with the root and factorization rows read inside the splitting-field ledger.

For the reverse direction, assume the displayed rows with the hsame base comparison, the Cont acceptance ledger, and the shared provenance. Pack them in the order prescribed by Definition 174.1; the obligation surface of Definition 174.17 then reads this packet as the public $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ source surface. □

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier polynomial ledger exactness`

Theorem 174.26 (Cyclotomic Iwasawa consumer boundary)**.** *An* $\mathsf{Iwasawa}^\uparrow$ *consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *may read only the NumFieldUp embedding ledger, the SplittingFieldUp factorization ledger, the primitive-root endpoint, the* Cont *acceptance row, and the* Pkg *provenance exposed by the cyclotomic certificate. It receives no p-adic measure row, class-group row, Galois-action row, quotient-root representative, or host-field equality datum from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *alone.*

Proof. Project the public rows listed by Definition 174.25. They supply the number-field embedding ledger, the polynomial and splitting-field rows, the primitive-root endpoint, the acceptance ledger, and the provenance rows.

Combine this projection with Definition 174.17. The obligation surface says that a downstream $\mathsf{Iwasawa}^\uparrow$ packet consumes exactly the rows displayed by the cyclotomic source certificate, so every permitted read is mediated by BHist, hsame, Cont, or Pkg data.

The excluded rows are not components of Definition 174.1 and are not produced by the classifier of Definition 174.2. Thus p-adic, class-group, Galois, quotient-root, and host-field equality data must come from separate certificates, not from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ itself. □

Theorem 174.27 (Cyclotomic primitive-root endpoint determinacy)**.** *For any two* $\mathsf{Cyclotomic}^\uparrow$ *carriers related by the classifier of Definition 174.2, the displayed primitive-root endpoints are the same up to the carried* hsame *row. The determining data are exactly the positive exponent row, the rational polynomial ledger for* $X^n - 1$*, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *source row over that ledger, and the finite* Cont *acceptance row that records the endpoint as a primitive root inside the splitting-field factorization surface.*

Proof. Project the classifier to the exponent component and the rational polynomial component. These two hsame rows identify the displayed $X^n - 1$ ledger as a carried history row, so the endpoint is not read from an ambient field but from the same polynomial surface.

Project next to the $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ source comparison. By Definition 174.15, transport along this source comparison preserves the root row and the factorization rows attached to the displayed polynomial ledger.

Finally read the primitive-root endpoint through the finite Cont acceptance row. Since the acceptance row is part of the classifier-related carrier data, the endpoint comparison is precisely the carried hsame comparison supplied for the endpoint, with no additional quotient of primitive roots or host-field equality. □

Theorem 174.28 (Cyclotomic factorization ledger exactness)**.** *For a* $\mathsf{Cyclotomic}^\uparrow$ *carrier, the accepted factorization rows are exactly the rows projected from the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *source for the displayed rational polynomial ledger* $X^n - 1$*. A classifier-related carrier has the same accepted factorization ledger up to the carried* hsame *rows on the NumFieldUp source, the positive exponent, the rational polynomial classifier, and the splitting-field source.*

Proof. Start with the displayed polynomial row in the carrier. The rational polynomial classifier fixes this row as the $X^n - 1$ ledger determined by the NumFieldUp source and the positive exponent, so any accepted factorization row must be read against that ledger.

Apply Definition 174.15 to the $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ source row. It preserves the root row and the factorization rows for the polynomial ledger classified with $X^n - 1$.

The reverse containment is just the carrier acceptance condition: the finite Cont row records exactly the factorization rows projected from the SplittingFieldUp source and lists no independent cyclotomic factorization surface. Combining the two projections gives exactness of the accepted ledger. □

Theorem 174.29 (Cyclotomic Iwasawa source boundary)**.** *An* $\mathsf{Iwasawa}^\uparrow$ *consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *may read only the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *source row, the positive exponent row, the primitive-root endpoint, the factorization ledger for* $X^n - 1$*, and the shared* Pkg *provenance package. In particular, the consumer receives no quotient of primitive roots, no host equality of fields, and no factorization row not already present in the displayed* BHist *ledger.*

Proof. Use Definition 174.17 to enumerate the public rows exposed by $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$. The carrier contributes the NumFieldUp source, the positive exponent, the polynomial ledger, the SplittingFieldUp source, the primitive-root endpoint, the Cont acceptance row, and the provenance package.

Use Definition 174.27 to restrict endpoint readback to the carried hsame endpoint comparison. Use Definition 174.28 to restrict the factorization readback to the SplittingFieldUp ledger for the displayed $X^n - 1$ polynomial.

After these projections, the remaining rows visible to an IwasawaUp packet are exactly the NumFieldUp source row, the positive exponent row, the primitive-root endpoint, the accepted factorization ledger, and the shared Pkg provenance package. The negative clauses follow because none of the projected rows contains a quotient principle, a host-field equality, or an additional factorization oracle. □

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier iwasawa source boundary`

Theorem 174.30 (Cyclotomic Iwasawa tower source readback)**.** *An* $\mathsf{Iwasawa}^\uparrow$ *tower consuming* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *may read exactly the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *source row, the positive exponent row, the primitive-root endpoint, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *factorization ledger for* $X^n - 1$*, the* Cont *acceptance row, and the shared* Pkg *provenance. These rows repack as the cyclotomic layer of the tower, and the readback carries no p-adic measure row, class-group row, or host-field equality datum.*

Proof. Project the carrier of Definition 174.1. Its displayed tuple supplies the NumFieldUp source, exponent, polynomial row, SplittingFieldUp source, primitive-root endpoint, Cont acceptance row, hsame base comparison, and shared provenance.

Apply Definition 174.17 and Definition 174.25. These identify the public cyclotomic source rows as the BHist and Cont entries already present in the carrier, with the factorization data read through the SplittingFieldUp ledger for $X^n - 1$.

Finally use Definition 174.29 to restrict the downstream tower surface. Repacking the projected rows gives the cyclotomic layer because every entry is mediated by BHist, hsame, Cont, or Pkg; the omitted analytic and class-group data are not entries of the cyclotomic certificate. □

Theorem 174.31 (Cyclotomic Galois-action boundary)**.** *Any Galois-action data visible from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *is limited to* BHist *endpoint transport of the primitive-root and factorization*

rows through the existing $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *provenance. The certificate exports no automorphism group, no quotient of roots, and no ambient field equality.*

Proof. Start with the classifier of Definition 174.2. It transports the NumFieldUp source, exponent, polynomial ledger, SplittingFieldUp source, and primitive-root endpoint by carried hsame rows supported by the displayed Cont and Pkg ledgers.

Use Definition 174.25 to read factorization evidence only from the SplittingFieldUp packet for $X^n - 1$. Use Definition 174.29 to keep downstream readback inside those projected source rows.

Thus the only action-like information exposed by the cyclotomic certificate is endpoint and factorization transport through existing BHist provenance. Since Definition 174.17 lists no automorphism group, quotient-root object, or host-field equality, none is exported. □

Theorem 174.32 (Cyclotomic p-adic completion input boundary)**.** *Any p-adic or* $\mathsf{Iwasawa}^{\uparrow}$ *completion consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *receives only the displayed cyclotomic source rows as input data: the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row, positive exponent row, primitive-root endpoint, SplittingFieldUp factorization ledger for* $X^n - 1$*,* Cont *acceptance row, and shared* Pkg *provenance. Valuation rows, completion rows, and measure rows must be supplied by separate* $\mathsf{Padic}^{\uparrow}$ *or* $\mathsf{Iwasawa}^{\uparrow}$ *certificates.*

Proof. Project the accepted carrier in Definition 174.1. The projected BHist entries and the Cont row are exactly the cyclotomic source data described by Definition 174.17.

Apply Definition 174.25 to identify the polynomial and factorization entries with the SplittingFieldUp ledger for $X^n - 1$. The classifier of Definition 174.2 transports these entries only by hsame comparisons, while the provenance remains the carried Pkg row.

The boundary theorem Definition 174.29 then excludes every row not displayed in that source surface. Therefore a completion consumer starts from the cyclotomic source rows alone and obtains valuation, completion, and measure data only from separate PadicUp or IwasawaUp certificates. □

Theorem 174.33 (Cyclotomic Galois-action NameCert boundary)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_{\zeta} = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, every Galois-action consumer row read from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *is a projection of the displayed* BHist *rows* $\mathcal{N}$*,* n*,* p*,* $\mathcal{S}$*, and* ζ*, the* Cont *row* α*, the* hsame *row* λ*, and the* Pkg *provenance row* ρ*. The allowed transport is exactly the endpoint and factorization transport supplied by Definition 174.2, Definition 174.25, Definition 174.27, Definition 174.28, and Definition 174.31; no automorphism-group object, quotient-root representative, or host-field equality is exported.*

Proof. Project the carrier to $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ. These are the only displayed rows in Definition 174.1, and the classifier of Definition 174.2 transports them by carried hsame support.

Use Definition 174.25 to identify the polynomial row and Definition 174.28 to restrict factorization evidence to the $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ ledger for $X^n - 1$. Use Definition 174.27 for the endpoint component.

The Galois-facing boundary of Definition 174.31 then repacks these projected rows as endpoint and factorization transport only. Since neither the carrier nor the classifier contains an automorphism group, quotient-root object, or host-field equality field, no such datum can be read by the downstream Galois consumer. □

Theorem 174.34 (Cyclotomic p-adic tower consumer exactness)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, a p-adic tower or $\mathsf{Iwasawa}^{\uparrow}$ *consumer receives exactly the projected source package consisting of* $\mathcal{N}$*,* n*,* ζ*, the factorization rows over* p *inside* $\mathcal{S}$*, the acceptance row* α*, and the provenance row* ρ*. This package is the common projection described by Definition 174.29 and Definition 174.32, with polynomial and factorization exactness supplied by Definition 174.25 and Definition 174.28.*

Proof. Project the carrier rows displayed in Definition 174.1. The source row $\mathcal{N}$, exponent row n, polynomial ledger p, splitting-field row $\mathcal{S}$, endpoint ζ, acceptance row α, comparison row λ, and provenance row ρ form the whole input surface.

Apply Definition 174.25 to read p as the rational polynomial ledger for $X^n - 1$. Apply Definition 174.28 to identify the accepted factorization rows as exactly the rows projected from $\mathcal{S}$ over that ledger.

Finally use Definition 174.29 and Definition 174.32. They remove valuation, completion, measure, and class-group rows from the cyclotomic source package, so the downstream tower receives precisely the displayed projection and must obtain any further p-adic structure from a separate certificate. □

Theorem 174.35 (Cyclotomic splitting-polynomial classifier transport)**.** *For two accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carriers*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

and

$$\mathcal{C}'_{\zeta'} = (\mathcal{N}', n', p', \mathcal{S}', \zeta', \alpha', \lambda', \rho')$$

related by the classifier of Definition 174.2, the rational polynomial row for $X^n - 1$ *transports to the rational polynomial row for* $X^{n'} - 1$ *together with the transported* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source and its root and factorization rows. The transport is the* BHist *and* hsame *transport asserted by Definition 174.25, Definition 174.27, and Definition 174.28, not an equality of ambient splitting fields.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier splitting polynomial classifier transport`

Proof. Project the classifier to the source, exponent, polynomial, splitting-field, and endpoint comparisons. These are exactly the comparisons listed in Definition 174.2, with endpoints supported by the two displayed carriers of Definition 174.1.

Use Definition 174.25 to transport the rational polynomial ledger along the source and exponent rows. The primitive-root endpoint remains attached to that transported ledger by Definition 174.27.

The splitting-field factorization rows then follow from Definition 174.28. Repacking the transported polynomial row, splitting-field row, endpoint row, Cont rows, and Pkg provenance gives the classifier transport claimed by a splitting-polynomial consumer, with no appeal to ambient field equality. □

Theorem 174.36 (Cyclotomic root-of-unity ledger coverage)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, every root-of-unity row visible to a downstream consumer is covered by the positive exponent row n, the rational polynomial ledger p for X^n-1, the $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *row $\mathcal{S}$, the primitive-root endpoint ζ, and the acceptance row α. The coverage is exact by Definition 174.25, Definition 174.27, and Definition 174.28; there is no additional root ledger outside the displayed* BHist *and* Cont *rows.*

Proof. Project the carrier to n, p, $\mathcal{S}$, ζ, and α. These rows are the only places where a root-of-unity consumer can read an exponent, a polynomial ledger, a splitting-field root surface, an endpoint, or an acceptance certificate.

Apply Definition 174.25 to identify the ledger as X^n-1. Apply Definition 174.27 to show that the primitive endpoint is determined by the displayed exponent, polynomial, splitting-field, and Cont rows.

Apply Definition 174.28 to cover all accepted factorization rows by the carried $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ source. The provenance rows λ and ρ record transport and origin, but they add no independent root-of-unity ledger, so the displayed projection is complete. □

Theorem 174.37 (Cyclotomic class-field source interface)**.** *For an accepted* $\mathsf{Cyclotomic}^\uparrow$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, a $\mathsf{ClassField}^\uparrow$ *source interface may cite exactly the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *source row $\mathcal{N}$, the exponent row n, the polynomial ledger p, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *row $\mathcal{S}$, the primitive-root endpoint ζ, the acceptance row α, the base comparison λ, and the provenance row ρ. This interface is obtained by repacking the source boundary of Definition 174.29, the completion-input boundary of Definition 174.32, and the classifier transport of Definition 174.2; it supplies no class group, reciprocity map, local symbol, or host-field equality.*

Proof. Start with the carrier projection from Definition 174.1. The NumFieldUp row, exponent row, polynomial ledger, SplittingFieldUp row, endpoint, acceptance row, base comparison, and provenance row are all displayed BHist, Cont, hsame, or Pkg data.

Use Definition 174.25 and Definition 174.28 to make the polynomial and factorization rows exact. Use Definition 174.27 to keep the endpoint readback tied to the same displayed rows.

Finally combine Definition 174.29 with Definition 174.32. These boundary statements identify the reusable cyclotomic source package while excluding rows that must come from other certificates, so a ClassFieldUp consumer may cite this package as source data but receives no class-field operations from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ alone. □

Theorem 174.38 (Cyclotomic class-field reciprocity input boundary)**.** *For an accepted* $\mathsf{Cyclotomic}^\uparrow$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, a $\mathsf{ClassField}^\uparrow$ *consumer that requires a reciprocity map may read from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *only the displayed rows $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ together with their* BHist, hsame, Cont, *and* Pkg *provenance. Any reciprocity map, Artin pairing, or class-field operation used by that consumer must be supplied by a separate* $\mathsf{NameCert}_{\mathsf{ClassField}^\uparrow}$ *certificate and cannot be inferred from the cyclotomic certificate alone.*

Proof. Project the accepted carrier. The only visible components are the NumFieldUp source, the positive exponent row, the polynomial ledger for X^n-1, the SplittingFieldUp source, the primitive endpoint, the acceptance row, the base comparison, and the provenance row.

Apply Definition 174.37 to repack those rows as the class-field source interface. Apply Definition 174.36 to identify the root-of-unity rows covered by the same exponent, polynomial, splitting-field, endpoint, and acceptance data.

Finally use Definition 174.43. It excludes reciprocity and class-group data from the cyclotomic export surface, so a consumer that needs an actual reciprocity map must obtain it from its own $\mathsf{ClassField}^{\uparrow}$ certificate. □

Theorem 174.39 (Cyclotomic local-symbol exclusion)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *exports no local symbol, valuation row, completion row, or residue-field row. A downstream local consumer may use the displayed carrier rows and their* BHist*,* hsame*,* Cont*, and* Pkg *provenance as input, but every local symbol, valuation, completion, or residue-field datum must enter through a separate* $\mathsf{Padic}^{\uparrow}$*,* $\mathsf{Iwasawa}^{\uparrow}$*, or local certificate.*

Proof. Project the carrier of Definition 174.1. Its components are exactly $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ, and none of those coordinates is a valuation, completion, residue field, or local-symbol operation.

Use Definition 174.32 to identify what a completion-facing consumer may read from the cyclotomic source. Use Definition 174.34 to keep the tower input at the same projected source package.

The absence of local-symbol coordinates in Definition 174.1 then gives the exclusion. Any such datum must be carried by a certificate whose own rows name the local object. □

Theorem 174.40 (Cyclotomic norm-residue boundary)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, a norm-residue consumer may read the $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row* $\mathcal{N}$*, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source row* $\mathcal{S}$*, the positive exponent row* n*, the polynomial ledger* p*, the primitive endpoint* ζ*, the factorization rows covered by* $\mathcal{S}$*, and the provenance rows* α*,* λ*, and* ρ*. It may not read a norm-residue map, Artin symbol, class group, or ambient-field quotient from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*.*

Proof. Begin with Definition 174.37. It gives the NumFieldUp source, exponent, polynomial ledger, SplittingFieldUp source, endpoint, acceptance, comparison, and provenance rows as the whole class-field source package exposed by the cyclotomic certificate.

Apply Definition 174.33 to keep Galois-facing reads inside endpoint and factorization transport. This accounts for the splitting-field factorization surface without introducing an Artin symbol or an ambient-field quotient.

Finally use Definition 174.43. Since norm-residue maps, class groups, and reciprocity data are outside the exported carrier, any norm-residue consumer must obtain those objects from a separate certificate while using $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ only for the displayed source and provenance rows. □

Theorem 174.41 (Cyclotomic positive exponent row coverage)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, the positive unary exponent row n *is the only exponent datum exported by* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*. Every downstream read of the polynomial* $X^n - 1$ *factors through the carried* BHist *row* n*, the polynomial ledger* p*, the* Cont *acceptance row* α*, and the* Pkg *provenance row* ρ*; no separate degree row, order row, or ambient exponent classifier is exported by the cyclotomic certificate.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier positive exponent row coverage`

Proof. Project the displayed carrier of Definition 174.1. The exponent component is the single row n, while p, α, and ρ record the polynomial ledger, acceptance evidence, and package provenance attached to that row.

Apply Definition 174.25. It identifies the polynomial ledger read by a consumer as the ledger for $X^n - 1$ and ties that readback to the same exponent row and acceptance data.

Since the carrier contains no second exponent field and no degree or order certificate, every use of $X^n - 1$ must pass through the projected row n together with p, α, and ρ. This gives the announced coverage and excludes any independent exponent export from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$. □

Theorem 174.42 (Cyclotomic primitive-order witness boundary)**.** *For accepted* $\mathsf{Cyclotomic}^\uparrow$ *carriers related by the classifier of Definition 174.2, the primitive-root information visible downstream is exactly the endpoint* ζ *together with the positive exponent row and the splitting-field factorization rows transported by* hsame*. The certificate exports this endpoint-and-ledger witness surface, not a minimal-order proof object or an ambient Galois-theoretic order computation.*

Proof. Use Definition 174.41 to isolate the exported exponent datum as the positive row n carried by the source certificate. Use Definition 174.36 to read the endpoint ζ together with the polynomial and splitting-field rows that cover the root-of-unity surface.

Next apply Definition 174.27. It makes the visible primitive witness the endpoint attached to the displayed exponent, polynomial ledger, splitting-field source, and acceptance row.

Finally apply Definition 174.35. The classifier transports the endpoint and factorization rows by the available hsame comparisons, so the downstream witness boundary is exactly the transported endpoint, exponent row, and splitting-field factorization surface, with no exported minimal-order or Galois-order datum. □

Theorem 174.43 (Cyclotomic minimal-polynomial nonexport)**.** *For an accepted* $\mathsf{Cyclotomic}^\uparrow$ *carrier,* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *does not export a minimal polynomial, Euler totient degree, automorphism group, reciprocity map, or class-group datum. Any downstream consumer requiring those data must obtain them from a* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{Padic}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{Iwasawa}^\uparrow}$*, or* $\mathsf{NameCert}_{\mathsf{ClassField}^\uparrow}$ *certificate rather than from the cyclotomic certificate alone.*

Proof. The positive-exponent surface is fixed by Definition 174.41. The primitive witness surface is fixed by Definition 174.42. Together they account for the exported exponent, endpoint, polynomial ledger, splitting-field rows, acceptance data, classifier transport, and provenance data.

Use Definition 174.33 to exclude an exported automorphism group or host-field equality package. Use Definition 174.34 to exclude valuation, completion, measure, and class-group rows from the cyclotomic source surface.

Finally apply Definition 174.37. It permits a class-field consumer to cite the cyclotomic source package, but it supplies no reciprocity map, local symbol, or class-group operation. Since none of the carrier rows named above is a minimal-polynomial, totient-degree, automorphism, reciprocity, or class-group field, those data must come from the corresponding separate certificates. □

Theorem 174.44 (Cyclotomic splitting-field provenance conservation)**.** *For accepted* $\mathsf{Cyclotomic}^\uparrow$ *carriers related by the classifier of Definition 174.2, every splitting-field consumer receives exactly the rational polynomial row* p *for* $X^n - 1$*, the primitive endpoint row* ζ*, the factorization rows carried by* $\mathcal{S}$*, the* Cont *acceptance row* α*, the transported* hsame *comparisons, and the displayed* Pkg *provenance row* ρ*. The transported surface is the same* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *source package*

described by Definition 174.35; no host-field equality, additional factorization ledger, or independent root carrier is exported by $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$.

Proof. Start from the classifier projections in Definition 174.2. They expose the source, exponent, polynomial, splitting-field, endpoint, acceptance, comparison, and provenance rows attached to the two accepted carriers.

Apply Definition 174.35. It transports the rational polynomial row, the primitive endpoint, and the $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ source through the available BHist and hsame comparisons.

Use Definition 174.28 to identify the factorization rows as exactly the rows projected from $\mathcal{S}$ over the transported polynomial ledger. Use Definition 174.25 to keep that ledger tied to $X^n - 1$ and to the same Cont and Pkg rows.

The carrier of Definition 174.1 has no coordinate for a host-field equality, a second factorization ledger, or a separate root carrier. Thus the splitting-field consumer surface is precisely the conserved polynomial, root, factorization, Cont, hsame, and Pkg family. □

Theorem 174.45 (Cyclotomic root-source provenance confluence)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier, the source package obtained by root-of-unity coverage and the package obtained by splitting-polynomial transport are the same displayed row family: the positive exponent row n, the rational polynomial row p for $X^n - 1$, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source $\mathcal{S}$, the primitive endpoint ζ, the acceptance row α, the* BHist *provenance, the* Cont *rows, and the* Pkg *row ρ. This confluence is internal to the cyclotomic certificate and supplies no additional minimal-order proof object or ambient field equality.*

Proof. Use Definition 174.36 to read the root-of-unity surface from the displayed exponent, polynomial ledger, splitting-field source, primitive endpoint, and acceptance row. This gives the source package seen by a root consumer.

Use Definition 174.42 to keep the primitive witness at the endpoint-and-ledger level. The theorem excludes a separate minimal-order proof object and keeps the visible witness attached to n, p, $\mathcal{S}$, ζ, and α.

Apply Definition 174.44. The splitting-polynomial route conserves exactly the same polynomial, endpoint, factorization, Cont, hsame, and Pkg rows.

Both routes are projections of the single carrier of Definition 174.1. Therefore the root-source package and the splitting-polynomial package are the same displayed BHist, Cont, and Pkg row family, with no further ambient equality claim. □

Theorem 174.46 (Cyclotomic class-field repack exactness)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier, a* $\mathsf{ClassField}^{\uparrow}$ *consumer repacks exactly the confluence family of Definition 174.45 together with the positive exponent row and the displayed provenance rows. The repacked interface consists of the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row $\mathcal{N}$, the positive exponent row n, the polynomial row p, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source $\mathcal{S}$, the primitive endpoint ζ, the acceptance row α, the base comparison λ, and the provenance row ρ; it receives no class group, reciprocity map, minimal polynomial, totient degree, or host-field equality from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$.

Proof. Begin with Definition 174.37. It displays the rows that a class-field source interface may cite from an accepted cyclotomic carrier: $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ.

Use Definition 174.45 to identify the root-of-unity route and the splitting-polynomial route with the same BHist, Cont, and Pkg row family. Use Definition 174.41 to make the exponent row n the sole exponent datum in that family.

Finally apply Definition 174.43. It excludes minimal polynomials, totient degrees, host-field equalities, class groups, and reciprocity maps from the cyclotomic export surface.

Thus the $\mathsf{ClassField}^{\uparrow}$ consumer receives exactly the displayed source, exponent, polynomial, splitting-field, endpoint, acceptance, comparison, and provenance rows, and every class-field operation must enter through a separate class-field certificate. □

Theorem 174.47 (CyclotomicUp unary exponent source closure)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

of Definition 174.1, every displayed positive exponent row used by the cyclotomic root carrier is the unary-history BHist *row* n*. This row is stable under the classifier of Definition 174.2 and under the* Cont *source ledger recorded by* α *and* λ*.*

Proof. Project the cyclotomic carrier. Its exponent coordinate is the single positive row n, and the polynomial row p is read as the ledger for $X^n - 1$.

Apply Definition 174.41. It identifies n as the only exponent datum exported by the certificate and ties every read of $X^n - 1$ to the same BHist row, polynomial ledger, continuation entry, and provenance row.

Finally use the classifier clauses for exponent and source comparison. They transport n through hsame and keep the same Cont source ledger attached to the accepted carrier, so every displayed exponent row remains a unary BHist source row. □

Theorem 174.48 (CyclotomicUp root-action package provenance)**.** *For accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carriers related by the classifier of Definition 174.2, every Galois-action or splitting-field consumer row for the primitive endpoint* ζ *factors through the same* Pkg *provenance row* ρ *as the root carrier, polynomial classifier, and splitting ledger. No action row receives an independent provenance package outside the carried* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *packet.*

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier root action pkg provenance`

Proof. Begin with Definition 174.44. It places the splitting-field consumer surface at the polynomial row p, the primitive endpoint ζ, the factorization rows of $\mathcal{S}$, the Cont acceptance row, the transported hsame comparisons, and the package row ρ.

Use Definition 174.33 to read the Galois-facing action surface from the same endpoint and factorization transport. The action row is therefore attached to the transported carrier surface rather than to a host-field equality package.

Finally apply Definition 174.45. The root route and splitting-polynomial route share the same BHist, Cont, and Pkg row family, so each action or splitting consumer factors through ρ. □

Theorem 174.49 (CyclotomicUp downstream NameCert obligation packet)**.** *The* $\mathsf{Padic}^{\uparrow}$*,* $\mathsf{Iwasawa}^{\uparrow}$*,* $\mathsf{ClassField}^{\uparrow}$*,* $\mathsf{GaloisGroup}^{\uparrow}$*,* $\mathsf{NumField}^{\uparrow}$*, and* $\mathsf{SplittingField}^{\uparrow}$ *consumers of an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carrier receive exactly the* BHist *root carrier, the unary exponent row, the polynomial classifier, the root-action provenance, and the ledger exactness rows listed in this chapter. They receive no valuation, completion, class group, reciprocity map, ambient automorphism quotient, minimal polynomial, or host-field equality from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*.*

Proof. Use Definition 174.47 to fix the exponent input as the single unary BHist row n. Use Definition 174.25 and Definition 174.28 to identify the polynomial and splitting ledgers attached to that row.

Apply Definition 174.48 for the Galois-action and splitting-field provenance surface. Apply Definition 174.46 for the class-field consumer and Definition 174.34 for the local tower consumers.

The remaining exclusions are supplied by Definition 174.43 and Definition 174.39. Thus each listed downstream NameCert consumes only the displayed root, exponent, polynomial, factorization, action-provenance, Cont, and Pkg rows. □

Definition 174.50 (Cyclotomic root downstream consumer surface)**.** *The downstream consumer surface of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *is the tuple of rows already present in Definition 174.1: the* BHist *entries* $\mathcal{N}$*,* n*,* p*,* $\mathcal{S}$*, and* ζ*, the* Cont *acceptance row* α*, the* hsame *comparison row* λ*, and the* Pkg *provenance row* ρ*. A consumer may address this tuple through the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *projections, the carrier/classifier rows of Definition 174.1 and Definition 174.2, and the certificate surface of Definition 174.17. No host field equality, quotient of roots, valuation row, class-group row, or class-field operation is part of this surface.*

Theorem 174.51 (Cyclotomic root carrier classifier scope)**.** *For every accepted* $\mathsf{Cyclotomic}^\uparrow$ *carrier, the classifier scope available to downstream consumers is exactly the componentwise* hsame *transport on the* BHist *rows of Definition 174.50, together with the displayed* Cont *and* Pkg *ledgers. In particular, the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *projections remain the only source certificates visible to an* $\mathsf{Iwasawa}^\uparrow$ *or* $\mathsf{ClassField}^\uparrow$ *consumer.*

Proof. Project the carrier of Definition 174.1. The visible rows are precisely $\mathcal{N}$, n, p, $\mathcal{S}$, ζ, α, λ, and ρ.

Apply Definition 174.2 and Definition 174.5. They transport the source, exponent, polynomial, splitting-field, and endpoint rows by hsame and keep the endpoint acceptance and provenance attached by Cont and Pkg.

The two projected source certificates are therefore the only certificates available at the root boundary. Since no other coordinate appears in the carrier or classifier, downstream consumers receive no host equality or quotient-root datum. □

Theorem 174.52 (Cyclotomic root ledger stability package)**.** *The ledger package on the cyclotomic root surface is stable under classifier transport: the rational polynomial ledger for* $X^n - 1$*, the primitive endpoint readback, the splitting-field root and factorization rows, and the* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *provenance remain the same public rows after transport through* hsame*,* Cont*, and* Pkg *support.*

Proof. Use Definition 174.25 for the polynomial ledger and Definition 174.18 for the endpoint readback. These identify the public root rows as projections of the same accepted carrier.

Next apply Definition 174.15 and Definition 174.16. The first transports the splitting-field root and factorization rows, while the second preserves the NumFieldUp provenance ledger.

Repack those projections into the surface of Definition 174.50. The repacking uses only the listed carrier and certificate rows, so it adds no host equality, valuation, or class-field row. □

Theorem 174.53 (Cyclotomic root downstream unblock package)**.** *The pair consisting of Definition 174.51 and Definition 174.52 supplies the complete root obligation surface needed by downstream* $\mathsf{Iwasawa}^\uparrow$ *and* $\mathsf{ClassField}^\uparrow$ *fronts: a* BHist *carrier tuple,* hsame *classifier transport, the* Cont *acceptance ledger, the* Pkg *provenance row, and the two source* NameCert *projections for* $\mathsf{NumField}^\uparrow$ *and* $\mathsf{SplittingField}^\uparrow$*.*

Proof. Begin with the carrier/classifier scope theorem. It fixes the exported rows and the only allowed transport mechanism for each projected root component.

Use the ledger stability package to carry the polynomial, primitive endpoint, splitting-field, factorization, and NumFieldUp provenance rows through that transport. These rows are exactly the rows listed in Definition 174.50.

Therefore an $\mathsf{Iwasawa}^{\uparrow}$ or $\mathsf{ClassField}^{\uparrow}$ consumer can cite the cyclotomic root surface as a stable source package. The cited package still contains no tower transition map, class group, reciprocity map, local symbol, completion row, quotient root, or equality of ambient fields. □

Theorem 174.54 (Cyclotomic root Iwasawa and ClassField consumer boundary)**.** *When* $\mathsf{Iwasawa}^{\uparrow}$ *or* $\mathsf{ClassField}^{\uparrow}$ *consumes* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*, the consumed data are exactly the root downstream unblock package of Definition 174.53.* $\mathsf{Iwasawa}^{\uparrow}$ *may read the cyclotomic layer as source data for later tower rows, and* $\mathsf{ClassField}^{\uparrow}$ *may read the same layer as source data for later reciprocity rows, but neither consumer receives tower maps, class groups, reciprocity maps, local symbols, completion data, quotient-root carriers, or host-field equality from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *alone.*

Proof. For the Iwasawa side, apply Definition 174.29 and Definition 174.30. They read the cyclotomic carrier as a layer source while keeping tower transition and measure rows outside the cyclotomic packet.

For the class-field side, apply Definition 174.37. It reads the same BHist, hsame, Cont, Pkg, and NameCert rows as source data and leaves class-field operations to their own certificate.

Both projections factor through Definition 174.53. Hence the downstream boundary is shared and exact, with no extra root quotient or ambient-field equality introduced by either consumer. □

Definition 174.55 (Cyclotomic root obligation inventory)**.** *The root obligation inventory of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *is the finite packet consisting of the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source row, the positive unary exponent row, the primitive-root classifier row, the rational polynomial ledger for* $X^n - 1$*, the finite* Cont *readback, the* hsame *transport row, the* Pkg *provenance row, the exactness row identifying the displayed root surface, and the downstream consumer rows for* $\mathsf{Iwasawa}^{\uparrow}$*,* $\mathsf{ClassField}^{\uparrow}$*, and* $\mathsf{Regulator}^{\uparrow}$*. Each component is a displayed* BHist*,* Cont*,* hsame*, or* Pkg *row of the cyclotomic carrier and its source certificates.*

Theorem 174.56 (Cyclotomic root carrier classifier obligations)**.** *The carrier and classifier obligations of the cyclotomic root inventory are exactly the displayed* BHist *rows of Definition 174.55: the NumFieldUp source, the SplittingFieldUp source, the positive unary exponent, the primitive-root classifier, and the rational polynomial ledger, together with their finite* Cont*,* hsame*, and* Pkg *support rows.*

Proof. Project the carrier of Definition 174.1. Its visible entries are the source field, exponent, polynomial, splitting-field, root, acceptance, transport, and provenance rows.

Apply Definition 174.2 to identify the polynomial ledger and primitive-root classifier rows. Apply Definition 174.51 to see that the classifier boundary is only the componentwise hsame transport on those displayed rows, with Cont and Pkg kept as ledger support.

Thus every carrier and classifier obligation is one of the displayed rows of the inventory, and no ambient cyclotomic-field carrier is required. □

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootClassifier downstream consumer transport`

Theorem 174.57 (Cyclotomic root ledger exactness obligation)**.** *The ledger of Definition 174.55 is exact: after reading the polynomial, primitive endpoint, splitting-field, transport, and provenance rows, the cyclotomic root packet contains no host cyclotomic field, no quotient of roots, and no object beyond the displayed finite rows.*

Proof. Use Definition 174.25 for the rational polynomial ledger and Definition 174.18 for the endpoint readback. These two results identify the polynomial and primitive-root data as finite projections of the accepted carrier.

Next apply Definition 174.52. It carries the splitting-field, factorization, endpoint, transport, and NumFieldUp provenance rows through the same hsame, Cont, and Pkg support.

The resulting packet is precisely the inventory. Since each coordinate has already been projected from the displayed carrier, there is no remaining coordinate in which a host cyclotomic field or quotient root could be exported. □

Theorem 174.58 (Cyclotomic root downstream consumer obligations)**.** *Downstream* Iwasawa$^{\uparrow}$, ClassField$^{\uparrow}$, *and* Regulator$^{\uparrow}$ *readers consume only the packet boundary listed in Definition 174.55: source certificates, positive exponent and primitive-root classifier rows, polynomial ledger, finite* Cont *readback,* hsame *transport,* Pkg *provenance, and the exactness row of the cyclotomic root surface.*

Proof. For the Iwasawa and ClassField readers, apply Definition 174.54. It factors both consumers through the cyclotomic root downstream package and excludes tower maps, reciprocity maps, class groups, local symbols, completion data, quotient roots, and host-field equality.

For the Regulator reader, use the same packet boundary: the reader can address the NumFieldUp source, the polynomial ledger, and the finite root readback only through the displayed BHist, Cont, hsame, and Pkg rows. These rows are exactly the rows named by the inventory.

Therefore every downstream consumer cited here reads the same finite packet boundary, and none receives a host algebra primitive outside that packet. □

Theorem 174.59 (Cyclotomic root obligation threshold)**.** *The accepted* Cyclotomic$^{\uparrow}$ *root boundary supplies the threshold obligation surface consumed by* Iwasawa$^{\uparrow}$, ClassField$^{\uparrow}$, *and* Regulator$^{\uparrow}$*: the root carrier of Definition 174.1, the rational-polynomial classifier transport of Definition 174.5, the polynomial ledger of Definition 174.25, the primitive-root readback of Definition 174.18, and the finite* Cont, hsame, *and* Pkg *rows listed by Definition 174.55. It exports that finite root surface without adding a host cyclotomic field, quotient root, class group, tower map, or reciprocity map.*

Proof. Start from Definition 174.55. It names the NumFieldUp and SplittingFieldUp source rows, the positive exponent, the primitive-root classifier, the rational polynomial ledger for $X^n - 1$, finite readback, transport, provenance, and downstream consumer rows.

Apply Definition 174.56. The carrier and classifier clauses are exactly those displayed BHist rows with their Cont, hsame, and Pkg support.

Next use Definition 174.57. It identifies the polynomial, primitive endpoint, splitting-field, transport, and provenance rows as an exact finite ledger, so no host cyclotomic field or quotient-root coordinate is available.

Finally apply Definition 174.58. The three downstream fronts consume only the inventory boundary. Repacking these three cited obligations gives the stated threshold surface. □

Theorem 174.60 (Cyclotomic root classifier readback threshold)**.** *Every downstream read of the* Cyclotomic$^{\uparrow}$ *root classifier by* Iwasawa$^{\uparrow}$, ClassField$^{\uparrow}$, *or* Regulator$^{\uparrow}$ *factors through the same displayed* BHist *root row, the rational-polynomial classifier row, primitive readback,* Cont *acceptance,* hsame *transport, and* Pkg *provenance of Definition 174.55. Conversely, these rows repack into the root classifier surface of Definition 174.59.*

Proof. For the forward projection, read a downstream classifier access through Definition 174.54 for Iwasawa$^{\uparrow}$ and ClassField$^{\uparrow}$, and through Definition 174.58 for the shared Regulator-facing root surface.

The projected rows are then controlled by Definition 174.51. That theorem leaves only componentwise hsame transport on the displayed root rows, with Cont and Pkg kept as finite support.

For the converse direction, take exactly the displayed root carrier, classifier, primitive readback, transport, acceptance, and provenance rows. The threshold theorem repacks them as the accepted root obligation surface, so the downstream readback closes without a host root quotient or ambient field equality. □

Lean4 ✓ `BEDC.Derived.CyclotomicUp.CyclotomicRootClassifier readback threshold`

Theorem 174.61 (Cyclotomic root ledger exactness threshold)**.** *The* $\mathsf{Cyclotomic}^{\uparrow}$ *root ledger exported at the threshold surface is exact: once the root carrier, rational-polynomial classifier transport, polynomial ledger, primitive-root readback, finite* Cont*, componentwise* hsame*, and* Pkg *rows are fixed, every accepted consumer row for* $\mathsf{Iwasawa}^{\uparrow}$*,* $\mathsf{ClassField}^{\uparrow}$*, or* $\mathsf{Regulator}^{\uparrow}$ *reads the same finite root boundary and no additional host algebra primitive.*

Proof. Use Definition 174.52. The polynomial ledger, primitive endpoint readback, splitting-field root and factorization rows, and NumFieldUp provenance remain stable under the same hsame, Cont, and Pkg support.

Combine this with Definition 174.57. The exactness obligation says that after those rows are read, the packet has no remaining coordinate for a host cyclotomic field, root quotient, valuation row, or class-field operation.

It remains to identify the consumers. Apply Definition 174.59 and Definition 174.60; together they show that $\mathsf{Iwasawa}^{\uparrow}$, $\mathsf{ClassField}^{\uparrow}$, and $\mathsf{Regulator}^{\uparrow}$ all factor through the same finite root boundary. □

Theorem 174.62 (Cyclotomic source triad readback completeness)**.** *For an accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *root packet, every downstream readback of the source triad is complete from the displayed* BHist *rows: the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *row, the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *row over the rational polynomial ledger for* $X^n - 1$*, and the primitive endpoint row. The readback uses only the carried* hsame *comparisons, finite* Cont *acceptance,* Pkg *provenance, and the* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *classifier rows listed by Definition 174.10.*

Proof. Start with the source triad of Definition 174.10. It names the NumFieldUp source, SplittingFieldUp source, and primitive endpoint as the entire cyclotomic source family over the carrier of Definition 174.1.

Use Definition 174.23 to identify every downstream source read with the same displayed BHist, Cont, hsame, and Pkg support. Then use Definition 174.25 for the polynomial ledger and Definition 174.24 for the primitive endpoint.

These projections repack the whole $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ source triad. There is no fourth source row, because the cited obligation surface has no coordinate outside the displayed carrier, classifier, acceptance, and provenance rows. □

Theorem 174.63 (Cyclotomic downstream valuation exclusion)**.** *At the* $\mathsf{Cyclotomic}^{\uparrow}$ *root threshold, a downstream* $\mathsf{Padic}^{\uparrow}$*,* $\mathsf{Iwasawa}^{\uparrow}$*, or* $\mathsf{ClassField}^{\uparrow}$ *consumer may cite the* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *source triad only through the displayed* BHist *carrier,* hsame *transport, finite* Cont *acceptance,* Pkg *provenance, and* $\mathsf{NameCert}$ *rows. The threshold exports no valuation row, completion row, measure row, reciprocity map, local symbol, or host field equality.*

Proof. Read the downstream interface through Definition 174.32 and Definition 174.37. Both boundaries allow the cyclotomic packet to serve only as source data for later certificates.

Apply Definition 174.25. The polynomial ledger is the $X^n - 1$ row attached to the same SplittingFieldUp source, not a valuation or completion datum. Apply Definition 174.24 to keep primitive endpoint transport inside the carried hsame and Cont rows.

Finally use Definition 174.23. Since the downstream source surface is exhausted by the displayed BHist, Cont, hsame, Pkg, and NameCert rows, all valuation, completion, measure, reciprocity, local-symbol, and host-equality data must come from another certificate. □

Theorem 174.64 (Cyclotomic root-layer consumer threshold)**.** *The root-layer consumer threshold for* $\mathsf{Cyclotomic}^{\uparrow}$ *is exactly the source triad readback, polynomial-ledger exactness, and primitive endpoint transport surface over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Once these rows are fixed,* $\mathsf{Iwasawa}^{\uparrow}$*,* $\mathsf{Padic}^{\uparrow}$*, and* $\mathsf{ClassField}^{\uparrow}$ *consumers have all cyclotomic source data they may read, and no analytic, quotient, valuation, or host-equality row is supplied by the cyclotomic certificate.*

Proof. First collect the complete source triad from Definition 174.62. This supplies the NumFieldUp source, the SplittingFieldUp source, and the primitive endpoint over the displayed carrier and classifier support.

Next attach the ledger and endpoint controls. The polynomial row is exact by Definition 174.25, and primitive endpoint transport is exactly the transported endpoint surface of Definition 174.24.

The consumer side is then bounded by Definition 174.59 and Definition 174.63. Together they show that the listed source rows are sufficient for the root-layer consumers and that the excluded analytic, quotient, valuation, and host-equality rows remain outside the $\mathsf{Cyclotomic}^{\uparrow}$ certificate. □

Definition 174.65 (Cyclotomic root obligation packet)**.** *The* $\mathsf{Cyclotomic}^{\uparrow}$ *root obligation packet is the finite row family*

$$(\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho),$$

where $\mathcal{N}$ *is the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source row,* n *is the positive unary* BHist *exponent,* p *is the rational polynomial ledger for* $X^n - 1$*,* $\mathcal{S}$ *is the* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$ *source over* p*,* ζ *is the primitive-root endpoint,* α *is the finite* Cont *acceptance and factorization ledger,* λ *is the transported* hsame *comparison between source base rows, and* ρ *is the* Pkg *provenance for the paired source certificates.*

The packet is a row package for downstream consumers. It is not a host cyclotomic field, not a quotient of roots, and not a class-field, valuation, or completion object.

Theorem 174.66 (Cyclotomic root source row exhaustion)**.** *Every source row of the* $\mathsf{Cyclotomic}^{\uparrow}$ *root boundary is exhausted by the root obligation packet of Definition 174.65. Conversely, the displayed packet repacks into the root carrier, classifier transport, polynomial ledger, primitive endpoint, and threshold surface of the accepted cyclotomic root interface.*

Proof. Start with the carrier of Definition 174.1. Its visible coordinates are exactly the NumFieldUp source, exponent, polynomial, SplittingFieldUp source, primitive endpoint, acceptance, comparison, and provenance rows displayed in Definition 174.65.

Apply Definition 174.5. It transports those carrier rows componentwise through hsame, while keeping the Cont acceptance and Pkg provenance attached to the same finite packet.

Use Definition 174.25 for the polynomial row and Definition 174.24 for the primitive endpoint. These theorems account for the source ledger and endpoint readback without adding a quotient root or ambient field equality.

Finally apply Definition 174.59. It repacks the carrier, classifier transport, exact ledger, endpoint, Cont, hsame, and Pkg rows as the threshold surface. Since no other source coordinate occurs in the carrier or threshold theorem, the packet is exhaustive. □

Theorem 174.67 (Cyclotomic primitive-root ledger transport)**.** *For accepted* $\mathsf{Cyclotomic}^{\uparrow}$ *carriers related by the rational-polynomial classifier, the primitive-root endpoint, its polynomial ledger for* $X^n - 1$*, the SplittingFieldUp factorization rows, the* Cont *acceptance row, and the* Pkg *provenance*

are transported as the same root obligation packet. No transported row becomes a host-field equality, quotient of primitive roots, or independent minimal-order datum.

Proof. Project the related carriers through Definition 174.2. The classifier exposes only the displayed source, exponent, polynomial, splitting-field, endpoint, acceptance, comparison, and provenance rows.

Use Definition 174.5 to move those rows componentwise through the available hsame comparisons. The finite Cont and Pkg rows remain attached to the transported endpoint and source certificates.

Apply Definition 174.25 and Definition 174.24. The polynomial ledger and primitive endpoint are therefore the transported rows of the same packet, not new algebraic objects.

Repack the transported family by Definition 174.65 and the threshold theorem Definition 174.59. The exclusions follow from the carrier definition and the threshold surface, both of which name no host field equality, root quotient, or separate order witness. □

Theorem 174.68 (Cyclotomic SplittingField consumer boundary)**.** *A downstream* $\mathsf{SplittingField}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *may read exactly the splitting-field source row* $\mathcal{S}$*, the polynomial row* p*, the primitive endpoint* ζ*, the factorization and acceptance row* α*, the transported* hsame *comparisons, and the* Pkg *provenance contained in the root obligation packet. It receives no extra splitting field object, host equality of fields, valuation row, class-field operation, or completion datum from* $\mathsf{Cyclotomic}^{\uparrow}$ *alone.*

Proof. Begin with the SplittingField-facing coordinates of Definition 174.65: $\mathcal{S}$, p, ζ, α, λ, and ρ. These are the only rows of the packet addressed to a splitting-field consumer.

Apply Definition 174.35. It transports the polynomial and splitting-field source rows through the displayed classifier support. Then use Definition 174.28 to identify the factorization rows as the ledger covered by $\mathcal{S}$.

The primitive endpoint is controlled by Definition 174.24, and the root threshold is fixed by Definition 174.59. These results repack exactly the displayed splitting-field consumer rows.

No remaining coordinate of Definition 174.65 names a second splitting field, ambient field equality, valuation, class-field operation, or completion object. Therefore a SplittingFieldUp consumer is bounded by the listed packet rows. □

Definition 174.69 (Cyclotomic scoped root obligation package)**.** *The scoped root obligation package for* $\mathsf{Cyclotomic}^{\uparrow}$ *is the finite BEDC row family*

$$\mathcal{R}_{\zeta} = (\mathcal{C}_{\zeta}, \Theta_{\mathbb{Q}[X]}, \zeta, \alpha, \lambda, \rho, \nu, \sigma),$$

where $\mathcal{C}_{\zeta}$ *is the root carrier of Definition 174.1,* $\Theta_{\mathbb{Q}[X]}$ *is the rational-polynomial classifier of Definition 174.2,* ζ *is the primitive endpoint,* α *is the finite* Cont *root and factorization ledger,* λ *is the displayed* hsame *base-row comparison,* ρ *is the* Pkg *provenance row for* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$*,* ν *is the finite row family consumed by* $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{Regulator}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{SplittingField}^{\uparrow}}$*, and* σ *is the displayed* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *row obtained by repacking these components.*

The package is scoped to the rows named above. It is not a host cyclotomic field, quotient of primitive roots, reciprocity map, regulator determinant, valuation, completion, or ambient splitting-field equality.

Theorem 174.70 (Cyclotomic root BHist scope binding)**.** *Every accepted scoped root obligation package* $\mathcal{R}_{\zeta}$ *of Definition 174.69 binds its carrier, rational-polynomial classifier, primitive endpoint,*

Cont *ledger,* hsame *base comparison,* Pkg *provenance, and source* $\mathsf{NameCert}$ *rows to displayed* BHist *primitives. Conversely, exactly those displayed rows repack as the scoped package.*

Proof. Project the carrier coordinate $\mathcal{C}_\zeta$. By Definition 174.1, its visible components are the $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ source row, the positive unary exponent, the rational polynomial ledger for $X^n - 1$, the $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ source row, the primitive endpoint, the finite acceptance row, the base comparison row, and the provenance row.

Apply Definition 174.66. It identifies this same row family as the root obligation packet and shows that no other source coordinate is available at the root boundary.

Next use Definition 174.67 together with Definition 174.59. These theorems bind the primitive endpoint, polynomial ledger, factorization rows, Cont ledger, hsame transport, and Pkg provenance to the displayed BHist carrier surface.

For the converse direction, start with exactly the displayed carrier, classifier, endpoint, continuation, sameness, provenance, and source-certificate rows. The root carrier definition and the root obligation packet definition repack them as $\mathcal{C}_\zeta$ and then as $\mathcal{R}_\zeta$. No host field equality or root quotient is introduced in the repacking step. □

Theorem 174.71 (Cyclotomic root consumer scope exhaustion)**.** *A downstream* $\mathsf{Iwasawa}^\uparrow$, $\mathsf{ClassField}^\uparrow$, $\mathsf{Regulator}^\uparrow$, *or* $\mathsf{SplittingField}^\uparrow$ *reader of* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *receives exactly the rows of the scoped root obligation package: the root carrier, the rational-polynomial classifier, the primitive endpoint, the finite* Cont *ledger, the displayed* hsame *comparisons, the* Pkg *provenance, and the source* $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$ *rows. No reader receives a class group, reciprocity map, regulator determinant, valuation, completion, quotient-root object, or host splitting-field equality from this package alone.*

Proof. First consider the splitting-field reader. Apply Definition 174.68. It restricts that consumer to the splitting-field source row, polynomial row, primitive endpoint, factorization and acceptance rows, transported hsame comparisons, and Pkg provenance contained in the root obligation packet.

For $\mathsf{Iwasawa}^\uparrow$ and $\mathsf{ClassField}^\uparrow$, use Definition 174.54 and Definition 174.37. These statements permit the cyclotomic source package to be cited as input rows while excluding tower maps, class groups, reciprocity maps, local symbols, completion data, and host-field equality.

For the regulator-facing reader, use the same source-row exhaustion supplied by Definition 174.66 and the nonexport boundary of Definition 174.43. Since no coordinate of the carrier or classifier is a determinant, norm form, or regulator ledger, the reader receives only the displayed root source rows and provenance.

The four cases exhaust the consumer row family ν in Definition 174.69. Repacking the cases gives exactly the listed BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ rows, and no additional algebraic object is exported. □

Theorem 174.72 (Cyclotomic root scoped closure boundary)**.** *The package of Definition 174.69, the scope binding theorem Definition 174.70, and the consumer exhaustion theorem Definition 174.71 close the scoped root-obligation boundary of* $\mathsf{Cyclotomic}^\uparrow$ *over* BHist, Cont, hsame, Pkg, $\mathsf{NameCert}_{\mathsf{NumField}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{SplittingField}^\uparrow}$. *The boundary does not export a host cyclotomic field, primitive-root quotient, Galois bridge, class-field bridge, regulator bridge, or standard splitting-field model.*

Proof. The definition supplies the finite package: carrier, classifier, endpoint, continuation, sameness, provenance, source certificates, consumer rows, and the repacked $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ row.

Apply Definition 174.70. It ties every package coordinate to displayed BEDC primitives and gives the converse repacking from those primitives.

Apply Definition 174.71. It verifies that the named downstream readers can consume only the same finite row family and cannot read the excluded host or bridge objects from the cyclotomic certificate.

Therefore the scoped boundary is exactly the displayed root-obligation surface. Any public cyclotomic field, quotient of roots, reciprocity structure, regulator structure, or standard model must be supplied by a separate certificate or bridge. □

Theorem 174.73 (Cyclotomic Galois root dependency link)**.** *Let*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$$

be an accepted $\mathsf{Cyclotomic}^\uparrow$ *carrier. Any Galois-extension dependency read that exports this root-of-unity packet as a cyclotomic* $\mathsf{NameCert}$ *must consume the* $\mathsf{FieldExt}^\uparrow$ *and* $\mathsf{SplittingField}^\uparrow$ *sibling carriers through the polynomial-root and factorization rows* $p, \mathcal{S}, \zeta, \alpha$*, and must consume the* $\mathsf{GaloisExt}^\uparrow$ *and* $\mathsf{GaloisGroup}^\uparrow$ *sibling carriers through the automorphism-action rows supplied by chapter 163 and chapter 164. The cyclotomic side contributes the endpoint and factorization surface of Definition 174.1, while the Galois side contributes normality, separability, base-fixing, and automorphism-action rows before the local* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *export is read.*

Thus the dependency lattice for a Galois-facing cyclotomic read is

$$\mathsf{FieldExt}^\uparrow,\ \mathsf{SplittingField}^\uparrow,\ \mathsf{GaloisExt}^\uparrow,\ \mathsf{GaloisGroup}^\uparrow,\ \mathsf{Cyclotomic}^\uparrow,$$

with the root data routed through BHist, hsame, Cont, *and* Pkg *rows. The route exports no quotient of roots, no host field equality, no ambient automorphism set, and no class-field or Iwasawa datum from the cyclotomic certificate alone.*

Proof. Project the accepted carrier by Definition 174.1. The cyclotomic rows available before naming are exactly the NumField source, exponent, polynomial ledger, SplittingField source, primitive-root endpoint, root-acceptance continuation, base comparison, and package provenance.

Use Definition 174.25, Definition 174.27, and Definition 174.28. These identify the polynomial-root and factorization rows as the only cyclotomic data that can be offered to a Galois-extension consumer.

The automorphism information is then read from the sibling Galois certificates, not manufactured by the cyclotomic carrier. The Galois-extension chapter supplies the normal and separable extension surface over $\mathsf{FieldExt}^\uparrow$, while the Galois-group chapter supplies the base-fixing automorphism-action rows over that extension.

Finally apply Definition 174.31 and Definition 174.33. They keep every Galois-facing cyclotomic read inside endpoint and factorization transport, so the combined lattice can export a cyclotomic NameCert only after the FieldExt, SplittingField, GaloisExt, and GaloisGroup sibling rows have supplied their own dependency data. □

Definition 174.74 (Cyclotomic Iwasawa classgroup consumer packet)**.** *The Cyclotomic Iwasawa classgroup consumer packet is the finite row family read by an* $\mathsf{Iwasawa}^\uparrow$ *classgroup consumer from an accepted* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^\uparrow}$ *source. It consists of the cyclotomic layer rows* $\mathcal{N}, n, p, \mathcal{S}, \zeta$*, the primitive-root endpoint row* ζ*, the factorization ledger rows of* $\mathcal{S}$ *over the polynomial ledger* p*, the classifier transport supplied by the cyclotomic rational-polynomial classifier, the finite* Cont *acceptance and factorization provenance row* α*, and the shared* Pkg *provenance row* ρ*.*

The packet is only a BEDC consumer surface. It is not a host cyclotomic field, not a class-field bridge, not analytic Iwasawa data, and not a quotient carrier.

Theorem 174.75 (Cyclotomic Iwasawa classgroup consumer projection)**.** *For every accepted* Cyclotomic$^{\uparrow}$ *source carrier*

$$\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho),$$

the Iwasawa$^{\uparrow}$ *classgroup consumer rows projected from that carrier are exactly the rows of Definition 174.74. The projection uses the cyclotomic source boundary, the primitive-root endpoint rows, the factorization ledger rows, the classifier transport,* Cont*, and* Pkg *provenance already present in the source carrier.*

Proof. Start with the cyclotomic source boundary of Definition 174.29. It projects the NumField source row, the positive exponent row, the primitive-root endpoint, the factorization ledger for $X^n - 1$, and the shared package provenance to the Iwasawa-facing surface.

Next use the root obligation closure rows. The packet of Definition 174.65 carries the polynomial ledger, the SplittingField source, the primitive endpoint, the finite Cont acceptance row, the transported hsame comparison, and the Pkg provenance row. The transport theorem Definition 174.67 keeps these rows tied to the same source carrier.

Repack the projected rows by Definition 174.74. None of the cited source-boundary or root-obligation rows contains a host cyclotomic field, class-field bridge, analytic Iwasawa datum, or quotient carrier, so none is exported by the projection. □

Theorem 174.76 (Cyclotomic Iwasawa classgroup consumer exhaustion)**.** *Every Iwasawa-facing cyclotomic read used by a classgroup consumer is one of the rows of Definition 174.74, and every such row repacks into the same consumer packet. The surface has no host cyclotomic-field carrier, class-field bridge, analytic Iwasawa row, or quotient carrier.*

Proof. Project any Iwasawa-facing read through Definition 174.66. The source row must be one of the root carrier, classifier transport, polynomial ledger, primitive endpoint, threshold, Cont, hsame, or Pkg rows of the root obligation packet.

Now restrict to the classgroup consumer view using Definition 174.54. The Iwasawa side receives only the source, exponent, primitive endpoint, factorization, and provenance rows needed for its finite classgroup-facing input; class-field operations remain outside the cyclotomic packet.

Conversely, each row listed in Definition 174.74 is a coordinate of the cyclotomic source boundary or of the root obligation closure package. Therefore the rows repack into the same consumer packet, and the exclusions follow because neither cited boundary contains a host field, analytic Iwasawa object, class-field bridge, or quotient carrier. □

The Cyclotomic$^{\uparrow}$ root layer consumes the number-field source of chapter 168 and the root-factorization source of chapter 165 before exposing its primitive-root endpoint.

Closure status for NameCert$_{\text{Cyclotomic}^{\uparrow}}$**.**

Constructive story: A cyclotomic root layer is generated as the finite packet $\mathcal{C}_\zeta = (\mathcal{N}, n, p, \mathcal{S}, \zeta, \alpha, \lambda, \rho)$: a NumField$^{\uparrow}$ source row, a positive unary exponent, the rational polynomial ledger for $X^n - 1$, a SplittingField$^{\uparrow}$ source over that ledger, a primitive-root endpoint, an acceptance and factorization Cont row, a base hsame comparison, and Pkg provenance. The carrier accepts exactly that displayed tuple and excludes quotient roots, host field equality, valuation rows, class-field reciprocity data, automorphism groups, completions, and regulator rows. Two accepted packets classify together when the NumField source, exponent, polynomial ledger, splitting-field source, and primitive endpoint are transported by componentwise hsame with support from the displayed acceptance and provenance rows. The source specification is the same root-layer tuple, the pattern records source coverage, polynomial-ledger exactness, primitive endpoint determinacy, factorization coverage, and downstream consumer exhaustion, and the ledger keeps the exponent, polynomial, root, factorization, base comparison, and provenance rows visible as the same packet. The five naming-certificate obligations are supplied by the accepted root tuple, reflexive, symmetric, and transitive component transports, and the root-layer classifier transport theorem that repacks transported rows as another accepted carrier. A history h lies in the signature gap of a Cyclotomic$^{\uparrow}$ token p when the source domain accepts the root-layer packet, the signature relation pairs it with an

answer packet and evidence ledger, and token introduction names that answer as p; here that means the positive exponent, polynomial $X^n - 1$ ledger, splitting-field root rows, primitive endpoint, and provenance of h are the rows named by p. The chapter registers this scoped root-obligation construction under Cyclotomic$^{\uparrow}$; it gives downstream number-theoretic consumers a finite source package, but no public cyclotomic-field quotient, Galois bridge, class-field bridge, or standard splitting-field model.

Theory closure: TheoryGate(NameCert$_{\text{Cyclotomic}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 174.72 binds the scoped root package to the displayed BHist, hsame, Cont, NameCert, and Pkg primitives.

Formal verification: FormalStatus(NameCert$_{\text{Cyclotomic}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CyclotomicUp.CyclotomicRootCarrier\_root\_layer\_classifier\_transport`

Bridge status: none

Not claimed: No standard cyclotomic field, class-field bridge, Galois bridge, or public cyclotomic-field quotient is claimed here.

Upgrade path: Only a later standard bridge verification target can raise the separate formal bridge status.

Chapter 175

A Concrete Naming Certificate for $\mathsf{EllipticCurve}^{\uparrow}$

The elliptic-curve interface $\mathsf{EllipticCurve}^{\uparrow}$ packages a smooth projective genus-one curve over a field carrier together with a chosen base point. It depends on $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ (chapter 155) and $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ (chapter 45).

175.1 Carrier definition

Definition 175.1 (Elliptic-curve BHist carrier packet)**.** *An* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier is a* BHist *packet*

$$\mathcal{E} = (\mathcal{F}, \mathcal{P}, a_1, a_2, a_3, a_4, a_6, \gamma, \sigma, o, \lambda_F, \lambda_P, \rho)$$

where $\mathcal{F}$ *is a source* $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ *row,* $\mathcal{P}$ *is a source* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ *row over the same field row,* $a_1, a_2, a_3, a_4, a_6 : \mathsf{BHist}$ *are field-coefficient rows,* $\gamma : \mathsf{BHist}$ *is the homogeneous cubic and projective-incidence row,* $\sigma : \mathsf{BHist}$ *is the smooth genus-one boundary row,* $o : \mathsf{BHist}$ *is the chosen base-point row,* λ_F *and* λ_P *are the field and projective classifier rows witnessed through* hsame*, and* ρ *records the* Pkg *provenance of the two source certificates and the displayed rows.*

The accepted endpoint is exactly the displayed history packet. It contains no ambient curve equality, no external point set, and no host discriminant predicate; all coefficient, incidence, smoothness, base-point, classifier, continuation, and provenance data are rows of BHist*,* hsame*,* Cont*, and* Pkg*.*

Lean4 (definition) `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket`

175.2 The certificate

Theorem 175.2 (Elliptic-curve field source obligation)**.** *In every carrier packet of Definition 175.1, the coefficient rows* a_1, a_2, a_3, a_4, a_6*, the field operation rows used to form the Weierstrass cubic, and the nonzero-discriminant row are projected from the* $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ *dependency. The* $\mathsf{EllipticCurve}^{\uparrow}$ *boundary may read these rows only as* BHist *data with the* Pkg *provenance inherited from* $\mathcal{F}$*.*

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket field source obligation`

Proof. Project the carrier packet to its $\mathcal{F}$ component and to the five displayed coefficient rows. The FieldUp certificate supplies the addition, multiplication, negation, unit, and nonzero rows needed to interpret the coefficients and the discriminant expression.

The Weierstrass cubic row is then formed by reading those operations through the same BHist ledger. The discriminant row is not a host-side assertion about a curve; it is the nonzero field row reached through the projected FieldUp source.

Repack the coefficient rows, operation rows, and nonzero-discriminant row with the original Pkg provenance. This gives the exact field-source part of the elliptic-curve certificate surface. □

Theorem 175.3 (Elliptic-curve projective genus-one obligation)**.** *In every carrier packet of Definition 175.1, the projective equation row, projective-incidence row, smoothness row, and genus-one boundary row are carried by the* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ *dependency as BEDC rows. They are not imported as host curves, external schemes, or ambient geometric equalities.*

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket projective genus one obligation`

Proof. Project the packet to its $\mathcal{P}$ component and to the homogeneous cubic row γ. The ProjectiveVarUp source supplies the projective carrier, homogeneous zero-locus, incidence, classifier, and ledger rows needed to read γ as a projective BEDC row.

Next project the smooth genus-one boundary row σ. Its smoothness and genus-one readings are attached to the same projective package, so the row is routed through the ProjectiveVarUp carrier and exactness surface rather than through an external curve object.

Repacking $\mathcal{P}$, γ, and σ records the projective equation, incidence, smoothness, and genus-one data as the projective dependency portion of the $\mathsf{EllipticCurve}^{\uparrow}$ carrier. □

Theorem 175.4 (Elliptic-curve base-point stability obligation)**.** *The chosen base-point row o in Definition 175.1 is stable under the inherited projective classifier and the inherited field classifier. If the field source is transported by λ_F and the projective source is transported by λ_P, the transported packet carries a base-point row connected to o by* hsame *and accepted by the same* Cont *provenance surface.*

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket basepoint stability obligation`

Proof. Start with the base-point row o and the projective classifier row λ_P. Projective transport preserves the projective incidence row, so the image of o remains accepted by the transported projective carrier.

Use the field classifier row λ_F to transport the coordinate and coefficient readings used by the base-point incidence test. The same FieldUp source rows supply the operation and nonzero data needed after transport.

The continuation row records that the transported endpoint is read through the same base-point provenance route. Repack the transported field source, projective source, incidence row, and base-point row to obtain the stable $\mathsf{EllipticCurve}^{\uparrow}$ packet. □

Theorem 175.5 (Elliptic-curve classifier transport obligation)**.** *Classified replacement of the field source and the projective source transports the whole carrier packet of Definition 175.1. Componentwise* hsame *transports the coefficient, cubic, smoothness, genus-one, and base-point rows, while the displayed* Cont *rows preserve their acceptance and the* Pkg *row preserves their provenance.*

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket classifier transport obligation`

Proof. Project a classifier witness into its field part λ_F and projective part λ_P. The field part transports the coefficient and operation rows; the projective part transports the homogeneous cubic, incidence, smoothness, and genus-one rows.

Apply componentwise hsame to the displayed BHist entries. Each transported entry is accepted through its original Cont row after replacing the source endpoint by the classified endpoint.

Finally carry the provenance row ρ along the same componentwise route. Repacking the transported entries gives the full replacement carrier packet, with no additional quotient or host equality inserted at the boundary. □

Theorem 175.6 (Base-point readback obligation)**.** *For every* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier packet of Definition 175.1, the base-point row* o *is readable as a point row of the carried* $\mathsf{ProjectiveVar}^{\uparrow}$ *surface. If* $o\mathsf{hsame}o'$ *and the* $\mathsf{ProjectiveVar}^{\uparrow}$ *classifier transports the point row from* o *to* o'*, then replacing* o *by* o' *gives a carrier packet with the same coefficient, cubic, smooth genus-one, field, classifier, and* Pkg *provenance rows.*

Proof. Project the $\mathsf{ProjectiveVar}^{\uparrow}$ source certificate $\mathcal{P}$ from the carrier packet. Its point readback clause supplies the carrier row containing o, and the incidence ledger records that o lies on the displayed cubic row γ.

Apply the hsame transport hypothesis to the point row. The $\mathsf{ProjectiveVar}^{\uparrow}$ classifier transports incidence along this row, so the replacement point o' remains attached to the same projective carrier and the same cubic row.

The remaining rows are unchanged projections of the original packet. Repacking them with o' yields the transported $\mathsf{EllipticCurve}^{\uparrow}$ packet, and no field coefficient, smooth genus-one boundary, classifier, or provenance row is altered. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket basepoint readback obligation`

Theorem 175.7 (Smooth projective carrier obligation)**.** *An accepted* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier is accepted only through the* $\mathsf{ProjectiveVar}^{\uparrow}$ *projective-carrier, incidence, smoothness, genus-one, and point rows together with the* $\mathsf{Field}^{\uparrow}$ *scalar rows for the displayed equation coefficients. In particular, smoothness and genus-one status are certificate rows over the carried projective variety and field source, not host-level assertions about an unrecorded curve.*

Proof. Unpack an accepted carrier packet. The projective carrier and incidence rows are projections of $\mathcal{P}$, while the coefficient and scalar rows used by γ are projections of $\mathcal{F}$.

The smooth genus-one boundary row σ is then checked against those same projections. Its scope is the displayed projective carrier over the displayed field coefficients, so there is no separate ambient curve object to validate.

Finally attach the base-point row by Definition 175.6. The accepted carrier is therefore exactly the smooth genus-one projective carrier with the named base point and the named field dependency rows. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket smooth projective carrier obligation`

Theorem 175.8 (Field dependency ledger obligation)**.** *All coefficient and scalar comparisons in an* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier packet descend through the* $\mathsf{Field}^{\uparrow}$ *classifier and the* Pkg *provenance ledger. If two packets have* hsame*-transported equation rows and the* $\mathsf{Field}^{\uparrow}$ *source certificate classifies their coefficient rows as the same scalar data, then every scalar comparison used by the projective incidence, smoothness, genus-one, and base-point clauses is transported by the same finite ledger.*

Proof. Read the coefficient rows a_1, a_2, a_3, a_4, a_6 from the carrier packet of Definition 175.1. Those rows are not interpreted directly; they are projected through the $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ source certificate $\mathcal{F}$.

Use the $\mathsf{Field}^{\uparrow}$ classifier to transport each scalar comparison along the displayed hsame relation on coefficient and cubic rows. The finite Pkg provenance row records the order in which these transported scalar rows feed the projective incidence, smooth genus-one, and base-point checks.

Repack the transported scalar rows with the unchanged projective certificate rows. The result is the same dependency ledger for the elliptic-curve packet, now read over the transported coefficient and cubic rows. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket field dependency ledger obligation`

Theorem 175.9 (EllipticCurveUp NameCert exactness obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$ *obligation surface consists exactly of the carrier packet of Definition 175.1, the field-source rows of Definition 175.2, the projective genus-one rows of Definition 175.3, the base-point stability row of Definition 175.4, the classifier transport row of Definition 175.5, the base-point readback of Definition 175.6, the smooth projective validation of Definition 175.7, the field dependency transport of Definition 175.8, and the ledger exactness asserting that no row outside* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ *is exported.*

Proof. Soundness is obtained by projecting a public elliptic-curve certificate to its listed packet rows. The carrier definition supplies the field source, projective-variety source, equation, smoothness, genus-one, base-point, and provenance rows.

Completeness goes in the reverse direction. Given exactly those rows with the field-source, projective genus-one, base-point, classifier, readback, smooth projective, and field dependency clauses, assemble the tuple of Definition 175.1 and read it as the public $\mathsf{EllipticCurve}^{\uparrow}$ surface.

The exclusion clause follows from the same projection list. Since every accepted row is one of the displayed BHist rows or one of the two source $\mathsf{NameCert}$ projections, the certificate exports no unrecorded host curve, no external equation equality, and no standard bridge row. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket semantic name certificate`

Theorem 175.10 (Elliptic-curve Weierstrass coefficient ledger)**.** *In the carrier packet of Definition 175.1, the five coefficient rows* a_1, a_2, a_3, a_4, a_6 *and every scalar operation used by the displayed Weierstrass cubic are projected through the* $\mathsf{Field}^{\uparrow}$ *source certificate and the* Pkg *ledger. The cubic row is therefore a BEDC row over the inherited field source, not a host polynomial equality.*

Proof. Project the packet to its field source $\mathcal{F}$ and to the coefficient rows a_1, a_2, a_3, a_4, a_6. The field source obligation of Definition 175.2 supplies the addition, multiplication, negation, unit, and nonzero rows used by the cubic.

Next read the provenance component ρ of the packet. It records that the coefficient and scalar-operation rows enter the cubic through the same Pkg ledger as the $\mathsf{Field}^{\uparrow}$ source.

Repacking these projections gives the coefficient ledger. Since every scalar row comes from $\mathcal{F}$ and ρ, there is no unrecorded host polynomial equality in the certificate surface. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket weierstrass coefficient ledger`

Theorem 175.11 (Elliptic-curve base-point incidence exactness)**.** *Base-point acceptance in an* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier packet is exactly projective point carriage plus incidence with the displayed cubic under the inherited* $\mathsf{ProjectiveVar}^{\uparrow}$ *classifier. Replacing it by an ambient point-set membership predicate or by host curve equality changes the certificate surface.*

Proof. Project the packet to its projective source $\mathcal{P}$, cubic row γ, and base-point row o. The projective genus-one obligation of Definition 175.3 supplies the projective carrier and incidence rows attached to γ.

Use Definition 175.6 to read o as a point row of the carried projective surface. The base-point stability row of Definition 175.4 transports that reading through the inherited projective classifier.

The exactness obligation of Definition 175.9 excludes rows outside the displayed packet and its two source certificates. Thus base-point acceptance is precisely carriage plus incidence with γ under the inherited classifier. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket basepoint incidence exactness`

Theorem 175.12 (Elliptic-curve field-projective source compatibility)**.** *Transporting the* $\mathsf{Field}^{\uparrow}$ *source and the* $\mathsf{ProjectiveVar}^{\uparrow}$ *source together transports the Weierstrass cubic, smooth genus-one row, and base-point row of an* $\mathsf{EllipticCurve}^{\uparrow}$ *packet. The transported packet adds no host curve equality and no external comparison between projective models.*

Proof. Project the classifier transport witnesses λ_F and λ_P from the carrier packet. The classifier transport obligation of Definition 175.5 applies λ_F to the coefficient and scalar rows and applies λ_P to the cubic, incidence, smoothness, genus-one, and base-point rows.

The field dependency ledger of Definition 175.8 keeps every scalar comparison on the $\mathsf{Field}^{\uparrow}$ side. The base-point stability row of Definition 175.4 keeps point acceptance on the $\mathsf{ProjectiveVar}^{\uparrow}$ side.

Repack the transported field source, projective source, cubic, smooth genus-one row, base-point row, classifier rows, and provenance row. The result is a transported $\mathsf{EllipticCurve}^{\uparrow}$ packet whose compatibility is witnessed entirely by the two source certificates and their BEDC rows. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket field projective source compatibility`

Closure status for $\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$.

Constructive story: An elliptic curve is generated as a BHist packet containing a $\mathsf{Field}^{\uparrow}$ source row, a $\mathsf{ProjectiveVar}^{\uparrow}$ source row over the same field, five field-coefficient rows, a homogeneous cubic and incidence row, a smooth genus-one boundary row, a chosen base-point row, classifier transports for the two sources, and Pkg provenance. The carrier accepts exactly packets with those coefficient, cubic, smoothness, genus-one, base-point, field, projective, continuation, and provenance rows; it excludes an ambient curve object, host discriminant predicate, external point set, group law, Weierstrass standard bridge, and equality between curve models. Two accepted packets classify together when the inherited field classifier transports coefficient and scalar-operation rows, the inherited projective classifier transports the cubic, incidence, smoothness, genus-one, and base-point rows, and componentwise hsame plus Cont keeps each row accepted. The source specification is this field-projective carrier packet, the pattern records field-source obligations, projective genus-one obligations, base-point stability, classifier transport, smooth projective validation, and field dependency ledgers, while the ledger keeps the raw coefficient rows, cubic row, base point, source classifiers, and provenance visible. The five naming-certificate obligations hold because an accepted packet inhabits the carrier, the inherited field and projective classifiers provide reflexivity, symmetry, and transitivity, and the classifier transport theorem repacks every transported coefficient, incidence, and base-point row as another accepted packet. A history h lies in the signature gap of an $\mathsf{EllipticCurve}^{\uparrow}$ token p when the source domain accepts this packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; unfolded, the field row, projective row, Weierstrass coefficients, cubic incidence, smooth genus-one row, and base point of h are the rows encoded by p. The chapter registers this smooth projective genus-one packet under $\mathsf{EllipticCurve}^{\uparrow}$; it introduces no elliptic-curve group operation, no external Weierstrass bridge, and no independent curve-equality primitive.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$, maturePackageClosed)

Scope closed: The semantic certificate is the public exported $\mathsf{EllipticCurve}^{\uparrow}$ carrier packet over the inherited $\mathsf{Field}^{\uparrow}$ and $\mathsf{ProjectiveVar}^{\uparrow}$ sources, with the displayed coefficient, cubic, base-point, transport, classifier, and provenance rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.EllipticCurveUp.EllipticCurveCarrierPacket\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: The chapter does not close an elliptic-curve group law, a standard Weierstrass bridge, or external equality between curve models.

Upgrade path: No further formal-axis upgrade remains for the recorded field-projective genus-one bridge.

Definition 175.13 (Elliptic-curve Weierstrass admission profile)**.** *A Weierstrass admission profile for the public* $\mathsf{EllipticCurve}^{\uparrow}$ *surface is a finite row family*

$$W = (\mathcal{F}, \mathcal{P}, a_1, a_2, a_3, a_4, a_6, \gamma, \sigma, o, \lambda_F, \lambda_P, \rho)$$

with the following boundary readings. The row $\mathcal{F}$ *is a* $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ *source row; the five rows* $a_1, a_2, a_3, a_4, a_6 : \mathsf{BHist}$ *and the scalar operations used in the Weierstrass cubic are read through that field source;* $\mathcal{P}$ *is a* $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ *source row over the same field row;* $\gamma : \mathsf{BHist}$ *is the homogeneous cubic incidence row over the five displayed coefficients;* $\sigma : \mathsf{BHist}$ *is the smooth genus-one boundary row over that projective cubic;* $o : \mathsf{BHist}$ *is the chosen base-point incidence row;* λ_F *and* λ_P *are the inherited field and projective classifier transport rows; and* ρ *is the* Pkg *provenance row naming exactly these source, coefficient, cubic, smoothness, base-point, and transport entries.*

The profile has no coordinate for an elliptic-curve group operation, no coordinate for equality with an external curve model, and no coordinate for host-level equality between a standard Weierstrass presentation and a projective carrier. Such data may be discussed only after a separate row is supplied outside this admission profile.

Lean4 (definition) `BEDC.Derived.EllipticCurveUp.EllipticCurveUp`

Theorem 175.14 (Elliptic-curve Weierstrass bridge boundary)**.** *Let* W *be a Weierstrass admission profile as in Definition 175.13. If every standard-presentation datum in* W *is admitted only through the* $\mathsf{Field}^{\uparrow}$ *source row, the* $\mathsf{ProjectiveVar}^{\uparrow}$ *source row, the five coefficient rows, the cubic incidence row, the smooth genus-one row, the base-point row, the two classifier transport rows, and the* Pkg *provenance row listed in Definition 175.1, then* W *repacks as the same public* $\mathsf{EllipticCurve}^{\uparrow}$ *carrier packet. Projecting the public* $\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$ *surface recovers exactly those rows, and exports no elliptic-curve group law, no external curve equality, and no equality between a host Weierstrass model and the carried projective model.*

Proof. Start with the field side of the profile. By Definition 175.2, the five coefficient rows and the scalar operation rows used by the cubic are readable only through the $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ source $\mathcal{F}$. By Definition 175.10, their contribution to the Weierstrass equation is the displayed cubic row γ together with its Pkg provenance, not a host polynomial equality.

Project the geometric side next. By Definition 175.3, the cubic incidence row γ and the smooth genus-one row σ are carried by the $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$ dependency as BEDC rows. By Definition 175.7, smoothness and genus-one status are checked against the same field and projective projections, so the profile does not introduce a second curve object.

For the chosen point, Definition 175.11 identifies base-point acceptance with projective point carriage plus incidence with γ under the inherited projective classifier. The base-point row therefore repacks with $\mathcal{P}$, γ, and σ as the same point coordinate o of the public packet; it is not an external point-set membership predicate.

Now apply the two transport rows. The classifier transport obligation of Definition 175.5 transports coefficients, cubic, smoothness, genus-one, and base-point rows componentwise through λ_F, λ_P, hsame, and Cont. The field-projective compatibility theorem, Definition 175.12, says that this simultaneous transport still repacks as an $\mathsf{EllipticCurve}^{\uparrow}$ packet and adds no host comparison between projective models.

It remains to identify the public export. By Definition 175.9, the public $\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$ surface consists exactly of the carrier packet, the field-source rows, the projective genus-one rows, the base-point rows, the classifier transport rows, and the ledger exactness over BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{ProjectiveVar}^{\uparrow}}$. These are precisely the coordinates of W. Hence projecting the public surface recovers the same tuple, while any group law row, host curve-equality row, or external Weierstrass-to-projective equality row would require a coordinate absent from both Definition 175.13 and Definition 175.1. □

Lean4 ✓ `BEDC.Derived.EllipticCurveUp.EllipticCurveUp StdBridge`

Chapter 176

A Concrete Naming Certificate for $\mathsf{AbelianCat}^{\uparrow}$

The abelian-category interface $\mathsf{AbelianCat}^{\uparrow}$ packages an additive category in which every morphism has a kernel and cokernel and the canonical epi-mono factorisation is an isomorphism. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) and $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ (chapter 42).

176.1 Carrier definition

Definition 176.1 (AbelianCatUp additive kernel-cokernel carrier)**.** *An* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier is a concrete* BHist *package*

$$\mathcal{A} = (\mathcal{C}, \mathcal{H}, \mathcal{Z}, \mathcal{B}, \mathcal{G}, \mathcal{K}, \mathcal{Q}, \mathcal{F})$$

with the following displayed rows.

1. $\mathcal{C}$ *is a* $\mathsf{Cat}^{\uparrow}$ *carrier and classifier row, with object carrier, morphism carrier, identity rows, composition rows, associativity, unit laws, and componentwise* hsame *transport.*
2. $\mathcal{H}(A, B)$ *is the visible hom carrier row for each displayed pair of objects* A, B*, classified by the morphism classifier inherited from* $\mathcal{C}$*.*
3. $\mathcal{Z}(A, B)$ *gives the visible zero morphism row* $0_{A,B} : A \to B$*.*
4. $\mathcal{B}(A, B)$ *gives the visible binary biproduct rows for* A *and* B*, including the object* $A \oplus B$*, projections, injections, and their four classifier equations.*
5. $\mathcal{G}(A, B)$ *is an* $\mathsf{AbGroup}^{\uparrow}$ *enrichment row on* $\mathcal{H}(A, B)$*, with addition, zero, inverse, commutativity, and classifier congruence displayed in the hom row.*
6. $\mathcal{K}(f)$ *gives, for every visible morphism* $f : A \to B$*, an object* $\ker(f)$*, a morphism* $k_f : \ker(f) \to A$*, a zero-composite row, and the universal factorisation ledger through* k_f*.*
7. $\mathcal{Q}(f)$ *gives, for every visible morphism* $f : A \to B$*, an object* $\operatorname{coker}(f)$*, a morphism* $q_f : B \to \operatorname{coker}(f)$*, a zero-composite row, and the universal cofactorisation ledger through* q_f*.*
8. $\mathcal{F}(f)$ *is the visible epi–mono factorisation ledger for* f*, displaying image and coimage objects, the quotient-side arrow, the inclusion-side arrow, the canonical comparison, and the classifier row saying that the recomposed morphism is* f*.*

No object in this carrier is supplied by an external quotient or hidden subobject classifier. The kernel, cokernel, image, coimage, and comparison objects are selected rows of the same BHist *package.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatTasteGate single carrier alignment`

Theorem 176.2 (AbelianCatUp carrier classifier obligation)**.** *Let $\mathcal{A}$ be an* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier. If two presentations of $\mathcal{A}$ are related by componentwise* hsame *on the* $\mathsf{Cat}^{\uparrow}$ *carrier, on every hom carrier, on every zero, biproduct,* $\mathsf{AbGroup}^{\uparrow}$ *enrichment, kernel, cokernel, image, coimage, comparison, and factorisation row, then the package carrier and every displayed row are transported to a classified presentation of the same* $\mathsf{AbelianCat}^{\uparrow}$ *carrier.*

Proof. Start with the $\mathsf{Cat}^{\uparrow}$ carrier row. Its object, morphism, identity, and composition classifiers are part of $\mathcal{C}$, so componentwise hsame transports the category carrier and the source and target data of each visible morphism.

For each pair of transported objects A, B, the hom row $\mathcal{H}(A, B)$ is classified by the transported morphism classifier. The zero row, biproduct object, projections, and injections are displayed rows over the same endpoints, so the $\mathsf{Cat}^{\uparrow}$ identity, composition, and classifier stability fields transport their typing and equations.

It remains to transport the additive and exactness rows. The $\mathsf{AbGroup}^{\uparrow}$ enrichment supplies hsame-stable addition, zero, inverse, and commutativity on each hom row. The kernel, cokernel, image, coimage, comparison, and factorisation ledgers are rows indexed by visible morphisms, so transporting the morphism row transports the indexed ledger row and its displayed composition equations. Repacking these transported projections gives the same $\mathsf{AbelianCat}^{\uparrow}$ carrier presentation. □

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier classifier transport`

Theorem 176.3 (AbelianCatUp additive zero-biproduct obligation)**.** *For an* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier $\mathcal{A}$, the zero morphisms, hom-row addition, and binary biproduct projections and injections are exactly the visible additive rows inherited from* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *on each hom carrier and from* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *on identities, composition, and biproduct equations.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier zero biproduct rows`

Proof. Fix displayed objects A and B. The hom row $\mathcal{H}(A, B)$ carries the $\mathsf{AbGroup}^{\uparrow}$ enrichment row $\mathcal{G}(A, B)$, so its zero element is the displayed zero morphism $0_{A,B}$ and its binary operation is the displayed hom-addition row. The $\mathsf{AbGroup}^{\uparrow}$ classifier congruence field supplies the transport of these rows under hom-classifier equivalence.

The biproduct row $\mathcal{B}(A, B)$ is a $\mathsf{Cat}^{\uparrow}$ row: it supplies the object $A \oplus B$, projections, injections, and the four equations expressed by the category morphism classifier. The zero morphisms appearing in those equations are the same $\mathcal{Z}$ rows selected by the hom $\mathsf{AbGroup}^{\uparrow}$ zero fields.

Thus the additive part is not an extra semantic layer. The hom addition and zero rows are the $\mathsf{AbGroup}^{\uparrow}$ visible operation rows, and the biproduct typing and equations are the $\mathsf{Cat}^{\uparrow}$ visible composition rows applied to the displayed projections and injections. □

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier additive readback`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatKernelCokernelCarrier zero biproduct readback`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier zero additive kernel boundary`

Theorem 176.4 (AbelianCatUp kernel-cokernel factorisation obligation)**.** *For every visible morphism $f : A \to B$ in an* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier, the package exposes kernel, cokernel, image, coimage, canonical comparison, and epi–mono factorisation rows. The classified factorisation of f is obtained from these rows and no hidden quotient object or external subobject is used.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatKernelCokernelCarrier factorization rows`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatKernelCokernel visible factorization`

Proof. Project the kernel row $\mathcal{K}(f)$. It contains $\ker(f)$, the morphism $k_f : \ker(f) \to A$, the zero-composite classifier for $f \circ k_f$, and the factorisation ledger for every displayed morphism whose composite with f is classified as zero.

Project the cokernel row $\mathcal{Q}(f)$. It contains $\operatorname{coker}(f)$, the morphism $q_f : B \to \operatorname{coker}(f)$, the zero-composite classifier for $q_f \circ f$, and the cofactorisation ledger for every displayed morphism out of B whose precomposition with f is classified as zero.

The image, coimage, comparison, and epi–mono factorisation data are the visible rows of $\mathcal{F}(f)$. Category composition stability types the recomposition, while the factorisation classifier row identifies that recomposition with f. Since every object and arrow used in the argument is a projection of $\mathcal{K}(f)$, $\mathcal{Q}(f)$, or $\mathcal{F}(f)$, the proof does not appeal to any object outside the displayed BHist package. □

176.2 The certificate

Definition 176.5 (AbelianCatUp zero-biproduct-kernel surface)**.** *The* $\mathsf{AbelianCat}^{\uparrow}$ *zero-biproduct-kernel surface over* BHist *is the displayed obligation package carried by an* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier $\mathcal{A}$. It consists of the following rows.*

1. *The* $\mathsf{Cat}^{\uparrow}$ *object and morphism carriers, with identity, composition, associativity, unit, source, target, and morphism-classifier rows.*
2. *For each displayed object pair A, B, a hom carrier $\mathcal{H}(A, B)$ and an* $\mathsf{AbGroup}^{\uparrow}$ *classifier on that hom row, including visible addition, zero, inverse, commutativity, and additive classifier congruence.*
3. *A zero-object row $0_{\mathcal{A}}$ with displayed maps $0_{\mathcal{A}} \to A$ and $A \to 0_{\mathcal{A}}$ classified through the inherited* $\mathsf{Cat}^{\uparrow}$ *morphism classifier.*
4. *For each displayed pair A, B, a binary biproduct row $A \oplus B$ with projections, injections, the two diagonal identity rows, and the two off-diagonal zero rows read in the hom-wise* $\mathsf{AbGroup}^{\uparrow}$ *classifiers.*
5. *For each visible morphism $f : A \to B$, a kernel row $\ker(f) \xrightarrow{k_f} A$ with zero-composite and universal factorisation ledger entries.*
6. *For each visible morphism $f : A \to B$, a cokernel row $B \xrightarrow{q_f} \operatorname{coker}(f)$ with zero-composite and universal cofactorisation ledger entries.*
7. *An exactness row whose image, coimage, canonical comparison, and epi–mono recomposition entries are visible projections of the same* BHist *package.*
8. *A ledger provenance row recording the source row for every carrier, classifier, structural map, universal witness, and recomposition certificate used by the preceding rows.*

This surface is a $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *obligation interface: it names the rows downstream category and homological chapters may consume.*

Lean4 (definition) `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface`

Theorem 176.6 (AbelianCatUp zero-object obligation)**.** *For the surface of Definition 176.5, the zero-object row is classifier-stable. If A and A' are related by the* $\mathsf{Cat}^{\uparrow}$ *object classifier, then the displayed rows $0_{\mathcal{A}} \to A$, $A \to 0_{\mathcal{A}}$, $0_{\mathcal{A}} \to A'$, and $A' \to 0_{\mathcal{A}}$ are related by the inherited morphism classifier, and the two composites through $0_{\mathcal{A}}$ are read as hom-wise* $\mathsf{AbGroup}^{\uparrow}$ *zero elements.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface zero object transport`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface zero object boundary`

Proof. The zero object itself is a displayed carrier row of the same BHist package as the $\mathsf{Cat}^{\uparrow}$ object carrier. Transporting A to A' along the object classifier therefore transports the source and target typing of the two visible maps attached to $0_{\mathcal{A}}$.

The morphism classifier of $\mathsf{Cat}^{\uparrow}$ then transports the two maps and their composites. When a composite is viewed inside a hom row, the $\mathsf{AbGroup}^{\uparrow}$ classifier on that hom row identifies the displayed composite with the listed zero element.

Thus classifier stability is obtained by projecting the object row, then the morphism row, then the hom-wise zero classifier. No object outside the displayed carrier is introduced. □

Theorem 176.7 (AbelianCatUp biproduct additive hom obligation)**.** *For the surface of Definition 176.5, each binary biproduct row preserves the hom-wise* $\mathsf{AbGroup}^{\uparrow}$ *structure. The projections and injections of $A \oplus B$ are classified morphisms, their diagonal composites are the hom-wise additive identity rows, and their off-diagonal composites are the hom-wise zero rows.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface factor tail transport`

Proof. Fix displayed objects A and B. The biproduct row supplies the object $A \oplus B$ together with projections and injections typed by the $\mathsf{Cat}^{\uparrow}$ source and target rows.

Composition in $\mathsf{Cat}^{\uparrow}$ types the four projection-injection composites. The two diagonal composites are classified as the identity rows in the appropriate hom carriers, while the two off-diagonal composites are classified as the zero rows selected by the hom-wise $\mathsf{AbGroup}^{\uparrow}$ structures.

The additive compatibility is therefore hom-local. Each equation is read inside a single $\mathcal{H}(X, Y)$, and the $\mathsf{AbGroup}^{\uparrow}$ classifier congruence transports addition, zero, and inverse across the same morphism classifier that types the biproduct maps. □

Theorem 176.8 (AbelianCatUp kernel-cokernel obligation)**.** *For the surface of Definition 176.5, kernel and cokernel rows are stable under the* $\mathsf{Cat}^{\uparrow}$ *morphism classifier. If visible morphisms f and g are related by that classifier, then the displayed rows* $\ker(f)$, k_f, $\operatorname{coker}(f)$, *and q_f transport to the corresponding rows for g together with their zero-composite and universal ledger entries.*

Proof. Begin with a classifier relation between the visible morphisms f and g. The kernel and cokernel rows are indexed by visible morphism rows, so transport along the morphism classifier carries the index f to the index g.

For kernels, this transport carries the object $\ker(f)$, the map k_f, the zero-composite row for $f \circ k_f$, and the factorisation ledger through k_f. The target statement for g is exactly the transported indexed row.

For cokernels, the same argument is dual at the displayed-row level: the object $\operatorname{coker}(f)$, the map q_f, the zero-composite row for $q_f \circ f$, and the cofactorisation ledger transport along the same morphism-classifier relation. □

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatKernelCokernelCarrier classifier transport`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier factor unary closure`

Theorem 176.9 (AbelianCatUp exact-sequence obligation)**.** *For the surface of Definition 176.5, the exactness row is read only through displayed kernel and cokernel factorisation classifiers. Every exact-sequence assertion in the surface is a statement about the listed kernel, cokernel, image, coimage, comparison, and recomposition rows of the same* BHist *package.*

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatKernelCokernel recomposition audit row`
Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatAdditiveCarrier factor append readback`

Proof. An exactness assertion is first reduced to the visible morphism whose image and coimage rows are listed in the package. The kernel and cokernel rows provide the zero-composite classifiers and the universal ledger entries required to factor through those rows.

The image, coimage, and comparison entries are then projected from the factorisation ledger. Their recomposition row is typed by $\mathsf{Cat}^{\uparrow}$ composition and classified as the original visible morphism by the displayed recomposition classifier.

Consequently the exactness predicate has no separate hidden carrier. It is a reading discipline for the kernel, cokernel, image, coimage, comparison, and factorisation rows already present in the surface. □

Theorem 176.10 (AbelianCatUp NameCert obligation package)**.** *The surface of Definition 176.5, together with Definition 176.6, Definition 176.7, Definition 176.8, and Definition 176.9, repacks as the paper-side* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *obligation package for downstream category and homological chapters.*

Proof. The carrier and classifier fields are the first two rows of Definition 176.5. They expose the $\mathsf{Cat}^{\uparrow}$ object and morphism rows, the hom carriers, and the hom-wise $\mathsf{AbGroup}^{\uparrow}$ classifiers.

The structural stability fields are supplied by the four obligation theorems. The zero-object theorem gives the classifier-stable zero-object row; the biproduct theorem gives the additive hom compatibility of projections and injections; the kernel-cokernel theorem gives stability of universal rows under the morphism classifier; the exact-sequence theorem restricts exactness to the displayed factorisation classifiers.

The ledger field is the final row of the surface. Repacking these projections gives a single $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ obligation package whose consumer chapters cite concrete rows rather than an unspecified abelian-category interface. □

Theorem 176.11 (AbelianCatUp NameCert obligation surface)**.** *An* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier* $\mathcal{A}$ *satisfying Definition 176.2, Definition 176.3, and Definition 176.4 supplies the following ten-field* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *obligation surface.*

1. *Traditional target: an abelian category with additive hom groups, binary biproducts, kernels, cokernels, and canonical epi–mono factorisations.*
2. *BEDC source: the concrete* BHist *package of Definition 176.1.*
3. *Carrier: the displayed object and morphism rows of the* $\mathsf{Cat}^{\uparrow}$ *component together with the visible hom carriers.*
4. *Classifier: the componentwise* hsame *classifier on objects, morphisms, hom elements, additive rows, kernel rows, cokernel rows, and factorisation rows.*

5. *Stability obligations:* $\mathsf{Cat}^{\uparrow}$ *composition and identity stability,* $\mathsf{AbGroup}^{\uparrow}$ *hom-addition stability, biproduct equation stability, and componentwise* hsame *transport.*
6. *Ledger: source, hom, zero, addition, biproduct, kernel, cokernel, image, coimage, comparison, and epi–mono factorisation provenance rows.*
7. *Core theorem list: Definition 176.2, Definition 176.3, and Definition 176.4.*
8. *Exactness predicate: every visible morphism has displayed kernel, cokernel, image, coimage, comparison, and classified recomposition rows.*
9. *Absent standard bridge: no external category of abelian groups, modules, sheaves, or complexes is identified here.*
10. *Status:* ProofTarget *for a later Lean theorem in* BEDC.Derived.AbelianCatUp.

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface semantic name certificate`

Proof. The carrier, classifier, and stability fields are projections of Definition 176.1. The transport requirement is exactly Definition 176.2, which repacks componentwise hsame transport across the category, hom, additive, kernel, cokernel, and factorisation rows.

The additive entries of the surface are supplied by Definition 176.3. That theorem identifies the hom addition and zero morphism rows with the $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ visible operation rows and identifies the biproduct typing and equations with the $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ visible composition rows.

The exactness and ledger entries are supplied by Definition 176.4. For each visible morphism it projects kernel, cokernel, image, coimage, comparison, and recomposition rows from the package and records that no hidden quotient object is used. These three projections assemble the stated ten-field $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ obligation surface. □

Theorem 176.12 (AbelianCatUp hom zero morphism uniqueness)**.** *Let* $\mathcal{A}$ *be an* $\mathsf{AbelianCat}^{\uparrow}$ *additive kernel-cokernel carrier and view its zero-biproduct-kernel surface as in Definition 176.5. Fix displayed objects* A *and* B*. Write* $\mathcal{H}(A,B)$ *for the displayed hom carrier,* $\sim_{A,B}$ *for its inherited hom classifier,* $+_{A,B}$ *for its displayed hom addition, and* $0_{A,B}$ *for its displayed zero morphism. If a carried morphism* $u \in \mathcal{H}(A,B)$ *satisfies*

$$u +_{A,B} f \sim_{A,B} f \qquad \text{and} \qquad f +_{A,B} u \sim_{A,B} f$$

for every carried $f \in \mathcal{H}(A,B)$*, then*

$$u \sim_{A,B} 0_{A,B}.$$

Proof. Unpack the hom row selected by Definition 176.1. It carries the $\mathsf{AbGroup}^{\uparrow}$ enrichment row $\mathcal{G}(A,B)$. By Definition 176.3, the addition operation of this enrichment is $+_{A,B}$ and its identity element is the displayed zero morphism $0_{A,B}$.

Apply Definition 42.33 to the enrichment and then Definition 41.122 to the resulting group reduct. The retained monoid certificate has the same carrier $\mathcal{H}(A,B)$, the same classifier $\sim_{A,B}$, the same operation $+_{A,B}$, and identity $0_{A,B}$. Hence the monoid right-identity row says that $0_{A,B}$ is a right identity for every carried hom element.

The first displayed hypothesis says that u is a left identity for every carried hom element. Since u is carried and $0_{A,B}$ is carried by the zero row, the inputs of Definition 40.15 are satisfied with $e = u$ and $e' = 0_{A,B}$. Its conclusion is exactly $u \sim_{A,B} 0_{A,B}$, because the monoid reduct did not change the hom classifier. □

Lean4 ✓ `BEDC.Derived.AbelianCatUp.AbelianCatHomZeroMorphism uniqueness`

Closure status for $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$.

Constructive story: An abelian category is carried here as one displayed BHist package built on an already certified $\mathsf{Cat}^{\uparrow}$ surface and hom-wise $\mathsf{AbGroup}^{\uparrow}$ rows: the package accepts object and morphism histories only when it also exposes zero morphisms, biproducts, additive hom groups, kernels, cokernels, image–coimage comparison, and epi–mono factorisation rows, while any hidden quotient, subobject classifier, module category, or sheaf carrier is left outside. Two such packages count as the same only by componentwise history-equality through the category carrier, every hom carrier, the additive rows, and the kernel–cokernel and exactness ledgers, so the classifier is conditional transport of all displayed rows rather than equality of ambient categories. The source is the paired $\mathsf{Cat}^{\uparrow}$ and $\mathsf{AbGroup}^{\uparrow}$ certificate surface, the pattern is the zero-biproduct-kernel-cokernel inventory with the exactness comparison row, and the ledger keeps the raw category, hom, structural-map, universal-factorisation, and recomposition witnesses visible for downstream homological use. Because the category and abelian-group classifiers are already equivalence relations and every listed structural row is transported componentwise, an admitted package supplies carrier habitation, the classifier is reflexive, symmetric, and transitive, and any classified presentation repacks as an admitted abelian-category package. A package h lies in the signature gap of an $\mathsf{AbelianCat}^{\uparrow}$ token p when the source-domain accepts its category and hom-additive rows, the signature relation pairs that package with an answer package and evidence ledger, and the token-introduction relation names the answer as p; unfolded, this says that the same displayed kernels, cokernels, biproducts, hom zeros, and exact factorisation rows are the data encoded by p. The chapter registers this displayed additive exactness surface under the name $\mathsf{AbelianCat}^{\uparrow}$; it introduces no standard abelian category, module category, sheaf model, or external equality beyond the existing BHist rows and their transport.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public surface exports the zero-biproduct, kernel-cokernel, exactness, NameCert, and hom-zero uniqueness rows carried by the displayed BHist package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.AbelianCatUp.AbelianCatZeroBiproductKernelSurface\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not identify standard abelian categories, modules, sheaves, complexes, or a checked external bridge.

Upgrade path: No further paper-axis upgrade remains for the displayed additive exactness surface.

Theorem 176.13 (AbelianCatUp zero morphism right composition absorption)**.** *Let $\mathcal{A}$ be an $\mathsf{AbelianCat}^{\uparrow}$ additive kernel-cokernel carrier and view its zero-biproduct-kernel surface as in Definition 176.5. Fix displayed objects X, A, and B. Write $\mathcal{H}(Y,Z)$ for the displayed hom carrier, $\sim_{Y,Z}$ for its hom classifier, $+_{Y,Z}$ for hom addition, and $0_{Y,Z}$ for the displayed zero morphism. If $g \in \mathcal{H}(A,B)$ is carried, then the displayed composite with the zero morphism in the right composition slot is classified with the displayed zero morphism in the target hom row:*

$$g \circ 0_{X,A} \sim_{X,B} 0_{X,B}.$$

Proof. The hom rows $\mathcal{H}(X,A)$ and $\mathcal{H}(X,B)$ are part of the carrier of Definition 176.1. By Definition 176.3, their displayed additions and zero morphisms are the additions and units of the corresponding hom-wise $\mathsf{AbGroup}^{\uparrow}$ enrichment rows. In particular,

$$0_{X,A} +_{X,A} 0_{X,A} \sim_{X,A} 0_{X,A}.$$

The $\mathsf{Cat}^{\uparrow}$ composition row types the composite $u := g \circ 0_{X,A}$ as a carried element of $\mathcal{H}(X,B)$.

Project the right-slot additivity of composition from the additive $\mathsf{AbelianCat}^{\uparrow}$ carrier, read through the biproduct additive hom obligation of Definition 176.7. For the fixed carried morphism $g : A \to B$, postcomposition sends hom addition in $\mathcal{H}(X,A)$ to hom addition in $\mathcal{H}(X,B)$, so at the zero pair it supplies

$$g \circ (0_{X,A} +_{X,A} 0_{X,A}) \sim_{X,B} (g \circ 0_{X,A}) +_{X,B} (g \circ 0_{X,A}).$$

Composition classifier stability transports the source zero-unit comparison through the same right slot, giving

$$g \circ (0_{X,A} +_{X,A} 0_{X,A}) \sim_{X,B} g \circ 0_{X,A}.$$

By symmetry and transitivity of $\sim_{X,B}$, these two comparisons classify u as additively idempotent:

$$u +_{X,B} u \sim_{X,B} u.$$

Now read the hom-wise $\mathsf{AbGroup}^{\uparrow}$ enrichment of $\mathcal{H}(X, B)$ through Definition 42.33. The group reduct has the same carrier, the same classifier $\sim_{X,B}$, the same operation $+_{X,B}$, and the same unit $0_{X,B}$. Applying Definition 41.114 in additive notation, with $a = u$ and $b = u$, forces the right repeated summand to be the additive unit:

$$u \sim_{X,B} 0_{X,B}.$$

Substituting $u = g \circ 0_{X,A}$ gives the asserted classification. □

Theorem 176.14 (AbelianCatUp hom additive inverse uniqueness)**.** *Let $\mathcal{A}$ be an $\mathsf{AbelianCat}^{\uparrow}$ additive kernel-cokernel carrier and view its zero-biproduct-kernel surface as in Definition 176.5. Fix displayed objects A and B. Write $\mathcal{H}(A, B)$ for the displayed hom carrier, $\sim_{A,B}$ for its inherited hom classifier, $+_{A,B}$ for its displayed hom addition, and $0_{A,B}$ for its displayed zero morphism. If carried morphisms $f, u, v \in \mathcal{H}(A, B)$ satisfy*

$$u +_{A,B} f \sim_{A,B} 0_{A,B} \qquad \text{and} \qquad f +_{A,B} u \sim_{A,B} 0_{A,B}$$

with $\nu = u$, and also satisfy

$$v +_{A,B} f \sim_{A,B} 0_{A,B} \qquad \text{and} \qquad f +_{A,B} v \sim_{A,B} 0_{A,B},$$

then

$$u \sim_{A,B} v$$

with $\nu = u$. Equivalently, any two carried two-sided additive inverse presentations of the same carried hom morphism are identified by the inherited hom classifier.

Proof. Unpack the hom row selected by Definition 176.1. The row $\mathcal{H}(A, B)$ carries the $\mathsf{AbGroup}^{\uparrow}$ enrichment $\mathcal{G}(A, B)$. By Definition 176.3, the operation of this enrichment is the displayed hom addition $+_{A,B}$ and its identity is the displayed zero morphism $0_{A,B}$.

Apply Definition 42.33 to this enrichment. The retained $\mathsf{Group}^{\uparrow}$ package has the same carried hom elements, the same classifier $\sim_{A,B}$, the same operation $+_{A,B}$, the same identity $0_{A,B}$, and the inverse laws and multiplication congruence required for the group inverse-uniqueness argument.

Now read Definition 41.59 in this retained additive group package, with middle element f, left inverse candidate u, and right inverse candidate v. The hypothesis

$$u +_{A,B} f \sim_{A,B} 0_{A,B}$$

with $\nu = u$ is exactly the left-inverse comparison $u +_{A,B} f \sim_{A,B} 0_{A,B}$, and the hypothesis

$$f +_{A,B} v \sim_{A,B} 0_{A,B}$$

is exactly the right-inverse comparison for v. The theorem therefore gives

$$u \sim_{A,B} v$$

with $\nu = u$, because the group reduct did not change the hom classifier. The remaining two displayed comparisons record that both candidates are two-sided inverse presentations, but the uniqueness comparison itself needs only one left-inverse presentation and one right-inverse presentation against the same carried middle morphism. □

Chapter 177

A Concrete Naming Certificate for $\mathsf{DerivedFunctor}^{\uparrow}$

The derived-functor interface $\mathsf{DerivedFunctor}^{\uparrow}$ packages the right- or left-derived R^iF / L_iF of an additive functor between abelian categories. It depends on $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ (chapter 176) and $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ (chapter 98).

177.1 Carrier definition

Definition 177.1 (Derived-functor history carrier)**.** *For $h : \mathsf{Hist}$, the predicate* $\mathsf{DerivedFunctorCarrier}(h)$ *holds exactly when there are histories*

$$F, R, H, i, c : \mathsf{Hist}$$

read respectively as an additive-functor trace, a chosen resolution trace, a homology trace, a unary degree row, and the intermediate resolved trace, such that

$$\mathsf{UnaryHistory}(i) \wedge \mathsf{Cont}(F, R, c) \wedge \mathsf{Cont}(c, H, h).$$

The carrier is the concrete BHist *predicate generated by this tuple. The degree row is not a host-level integer choice; it is the displayed unary history used by the homology trace, while the two* Cont *rows record first the functor-to-resolution passage and then the homology readback that produces h.*

Lean4 (definition) `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier`

Definition 177.2 (DerivedFunctorUp resolution-spine carrier)**.** *A* $\mathsf{DerivedFunctor}^{\uparrow}$ *resolution-spine carrier is a* BHist *packet whose public rows consist of an* $\mathsf{AbelianCat}^{\uparrow}$ *source certificate, a* $\mathsf{Homology}^{\uparrow}$ *source certificate, an object row $X : \mathsf{BHist}$, a finite resolution spine*

$$R_0 \to R_1 \to \cdots \to R_n \to X,$$

cycle rows $Z_i : \mathsf{BHist}$, boundary rows $B_i : \mathsf{BHist}$, a displayed additive-functor row $F : \mathsf{BHist}$, and a Pkg *provenance row for the resolution ledger. The arrows in the finite spine are admissible exactly when their source and target rows are classified by the* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source surface, and the rows Z_i and B_i are read through the* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ *cycle and boundary classifiers at the displayed degree.*

Theorem 177.3 (Resolution-spine carrier obligation)**.** *The resolution-spine carrier of Definition 177.2 is closed under* hsame *transport of the object row and under* Cont *extension of the finite resolution spine. Transporting X to X' along XhsameX' replaces the endpoint object row while preserving the admissible* $\mathsf{AbelianCat}^{\uparrow}$ *source and arrow rows; appending one admissible* Cont *step to the finite spine gives another carried resolution ledger with the same* Pkg *provenance extended by that visible step.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorResolutionSpineCarrier obligation`

Proof. Unpack the carrier packet into its $\mathsf{AbelianCat}^{\uparrow}$ source rows, $\mathsf{Homology}^{\uparrow}$ source rows, object row, finite spine, functor row, and Pkg provenance row.

For object transport, apply the $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ classifier transport to the object row. The admissible arrow rows are then read with the transported endpoint, and the homology cycle and boundary rows remain attached to the same displayed degree because no cycle row is changed.

For spine extension, append the extra admissible arrow as one more Cont ledger row. The finite spine is still a BHist packet, the new endpoint is classified by the same $\mathsf{AbelianCat}^{\uparrow}$ source surface, and the provenance row is repacked as the old Pkg row followed by the displayed continuation step. □

Theorem 177.4 (Cycle-boundary classifier obligation)**.** *For two accepted* $\mathsf{DerivedFunctor}^{\uparrow}$ *resolution-spine packets, the public classifier compares derived-functor rows by the* $\mathsf{Homology}^{\uparrow}$ *cycle classifier modulo the displayed boundary rows. The* $\mathsf{AbelianCat}^{\uparrow}$ *source certificate supplies the admissible object and arrow transport needed to compare the selected resolution spines, while the* $\mathsf{Homology}^{\uparrow}$ *source certificate supplies the cycle and boundary comparison rows.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier cycle boundary classifier obligation`

Proof. Start with two carried packets and project their object, arrow, cycle, boundary, functor, and provenance rows. The $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ source compares the object row and every admissible arrow row in the selected finite spines, so both packets are read over classified resolution data.

Next project the $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ source. Its cycle classifier compares the displayed cycle rows at the selected degree, and its boundary classifier records exactly which boundary rows may be used to identify two cycles.

Repack these two comparisons as the $\mathsf{DerivedFunctor}^{\uparrow}$ classifier. The abelian-category part accounts only for transport of the resolution spine, while the homology part decides the public endpoint class by cycle comparison modulo the listed boundaries. □

Theorem 177.5 (Homology readback obligation)**.** *Every accepted* $\mathsf{DerivedFunctor}^{\uparrow}$ *endpoint reads back to a* $\mathsf{Homology}^{\uparrow}$ *cycle class attached to the selected resolution degree. If two accepted endpoints are boundary-equivalent through the displayed boundary rows, then they have the same public* $\mathsf{DerivedFunctor}^{\uparrow}$ *classifier.*

Proof. Read an accepted endpoint by unpacking its resolution-spine carrier. The selected degree row chooses the cycle row Z_i and boundary row B_i already carried by the packet, and the $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ source classifies Z_i as the visible cycle class.

For two endpoints, use the displayed boundary-equivalence row as a $\mathsf{Homology}^{\uparrow}$ boundary classifier witness. The homology certificate transports the cycle classifier across that boundary row, producing the same public homology class.

The $\mathsf{DerivedFunctor}^{\uparrow}$ classifier is defined by this homology readback after the $\mathsf{AbelianCat}^{\uparrow}$ resolution rows have been transported. Therefore boundary-equivalent endpoints have the same public classifier. □

Theorem 177.6 (Functorial transport obligation)**.** *An* $\mathsf{AbelianCat}^{\uparrow}$ *morphism row transported through the displayed additive functor sends accepted resolution spines to accepted resolution spines and preserves the* $\mathsf{Homology}^{\uparrow}$ *classifier on endpoints. The transported packet keeps the same* Pkg *provenance form, with each functorial arrow image recorded as a visible* Cont *row.*

Proof. Project the source morphism row and the displayed additive-functor row from the carrier. The $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ source transports the morphism through admissible object and arrow rows, so every arrow in the resolution spine has an admissible functorial image.

Assemble the image spine by the same finite Cont order as the original spine. Each image arrow contributes one continuation row, and the Pkg provenance row records these continuations as the functorial image of the original ledger.

Finally project the endpoint cycle and boundary rows through the $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ classifier. Since the functorial image respects the displayed boundary rows, the endpoint cycle class is transported to the same public classifier value in the image packet. □

Theorem 177.7 (DerivedFunctorUp ledger exactness obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ *surface consists exactly of the* $\mathsf{AbelianCat}^{\uparrow}$ *source rows,* $\mathsf{Homology}^{\uparrow}$ *cycle and boundary rows, the finite resolution spine, the functor row, the classifier transport rows, and* Pkg *provenance. It exports no host quotient of complexes and no external abelian-category equality beyond the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{AbelianCat}^{\uparrow}$*, and* $\mathsf{Homology}^{\uparrow}$ *rows.*

Proof. Soundness is obtained by unpacking a carried packet. The only public rows are the two source certificates, the finite spine, the functor row, the cycle and boundary rows, classifier transport, and the provenance row.

Completeness repacks exactly those rows. Given the $\mathsf{AbelianCat}^{\uparrow}$ object and arrow rows, the $\mathsf{Homology}^{\uparrow}$ cycle and boundary rows, the finite Cont spine, the functor row, and the Pkg provenance row, the resolution-spine carrier of Definition 177.2 is reconstructed without adding any host quotient.

The exactness boundary follows because every classifier theorem above projects from this same packet and every accepted endpoint reads back through the $\mathsf{Homology}^{\uparrow}$ cycle classifier. There is no exported row naming an equality of complexes or an external abelian-category equality, so such data cannot enter the public $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ surface. □

Theorem 177.8 (DerivedFunctorUp source-coupled homology readback)**.** *Every packet satisfying the resolution-spine carrier of Definition 177.2 projects one finite* BHist *resolution spine whose object and arrow rows are consumed by* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *and whose cycle, boundary, and unary-degree rows are consumed by* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$*. The two readings have the same* Pkg *provenance row, so the public* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ *surface cannot split them into unrelated resolution and homology sources.*

Proof. Unpack the carried packet into its $\mathsf{AbelianCat}^{\uparrow}$ source certificate, $\mathsf{Homology}^{\uparrow}$ source certificate, object row, finite resolution spine, functor row, displayed unary degree, cycle rows, boundary rows, and Pkg provenance.

Project the object and arrow rows to the $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ source surface. These are exactly the rows that classify the endpoint object and every admissible arrow in the finite spine.

Project the displayed unary degree, cycle rows, and boundary rows to the $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ source surface. They are read at the same selected degree and over the spine already classified by the abelian-category source rows.

The shared Pkg provenance row is part of the same carrier packet, not a separate input. Therefore the abelian-category transport side and the homology readback side are two projections of one BHist ledger, and no unrelated second spine is available to the public certificate. □

Theorem 177.9 (DerivedFunctorUp boundary over transported resolution)**.** *After* hsame *transport of the object row and* Cont *extension of the finite resolution spine, the selected boundary-equivalence row still compares the* $\mathsf{Homology}^{\uparrow}$ *cycle rows over the transported* $\mathsf{AbelianCat}^{\uparrow}$ *resolution data. Thus boundary readback remains attached to the transported source resolution rather than to an independent homology packet.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier boundary over transported resolution`

Proof. Use Definition 177.3 to transport the endpoint object row and extend the finite spine by the displayed continuation step. The result is again a carried resolution ledger with the same visible provenance form.

Apply Definition 177.4 to the transported carried packets. The abelian-category rows compare the transported object and arrow data, while the homology rows compare the selected cycles modulo the displayed boundary rows.

Finally read the endpoint through Definition 177.5. The boundary-equivalence witness is interpreted by the $\mathsf{Homology}^{\uparrow}$ source over the transported resolution data, so the public derived-functor classifier is preserved by the combined transport and readback. □

Theorem 177.10 (DerivedFunctorUp downstream consumer package)**.** *A downstream* $\mathsf{DerivedCat}^{\uparrow}$ *or* $\mathsf{SpectralSeq}^{\uparrow}$ *consumer may receive precisely the shared source certificates, finite spine, functor row, unary degree, cycle-boundary rows, classifier transport, and* Pkg *provenance carried by the public* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ *surface. It receives no host quotient of complexes and no external abelian-category equality.*

Proof. Start with the coupled source packet of Definition 177.8. It supplies one finite BHist spine together with the $\mathsf{AbelianCat}^{\uparrow}$ source rows and the $\mathsf{Homology}^{\uparrow}$ cycle, boundary, and degree rows that read that same spine.

Use Definition 177.9 for the consumer-facing transport step. The classifier rows remain tied to the transported resolution data, and the selected boundary comparison continues to read the homology endpoint over those transported rows.

Combine these projections with Definition 177.7. The exact public package is the source certificates, finite spine, functor row, unary degree, cycle-boundary rows, classifier transport, and Pkg provenance, with no exported host quotient of complexes and no external abelian-category equality. □

Definition 177.11 (DerivedFunctorUp exact-triangle boundary carrier)**.** *A* $\mathsf{DerivedFunctor}^{\uparrow}$ *exact-triangle boundary carrier is a concrete* BHist *packet whose public rows consist of one* $\mathsf{AbelianCat}^{\uparrow}$ *source row, the* $\mathsf{Homology}^{\uparrow}$ *cycle and boundary rows at the displayed degree, three resolution-spine packets*

$$R_A \to A, \qquad R_B \to B, \qquad R_C \to C,$$

the connecting-morphism row $\partial : C \to A[1]$*, and a* Pkg *provenance row for the boundary ledger. Each resolution-spine packet is a row of the form named in Definition 177.2; the* $\mathsf{AbelianCat}^{\uparrow}$ *source row classifies the admissible arrows in the exact-triangle source row, the* $\mathsf{Homology}^{\uparrow}$ *rows classify cycles and displayed boundaries, and the* Pkg *row records precisely the three spines, the connecting row, and the visible continuation ledgers that relate them.*

Lean4 (definition) `BEDC.Derived.DerivedFunctorUp.DerivedFunctorExactTriangleBoundaryCarrier`

Theorem 177.12 (Exact-triangle boundary carrier scope)**.** *The carrier of Definition 177.11 is closed under* hsame *transport of the* $\mathsf{AbelianCat}^{\uparrow}$ *source row and under* Cont *extension of each of the three displayed resolution spines. Transporting the source row preserves the admissible arrow rows for the exact triangle, and extending any one of* $R_A \to A$*,* $R_B \to B$*, or* $R_C \to C$ *by a displayed continuation step produces another exact-triangle boundary carrier with the same connecting-morphism row and with the* Pkg *provenance row extended by that visible step.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorExactTriangleBoundaryCarrier scope`

Proof. Unpack Definition 177.11. Each of the three spine rows is an instance of the resolution-spine packet of Definition 177.2, so the object rows, arrow rows, cycle rows, boundary rows, functor row, and provenance row are all visible BHist data.

For hsame transport of the source row, apply Definition 177.3 to read each spine over the transported $\mathsf{AbelianCat}^{\uparrow}$ classifier. The homology cycle and boundary rows remain attached to the same displayed degree, and the connecting-morphism row is transported as an admissible arrow row over the same source surface.

For Cont extension, apply Definition 177.3 separately to the affected spine. The other two spines and the connecting row are unchanged, and the boundary carrier is repacked by appending the displayed continuation row to the Pkg provenance ledger. □

Theorem 177.13 (Connecting-morphism readback)**.** *For every accepted exact-triangle boundary carrier, the connecting morphism* $\partial : C \to A[1]$ *is read back from the* $\mathsf{Homology}^{\uparrow}$ *boundary classifier together with the* $\mathsf{AbelianCat}^{\uparrow}$ *admissible-arrow transport. The boundary classifier supplies the row identifying the target cycle class modulo displayed boundaries, while the admissible-arrow transport supplies the source and target rows over the three resolution spines.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorExactTriangleBoundaryCarrier connecting morphism readback`

Proof. Begin with an accepted carrier and project the three resolution-spine packets supplied by Definition 177.11. By Definition 177.4, their endpoint comparisons are computed by the $\mathsf{Homology}^{\uparrow}$ cycle classifier modulo the displayed boundary rows.

Next project the connecting-morphism row. The source and target rows are admissible because the same $\mathsf{AbelianCat}^{\uparrow}$ source surface classifies the exact-triangle arrows, and Definition 177.6 transports those admissible rows through the displayed functorial image of the resolution data.

Finally read the target endpoint with Definition 177.5. The $\mathsf{Homology}^{\uparrow}$ boundary classifier is exactly the displayed witness that turns the target cycle into the connecting class, so the public readback of ∂ is obtained without adding a quotient of complexes or any external equality of abelian categories. □

Theorem 177.14 (Long-exact ledger surface)**.** *The long-exact ledger surface of an accepted exact-triangle boundary carrier consists exactly of the three resolution-spine rows, the displayed cycle and boundary rows, the connecting-morphism row, the* Cont *ledgers relating the three spines and their endpoint readbacks, and the* Pkg *provenance row. It exports no host quotient of complexes and no external exact-category equality beyond the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{AbelianCat}^{\uparrow}$*, and* $\mathsf{Homology}^{\uparrow}$ *rows.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorExactTriangleBoundaryCarrier long exact ledger surface`

Proof. Soundness follows by unpacking the boundary carrier of Definition 177.11. The only public rows named by the packet are the $\mathsf{AbelianCat}^{\uparrow}$ source row, the $\mathsf{Homology}^{\uparrow}$ cycle and boundary rows, the three resolution spines, the connecting row, the Cont ledgers, and the Pkg provenance row.

Completeness repacks exactly those rows. Use Definition 177.2 to recognize each of the three spines, then use Definition 177.12 to close the packet under the displayed hsame and Cont transports.

The connecting part is supplied by Definition 177.13, and the endpoint classes are the homology readbacks of Definition 177.5. Applying Definition 177.7 then shows that the public surface is exhausted by the listed rows, so no host quotient of complexes or external exact-category equality is exported. □

Theorem 177.15 (Derived-functor resolution source)**.** *If* $\mathsf{DerivedFunctorCarrier}(h)$ *holds, then there are histories* $F, R, H, i, c : \mathsf{Hist}$ *witnessing the additive-functor trace, resolution trace, homology trace, unary degree row, and intermediate resolved trace with*

$$\mathsf{UnaryHistory}(i) \wedge \mathsf{Cont}(F, R, c) \wedge \mathsf{Cont}(c, H, h).$$

The functor and resolution rows are scoped by the cited $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source surface, and the homology and degree rows are scoped by the cited* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ *source surface.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier resolution source scope`

Proof. Unpack Definition 177.1. The carrier witness is already the five-history tuple (F, R, H, i, c) together with the displayed unary and continuation rows.

The additive-functor and resolution histories are interpreted in the abelian-category dependency because the resolution is a chain-object witness over the same abelian source. Thus their carrier and classifier obligations are read through $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$.

The homology trace and the degree row are interpreted in the homology dependency. The row $\mathsf{UnaryHistory}(i)$ supplies the degree index, and the second continuation row $\mathsf{Cont}(c, H, h)$ records the homology readback from the resolved trace to the carried derived-functor history. □

Theorem 177.16 (Derived-functor classifier stability)**.** *Let* $h, h' : \mathsf{Hist}$ *be carried histories with* $\mathsf{DerivedFunctorCarrier}(h)$ *and* $\mathsf{DerivedFunctorCarrier}(h')$*. If* $h\mathsf{hsame}h'$*, then the* $\mathsf{DerivedFunctor}^{\uparrow}$ *classifier transports from* h *to* h'*: the additive-functor, resolution, homology, unary-degree, and intermediate rows of any carrier witness for* h *may be replaced by* hsame*-related rows in a carrier witness for* h'*, and the two continuation rows remain valid by* Cont *congruence.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier classifier stability`

Proof. Start with a carrier witness for h and unpack it as (F, R, H, i, c) with $\mathsf{UnaryHistory}(i)$, $\mathsf{Cont}(F, R, c)$, and $\mathsf{Cont}(c, H, h)$. Also unpack the carrier witness for h' as (F', R', H', i', c') with the corresponding unary and continuation rows.

The source certificate $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ transports the additive-functor and resolution rows along their classifier comparisons. The source certificate $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ transports the homology trace and the unary degree row, preserving the unary carrier of the degree row.

It remains to transport the two continuation rows. Apply the Cont congruence facts to the transported functor and resolution rows to obtain the resolved intermediate row, and then apply Cont congruence again to the transported intermediate and homology rows. The final endpoint is identified with h' by the displayed hypothesis $h\mathsf{hsame}h'$, so the transported tuple is again a valid $\mathsf{DerivedFunctor}^{\uparrow}$ classifier witness. □

177.2 The certificate

Theorem 177.17 (Derived-functor NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ *obligation surface consists of the carrier predicate of Definition 177.1, the classifier transported in Definition 177.16, the source-witness extraction of Definition 177.15, the exactness clause that every accepted derived-functor row unpacks into exactly those* BHist *witnesses, and the ledger clause that records only the resolution, degree, homology, and boundary rows named by the carrier.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier namecert obligation surface`

Proof. The carrier field is Definition 177.1: it is a predicate on Hist with concrete additive-functor, resolution, homology, degree, and intermediate witnesses. The source field is Definition 177.15, which assigns those witnesses to $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$.

The classifier and stability fields are exactly Definition 177.16. Transport is not a new relation; it is the restriction of hsame to the five carrier rows, with Cont congruence preserving the two displayed continuation ledgers.

Exactness is the bidirectional reading of the same data. Soundness reads each accepted row from the carrier tuple, and completeness repacks any tuple with $\mathsf{UnaryHistory}(i)$, $\mathsf{Cont}(F, R, c)$, and $\mathsf{Cont}(c, H, h)$ into the carrier. These rows reassemble the public $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ obligation surface. □

Theorem 177.18 (Derived-functor ledger policy scope)**.** *The* $\mathsf{DerivedFunctor}^{\uparrow}$ *ledger records only the chosen resolution row* R*, the unary degree row* i*, the homology row* H*, the two continuation rows* $\mathsf{Cont}(F, R, c)$ *and* $\mathsf{Cont}(c, H, h)$*, and the exactness boundary that repacks these rows into* $\mathsf{DerivedFunctorCarrier}(h)$*. It records no quotient representatives, no choice data, and no additional host presentation of derived functors.*

Proof. Read the ledger from Definition 177.1. The only hidden rows in the carrier are the resolution row, the unary degree row, the homology row, and the intermediate continuation boundary from the additive-functor trace through the resolved trace to the carried history.

Apply Definition 177.15 to identify which source certificate scopes each row. The abelian-category certificate scopes the functor and resolution source, while the homology certificate scopes the homology and unary degree source.

Finally apply Definition 177.17. Its exactness clause says that accepted rows are exhausted by this carrier tuple. Since neither the carrier nor the exactness repacking contains quotient representatives, choice data, or an ambient host presentation, the ledger cannot expose any such row. □

Definition 177.19 (Derived-functor delta-splice surface)**.** *A* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface is a displayed* BHist *packet over* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ *whose public rows consist of short-exact source rows*

$$0 \to A \to B \to C \to 0,$$

selected finite resolution rows for A*,* B*, and* C*, cycle rows* $Z_i(A)$*,* $Z_i(B)$*,* $Z_i(C)$*, boundary rows* $B_i(A)$*,* $B_i(B)$*,* $B_i(C)$*, and a connecting row*

$$\delta_i : Z_i(C)/B_i(C) \to Z_{i-1}(A)/B_{i-1}(A).$$

The packet also carries finite Cont *projection ledgers from the displayed boundary rows to* δ_i*,* hsame *transport witnesses comparing the chosen resolution and homology rows across the short-exact source row, and a* Pkg *provenance row naming the AbelianCatUp and HomologyUp certificates used to read the packet.*

Theorem 177.20 (Derived-functor short-exact source scope)**.** *The packet scope of a* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface is exactly the* $\mathsf{AbelianCat}^{\uparrow}$ *short-exact source-row data together with the* $\mathsf{Homology}^{\uparrow}$ *cycle and boundary data named in Definition 177.19. It exports no additional complex equality, no ambient abelian-category object equality, and no host quotient representative for the displayed homology rows.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorDeltaSpliceSurface short exact source scope`

Proof. Project the delta-splice packet into its named rows. The short-exact source row, the three selected resolution rows, and the admissible arrows between them are read through $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$.

The cycle rows and boundary rows are read through $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ at the displayed degrees. These rows supply the only homology data used by the packet; the notation $Z_i(-)/B_i(-)$ is the public readback of those rows, not an extra host quotient.

Conversely, given exactly these AbelianCatUp source rows and HomologyUp cycle and boundary rows, the packet is recovered by repacking the displayed Cont ledgers, hsame witnesses, and Pkg provenance. No row remains available for an ambient equality of complexes or for an external object equality, so the scope is precisely the listed source data. □

Theorem 177.21 (Derived-functor connecting row ledger)**.** *In every* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface, the connecting row* δ_i *is reached by finite* Cont *readback from the displayed HomologyUp boundary rows and transports along the listed* hsame *witnesses. Thus replacing the selected resolutions or cycle-boundary representatives by* hsame*-related rows preserves the same public connecting row.*

Lean4 ✓ `BEDC.Derived.DerivedFunctorUp.DerivedFunctorDeltaSpliceSurface connecting row ledger`

Proof. Unpack the packet and isolate the boundary rows for C and A in adjacent degrees. The finite projection ledger contains a chain of Cont rows from these displayed boundary rows to the row named δ_i.

Use Cont associativity to compose the projection rows into a single readback ledger. This produces the connecting row from the same visible boundary data and does not require a chosen host representative of a quotient class.

Now apply the listed hsame transport witnesses to the selected resolutions and to the cycle-boundary rows. The HomologyUp classifier transports boundary readback along these witnesses, and the composed Cont ledger transports with it. Repacking the transported rows gives the same public δ_i row in the delta-splice surface. □

Theorem 177.22 (Derived-functor long exact splice coverage)**.** *Adjacent degree rows in a* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface splice into the visible long exact row by* Cont *associativity and HomologyUp boundary transport. Each neighboring pair uses only the carried short-exact source row, the selected resolution rows, the displayed cycle and boundary rows, the connecting row* δ_i*, and their* Pkg *provenance.*

Proof. Fix two adjacent displayed degree rows in the packet. Project their cycle rows, boundary rows, and connecting row from Definition 177.19.

The HomologyUp boundary classifier supplies the transport from cycles modulo boundaries at degree i to the boundary data read at degree $i-1$. The connecting row ledger of Definition 177.21 identifies this transport with the finite Cont readback named δ_i.

Compose the degree-i readback, the connecting-row readback, and the degree-$(i-1)$ readback by Cont associativity. The resulting finite ledger is exactly the adjacent segment of the long exact row, and repeating the same projection for each neighboring pair covers the displayed long exact splice without adding any row beyond the packet. □

Theorem 177.23 (Derived-functor AbelianCat-Homology consumer surface)**.** *Every downstream consumer of a* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface receives only the AbelianCatUp short-exact source rows, the HomologyUp cycle and boundary rows, the connecting row* δ_i*, the finite* Cont *ledgers, the* hsame *witnesses, and the* Pkg *provenance. Any consumer row that is invariant under these projections is therefore invariant under the whole delta-splice packet.*

Proof. Project the packet to the rows listed in Definition 177.19. These are exactly the source rows identified by Definition 177.20 together with the connecting ledger identified by Definition 177.21.

For a downstream consumer, supply those projected rows as its input packet. The long exact coverage theorem then provides every adjacent splice row as a finite Cont consequence of the same input, so no consumer has access to a hidden equality of complexes, an unlisted representative, or an external abelian-category presentation.

If the consumer predicate is invariant under the projected rows, transport the input packet by the displayed hsame witnesses and repack the same Pkg provenance. The consumer output is unchanged because every visible row it can read is either one of the projections or a finite Cont composite of them. □

Theorem 177.24 (Derived-functor triangle splice consumer boundary)**.** *A downstream consumer of the* $\mathsf{DerivedFunctor}^{\uparrow}$ *triangle-splice surface receives exactly the* $\mathsf{AbelianCat}^{\uparrow}$ *short-exact source rows, the* $\mathsf{Homology}^{\uparrow}$ *cycle-boundary rows, the connecting row, the finite* Cont *ledgers, the displayed* hsame *witnesses, and the* Pkg *provenance named by Definition 177.19. No consumer projection exposes an additional complex equality, an ambient object equality, or a host quotient representative.*

Proof. Unpack the displayed delta-splice surface. Its source rows are precisely the short-exact row, the selected finite resolution rows, the cycle rows, and the boundary rows listed in Definition 177.19.

Use Definition 177.20 to identify the $\mathsf{AbelianCat}^{\uparrow}$ source part, and use Definition 177.21 to identify the connecting row as a finite Cont readback from HomologyUp boundary data and hsame transports.

Now apply Definition 177.23. It says that a consumer reads only these projections and their finite Cont consequences. Repacking those rows gives the stated boundary: BHist packet rows, hsame witnesses, finite Cont ledgers, and Pkg provenance, with no additional host equality or quotient representative. □

Theorem 177.25 (Derived-functor triangle splice provenance exactness)**.** *The* Pkg *provenance row of a* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface is complete for the displayed splice packet: it names exactly the* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ *certificates needed to read the short-exact source, cycle-boundary, connecting,* Cont*, and* hsame *rows. It carries no host quotient of complexes and no external representative for the homology notation.*

Proof. Project the Pkg row in Definition 177.19. Its AbelianCatUp component accounts for the short-exact source row and the selected finite resolution rows, while its HomologyUp component accounts for the displayed cycle and boundary rows.

The connecting row is not a separate provenance source. By Definition 177.21, it is reached from the same boundary rows by finite Cont readback and transported by the listed hsame witnesses.

The long-exact splice coverage theorem Definition 177.22 composes adjacent rows without adding a new source package. Therefore the same Pkg provenance is exact for the whole delta-splice surface and leaves host quotients of complexes outside the exported packet. □

Theorem 177.26 (Derived-functor spectral-sequence input surface)**.** *A* $\mathsf{SpectralSeq}^{\uparrow}$ *consumer of a* $\mathsf{DerivedFunctor}^{\uparrow}$ *delta-splice surface may read only adjacent long-exact splice rows produced by Definition 177.22. Its input surface consists of the neighboring cycle-boundary rows, connecting row, finite* Cont *composites,* hsame *transport witnesses, and* Pkg *provenance of those adjacent rows.*

Proof. Fix a candidate $\mathsf{SpectralSeq}^{\uparrow}$ consumer and restrict attention to two neighboring displayed degrees in the delta-splice surface. Unpack Definition 177.19 at those degrees to obtain the local cycle rows, boundary rows, and connecting row.

Apply Definition 177.22. The theorem constructs the adjacent long-exact splice segment by Cont associativity and HomologyUp boundary transport, using only the carried short-exact source row, selected resolution rows, cycle-boundary rows, connecting row, and Pkg provenance.

Finally apply Definition 177.23. Since the consumer can read only projected rows and finite Cont consequences, the allowed $\mathsf{SpectralSeq}^{\uparrow}$ input is exactly the adjacent splice surface just constructed, with no parameter transport schema or host quotient row added. □

Theorem 177.27 (DerivedFunctorUp public NameCert package)**.** *The public package exported by* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ *is exactly the* $\mathsf{AbelianCat}^{\uparrow}$ *source rows, the* $\mathsf{Homology}^{\uparrow}$ *cycle and boundary rows, the finite resolution spine, the additive-functor row, the unary degree row, the classifier transports, the finite* Cont *ledgers, and the* Pkg *provenance already isolated by the scoped theorems. It exports no host quotient of complexes and no derived-category equality.*

Proof. Begin with the scoped obligation surface of Definition 177.17. It identifies the carrier, source, classifier, exactness, and ledger rows of $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ as the finite resolution spine, additive-functor row, homology row, unary degree, two continuation ledgers, and their source certificates.

Apply Definition 177.10 to pass from the carrier packet to the consumer-facing package. This keeps exactly the $\mathsf{AbelianCat}^{\uparrow}$ source rows, $\mathsf{Homology}^{\uparrow}$ cycle and boundary rows, visible classifier transports, finite Cont consequences, and Pkg provenance.

For triangle-splice consumers, use Definition 177.24 and Definition 177.25. These two theorems show that the connecting row, adjacent splice rows, and provenance are read from the same finite packet rather than from an ambient quotient of complexes.

Finally apply Definition 177.26. Every $\mathsf{SpectralSeq}^{\uparrow}$ input row is a neighboring long-exact splice segment obtained from those same projections and finite continuation composites. Therefore the exported public package is exhausted by the listed BEDC rows and contains no host quotient of complexes or derived-category equality. □

Closure status for $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$**.**

Constructive story: A derived functor is generated by taking an additive-functor trace, a chosen finite resolution trace, a homology trace, a unary degree row, and two kernel continuations: first the functor trace is continued by the resolution trace to a resolved row, then that row is continued by the homology trace to the carried endpoint. The carrier admits exactly those packets whose degree is a unary history and whose resolution, homology, exact-triangle, and splice ledgers are read through the cited $\mathsf{AbelianCat}^{\uparrow}$ and $\mathsf{Homology}^{\uparrow}$ certificates; host quotients of complexes and independent equalities of abelian categories are not accepted. Two packets are classified together when the functor, resolution, homology, degree, resolved row, and endpoint transport by hsame and the two continuation displays can be repacked, so the public equality is boundary-aware homology readback over transported resolution data rather than an ambient derived-category equality. The source is the coupled abelian-category and homology certificate pair, the pattern is the finite resolution spine with cycle-boundary and long-exact splice rows, and the ledger keeps Cont transitions, connecting rows, unary degrees, and

Pkg provenance visible for SpectralSeq$^{\uparrow}$ consumers. The five name-certificate obligations follow because an admitted resolution packet gives the carrier witness, history-equality and homology-boundary comparison give reflexive, symmetric, and transitive classification, and classifier stability transports the same continuation rows into another admitted packet. A carried endpoint h lies in the signature gap of a DerivedFunctor$^{\uparrow}$ token p when the source-domain accepts the functor, resolution, homology, and degree rows, the signature relation pairs them with an answer endpoint and evidence ledger, and the token-introduction relation names that answer as p; concretely, p records the same derived homology row at the displayed unary degree over the same resolution spine. The chapter registers this coupled resolution-and-homology construction under the name DerivedFunctor$^{\uparrow}$; no derived-category calculus, quotient of complexes, or standard bridge is introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{DerivedFunctor}^{\uparrow}}$, maturePackageClosed)

Scope closed: The closed scope is the resolution-spine carrier, the AbelianCat$^{\uparrow}$ and Homology$^{\uparrow}$ source rows, the downstream consumer package, the triangle-splice consumer boundary, the exported completeness boundary, the Cont ledger, and the Pkg provenance.

Formal verification: FormalStatus(NameCert$_{\mathsf{DerivedFunctor}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DerivedFunctorUp.DerivedFunctorCarrier\_classifier\_stability`

Bridge status: paperBridge

Not claimed: Full derived-category calculus and the standard derived-functor bridge are not claimed by this chapter.

Upgrade path: The next verification-axis obligation is the machine-checked standard bridge row for the existing paper bridge.

Chapter 178

A Concrete Naming Certificate for $\mathsf{SpectralSeq}^{\uparrow}$

The spectral-sequence interface $\mathsf{SpectralSeq}^{\uparrow}$ packages a sequence of bigraded objects with differentials whose successive cohomologies converge to a target. It depends on $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ (chapter 98) and $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ (chapter 176).

178.1 Carrier definition

Definition 178.1 (SpectralSeqUp BHist page carrier)**.** *A* $\mathsf{SpectralSeq}^{\uparrow}$ BHist *page carrier is a finite page packet*

$$\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$$

over the source rows $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$*. The row A is the displayed abelian-category surface in which the page objects and differential arrows live. The finite family $E = (E_r^{p,q})$ is the page-object ledger; each $E_r^{p,q}$ is an A-classified object row. The finite family $d = (d_r^{p,q})$ is the differential ledger, with*

$$d_r^{p,q} : E_r^{p,q} \to E_r^{p+r,q-r+1}$$

recorded as an A-classified morphism row. The row h records the homology readback identifying each successor page with the $\mathsf{Homology}^{\uparrow}$ *cycle row of d_r modulo its displayed boundary row. The row c records the finite convergence and filtration rows selected for the target object. The row λ is the* Cont *ledger ordering the finite page-to-page transitions, and ρ is the* Pkg *provenance row for the displayed source certificates, page rows, differential rows, homology readbacks, convergence rows, and continuation entries.*

Definition 178.2 (SpectralSeqUp page classifier)**.** *For two* $\mathsf{SpectralSeq}^{\uparrow}$ *page carriers $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ and $\mathcal{S}' = (A', E', d', h', c', \lambda', \rho')$, the page classifier holds when the following componentwise transport rows are displayed.*

1. $A\mathsf{hsame}A'$ *as* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source surfaces.*
2. $E_r^{p,q}\mathsf{hsame}E_r'^{p,q}$ *for every carried page object.*
3. $d_r^{p,q}\mathsf{hsame}d_r'^{p,q}$ *for every differential row, with source and target read through the transported page rows.*
4. $h_r^{p,q}\mathsf{hsame}h_r'^{p,q}$ *for every* $\mathsf{Homology}^{\uparrow}$ *cycle-boundary readback row relating a differential to the successor page.*

5. $c$hsamec' *for the displayed filtration and convergence rows.*
6. $\mathsf{Cont}(\lambda, \lambda')$ *for the finite page-transition ledger.*
7. ρhsameρ' *as* Pkg *provenance rows for exactly the listed page, differential, homology, convergence, and continuation entries.*

Thus the public classifier compares the finite spectral-sequence packet by transporting the displayed rows themselves, not by importing a host exact couple or an ambient equality of abelian categories.

Lean4 (definition) `BEDC.Derived.SpectralSeqUp.SpectralSeqPageClassifier`

Theorem 178.3 (SpectralSeqUp zero-page carrier)**.** *Fix an* $\mathsf{AbelianCat}^{\uparrow}$ *object row* A_0 *and a* Pkg *provenance row* ρ_0*. The finite packet with one page object row* $E_0 = A_0$*, empty differential ledger, identity* $\mathsf{Homology}^{\uparrow}$ *readback for* E_0*, empty convergence row, empty* Cont *transition ledger, and provenance* ρ_0 *is a valid* $\mathsf{SpectralSeq}^{\uparrow}$ BHist *page carrier.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier zero page carrier`

Proof. Project the selected $\mathsf{AbelianCat}^{\uparrow}$ object row as the source surface A and as the sole page-object entry E_0. The empty differential ledger supplies no morphism obligation, so the homology readback is the identity row on the same displayed object.

The convergence and transition components are the empty finite ledgers. Repack the object row, identity readback, empty Cont ledger, and Pkg provenance as the seven components of Definition 178.1. No exact-couple or quotient row is introduced. □

Theorem 178.4 (SpectralSeqUp identity transition ledger)**.** *Let* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ *be a* $\mathsf{SpectralSeq}^{\uparrow}$ BHist *page carrier. If* λ^{id} *is obtained from* λ *by adjoining a displayed identity* Cont *row from a carried page row to itself, and* ρ^{id} *records the same provenance entry, then*

$$\mathcal{S}^{\mathrm{id}} = (A, E, d, h, c, \lambda^{\mathrm{id}}, \rho^{\mathrm{id}})$$

is again a $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier, and the page-classifier rows between* $\mathcal{S}$ *and* $\mathcal{S}^{\mathrm{id}}$ *are the original component rows together with the identity transition row.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier identity transition ledger`

Proof. Project the carrier components of $\mathcal{S}$. The source surface, page objects, differentials, homology readbacks, and convergence rows are unchanged, so their classifier transports are the original hsame rows.

The only new coordinate is the displayed identity Cont row in the finite transition ledger. Append that row to λ and append its provenance entry to ρ. Since the endpoint page is the same carried page row on both sides, the classifier clause for transitions is the identity continuation entry.

Repack the unchanged five carrier coordinates with λ^{id} and ρ^{id}. The seven clauses of Definition 178.2 are therefore preserved exactly by projection and the new identity transition row. □

Theorem 178.5 (SpectralSeqUp page classifier no-confusion)**.** *Every witness of the page classifier between* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ *and* $\mathcal{S}' = (A', E', d', h', c', \lambda', \rho')$ *decomposes into exactly the seven component transports listed in Definition 178.2: the* $\mathsf{AbelianCat}^{\uparrow}$ *source transport, page-object transports, differential transports,* $\mathsf{Homology}^{\uparrow}$ *readback transports, convergence transport, finite* Cont *ledger transport, and* Pkg *provenance transport. It contains no host exact-couple row and no ambient quotient row.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqPageClassifier no confusion`

Proof. Unfold the page classifier. A witness is a finite tuple whose coordinates are the seven displayed component transports, so projection gives the $\mathsf{AbelianCat}^{\uparrow}$ source row, page rows, differential rows, homology readbacks, convergence row, continuation ledger, and provenance row.

Conversely, repack those seven projected rows in the order of Definition 178.2. This rebuilds the original classifier witness without adding any coordinate.

No further row can be projected from the witness. In particular, neither a host exact couple nor an ambient quotient object appears in the classifier definition, so constructor inspection of the displayed tuple leaves exactly the seven transported components. □

178.2 The certificate

Theorem 178.6 (SpectralSeqUp obligation surface)**.** *Every* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier exposes exactly the source abelian-category surface, the source homology surface, the finite page-object ledger, the page classifier, the differential-square rows, the homology-page readback rows, the finite convergence rows, the* Cont *transition ledger, and the* Pkg *provenance row. These rows form the public* $\mathsf{NameCert}_{\mathsf{SpectralSeq}^{\uparrow}}$ *obligation surface available to downstream* $\mathsf{Homology}^{\uparrow}$, $\mathsf{AbelianCat}^{\uparrow}$, *and derived-category consumers.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier obligation surface`

Proof. Project the carrier of Definition 178.1. The projections give the abelian-category source row, the homology source row, the finite page ledger, the differential ledger, the homology readback row, the convergence row, the continuation ledger, and the provenance row.

The classifier of Definition 178.2 is then read component by component. It transports page objects, differential rows, homology readbacks, convergence rows, continuation entries, and provenance without adding any unlisted carrier.

Repack these projections as the named obligation surface. Since every exposed entry is a projection of the displayed packet or the classifier attached to that packet, the public certificate is exhausted by the listed rows. □

Theorem 178.7 (SpectralSeqUp differential ledger stability)**.** *If two* $\mathsf{SpectralSeq}^{\uparrow}$ *page carriers are related by the page classifier, then each transported differential row* $d_r^{p,q}$ *remains an admissible* $\mathsf{AbelianCat}^{\uparrow}$ *morphism row with the transported source and target pages, and the corresponding successor-page homology readback remains classified by the* $\mathsf{Homology}^{\uparrow}$ *source surface. Finite* Cont *extension of the page-transition ledger preserves the same property for the extended carried ledger.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier differential ledger`

Proof. Start with one differential row $d_r^{p,q} : E_r^{p,q} \to E_r^{p+r,q-r+1}$ from the carrier. The page classifier supplies hsame transport for the source page, target page, and the differential row itself, so the transported row is again typed by the transported $\mathsf{AbelianCat}^{\uparrow}$ source surface.

Project the homology readback row attached to this differential. The classifier also transports the corresponding $\mathsf{Homology}^{\uparrow}$ cycle-boundary entry, so the successor page continues to be read as the displayed homology page of the transported differential.

For a finite Cont extension, append the displayed transition row to λ and extend the provenance row by the same entry. The page packet is then repacked with all previous differential and homology rows unchanged and with the new transition recorded in the finite ledger. □

Theorem 178.8 (SpectralSeqUp convergence boundary)**.** *The* $\mathsf{SpectralSeq}^{\uparrow}$ *certificate exports only the displayed page, differential, homology-readback, filtration, convergence,* Cont*, and* Pkg *rows of Definition 178.1. It does not export a host exact couple, a quotient object outside the displayed* $\mathsf{Homology}^{\uparrow}$ *boundary rows, or an ambient equality of abelian categories beyond the transported* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source surface.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier convergence boundary`

Proof. Unpack the carrier and inspect the convergence component c. Its public content is the finite filtration and convergence ledger selected in the BHist packet, together with the page and homology rows needed to name its source.

The quotient information used by a successor page appears only through the $\mathsf{Homology}^{\uparrow}$ cycle-boundary readback row h. The theorem therefore reads no separate quotient object: it uses the displayed boundary classifier already carried by the homology source surface.

Finally, the abelian-category comparison is exactly the source-surface transport in the page classifier. Since the carrier has no row naming a host exact couple or an ambient category equality, those data cannot be exported by the public $\mathsf{NameCert}_{\mathsf{SpectralSeq}^{\uparrow}}$ boundary. □

Theorem 178.9 (SpectralSeqUp page-transition bridge)**.** *For a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier*

$$\mathcal{S} = (A, E, d, h, c, \lambda, \rho),$$

the finite Cont *ledger* λ *of Definition 178.1, transported through the page classifier of Definition 178.2, gives a* BHist*-stable bridge between each successive page row* $E_r^{p,q}$ *and the corresponding* $\mathsf{Homology}^{\uparrow}$ *readback row carried by* h*. The bridge exposes exactly the transported page-object rows, differential rows, successor homology rows,* Cont *transition entries, and* Pkg *provenance rows already listed in the spectral-sequence packet.*

Proof. Project the carrier to obtain the page ledger E, the differential ledger d, the homology readback ledger h, the transition ledger λ, and the provenance row ρ.

For each carried transition, apply the classifier clauses for the source page, target page, differential row, and homology readback row. These clauses transport the page endpoint and its successor readback componentwise through hsame while the same finite Cont entry records the page-to-page step.

Finally repack the transported page endpoint, its differential, its $\mathsf{Homology}^{\uparrow}$ readback, the relevant continuation entry, and the provenance row. Because every coordinate is projected from the original packet or from the classifier transport, the resulting bridge is stable as a BHist row and exports no extra exact-couple data. □

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier page transition bridge`

Theorem 178.10 (SpectralSeqUp convergence-filtration bridge)**.** *For* $\mathsf{SpectralSeq}^{\uparrow}$ *page carriers related by the classifier of Definition 178.2, the convergence row* c *is stable under* hsame *of the page packet and exposes exactly the finite filtration boundary needed by a derived-functor consumer. The exposed boundary consists of the transported convergence row, the page rows named by the finite filtration, the endpoint readbacks supplied by* h*, the* Cont *ledger* λ*, and the* Pkg *provenance row* ρ*.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier convergence filtration bridge`

Proof. Start with the classifier clause $c\mathsf{hsame}c'$. It transports the displayed convergence and filtration rows as rows of the same page packet rather than as ambient host objects.

Next combine that clause with the classifier clauses for λ and ρ. The continuation ledger records which finite page transitions support the filtration boundary, while the provenance row keeps those transitions tied to the same page, differential, homology, and convergence entries.

Apply Definition 178.8. It excludes host exact couples and quotient objects outside the displayed $\mathsf{Homology}^{\uparrow}$ boundary rows. The remaining exported data are precisely the finite filtration boundary rows and their Cont and Pkg witnesses. □

Theorem 178.11 (SpectralSeqUp DerivedFunctorUp consumer surface)**.** *A downstream* $\mathsf{DerivedFunctor}^{\uparrow}$ *row consuming a* $\mathsf{SpectralSeq}^{\uparrow}$ *certificate may use only the* $\mathsf{AbelianCat}^{\uparrow}$ *source row, the* $\mathsf{Homology}^{\uparrow}$ *source row, the page-object rows, the differential rows, the homology readbacks, the convergence-filtration rows, the* Cont *transition ledger, and the* Pkg *provenance listed in this chapter. It consumes no host exact couple, ambient quotient category, or equality of abelian categories outside the displayed* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source transport.*

Proof. Use Definition 178.6 to enumerate the rows exported by the spectral-sequence certificate. These are the source certificates, page objects, differentials, homology readbacks, convergence rows, continuation ledger, and provenance row.

Apply Definition 178.9 for the page-to-page bridge surface and Definition 178.10 for the convergence-facing boundary. Together they provide the transition and filtration rows needed by a derived-functor consumer.

Finally apply Definition 178.8. Since the certificate exports neither a host exact couple nor an ambient quotient category, the downstream row can consume only the displayed BEDC rows and their listed Cont and Pkg witnesses. □

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier derivedfunctor consumer surface`

Theorem 178.12 (SpectralSeq boundary rows enter successor cycles)**.** *Let* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ *be a* $\mathsf{SpectralSeq}^{\uparrow}$ BHist *page carrier. Fix a carried differential row* $d_r^{p,q}$*, and write its* $\mathsf{Homology}^{\uparrow}$ *readback on the BEDC history surface again as*

$$d_r^{p,q} : \mathsf{BHist} \to \mathsf{BHist}.$$

Assume that the displayed differential-square row for this differential is

$$\forall u : \mathsf{BHist},\ \mathsf{hsame}(d_r^{p,q}(d_r^{p,q}(u)), \mathsf{Empty}).$$

If a representative b *lies in the displayed boundary row for this differential,*

$$B_{d_r^{p,q}}(b),$$

then the successor-page readback row $h_r^{p,q}$ *classifies the same representative through the cycle row:*

$$Z_{d_r^{p,q}}(b).$$

Equivalently, every representative read by $h_r^{p,q}$ *from the displayed boundary subrow of* $d_r^{p,q}$ *enters the successor surface* $E_{r+1}^{p,q}$ *only through the cycle row used by the homology-page quotient.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier boundary row successor cycle readback`

Proof. The carrier description in Definition 178.1 gives, for the fixed differential row, a homology readback row identifying the successor page with the $\mathsf{Homology}^{\uparrow}$ cycle row of $d_r^{p,q}$ modulo its displayed boundary row. The obligation surface in Definition 178.6 exposes the differential-square row for the same displayed differential together with the matching homology-page readback row $h_r^{p,q}$.

Apply Definition 98.3 to the $\mathsf{Homology}^{\uparrow}$ differential read back from $d_r^{p,q}$ and to the representative b. The boundary hypothesis supplies the boundary-carrier premise, while the displayed differential-square row supplies the universal square-zero premise. The conclusion is exactly $Z_{d_r^{p,q}}(b)$ before taking the boundary quotient. Since $h_r^{p,q}$ reads the successor page from that cycle row modulo the displayed boundary row, the boundary representative is admitted to the successor-page surface as a cycle representative. □

Theorem 178.13 (SpectralSeqUp successor-page closure)**.** *Suppose a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier supplies a differential row* $d_r^{p,q}$*, its transported source and target page rows* $E_r^{p,q}$ *and* $E_r^{p+r,q-r+1}$*, and the displayed* $\mathsf{Homology}^{\uparrow}$ *cycle-boundary readback row identifying the successor page. Then the successor page is repacked as a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier over the same* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source, with the* Cont *page-transition ledger extended by the successor entry and the* Pkg *provenance retained for the displayed page, differential, homology-readback, convergence, and transition rows. No host quotient, host exact couple, or ambient category equality is introduced by the page transition.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier successor page closure`

Proof. Project the differential row, its source and target page rows, and the homology readback row from the carrier of Definition 178.1. These projections give the only data used to name the successor page.

Use the page classifier of Definition 178.2 to transport the source page, target page, differential, and homology readback componentwise. By Definition 178.7, the transported differential remains an admissible $\mathsf{AbelianCat}^{\uparrow}$ morphism row, and the transported readback remains classified by the displayed $\mathsf{Homology}^{\uparrow}$ source surface.

Repack the successor page by extending the finite Cont ledger with the displayed page-transition entry and retaining the same Pkg provenance rows. The boundary restriction of Definition 178.8 excludes any host quotient or exact-couple object outside the carried $\mathsf{Homology}^{\uparrow}$ cycle-boundary row, so the repacked object is again a $\mathsf{SpectralSeq}^{\uparrow}$ page carrier. □

Theorem 178.14 (SpectralSeq page-boundary exhaustion)**.** *Let* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ *be a* $\mathsf{SpectralSeq}^{\uparrow}$ BHist *page carrier. For every successor-page representative exposed by a displayed row* $h_r^{p,q}$*, the representative is exhausted by exactly the displayed page row* $E_r^{p,q}$*, differential row* $d_r^{p,q}$*,* $\mathsf{Homology}^{\uparrow}$ *cycle-boundary row,* Cont *transition entry, and* Pkg *provenance row carried by* $\mathcal{S}$*. No additional host exact couple, ambient quotient category, or uncarried page object contributes a boundary row to the successor representative.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier page boundary exhaustion`

Proof. Project the page row, differential row, homology readback row, continuation entry, and provenance entry from the carrier of Definition 178.1. These projections are the only rows on which the displayed successor readback $h_r^{p,q}$ is defined.

The classifier of Definition 178.2 transports these projected rows componentwise. Apply Definition 178.7 to keep the differential row in the carried $\mathsf{AbelianCat}^{\uparrow}$ morphism ledger, and apply Definition 178.13 to repack the transported cycle-boundary readback as the successor-page carrier.

Finally, Definition 178.8 rules out any boundary source outside the displayed $\mathsf{Homology}^{\uparrow}$ cycle-boundary row and the listed Cont and Pkg witnesses. Hence every representative exposed by $h_r^{p,q}$ is exhausted by the finite BEDC page ledger just projected. □

Theorem 178.15 (SpectralSeq visible target-filtration coverage)**.** *For a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$*, the visible target-filtration row* c *covers exactly the page rows, transition rows, homology readback rows, and convergence witnesses listed in Definition 178.1. It does not quantify over a host exact couple, an ambient quotient category, or any quotient object not named by the displayed* BHist *carrier.*

Proof. Read the target-filtration row c as one of the carried components in Definition 178.1. Its domain is therefore the same finite page inventory that supplies E, d, h, λ, and ρ.

Transport this inventory through the classifier of Definition 178.2. The differential part is constrained by Definition 178.7, while the successor-page part is constrained by Definition 178.13; both constraints remain inside the carried page rows.

The boundary statement of Definition 178.8 gives the exclusion clause. Since it admits only the displayed page, differential, homology, continuation, and provenance rows, the target-filtration row covers exactly those witnesses and no host exact-couple or ambient quotient-category data. □

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier visible target filtration coverage`

Theorem 178.16 (SpectralSeq finite continuation page-ledger closure)**.** *Let* $\mathcal{S}$ *be a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier and let* $\mathcal{L}'$ *be obtained from its finite* Cont *page ledger by adjoining finitely many displayed successor-page transition entries. If each adjoined entry is read through the page carrier, page classifier, differential ledger, convergence boundary, and successor-page closure of this section, then* $\mathcal{L}'$ *preserves the page carrier, classifier transport, and* $\mathsf{Homology}^{\uparrow}$ *readback rows of* $\mathcal{S}$*.*

Proof. Induct on the finite list of adjoined Cont entries. The empty list is the original ledger of Definition 178.1, so the carrier, classifier transport, and homology readback rows are unchanged.

For the induction step, project the next transition from the displayed page carrier and transport it through Definition 178.2. Apply Definition 178.7 to the associated differential row and Definition 178.8 to the associated boundary row.

Definition 178.13 repacks that transported entry as a successor-page carrier over the same source certificate. Appending this one entry to the induction ledger therefore preserves the carrier, classifier transport, and $\mathsf{Homology}^{\uparrow}$ readback rows; the finite induction gives the stated closure for $\mathcal{L}'$. □

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier cont page ledger closure`

Theorem 178.17 (SpectralSeqUp continuous page-transition closure)**.** *Let a* $\mathsf{SpectralSeq}^{\uparrow}$ *page carrier contain a displayed differential row* $d_r^{p,q}$*, the source and target page rows for that differential, a* $\mathsf{Homology}^{\uparrow}$ *cycle-boundary readback naming the successor page, and a finite* Cont *page-transition ledger whose next row records that readback. Then the successor page is again a* $\mathsf{SpectralSeq}^{\uparrow}$ *carrier over the same* $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ *source surface. Under the same transition, the transported differential remains an* $\mathsf{AbelianCat}^{\uparrow}$ *morphism row, the successor homology readback remains a* $\mathsf{Homology}^{\uparrow}$ *boundary row, and the finite transition ledger carries exactly the displayed page, differential, homology-readback, convergence, transition, and* Pkg *provenance rows. No ambient exact couple, host quotient equality, analytic convergence datum, or external page object is exported.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier cont page transition closure`

Proof. First read the differential surface. By Definition 178.7, the displayed row $d_r^{p,q}$ and its transported source and target rows remain within the $\mathsf{NameCert}_{\mathsf{AbelianCat}^\uparrow}$ morphism ledger selected by the page carrier. This gives the morphism component needed by a downstream derived-functor consumer.

Next form the successor carrier. Apply Definition 178.13 to the same differential row, the same source and target page rows, and the same $\mathsf{Homology}^\uparrow$ cycle-boundary readback. The resulting carrier is obtained by extending the finite Cont transition ledger with the displayed successor entry and by retaining the corresponding Pkg provenance rows.

Finally restrict the boundary of the repacked page. The exclusion clause of Definition 178.8 says that the only quotient information visible to the public page transition is the carried $\mathsf{Homology}^\uparrow$ cycle-boundary readback row. Hence the composite transition presents one closed consumer surface: successor page carrier, transported abelian morphism row, homology boundary row, finite Cont ledger, and provenance, with no additional host object. □

Definition 178.18 (SpectralSeqUp filtration ledger)**.** *For a* $\mathsf{SpectralSeq}^\uparrow$ *page carrier* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$*, the filtration ledger is the finite* BHist *packet* c *already named in Definition 178.1. It consists of the displayed filtration rows for the target object, the convergence rows relating stable page representatives to those filtration rows, the* $\mathsf{Homology}^\uparrow$ *cycle and boundary readbacks used to name each representative, and the* Pkg *provenance entries tying those rows to the carried page, differential, and transition ledgers.*

The public filtration ledger is therefore a subpacket of the carrier. It is not a host exact couple, an external quotient object, or an ambient abutment object outside the displayed BEDC rows.

Theorem 178.19 (SpectralSeqUp filtration transport)**.** *Let* $\mathcal{S} = (A, E, d, h, c, \lambda, \rho)$ *and* $\mathcal{S}' = (A', E', d', h', c', \lambda', \rho')$ *be* $\mathsf{SpectralSeq}^\uparrow$ *page carriers related by the page classifier of Definition 178.2. If* λ^+ *is obtained from* λ *by a finite* Cont *extension recording a displayed page transition, then the filtration ledger* c *transports to the filtration ledger* c' *and to the extended ledger over* λ^+*. The transport uses only the classifier rows* $c\mathsf{hsame}c'$*, the transported page, differential, and homology readback rows, and the finite* Cont *extension; it imports no host exact couple.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier filtration transport`

Proof. Project the filtration ledger c from Definition 178.18. Its entries are already part of the carrier of Definition 178.1.

Use the page classifier of Definition 178.2. It supplies $c\mathsf{hsame}c'$ and transports the page objects, differentials, and $\mathsf{Homology}^\uparrow$ cycle-boundary readback rows that name the filtration entries.

For the finite extension of λ, apply Definition 178.13. The successor step extends only the carried Cont transition ledger and retains the same Pkg provenance scope. By Definition 178.8, there is no exported exact couple or ambient quotient object to transport, so the filtration ledger remains the displayed BEDC subpacket. □

Theorem 178.20 (SpectralSeqUp abutment readback boundary)**.** *Every abutment representative exported by the filtration ledger* c *of a* $\mathsf{SpectralSeq}^\uparrow$ *page carrier is read through the displayed* $\mathsf{Homology}^\uparrow$ *cycle-boundary rows and the* Pkg *provenance row of the carrier. No representative is exported through a quotient object, exact-couple object, or abutment carrier not named in Definition 178.1.*

Lean4 ✓ `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier abutment readback boundary`

Proof. Unpack the filtration ledger using Definition 178.18. Each exported representative is attached to a convergence row in c and to the provenance entry ρ for the same carried page packet.

The representative itself is read back through the homology component h of Definition 178.1. The boundary statement Definition 178.8 identifies this as the displayed $\mathsf{Homology}^{\uparrow}$ cycle row modulo its displayed boundary row, not as a separate host quotient.

Finally apply Definition 178.13 to the page transition feeding the stable representative. The transition repacks the successor page using the carried differential, homology readback, filtration, Cont, and Pkg rows. Thus every abutment readback remains inside the displayed BEDC ledger. □

Theorem 178.21 (SpectralSeqUp page-classifier transport exactness)**.** *If two* $\mathsf{SpectralSeq}^{\uparrow}$ *page carriers are related by Definition 178.2, then every visible consumer package transported from one carrier to the other is exhausted by the source* $\mathsf{AbelianCat}^{\uparrow}$ *row, the* $\mathsf{Homology}^{\uparrow}$ *source row, the page-object rows, the differential rows, the successor-page readback rows, the convergence-filtration rows, the finite* Cont *transition ledger, and the* Pkg *provenance row already listed in the classifier. No host exact couple, quotient object outside the displayed* $\mathsf{Homology}^{\uparrow}$ *boundary, or ambient equality of abelian categories contributes a further transported row.*

Proof. Project the classifier clauses of Definition 178.2. They give the transported $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ source surface, every page-object row, every differential row with its transported source and target pages, every $\mathsf{Homology}^{\uparrow}$ cycle-boundary readback row, the filtration row, the finite Cont ledger, and the Pkg provenance row.

Next apply Definition 178.7. This keeps each differential inside the transported $\mathsf{AbelianCat}^{\uparrow}$ morphism ledger and keeps the corresponding successor readback classified by the displayed $\mathsf{Homology}^{\uparrow}$ source surface. Apply Definition 178.13 to repack the successor page over the same source certificate and the extended finite transition ledger.

Now apply Definition 178.19 and Definition 178.20. The first transports the convergence-filtration subpacket through the classifier and finite Cont extension. The second says that every abutment representative is read only through the displayed $\mathsf{Homology}^{\uparrow}$ cycle-boundary rows and the carried Pkg provenance.

Finally repack the transported rows into the consumer surface. The boundary exclusion in Definition 178.8 removes host exact couples, quotient objects outside the displayed homology boundary, and ambient equalities of abelian categories. Hence the transported package is exactly the surface named by the classifier and the four cited transport theorems. □

Theorem 178.22 (SpectralSeqUp AbCat and derived-functor scope binding)**.** *The page-carrier rows and transition rows of* $\mathsf{SpectralSeq}^{\uparrow}$ *consume only the displayed* $\mathsf{AbelianCat}^{\uparrow}$ *source rows and* $\mathsf{DerivedFunctor}^{\uparrow}$ *source rows named by Definition 178.6. In particular, a page object, differential, successor-page transition, or derived-functor consumer cannot read an ambient abelian category, an unlisted functor, or a host exact couple outside those displayed rows.*

Proof. Project the page-carrier and transition clauses exposed by Definition 178.6. The projected rows are the $\mathsf{NameCert}_{\mathsf{AbelianCat}^{\uparrow}}$ source surface, the page-object rows, the differential rows, and the finite transition ledger attached to the displayed $\mathsf{DerivedFunctor}^{\uparrow}$ source.

Next use Definition 178.11 to identify the derived-functor consumers with the same carrier and transition rows. The consumer surface has no extra field for an ambient abelian category or an unlisted functor.

Repack those projected rows as the scope witness. Since the repacked packet is literally the obligation-surface packet with no added spectral-sequence data, all page and transition consumers remain bound to the displayed $\mathsf{AbelianCat}^{\uparrow}$ and $\mathsf{DerivedFunctor}^{\uparrow}$ rows. □

Theorem 178.23 (SpectralSeqUp homology readback scope binding)**.** *The abutment rows and convergence rows of* $\mathsf{SpectralSeq}^{\uparrow}$ *factor through the displayed* $\mathsf{Homology}^{\uparrow}$ *readback rows already listed in Definition 178.6. They do not require a quotient object, convergence target, or boundary representative outside those cycle-boundary readback rows.*

Proof. Project from Definition 178.6 the homology readback rows, the successor-page rows, the convergence-filtration rows, and the abutment provenance row. These are the rows that name the visible $\mathsf{Homology}^{\uparrow}$ cycle and boundary data.

Apply Definition 178.20 to the abutment projection. It states that the abutment representative is read through the displayed cycle-boundary boundary and not through a host quotient.

Apply Definition 178.8 and Definition 178.19 to the convergence projection. They keep convergence and filtration transport inside the same displayed $\mathsf{Homology}^{\uparrow}$ readback rows. Repacking these projected rows gives the claimed scope binding. □

Theorem 178.24 (SpectralSeqUp continuation and package ledger scope binding)**.** *Every transition row, filtration row, and ledger row used by* $\mathsf{SpectralSeq}^{\uparrow}$ *is a finite* Cont*,* hsame*, or* Pkg *row from the displayed packet in Definition 178.6. No infinite transition ledger, ambient equality, or external package provenance is consumed by the chapter's certificate.*

Proof. Project the finite transition ledger, the filtration ledger, the hsame rows, and the Pkg provenance rows from Definition 178.6. These projections are already the ledger rows used by the page classifier and its transported consumer surface.

Use Definition 178.16 and Definition 178.17 to keep the transition steps inside the finite Cont ledger. Use Definition 178.21 to identify the transported package with the same hsame and Pkg rows.

Repack the projected ledger as the scope witness. Because the repacking adds no new row beyond the displayed packet, every transition, filtration, and package read is exactly one of the listed Cont, hsame, or Pkg dependencies. □

Closure status for $\mathsf{NameCert}_{\mathsf{SpectralSeq}^{\uparrow}}$.

Constructive story: A spectral sequence is carried as a finite page packet whose histories name the abelian-category source, the homology source, the page-object ledger, the differential ledger, the homology readback, the convergence row, the page-transition row, and the package provenance. The carrier accepts only packets in which the displayed page and differential rows are unary histories connected by finite Cont steps and sealed by a Pkg signature, while exact couples, infinite transition ledgers, and ambient quotient objects are excluded. Two page packets are classified together by transporting each component row: the abelian source, page objects, differentials, homology readbacks, convergence data, transition ledger, and provenance must match by hsame or the listed continuation comparison, not by an outside equality of spectral sequences. The source is the paired $\mathsf{AbelianCat}^{\uparrow}$ and $\mathsf{Homology}^{\uparrow}$ certificate surface, the pattern records successive page differentials and the rule that each next page is the displayed homology of the previous differential, and the ledger keeps every finite transition, filtration, readback, and provenance entry visible. Since the empty one-page packet gives an admitted carrier and the component classifiers transport by the already checked history and package rows, the name-certificate obligations reduce to carrier habitation, reflexive/symmetric/transitive rowwise comparison, and closure under successor-page transport. A packet h lies in the signature gap of a $\mathsf{SpectralSeq}^{\uparrow}$ token p when the source-domain accepts the abelian, homology, page, differential, and convergence rows, the signature relation pairs the resulting finite packet with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records that same finite page ledger and its homology-to-successor readbacks. The chapter registers this finite page-ledger construction under the name $\mathsf{SpectralSeq}^{\uparrow}$; it supplies a scoped certificate surface, not full convergence theory or a standard spectral-sequence bridge.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SpectralSeq}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper scope is the finite page-ledger construction, the displayed $\mathsf{AbelianCat}^{\uparrow}$, $\mathsf{DerivedFunctor}^{\uparrow}$, and $\mathsf{Homology}^{\uparrow}$ dependencies, the page-transition bridge of Definition 178.9, the convergence-filtration bridge of Definition 178.10, and the explicit exclusion of full convergence theory.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SpectralSeq}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SpectralSeqUp.SpectralSeqBHistPageCarrier\_obligation\_surface`

Bridge status: paperBridge

Not claimed: Full spectral-sequence convergence theory and machine-checked standard bridge data are not closed by this chapter.

Upgrade path: The remaining elevation is machine-checked standard bridge data, not additional paper theory closure.

Chapter 179

A Concrete Naming Certificate for $\mathsf{TriangulatedCat}^{\uparrow}$

The triangulated-category interface $\mathsf{TriangulatedCat}^{\uparrow}$ packages an additive category with a translation autoequivalence and a class of distinguished triangles satisfying the octahedral axiom. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) and $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ (chapter 160).

179.1 Carrier definition

Definition 179.1 (TriangulatedCat finite carrier)**.** *A* $\mathsf{TriangulatedCat}^{\uparrow}$ *carrier is the finite* BHist *packet* $\mathsf{TriangulatedCatPkt}(\mathcal{T})$ *with the following displayed rows.*

1. *A retained* $\mathsf{Cat}^{\uparrow}$ *row for the underlying category object, morphism, identity, and composition histories.*
2. *A retained* $\mathsf{DerivedCat}^{\uparrow}$ *row for the visible localization boundary used by the triangulated presentation.*
3. *An additive-category row recording the zero object, biproduct, addition on hom histories, and additive inverse histories.*
4. *A translation-autoequivalence row recording a shift history* Σ*, its inverse shift history, and the displayed unit and counit comparison histories.*
5. *A distinguished-triangle row recording triples* $X \to Y \to Z \to \Sigma X$ *as finite morphism-history ledgers.*
6. *An octahedral ledger row recording only the named faces, comparison morphisms, and* Cont *witnesses that are explicitly displayed in the packet.*
7. *Componentwise* hsame *rows for all category, derived-category, additive, shift, triangle, and octahedral histories.*
8. Cont *rows for shift transport, triangle rotation, triangle morphism composition, and octahedral-face composition.*
9. *A* Pkg *provenance row tying the retained dependency certificates and all displayed triangulated rows to one source packet.*

The carrier accepts no row that is not one of these displayed BHist, hsame, Cont, *or* Pkg *fields.*

Lean4 (definition) `BEDC.Derived.TriangulatedCatUp.TriangulatedCatFiniteCarrier`

Definition 179.2 (TriangulatedCat classifier)**.** *Two* TriangulatedCatPkt *carriers classify together when their retained* $\mathsf{Cat}^{\uparrow}$ *and* $\mathsf{DerivedCat}^{\uparrow}$ *rows classify by the corresponding dependency certificates and every additive, translation, triangle, octahedral-ledger,* Cont*, and* Pkg *row is related by the displayed componentwise* hsame *comparison. This classifier is a comparison of finite packet rows; it is not a host localization, a Verdier quotient, or an unstated equality of triangulated categories.*

Lean4 (definition) `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketClassifier`

179.2 The certificate

Theorem 179.3 (TriangulatedCat carrier obligation)**.** *Every accepted* TriangulatedCatPkt($\mathcal{T}$) *row projects to one of the displayed dependency, additive, translation, distinguished-triangle, octahedral-ledger,* hsame*,* Cont*, or* Pkg *rows of Definition 179.1. No host Verdier quotient object and no unlogged octahedral datum is carried by the* $\mathsf{TriangulatedCat}^{\uparrow}$ *surface.*

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier carrier obligation`

Proof. Unpack the carrier definition. The packet constructor lists the retained $\mathsf{Cat}^{\uparrow}$ and $\mathsf{DerivedCat}^{\uparrow}$ rows first, then the additive, translation-autoequivalence, distinguished-triangle, octahedral-ledger, componentwise hsame, Cont, and Pkg rows.

Projecting an accepted carrier therefore selects one of those coordinates. The categorical and derived rows are read through their dependency certificates, while the triangulated-specific rows are histories inside the same finite packet.

Conversely, each displayed coordinate repacks into the same packet by the carrier constructor. Constructor inversion leaves no separate case for a host Verdier quotient, an unlabelled localization equality, or octahedral data outside the listed ledger row. □

Theorem 179.4 (TriangulatedCat classifier stability obligation)**.** *The classifier of Definition 179.2 transports the finite* $\mathsf{TriangulatedCat}^{\uparrow}$ *carrier surface: classified packets have classified dependency rows and componentwise transported additive, shift, triangle, octahedral-ledger,* Cont*, and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier classifier stability`

Proof. Begin with a classifier witness between two displayed packets. Its dependency fields are the retained classifiers for the $\mathsf{Cat}^{\uparrow}$ and $\mathsf{DerivedCat}^{\uparrow}$ rows, so those two rows transport by the existing certificate surfaces.

The remaining classifier fields are componentwise hsame comparisons. Apply them separately to the additive-category row, the shift and inverse shift rows, the unit and counit comparison rows, the distinguished-triangle ledger, and the octahedral ledger.

The Cont rows transport because their source, middle, and target histories are among the same componentwise comparisons. The provenance row transports by the displayed Pkg comparison. Repacking these transported rows with the carrier constructor gives a classified target packet and no extra semantic equality is used. □

Theorem 179.5 (TriangulatedCat translation-triangle obligation scope)**.** *Every translated distinguished-triangle readback in an accepted* $\mathsf{TriangulatedCat}^{\uparrow}$ *packet is read only through the displayed translation-autoequivalence row, inverse shift row, unit and counit comparison histories, distinguished-triangle ledger, componentwise* hsame*,* Cont *rows for shift transport and triangle rotation,* Pkg *provenance,*

and the retained $\mathsf{Cat}^{\uparrow}$ *and* $\mathsf{DerivedCat}^{\uparrow}$ *dependency rows. It does not read host Verdier quotient semantics, unlogged exact-triangle objects, or ambient triangulated-category equality.*

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier translation triangle obligation scope`

Proof. Unpack rows 20–31 of Definition 179.1. A translated distinguished triangle is represented by the displayed shift histories, inverse shift row, unit and counit comparisons, the distinguished-triangle ledger, and the associated continuation rows.

Apply Definition 179.4. The classifier transports each listed component by its hsame comparison, while the retained $\mathsf{Cat}^{\uparrow}$ and $\mathsf{DerivedCat}^{\uparrow}$ rows supply the dependency certificates and the Pkg row records provenance.

Repack the visible shift and triangle rows through the carrier constructor. Constructor inversion has no coordinate for a host Verdier quotient, an unlogged exact-triangle object, or an ambient equality of triangulated categories, so every accepted readback stays inside the displayed packet surface. □

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier translation triangle scope`

Theorem 179.6 (TriangulatedCat shift autoequivalence obligation)**.** *The shift row of a* TriangulatedCatPkt *exports only the displayed* Σ *history, inverse-shift history, unit and counit comparison histories, their* BHist *entries, componentwise* hsame *comparisons, the* Cont *rows that transport the shift route, and the* Pkg *provenance row of Definition 179.1. It does not export an equality of host autoequivalences or an unlogged inverse functor.*

Proof. Unpack the carrier of Definition 179.1. The shift coordinate is one finite row in the same packet as the additive, distinguished-triangle, octahedral-ledger, Cont, and Pkg rows.

Apply the componentwise classifier transport of Definition 179.4 to the Σ, inverse-shift, unit, and counit histories. The transported data stay inside the listed BHist and hsame coordinates.

It remains to rule out a host autoequivalence equality. Constructor inversion on the packet has cases only for the displayed shift histories, their comparison rows, the relevant Cont witnesses, and the provenance row, so no separate equality coordinate can be projected. □

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier shift autoequivalence obligation`

Theorem 179.7 (TriangulatedCat distinguished-triangle rotation obligation)**.** *Every rotation read of a distinguished triangle in a* TriangulatedCatPkt *factors through the logged triangle row, the shift obligation of Definition 179.6, and the displayed* Cont *route for triangle rotation. No rotation is read from an ambient triangulated-category structure outside the finite packet.*

Proof. Unpack the distinguished-triangle coordinate of Definition 179.1. A triangle is present as a finite morphism-history ledger ending in the displayed Σ row.

The endpoint shift is therefore the shift row governed by Definition 179.6. By Definition 179.4, classifier transport carries the triangle histories, the shift endpoint, and the rotation continuation componentwise.

Constructor inversion on the packet leaves only the triangle ledger and the listed Cont rotation route as sources for a rotation read. Hence the certificate consumes rotation through the logged finite data rather than through a host triangulated-category operation. □

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier distinguished triangle rotation obligation`

Theorem 179.8 (TriangulatedCat octahedral Cont face coverage)**.** *Every octahedral face consumed by the* $\mathsf{TriangulatedCat}^{\uparrow}$ *certificate is one of the logged finite faces of the octahedral ledger, together with its comparison-morphism history and displayed* Cont *witness. The certificate has no access path to an octahedral face outside those packet rows.*

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatOctahedralLedger face cont coverage`
↪ variant `BEDC.Derived.TriangulatedCatUp.TriangulatedCatOctahedralLedger face cont witness`

Proof. Start with the octahedral coordinate of Definition 179.1. Its accepted rows are the finite face histories, comparison morphism histories, and Cont witnesses named in the ledger.

Use Definition 179.4 to transport each face together with its comparison morphism and continuation witness. This is componentwise transport of displayed packet rows, not a semantic octahedral axiom from outside the carrier.

Finally perform constructor inversion on the finite packet. A consumed face must project from one of the logged octahedral rows, and each such row carries the comparison history and Cont witness required by the certificate. □

Theorem 179.9 (TriangulatedCat octahedral ledger boundary)**.** *The octahedral obligation in the* $\mathsf{TriangulatedCat}^{\uparrow}$ *packet is bounded by the displayed octahedral ledger: it records finite faces, comparison morphism histories, and* Cont *witnesses, and it does not assert any unrecorded octahedral filler or external triangulated-category semantics.*

Proof. Read the octahedral coordinate of Definition 179.1. Its data are the named triangle faces, the comparison morphism histories between those faces, and the finite Cont rows witnessing the displayed composites.

Any use of the octahedral obligation must project through that coordinate. Thus a face comparison or composite can be cited only when the corresponding history and continuation row appears in the ledger.

If a purported octahedral datum is not in the displayed ledger, constructor inversion gives no packet coordinate from which to project it. Therefore the chapter exposes an octahedral boundary ledger, not an ambient octahedral oracle. □

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatOctahedralLedger boundary`

Theorem 179.10 (TriangulatedCat NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{TriangulatedCat}^{\uparrow}}$ *surface determined by Definition 179.1 and Definition 179.2 consists of the finite carrier rows, the componentwise classifier, carrier transport, the displayed octahedral ledger boundary, and the* Pkg *provenance row. It excludes host Verdier quotient semantics and octahedral data not logged in the packet.*

Proof. First project the carrier by Definition 179.3. This accounts for all dependency, additive, translation, distinguished-triangle, octahedral-ledger, hsame, Cont, and Pkg rows in the public surface.

Next apply Definition 179.4. The classifier is componentwise over those same rows, and its transport clauses repack the transported histories as another accepted carrier.

Finally apply Definition 179.9 to identify the octahedral part of the certificate. Since the boundary theorem permits only logged faces, comparison morphisms, and Cont witnesses, the public certificate has no remaining source for a host Verdier quotient or unlogged octahedral datum. □

Lean4 ✓ `BEDC.Derived.TriangulatedCatUp.TriangulatedCatFiniteCarrier obligation surface`

Closure status for $\mathsf{NameCert}_{\mathsf{TriangulatedCat}^{\uparrow}}$.

Constructive story: A triangulated-category packet is generated from finite dependency rows for $\mathsf{Cat}^{\uparrow}$ and $\mathsf{DerivedCat}^{\uparrow}$, additive and translation rows, distinguished-triangle rows, the logged octahedral faces, and the Cont/Pkg provenance that makes those rows visible at the BEDC boundary.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TriangulatedCat}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The scoped boundary binds the finite BHist carrier, the additive and shift rows, the distinguished-triangle rows, the octahedral ledger, the componentwise hsame classifier, the Cont rows, the Pkg provenance row, and the dependency rows for $\mathsf{Cat}^{\uparrow}$ and $\mathsf{DerivedCat}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TriangulatedCat}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.TriangulatedCatUp.TriangulatedCatPacketCarrier\_classifier\_stability`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close host Verdier quotient semantics, ambient triangulated-category equality, or octahedral data not logged in the displayed packet.

Upgrade path: No further paper-side theory closure upgrade remains for this chapter; formal bridge checking remains on the verification axis.

Chapter 180

A Concrete Naming Certificate for $\mathsf{HopfAlg}^{\uparrow}$

The Hopf-algebra interface $\mathsf{HopfAlg}^{\uparrow}$ packages a bialgebra carrier together with an antipode satisfying the convolution-inverse axiom. It depends on $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ (chapter 43) and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87).

180.1 Carrier definition

Definition 180.1 (HopfAlgUp BHist bialgebra carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *row* R *with multiplication ledger* μ_R *and unit ledger* η_R*, and fix a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *row* T *with tensor ledger* $\otimes_T$*. A concrete* $\mathsf{HopfAlg}^{\uparrow}$ *bialgebra carrier over* BHist *is the predicate*

$$\mathsf{HopfBialgCarrier}_{R,T}(h) \iff \exists a, t, m, c, u, e : \mathsf{BHist}.\ \mathsf{hsame}(h, a) \wedge \mathsf{RingCarrier}_R(a) \wedge \mathsf{TensorCarrier}_T(t) \wedge \mathsf{Cont}(\otimes_T, \mu_R, m$$

Here a *is the bialgebra row,* t *is the tensor-product row,* m *is the multiplication provenance row,* c *is the comultiplication provenance row,* u *is the unit ledger, and* e *is the counit ledger. The carrier is therefore anchored in* BHist *rows, with multiplication read through* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *and tensor/comultiplication provenance read through* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*.*

Definition 180.2 (HopfAlgUp antipode ledger classifier)**.** *For two concrete Hopf-algebra rows*

$$H = (a, t, s, u, e) \qquad \text{and} \qquad H' = (a', t', s', u', e')$$

over the same $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *sources, define*

$$H \sim_{\mathsf{HopfAlg}^{\uparrow}} H' \iff \mathsf{hsame}(a, a') \wedge \mathsf{hsame}(t, t') \wedge \mathsf{hsame}(s, s') \wedge \mathsf{hsame}(u, u') \wedge \mathsf{hsame}(e, e').$$

Thus the classifier compares the bialgebra row, the tensor-product row, the antipode row, the unit ledger, and the counit ledger by hsame*.*

180.2 The certificate

Theorem 180.3 (HopfAlgUp tensor-product row stability)**.** *Let* $H = (a, t, s, u, e)$ *be a concrete Hopf-algebra row satisfying Definition 180.1. If* $H \sim_{\mathsf{HopfAlg}^{\uparrow}} H'$ *with* $H' = (a', t', s', u', e')$*, then the tensor-product row of* H' *is again a valid* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *row for the transported bialgebra carrier. In particular, the multiplication and comultiplication provenance rows read by* Cont *from* t *transport to corresponding rows read from* t'*.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgBialgCarrier tensor product row stability`
Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfBialgCarrier tensor product row stability`

Proof. Unpack the concrete carrier. The witness exposes the bialgebra row, the tensor-product row, and the two Cont ledgers that read multiplication and comultiplication provenance from the tensor source.

The classifier hypothesis supplies $t\mathsf{hsame}t'$ and $a\mathsf{hsame}a'$. Transport the tensor carrier and the two continuation ledgers along these hsame comparisons, using the hsame stability field of $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ for the tensor row and continuation transport for the displayed Cont rows.

The resulting rows have the same ring and tensor sources as the original package, with endpoints replaced by their transported representatives. Hence t' remains the tensor-product row for the transported bialgebra carrier. □

Theorem 180.4 (HopfAlgUp antipode convolution-inverse obligation)**.** *Let $H = (a, t, s, u, e)$ satisfy the concrete carrier and classifier of Definition 180.1 and Definition 180.2. The antipode row s is admissible for* $\mathsf{HopfAlg}^{\uparrow}$ *exactly when there are two* BHist *ledger rows*

$$\mathsf{ConvLeft}(a, t, s, u, e) \qquad \textit{and} \qquad \mathsf{ConvRight}(a, t, s, u, e)$$

whose Cont *provenance composes the comultiplication row, the antipode row, the multiplication row, the unit ledger, and the counit ledger so that the two convolution composites land on the unit–counit endpoint.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfBialgCarrier antipode convolution inverse obligation`

Proof. Start from the carrier witness. It gives the bialgebra row a, the tensor row t, the multiplication provenance read through $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$, the comultiplication provenance read through $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, and the unit and counit ledgers.

For the left convolution row, compose the comultiplication continuation with the tensor row that applies s on the first component and the identity ledger on the second component. Then compose with the multiplication continuation and compare the result with the unit–counit ledger endpoint.

For the right convolution row, use the same continuation spine with s placed on the second component. The two displayed rows are the two constructive obligations; no extra carrier is required beyond the BHist ledgers already unpacked from the concrete package. □

Theorem 180.5 (HopfAlgUp NameCert obligation surface)**.** *The data of Definition 180.1, Definition 180.2, Definition 180.3, and Definition 180.4 form the concrete obligation surface for a* $\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$ *over* BHist*. The surface consists of the carrier, the* hsame *classifier, tensor-row stability, multiplication and comultiplication provenance through* Cont*, and the two antipode convolution-inverse ledger rows.*

Proof. The carrier and classifier provide the object rows and equality policy. Reflexivity, symmetry, and transitivity are inherited componentwise from hsame over the bialgebra row, tensor row, antipode row, unit ledger, and counit ledger.

Tensor-row stability supplies the transport rule needed by the certificate: replacing a representative by an hsame representative preserves the tensor source and the multiplication/comultiplication provenance read from it. The ring multiplication row is retained from $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$, and the tensor row is retained from $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$.

Finally, the antipode theorem packages the two convolution-inverse rows. These rows are exactly the Hopf-algebra-specific obligations beyond the bialgebra carrier, so the listed data are the $\mathsf{NameCert}_{\mathsf{HopfAlg}^\uparrow}$ obligation surface. □

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgBialgCarrier namecert obligation surface`

Lemma 180.6 (Two-step continuation middle cancellation)**.** *For histories* $c, m, s, s', L, L', q, q' : \mathsf{BHist}$*, assume*

$$\mathsf{Cont}(c, s, L) \wedge \mathsf{Cont}(L, m, q)$$

and

$$\mathsf{Cont}(c, s', L') \wedge \mathsf{Cont}(L', m, q').$$

If $\mathsf{hsame}(q, q')$*, then* $\mathsf{hsame}(s, s')$*.*

Proof. Apply the third cancellation clause of Definition 4.52 to the two continuation spines

$$c \xrightarrow{s} L \xrightarrow{m} q \qquad \text{and} \qquad c \xrightarrow{s'} L' \xrightarrow{m} q'.$$

The shared prefix is c, the shared suffix is m, and the endpoint comparison is the displayed $\mathsf{hsame}(q, q')$. The cancellation clause returns $\mathsf{hsame}(s, s')$. □

Theorem 180.7 (HopfAlgUp antipode uniqueness from convolution-inverse witnesses)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Ring}^\uparrow}$ *row* R *and a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^\uparrow}$ *row* T*. Let* $h : \mathsf{BHist}$ *satisfy* $\mathsf{HopfBialgCarrier}_{R,T}(h)$*, and let* $a, t, m, c, u, e : \mathsf{BHist}$ *be carrier rows exposed by Definition 180.1. Let* $s, s' : \mathsf{BHist}$ *be two antipode rows over these same carrier rows.*

Assume both s *and* s' *satisfy the full antipode obligation of Definition 180.4: each has a* ConvLeft *packet and a* ConvRight *packet landing on a unit–counit endpoint. Write the left packets as* L *and* L'*, and write their unit–counit endpoints as* q *and* q'*. Assume the endpoint packets are represented by*

$$\mathsf{Cont}(u, e, q) \qquad \textit{and} \qquad \mathsf{Cont}(u, e, q'),$$

and that the left convolution packets expose the continuation faces

$$\mathsf{Cont}(c, s, L) \wedge \mathsf{Cont}(L, m, q)$$

and

$$\mathsf{Cont}(c, s', L') \wedge \mathsf{Cont}(L', m, q').$$

Then

$$\mathsf{hsame}(s, s').$$

Consequently, for $H = (a, t, s, u, e)$ *and* $H' = (a, t, s', u, e)$*, the classifier of Definition 180.2 gives* $H \sim_{\mathsf{HopfAlg}^\uparrow} H'$*.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgAntipodeClassifier convolution inverse unique`

Proof. The two unit–counit endpoint rows have the same source u and the same tail e. Applying Definition 4.42 to $\mathsf{Cont}(u, e, q)$ and $\mathsf{Cont}(u, e, q')$, with reflexivity on u, e, and q, gives the endpoint comparison $\mathsf{hsame}(q, q')$.

Now apply Definition 180.6 to the two displayed left convolution spines. This yields $\mathsf{hsame}(s, s')$.

The right convolution packets certify that both rows are full two-sided antipode witnesses for $\mathsf{HopfAlg}^\uparrow$; uniqueness is already forced by the shared left convolution face and the common unit–counit endpoint. Since the bialgebra row, tensor row, unit ledger, and counit ledger are the same in H and H', Definition 180.2 then packages the componentwise comparison as $H \sim_{\mathsf{HopfAlg}^\uparrow} H'$. □

↪variant BEDC.Derived.HopfAlgUp.HopfAlgBialgCarrier antipode convolution inverse unique

Theorem 180.8 (HopfAlgUp antipode classifier transport)**.** *Let $H = (a, t, s, u, e)$ and $H' = (a', t', s', u', e')$ be two $\mathsf{HopfAlg}^{\uparrow}$ rows whose ring, tensor, unit, and counit sources are paired by the carrier classifier. Assume the left and right convolution packets of their antipode obligations land on unit–counit endpoints that are themselves classified. Then $\mathsf{hsame}(s, s')$, and the two five-tuples are related by the classifier of Definition 180.2.*

Proof. Start with the antipode obligation rows supplied by Definition 180.4. They expose left and right convolution packets for s and s', and by hypothesis their unit–counit endpoints are classified.

Transport the bialgebra, tensor, unit, and counit source rows along the given carrier classifier comparisons. This places the two left convolution spines in the same continuation shape, with classified source and endpoint rows.

Apply Definition 180.6 to the transported left convolution packets. The classified unit–counit endpoints give the endpoint comparison required by the cancellation lemma, so the middle antipode rows satisfy $\mathsf{hsame}(s, s')$.

The right convolution packets ensure that both middle rows are full two-sided antipode witnesses for the same transported Hopf algebra surface. Applying Definition 180.7 packages this middle-row comparison with the source comparisons.

The classifier of Definition 180.2 is exactly the five-coordinate ledger classifier for (a, t, s, u, e) and (a', t', s', u', e'), so these comparisons give $H \sim_{\mathsf{HopfAlg}^{\uparrow}} H'$. □

Lean4 ✓ BEDC.Derived.HopfAlgUp.HopfAlgAntipodeClassifier transport

Theorem 180.9 (HopfAlgUp bialgebra obligation inventory)**.** *The carrier obligations for the displayed $\mathsf{HopfAlg}^{\uparrow}$ certificate are exactly the $\mathsf{Ring}^{\uparrow}$ source row, the $\mathsf{TensorProduct}^{\uparrow}$ source row, the bialgebra row, the multiplication and comultiplication Cont rows, and the unit and counit rows carried by Definition 180.1.*

Proof. Project the carrier witness of Definition 180.1. It names the bialgebra row a, the tensor-product row t, the multiplication provenance m, the comultiplication provenance c, the unit ledger u, and the counit ledger e.

The source certificates are exactly the two rows cited by the definition: $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ supplies the ring source for multiplication and unit, and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ supplies the tensor source for tensor and comultiplication provenance. The stability theorem Definition 180.3 shows that these are the rows transported by the classifier, so no additional carrier obligation is present. □

Theorem 180.10 (HopfAlgUp antipode ledger obligation)**.** *The antipode obligations for the displayed $\mathsf{HopfAlg}^{\uparrow}$ certificate are exactly the two convolution-inverse ledger rows $\mathsf{ConvLeft}(a, t, s, u, e)$ and $\mathsf{ConvRight}(a, t, s, u, e)$ together with their unit-counit endpoint comparisons.*

Lean4 ✓ BEDC.Derived.HopfAlgUp.HopfAlgAntipodeClassifier ledger obligation

Proof. Start with Definition 180.2. The classifier places the antipode row s in the same five-coordinate ledger as the bialgebra, tensor, unit, and counit rows.

Apply Definition 180.4. It exposes precisely the left and right convolution packets and identifies their endpoint comparisons with the unit-counit ledger. The transport theorem Definition 180.8 then shows that classified antipode rows preserve those two packets, leaving no further antipode ledger obligation outside the two convolution faces. □

Theorem 180.11 (HopfAlgUp consumer boundary obligation)**.** *Any downstream consumer of the displayed* $\mathsf{HopfAlg}^{\uparrow}$ *certificate may project only the carrier row, the classifier row, tensor-row stability, antipode uniqueness and transport, and the* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *provenance rows.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgBialgCarrier consumer boundary obligation`

Proof. The carrier and provenance rows are those of Definition 180.1. The classifier row is Definition 180.2, and tensor stability is Definition 180.3.

For antipode information, a consumer can use only the two convolution-inverse rows of Definition 180.4, the uniqueness theorem Definition 180.7, and the transport theorem Definition 180.8. These rows exhaust the public boundary: bialgebra carrier data, classifier data, tensor-row transport, antipode uniqueness and transport, and the two source-certificate provenance rows. □

Theorem 180.12 (HopfAlgUp bialgebra source consumer readback)**.** *From the displayed* $\mathsf{HopfAlg}^{\uparrow}$ *carrier witness, a downstream consumer can read exactly the* $\mathsf{Ring}^{\uparrow}$ *source row, the* $\mathsf{TensorProduct}^{\uparrow}$ *source row, the bialgebra carrier row, the multiplication and comultiplication* Cont *rows, and the unit and counit rows. These are the source rows named by the carrier and no further algebra object is exported.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgBialgCarrier source consumer readback`

Proof. Project the carrier witness through Definition 180.1. Its source coordinates are the $\mathsf{Ring}^{\uparrow}$ and $\mathsf{TensorProduct}^{\uparrow}$ $\mathsf{NameCert}$ rows, and its operation coordinates are the multiplication, comultiplication, unit, and counit rows.

Use Definition 180.3 to read these rows through the classifier without changing the source certificates. The theorem identifies the tensor row and the bialgebra row as transported data rather than as new carrier choices.

Thus consumer readback is exhausted by the two source certificates, the bialgebra carrier, and the four operation-ledger rows. The carrier definition contains no additional public algebra row to project. □

Theorem 180.13 (HopfAlgUp antipode endpoint ledger exhaustion)**.** *The antipode obligation exposes only the two convolution packets* $\mathsf{ConvLeft}(a, t, s, u, e)$ *and* $\mathsf{ConvRight}(a, t, s, u, e)$ *together with their unit-counit endpoint comparisons. No further multiplication, comultiplication, tensor, or endpoint equality row is part of the antipode ledger.*

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgAntipodeClassifier endpoint ledger exhaustion`

Proof. Read the antipode ledger classifier from Definition 180.2. It places the antipode row inside the same endpoint ledger as the bialgebra, tensor, unit, and counit coordinates.

Apply Definition 180.10. The obligation statement exposes exactly the two convolution faces and their unit-counit endpoint comparisons.

Finally apply Definition 180.8. Transport preserves those packets and endpoint comparisons, so it cannot add an independent tensor row, operation row, or host equality witness to the antipode boundary. □

Theorem 180.14 (HopfAlgUp obligation public handoff)**.** *The public obligation handoff for downstream* $\mathsf{HopfAlg}^{\uparrow}$ *consumers is the package consisting of the bialgebra source-consumer readback of Definition 180.12, the antipode endpoint ledger exhaustion of Definition 180.13, and classifier transport through the displayed* hsame *rows.*

Proof. First collect the source and operation rows from Definition 180.12. This supplies the $\mathsf{Ring}^{\uparrow}$ row, the $\mathsf{TensorProduct}^{\uparrow}$ row, the bialgebra carrier, and the four operation-ledger rows.

Next attach the antipode rows from Definition 180.13. The only antipode data added to the handoff are the two convolution packets and their unit-counit endpoint comparisons.

Use Definition 180.8 and Definition 180.3 for classifier transport across these rows. Repacking the transported source, operation, and antipode inventories gives the public handoff surface, and the exhaustion clauses above rule out any additional consumer row. □

Closure status for $\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$.

Constructive story: A Hopf algebra is assembled from a displayed ring row and tensor-product row by continuing the tensor source into multiplication and comultiplication ledgers, then attaching unit, counit, and antipode histories to the same bialgebra endpoint. The carrier accepts exactly those BHist packages whose algebra row is carried by $\mathsf{Ring}^{\uparrow}$, whose tensor row is carried by $\mathsf{TensorProduct}^{\uparrow}$, and whose multiplication, comultiplication, unit, and counit rows are witnessed by Cont; an external algebra object or host tensor category is not part of the carrier. Two Hopf rows are classified componentwise by history-equality of the bialgebra row, tensor row, antipode row, unit ledger, and counit ledger, and antipode transport is further checked by the left and right convolution continuations landing on the same unit–counit endpoint. The source is the paired ring and tensor-product certificate surface, the pattern records bialgebra provenance plus the two convolution-inverse faces, and the ledger keeps multiplication, comultiplication, antipode, unit, counit, and package dependency rows visible. The five obligations hold because an admitted bialgebra row supplies habitation, componentwise hsame gives reflexivity, symmetry, and transitivity, and tensor-row stability plus convolution transport repack classified representatives as admitted Hopf rows. A package h lies in the signature gap of a $\mathsf{HopfAlg}^{\uparrow}$ token p when the source-domain accepts its ring and tensor rows, the signature relation pairs the bialgebra-and-antipode package with an answer package and evidence ledger, and the token-introduction relation names that answer as p; unfolded, this says that the multiplication, comultiplication, unit, counit, and two-sided antipode convolution witnesses are exactly the data named by p. The chapter registers this convolution-ledger construction under the name $\mathsf{HopfAlg}^{\uparrow}$; no standard Hopf algebra bridge, external tensor semantics, or independent antipode primitive is introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public handoff theorem exports the $\mathsf{Ring}^{\uparrow}$, $\mathsf{TensorProduct}^{\uparrow}$, bialgebra, antipode, unit, counit, BHist, Cont, hsame, and Pkg rows carried by the HopfAlgUp certificate surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$, axiomClean)

Bridge status: paperBridge

Not claimed: A standard bridge and full external Hopf-algebra theory are not claimed by this chapter.

Upgrade path: BridgeChecked status requires formal bridge-schema acceptance for the displayed HopfAlgUp surface.

Theorem 180.15 (HopfAlgUp antipode fixes the unit row)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *row* R *with multiplication ledger* μ_R *and unit ledger* η_R*, and fix a* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *row* T *with tensor ledger* $\otimes_T$*. Let* $h : \mathsf{BHist}$ *satisfy* $\mathsf{HopfBialgCarrier}_{R,T}(h)$*, and let*

$$a, t, m, c, u, e, s : \mathsf{BHist}$$

be the bialgebra row, tensor row, multiplication provenance row, comultiplication provenance row, unit ledger, counit ledger, and antipode row exposed by Definition 180.1 and Definition 180.2. Assume that s *satisfies the antipode obligation of Definition 180.4. Suppose the unit-row specialization of the left convolution packet exposes histories* $S_u, L_u, q_u : \mathsf{BHist}$ *with*

$$\mathsf{Cont}(u, s, S_u) \wedge \mathsf{Cont}(c, S_u, L_u) \wedge \mathsf{Cont}(L_u, m, q_u) \wedge \mathsf{Cont}(u, e, q_u),$$

and suppose the bialgebra unit row exposes the same unit–counit endpoint through the unit ledger:

$$\mathsf{Cont}(u, e, u).$$

Then the antipode endpoint on the unit row is classified with the unit row:

$$\mathsf{hsame}(S_u, u).$$

Consequently, if $H = (a, t, S_u, u, e)$ and $H_1 = (a, t, u, u, e)$ are the two five-coordinate Hopf rows obtained by replacing only the displayed antipode endpoint, then $H \sim_{\mathsf{HopfAlg}^\uparrow} H_1$ under the classifier of Definition 180.2.

Proof. The carrier witness supplies the unit ledger u and counit ledger e as the endpoint row of the bialgebra package. The antipode obligation supplies the two convolution-inverse packets; on the unit-row input, the displayed left packet is the continuation spine

$$u \xrightarrow{s} S_u \xrightarrow{c} L_u \xrightarrow{m} q_u,$$

with endpoint q_u classified as the unit–counit endpoint by the row $\mathsf{Cont}(u, e, q_u)$.

Compare this endpoint row with the bialgebra unit endpoint row $\mathsf{Cont}(u, e, u)$. Applying Definition 4.42 with reflexivity on the shared source u, on the shared tail e, and on the target representative gives

$$\mathsf{hsame}(q_u, u).$$

Thus the specialized convolution composite lands on the same endpoint as the unit row.

Now read the specialized convolution spine against the unit endpoint. The bialgebra unit specialization says that, on the unit input, the comultiplication and multiplication faces contribute no independent endpoint beyond the shared unit–counit row: the left convolution packet has the same outer source and terminal endpoint as the displayed unit row. Cancelling the common convolution context by the third clause of Definition 4.52, equivalently by the two-step cancellation form of Definition 180.6 after aligning the endpoint by $\mathsf{hsame}(q_u, u)$, identifies the middle endpoint selected by the antipode with the unit endpoint. Hence

$$\mathsf{hsame}(S_u, u).$$

For the final claim, the two Hopf rows have identical bialgebra row a, tensor row t, unit ledger u, and counit ledger e, and the antipode coordinates are related by the comparison just proved. The five-coordinate classifier in Definition 180.2 therefore gives $H \sim_{\mathsf{HopfAlg}^\uparrow} H_1$. □

Lean4 ✓ `BEDC.Derived.HopfAlgUp.HopfAlgAntipodeClassifier unit row fixed`

Chapter 181

A Concrete Naming Certificate for $\mathsf{MonoidalCat}^{\uparrow}$

The monoidal-category interface $\mathsf{MonoidalCat}^{\uparrow}$ packages a category with a tensor-product bifunctor, unit object, and coherent associator and unitor isomorphisms. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61).

181.1 Carrier definition

181.2 The certificate

Definition 181.1 (MonoidalCat singleton tensor instance)**.** *The singleton* BHist *monoidal-category instance uses the unary-continuation category of Definition 61.325 as its underlying* $\mathsf{Cat}^{\uparrow}$ *carrier. Its objects are carried unary histories, its displayed hom rows are* $\mathsf{CategoryHomCarrier}(a, b, f)$ *rows, and its tensor is continuation append:*

$$a \otimes b := \mathsf{append}(a, b), \qquad f \otimes g := \mathsf{append}(f, g).$$

The unit object is e*. The associator row from* $(x \otimes y) \otimes z$ *to* $x \otimes (y \otimes z)$ *and the left and right unitor rows from* $\mathsf{e} \otimes x$ *and* $x \otimes \mathsf{e}$ *to* x *are the* hsame *witnesses supplied by continuation associativity and the empty-continuation unit laws on the displayed* BHist *rows.*

Lean4 (definition) `BEDC.Derived.MonoidalCatUp.MonoidalCatSingletonTensor`

Theorem 181.2 (MonoidalCat singleton tensor carrier)**.** *In the singleton tensor instance of Definition 181.1, tensoring carried unary objects remains a carried unary object. If*

$$\mathsf{CategoryHomCarrier}(a, b, f)$$

and

$$\mathsf{CategoryHomCarrier}(c, d, g)$$

are displayed hom histories, then the tensor hom history $\mathsf{append}(f, g)$ *is carried by the same unary-continuation hom surface from* $\mathsf{append}(a, c)$ *to* $\mathsf{append}(b, d)$*.*

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton tensor carrier`

Proof. Unary object closure is the ordinary append closure for unary BHist rows.

For hom rows, first use the endpoint stability law package of Definition 61.326 to read both displayed morphisms as continuation tails over their endpoints. Then apply Definition 61.19 to the compatible tail rows after appending the source and target endpoints.

The resulting composite row has exactly the source $\mathsf{append}(a, c)$, target $\mathsf{append}(b, d)$, and displayed morphism $\mathsf{append}(f, g)$ required by the tensor carrier surface. □

Theorem 181.3 (MonoidalCat singleton tensor preserves identity homs)**.** *In the singleton tensor instance of Definition 181.1, let a and b be carried unary objects. The tensor of the identity hom histories $\mathsf{e} : a \to a$ and $\mathsf{e} : b \to b$ is classified as the identity hom on $a \otimes b$. Concretely,* $\mathsf{append}(\mathsf{e}, \mathsf{e})$ *is* hsame *to* e*, and the row gives*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(a, b), \mathsf{append}(a, b), \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton tensor identity hom`

Proof. The identity rows for a and b are the empty continuation rows supplied by Definition 61.325. Unary append closure gives the tensor object $\mathsf{append}(a, b)$ as a carried unary object.

Tensoring the two displayed identity histories gives $\mathsf{append}(\mathsf{e}, \mathsf{e})$. The empty-continuation unit laws of Definition 40.3 identify this displayed history with e by hsame.

Transport the identity row on $\mathsf{append}(a, b)$ along that hsame classifier row. The resulting displayed hom carrier is exactly $\mathsf{CategoryHomCarrier}(\mathsf{append}(a, b), \mathsf{append}(a, b), \mathsf{e})$, so the tensor preserves identity hom histories on the concrete singleton carrier. □

Theorem 181.4 (MonoidalCat singleton associator and unitors)**.** *For carried unary histories x, y, and z in the singleton tensor instance, the displayed histories $(x \otimes y) \otimes z$ and $x \otimes (y \otimes z)$ are related by* hsame*. The displayed histories $\mathsf{e} \otimes x$ and $x \otimes \mathsf{e}$ are each related to x by* hsame *on the same concrete* BHist *carrier.*

Proof. The associator row is continuation associativity applied to the three visible tails x, y, and z. Both bracketings reduce to the same iterated continuation history, so the classifier row is the corresponding hsame witness.

For the left unitor, use the left empty-continuation law to identify $\mathsf{append}(\mathsf{e}, x)$ with x. For the right unitor, use the right empty-continuation law to identify $\mathsf{append}(x, \mathsf{e})$ with x.

The category continuation-morphism tail theorems transport these three hsame rows through the displayed hom carrier, so the associator and both unitors live on the concrete unary-continuation category rather than on an external categorical carrier. □

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton associator unitors`

Theorem 181.5 (MonoidalCat singleton coherence laws)**.** *In the singleton tensor instance, the pentagon and triangle diagrams commute under the morphism classifier. For any carried unary histories appearing in either diagram, the two displayed paths have* hsame*-equal classifier rows because both paths reduce to the same iterated* Cont *tail.*

Proof. For the pentagon, expand each edge into the associator row of Definition 181.4. The two boundary paths are the two standard ways to reassociate a fourfold continuation tail, and the category fourfold associativity witness Definition 61.131 identifies their displayed histories by hsame.

For the triangle, expand the associator and the two unitor rows. The left path and the right path both normalize to the same twofold continuation tail after applying the empty-continuation unit laws.

Finally compose the classifier rows by transitivity of hsame. The displayed hom carrier is preserved along the comparison by the category stability law package, so the commuting diagrams are certified inside the BEDC morphism classifier. □

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton coherence laws`

Theorem 181.6 (MonoidalCat NameCert obligation surface)**.** *The singleton tensor instance assembles the following paper-side* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *obligation surface:*

1. *Traditional target: a monoidal category.*
2. *BEDC source:* $\mathsf{Cat}^{\uparrow}$, Cont, hsame, *and* CategoryHomCarrier.
3. *Carrier: unary* BHist *objects and continuation hom histories.*
4. *Classifier:* hsame *on displayed object and hom histories.*
5. *Stability: tensor carrier closure, identity-hom preservation, composition preservation, associator rows, unitor rows, pentagon coherence, and triangle coherence.*
6. *Ledger: tensor tails and the two coherence-path ledgers.*
7. *Core theorem list: Definition 181.2, Definition 181.3, Definition 181.7, Definition 181.4, Definition 181.5, and Definition 61.325.*
8. *Exactness: classifier equality of the displayed coherence paths.*
9. *Standard bridge: absent.*
10. *Status: paper-side obligation surface.*

Proof. The carrier and classifier fields are supplied by the unary-continuation category and its CategoryHomCarrier rows. The tensor field is the append operation in Definition 181.1.

The stability fields are discharged by Definition 181.2, Definition 181.3, Definition 181.7, and Definition 181.4. The coherence fields are discharged by Definition 181.5.

The ledger records only the displayed continuation tails and the two coherence paths. Exactness is the statement that the two paths in each coherence diagram are equal under hsame, and no standard external monoidal-category bridge is asserted here. □

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton semantic name certificate`

Theorem 181.7 (MonoidalCat singleton tensor preserves composition)**.** *In the singleton tensor instance of Definition 181.1, suppose*

$$\mathsf{CategoryHomCarrier}(a_0, a_1, f), \quad \mathsf{CategoryHomCarrier}(a_1, a_2, f'), \quad \mathsf{CategoryHomCarrier}(c_0, c_1, g), \quad \mathsf{CategoryHomCa}$$

are two composable pairs of displayed hom rows. Then the tensor composite and the tensor of component composites are both displayed hom rows from $\mathsf{append}(a_0, c_0)$ *to* $\mathsf{append}(a_2, c_2)$*, and their morphism classifiers agree:*

$$\begin{aligned}&\mathsf{CategoryHomCarrier}(\mathsf{append}(a_0, c_0), \mathsf{append}(a_2, c_2), \mathsf{append}(\mathsf{append}(f, g), \mathsf{append}(f', g'))),\\ &\mathsf{CategoryHomCarrier}(\mathsf{append}(a_0, c_0), \mathsf{append}(a_2, c_2), \mathsf{append}(\mathsf{append}(f, f'), \mathsf{append}(g, g'))),\\ &\quad \mathsf{hsame}(\mathsf{append}(\mathsf{append}(f, g), \mathsf{append}(f', g')), \mathsf{append}(\mathsf{append}(f, f'), \mathsf{append}(g, g'))).\end{aligned}$$

Equivalently, $(f \otimes g)$ *followed by* $(f' \otimes g')$ *is classifier-equal to* $(f' \circ f) \otimes (g' \circ g)$ *in the concrete singleton* $\mathsf{MonoidalCat}^{\uparrow}$ *certificate.*

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton tensor preserves composition`

Proof. By Definition 181.2, the tensor rows $\mathsf{append}(f, g)$ and $\mathsf{append}(f', g')$ are hom-carriers from $\mathsf{append}(a_0, c_0)$ to $\mathsf{append}(a_1, c_1)$ and from $\mathsf{append}(a_1, c_1)$ to $\mathsf{append}(a_2, c_2)$. Applying Definition 61.19 to these two tensor rows gives the first displayed carrier.

Applying Definition 61.19 to the pair f, f' gives the component composite $\mathsf{append}(f, f')$ from a_0 to a_2, and applying it to g, g' gives $\mathsf{append}(g, g')$ from c_0 to c_2. A second use of Definition 181.2 gives the second displayed carrier.

It remains to compare the displayed morphism histories. The four input hom-carrier rows expose unary membership of f, f', g, and g'. Hence Definition 9200.14, applied to the canonical append continuations for g followed by f' and for f' followed by g, gives

$$\mathsf{hsame}(\mathsf{append}(g, f'), \mathsf{append}(f', g)).$$

Repeated use of Definition 4.56 identifies the tensor composite with

$$\mathsf{append}(f, \mathsf{append}(\mathsf{append}(g, f'), g'))$$

and identifies the tensor of component composites with

$$\mathsf{append}(f, \mathsf{append}(\mathsf{append}(f', g), g')).$$

The reverse direction of Definition 4.51, with common left context f and common right context g', transports the middle comparison into the two displayed fourfold histories. Transitivity of hsame with the two associativity comparisons gives the required classifier equality. □

Theorem 181.8 (MonoidalCat singleton standard bridge)**.** *The singleton continuation tensor package of Definition 181.1, together with the tensor carrier row of Definition 181.2, the associator and unitor rows of Definition 181.4, the coherence rows of Definition 181.5, the semantic certificate of Definition 181.6, and the tensor composition row of Definition 181.7, determines the standard bridge rows for* $\mathsf{MonoidalCat}^{\uparrow}$ *on the singleton BEDC surface.*

The bridge reads objects as unary-history rows, morphisms as displayed unary-history hom rows, tensor as Cont *append, the unit as* e*, and equality as* hsame*. It exports exactly this singleton continuation package and no non-singleton monoidal category, host bifunctor, external object carrier, or ambient categorical coherence data.*

Proof. The carrier theorem supplies the object and morphism rows: carried unary histories remain carried after tensor append, and displayed hom histories tensor by appending their Cont tails.

The associator and unitor theorem supplies the structural comparison rows. The coherence theorem identifies the pentagon and triangle boundary paths by hsame, so the bridge has the standard coherence entries required for the singleton tensor surface.

The semantic certificate records the visible $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ carrier, classifier, stability, ledger, and exactness rows. The tensor-preserves-composition theorem supplies the bifunctorial composition row on the same displayed histories, while the identity-hom theorem supplies the identity row.

Thus every bridge entry is a row already present in the singleton continuation package: objects and morphisms are unary-history rows, tensor is Cont append, unit is e, and equality is hsame. Because no carrier coordinate names non-singleton objects or a host bifunctor, the bridge exports none of that data. □

Lean4 ✓ `BEDC.Derived.MonoidalCatUp.MonoidalCatUp StdBridge`

Theorem 181.9 (MonoidalCat singleton tensor consumer coverage)**.** *Every consumer read of the singleton tensor bridge of Definition 181.8 is one of the unary object rows, unary hom rows,* Cont *tensor rows,* e *unit rows,* hsame *associator, unitor, and coherence rows, identity-hom rows, composition-preservation rows, or the semantic* NameCert *ledger already listed for* $\mathsf{MonoidalCat}^{\uparrow}$*.*

The covered surface exports exactly the singleton continuation tensor package and no non-singleton object carrier, host bifunctor, external coherence object, or ambient monoidal-category structure.

Proof. Use Definition 181.2 for the unary object and hom rows and for tensor as continuation append. The identity-hom reads are the rows of Definition 181.3.

Use Definition 181.4 and Definition 181.5 for the associator, unitor, pentagon, and triangle rows. These rows are hsame comparisons over the same unary-history surface.

Use Definition 181.7 for the composition-preservation readers and Definition 181.6 for the semantic certificate ledger. The standard bridge of Definition 181.8 collects exactly these rows, so the listed families exhaust all consumer reads. □

Closure status for $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$**.**

Constructive story: A monoidal category at this seed level is the unary-continuation category with tensor given by appending the underlying histories: carried unary objects tensor to append(a, b), carried hom histories tensor to append(f, g), and the unit object is e. The carrier therefore accepts only the singleton tensor instance whose objects and morphisms are already admitted by the $\mathsf{Cat}^{\uparrow}$ continuation surface, while non-singleton monoidal categories and host bifunctor data remain outside the seed. Two displayed tensor rows are classified by the same history-equality used for the category object and hom rows; associator and unitor comparisons are the hsame witnesses supplied by continuation associativity and the empty-continuation laws, not an imported coherence theorem. The source is $\mathsf{Cat}^{\uparrow}$ over unary histories, the pattern records tensor closure, identity-hom preservation, composition preservation, associator, unitors, pentagon, and triangle rows, and the ledger keeps the tensor tails and the two coherence-path ledgers visible. Because e is carried, unary histories are closed under append, and hsame is an equivalence transported through the hom carrier, the five name-certificate obligations are obtained by the same componentwise carrier witness, reflexive/symmetric/transitive classifier, and closure under classified tensor representatives. A row h lies in the signature gap of a $\mathsf{MonoidalCat}^{\uparrow}$ token p when the source-domain accepts the unary category and tensor ledgers, the signature relation pairs the singleton tensor package with an answer package and evidence ledger, and the token-introduction relation names that answer as p; concretely, p encodes the continuation tensor together with its associator, unitor, and coherence rows. The chapter registers this singleton continuation tensor under the name $\mathsf{MonoidalCat}^{\uparrow}$ with a paper-side standard bridge whose rows are precisely unary objects, unary hom histories, Cont append tensor, e unit, and hsame equality; it does not register a general monoidal-category carrier.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature surface is the singleton standard bridge for $\mathsf{MonoidalCat}^{\uparrow}$: tensor carrier, identity-hom, tensor-composition, associator, unitor, coherence, semantic certificate, and singleton bridge rows over the CategoryUp continuation surface and the kernel Cont and hsame dependencies used by those rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.MonoidalCatUp.MonoidalCatSingleton\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: This chapter does not close an external standard model, host bifunctor data, or non-singleton monoidal categories.

Upgrade path: No further formal-axis upgrade is pending for the checked singleton continuation-tensor bridge.

Chapter 182

A Concrete Naming Certificate for $\mathsf{EnrichedCat}^{\uparrow}$

The enriched-category interface $\mathsf{EnrichedCat}^{\uparrow}$ packages a collection of objects with hom-objects valued in a fixed monoidal category, with composition and identity morphisms in that monoidal category. It depends on $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ (chapter 181) and $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61).

182.1 Carrier definition

Definition 182.1 (EnrichedCat BHist packet)**.** *An* $\mathsf{EnrichedCat}^{\uparrow}$ *carrier packet is the finite* BHist *tuple*

$$\mathcal{E} = (C_{\mathrm{obj}}, M_{\otimes}, H_{\mathrm{hom}}, H_{\mathrm{id}}, H_{\mathrm{comp}}, T_{\mathsf{hsame}}, P_{\mathsf{Pkg}}, R_{\mathsf{Cont}})$$

whose coordinates are, in order, the consumed $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *object boundary* C_{obj}*, the consumed* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *tensor boundary* $M_{\otimes}$*, the hom-object rows* H_{hom}*, the identity rows* H_{id}*, the composition rows* H_{comp}*, the componentwise* hsame *transport rows* T_{hsame}*, the* Pkg *provenance* P_{Pkg}*, and the finite* Cont *readbacks* R_{Cont}*.*

The carrier accepts exactly those packets for which the two consumed boundary coordinates are public certificate rows, every hom-object, identity, and composition coordinate is a displayed BHist *row over those boundaries, every transport coordinate is an* hsame *row between displayed coordinates, the provenance coordinate is a* Pkg *row for the same packet, and the readback coordinate is a finite* Cont *ledger for those rows.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatTasteGate single carrier alignment`

Theorem 182.2 (EnrichedCat hom-object carrier obligation)**.** *Every hom-object row used by the* $\mathsf{EnrichedCat}^{\uparrow}$ *certificate is a coordinate of the packet in Definition 182.1, with its object boundary read from the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *coordinate, its tensor boundary read from the consumed* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *coordinate, and its visible provenance and continuation reads carried by the same* Pkg *and* Cont *coordinates. No hom-object obligation is supplied by an implicit enriched-category carrier outside the displayed packet.*

Proof. Project the packet of Definition 182.1 to the H_{hom} coordinate. Its source and target object rows are read from C_{obj}, while its value object lies under the tensor boundary $M_{\otimes}$.

The visible provenance is the coordinate P_{Pkg}, and the permitted readbacks are exactly the finite routes in R_{Cont}. These are the same rows enumerated by Definition 182.4.

Repack the projected hom-object row with the same boundary, provenance, and readback coordinates. Classifier transport is supplied componentwise by Definition 182.5, and ledger exactness is supplied by Definition 182.6. □

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatSourceSurface hom object carrier obligation`

Theorem 182.3 (EnrichedCat tensor-composition scope)**.** *Every identity or composition row used by the* $\mathsf{EnrichedCat}^{\uparrow}$ *certificate is scoped by the packet in Definition 182.1: identities read the hom-object and tensor-unit rows, compositions read the two adjacent hom-object rows and the tensor-composition boundary, and all coherence, transport, provenance, and finite readback data are supplied by* T_{hsame}*,* P_{Pkg}*, and* R_{Cont}*. The scope does not include unlisted host-level enriched-category data.*

Proof. Project first to the identity coordinate H_{id}. The identity row uses the object boundary from C_{obj}, the hom-object row from H_{hom}, and the unit part of $M_{\otimes}$.

Project next to the composition coordinate H_{comp}. Its inputs are the adjacent hom-object rows and the tensor-composition part of $M_{\otimes}$, so the monoidal dependency is exactly the one described in Definition 182.7.

The component transport rows are then read from T_{hsame}, while provenance and finite ledgers are read from P_{Pkg} and R_{Cont}. Repacking these same coordinates gives the public certificate rows by Definition 182.4 and Definition 182.6. □

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatSourceSurface tensor composition scope`

182.2 The certificate

Theorem 182.4 (EnrichedCatUp source obligation)**.** *Every public source row of an* $\mathsf{EnrichedCat}^{\uparrow}$ *packet is one of the displayed* BHist *rows for the consumed* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *object boundary, the consumed* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *tensor boundary, the hom-object rows, the identity rows, the composition rows, the* hsame *transport rows, the* Pkg *provenance rows, and the finite* Cont *readback rows.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatCertificateSurface source obligation`

Proof. Unpack the packet as the named BHist tuple. The first projections are the two consumed certificates: the object boundary is the public boundary of $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$, and the tensor boundary is the public boundary of $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$.

The remaining projections are the enriched rows themselves. They record the hom-object assignment, the identity witnesses, composition witnesses, component hsame transports, package provenance, and the finite continuation readbacks.

Conversely, each displayed row is inserted into the packet by the corresponding constructor coordinate. Projection followed by repacking is judgmentally the same named tuple, so no further public source row can appear. □

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatSourceSurface source obligation`

Theorem 182.5 (EnrichedCatUp classifier transport obligation)**.** *The public classifier comparison for an* $\mathsf{EnrichedCat}^{\uparrow}$ *packet is the componentwise* hsame *transport of the object-boundary, tensor-boundary, hom-object, identity, composition, provenance, and continuation rows, and is not host equality of enriched categories.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatPublicRows classifier transport obligation`

Proof. Project the classifier comparison to each displayed row. On the consumed $\mathsf{NameCert}_{\mathsf{Cat}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{MonoidalCat}^\uparrow}$ boundaries, the comparison is exactly the already exported boundary hsame comparison.

For the enriched rows, transport is pointwise: hom-objects transport along the object boundary, identity and composition rows transport along the tensor boundary, and provenance and continuation rows transport by their named BHist coordinates.

Repack the transported coordinates into the public classifier row. The construction never compares host-level enriched categories; it compares only the displayed BHist rows and the hsame witnesses attached to them. □

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatSourceSurface classifier transport obligation`
Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatPublicPacket classifier transport obligation`

Theorem 182.6 (EnrichedCatUp ledger exactness obligation)**.** *Projection from an* $\mathsf{EnrichedCat}^\uparrow$ *certificate to its hom-object, identity, composition, tensor, provenance, and continuation ledger rows, followed by repacking those same rows in the displayed order, recovers exactly the public certificate ledger.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatPublicPacket ledger exactness obligation`

Proof. Start with the public certificate ledger and project the hom-object, identity, composition, tensor, Pkg, and Cont coordinates. These projections are the named coordinates of the certificate tuple.

Repacking uses those coordinates in the same order and with the same boundary certificates. The object and tensor rows are not recomputed; they are the consumed rows already present in the tuple.

Therefore the repacked ledger has the same projections as the original public ledger on every displayed coordinate. Since the certificate exposes no other ledger coordinate, the projection-and-repacking operation is exact. □

Theorem 182.7 (EnrichedCatUp monoidal-category boundary)**.** *The* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^\uparrow}$ *dependency of an* $\mathsf{EnrichedCat}^\uparrow$ *certificate is read only through tensor, unit, associator and unit-transport, and* Pkg *rows; no other monoidal-category host data is part of the public obligation surface.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatPublicPacket monoidal category boundary`

Proof. Inspect the monoidal dependency coordinates in the certificate tuple. The tensor and unit rows provide the objects used by the hom-object, identity, and composition entries.

The associator and unit-transport rows are the only coherence transports read by the enriched composition and identity rows. Provenance is recorded through the displayed Pkg coordinate attached to the consumed $\mathsf{NameCert}_{\mathsf{MonoidalCat}^\uparrow}$ packet.

All public reads of the monoidal dependency factor through these rows. Hence any two monoidal witnesses with the same displayed tensor, unit, coherence transport, and provenance rows are indistinguishable to the $\mathsf{EnrichedCat}^\uparrow$ certificate. □

Theorem 182.8 (EnrichedCatUp consumer readback boundary)**.** *A downstream* $\mathsf{Functor}^\uparrow$ *or* $\mathsf{NatTrans}^\uparrow$ *consumer of an* $\mathsf{EnrichedCat}^\uparrow$ *certificate reads only the displayed object, hom-object, identity, composition, transport, provenance, and finite* Cont *rows.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatSourceSurface consumer readback boundary`

Proof. Give the consumer its public readback map. By the source obligation, the map can project only from the displayed BHist tuple and its finite Cont readback rows.

The object and hom-object rows supply the source and target data for enriched functors. The identity, composition, and transport rows supply the compatibility witnesses read by functor and natural-transformation certificates.

Package provenance is available only through the Pkg rows, and finite continuations are available only through the listed Cont rows. Repacking these rows gives the same public readback packet, so the consumer boundary is exactly the displayed surface. □

Theorem 182.9 (EnrichedCat public packet source boundary)**.** *For an accepted* $\mathsf{EnrichedCat}^{\uparrow}$ *carrier, the public packet exposes exactly the consumed* $\mathsf{Cat}^{\uparrow}$ *object boundary, the consumed* $\mathsf{MonoidalCat}^{\uparrow}$ *tensor boundary, the hom-object rows, identity rows, composition rows, componentwise* hsame *transports,* Pkg *provenance, and finite* Cont *readbacks of Definition 182.1. Every* $\mathsf{Functor}^{\uparrow}$ *or* $\mathsf{NatTrans}^{\uparrow}$ *consumer factors its public read through these rows and through no additional host enriched-category datum.*

Lean4 ✓ `BEDC.Derived.EnrichedCatUp.EnrichedCatPublicPacket source boundary`

Proof. Start from the packet of Definition 182.1. Its first two coordinates are the consumed $\mathsf{Cat}^{\uparrow}$ and $\mathsf{MonoidalCat}^{\uparrow}$ boundaries, so the available source rows are constrained by Definition 182.4.

The remaining coordinates are the enriched rows themselves. Classifier movement is componentwise by Definition 182.5, and the monoidal dependency is the displayed tensor boundary isolated by Definition 182.7.

Finally apply Definition 182.8. It already identifies the $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ readback surface with the object, hom-object, identity, composition, transport, provenance, and finite continuation rows. Repacking those projections gives the same public packet, so every such consumer factors through exactly the listed boundary. □

Theorem 182.10 (EnrichedCat two-step composition reassociation)**.** *Let*

$$\mathcal{E} = (C_{\mathrm{obj}}, M_{\otimes}, H_{\mathrm{hom}}, H_{\mathrm{id}}, H_{\mathrm{comp}}, T_{\mathsf{hsame}}, P_{\mathsf{Pkg}}, R_{\mathsf{Cont}})$$

be an accepted $\mathsf{EnrichedCat}^{\uparrow}$ *carrier packet. Suppose* H_{hom} *contains three composable displayed hom-object rows*

$$H_{ab}, \quad H_{bc}, \quad H_{cd},$$

and suppose H_{comp} *contains the displayed composition rows needed for both two-step routes from these three rows to endpoint rows* L_{ad} *and* R_{ad}*. Thus the left route first composes* H_{cd} *with* H_{bc} *and then composes the result with* H_{ab}*, while the right route first composes* H_{bc} *with* H_{ab} *and then composes* H_{cd} *with the result.*

If the consumed $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *tensor boundary* $M_{\otimes}$ *supplies the associator row comparing the two tensor sources*

$$(H_{cd} \otimes H_{bc}) \otimes H_{ab} \quad \text{and} \quad H_{cd} \otimes (H_{bc} \otimes H_{ab}),$$

then L_{ad} *and* R_{ad} *are classified by the public* $\mathsf{EnrichedCat}^{\uparrow}$ *packet surface. The classifying comparison is a displayed* hsame *row read through* T_{hsame}*, with provenance in* P_{Pkg} *and finite readback in* R_{Cont}*; it uses no host-level enriched-category equality and no coherence datum outside the consumed* $\mathsf{MonoidalCat}^{\uparrow}$ *boundary.*

Proof. Unpack the accepted packet by Definition 182.1. The rows H_{ab}, H_{bc}, and H_{cd} are projected from H_{hom}, so their object boundary is read from C_{obj} and their tensor boundary is read from $M_{\otimes}$.

By Definition 182.3, each displayed composition row in the two routes is projected from H_{comp}. The left route uses the adjacent pair H_{cd}, H_{bc} and then the adjacent pair represented by that first composite together with H_{ab}. The right route uses the adjacent pair H_{bc}, H_{ab} and then the adjacent pair H_{cd} together with that first composite. In both cases the tensor-composition boundary is the same coordinate $M_{\otimes}$, and the route remains inside the displayed hom-object and composition rows of $\mathcal{E}$.

The only rebracketing needed to compare the two tensor sources is the associator row already exposed by the consumed $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ coordinate. By Definition 182.7, this associator is one of the public monoidal rows available to the enriched packet, not an additional host coherence theorem.

Transport the two-step composition source along that associator row. The component transport coordinate T_{hsame} carries the transported tensor source through the two displayed composition routes, so the resulting endpoint rows L_{ad} and R_{ad} are compared by a displayed hsame row. The provenance and finite continuation reads of this comparison are exactly the rows P_{Pkg} and R_{Cont} attached to the same packet.

Finally apply Definition 182.4 and Definition 182.5. They identify every public source and classifier row of the $\mathsf{EnrichedCat}^{\uparrow}$ certificate with one of the displayed BHist, hsame, Pkg, and Cont coordinates of $\mathcal{E}$. Repacking the transported endpoint comparison through those coordinates gives the public comparison between L_{ad} and R_{ad} on the same packet surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{EnrichedCat}^{\uparrow}}$.

Constructive story: An $\mathsf{EnrichedCat}^{\uparrow}$ packet is generated from a CategoryUp object boundary, a MonoidalCatUp tensor boundary, hom-object rows, identity rows, composition rows, componentwise hsame transport, Pkg provenance, and finite Cont readbacks. The classifier reads enriched structure only by projecting those finite BHist coordinates and transporting them componentwise; associativity and two-step composition are routed through the monoidal boundary already consumed by the packet. The ledger story is enrichment by visible dependency rows: hom objects, tensor composition, identity, reassociation, provenance, and readback remain attached to the same carrier, so no host-level enriched-category equality or off-packet coherence datum is introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{EnrichedCat}^{\uparrow}}$, seed)

Scope closed: This chapter binds the EnrichedCat BHist packet definition and the hom-object, tensor-composition, source, classifier-transport, ledger-exactness, monoidal-boundary, consumer-readback, public-source, and two-step-reassociation theorems for $\mathsf{EnrichedCat}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{EnrichedCat}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim host-level enriched-category equality, coherence data outside the consumed monoidal boundary, or an implicit enriched carrier beyond displayed rows.

Upgrade path: To reach obligationClosure, the existing checked theorem surfaces must be summarized into a formal closure target that records the full packet-level obligation assembly.

Chapter 183

A Concrete Naming Certificate for $\mathsf{Topos}^{\uparrow}$

The topos interface $\mathsf{Topos}^{\uparrow}$ packages a category with finite limits, exponentials, and a subobject classifier. It depends on $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ (chapter 61) and $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ (chapter 151), and is the substrate for sheaf-of-sets cohomology and internal logic.

183.1 Carrier definition

Definition 183.1 (Topos finite carrier)**.** *A* $\mathsf{Topos}^{\uparrow}$ *carrier is a finite* BHist *packet displaying a* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row, a* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *row, finite-limit rows, exponential rows, a subobject-classifier row, componentwise* hsame *comparisons,* Cont *rows connecting those structures to the public readback, and* Pkg *provenance for the category and sheaf sources. The carrier exports no ambient universe of sets, no host internal language, and no unlogged categorical object.*

Theorem 183.2 (Topos carrier obligation)**.** *Every accepted* $\mathsf{Topos}^{\uparrow}$ *packet is generated by the finite* BHist *carrier of Definition 183.1: its* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *row,* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *row, finite-limit rows, exponential rows, subobject-classifier row,* hsame *comparisons,* Cont *ledger, and* Pkg *provenance are all displayed. These are the only rows exported to downstream categorical or internal-logic consumers.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposFiniteCarrier obligation surface`

Proof. Project the carrier. It records the category and sheaf sources as explicit certificate rows and attaches the finite-limit, exponential, and subobject-classifier data to those sources.

The accepted classifier is componentwise over the displayed hsame rows. The continuation ledger connects each structural row to the public packet readback, while the package rows record source provenance.

Since the BHist packet has no ambient set universe or host internal-language coordinate, the carrier exports exactly the displayed finite rows. □

Theorem 183.3 (Topos finite-limit exponential scope)**.** *The finite-limit and exponential data of a* $\mathsf{Topos}^{\uparrow}$ *packet are read only from the displayed* BHist *rows, the* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *dependency row, the* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *dependency row, componentwise* hsame *transport, the* Cont *ledger, and* Pkg *provenance. The packet does not import an ambient complete category, external cartesian-closed structure, or host set-theoretic semantics.*

Proof. Read a finite-limit or exponential coordinate from the carrier. Its source is the displayed category row, with sheaf provenance available only through the named dependency certificate.

Transport is componentwise. The hsame rows move finite-limit, exponential, continuation, and provenance coordinates together without changing the packet shape.

Thus the finite-limit and exponential scope is exactly the displayed BEDC surface, not an ambient categorical universe. □

Lean4 ✓ `BEDC.Derived.ToposUp.ToposFiniteCarrier finite limit exponential scope`

183.2 The certificate

Theorem 183.4 (Topos subobject-classifier ledger exactness)**.** *Every subobject-classifier readback in an accepted* $\mathsf{Topos}^{\uparrow}$ *packet is determined by the displayed subobject-classifier row, finite-limit rows, exponential rows,* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *provenance rows, componentwise* hsame *transport, the* Cont *ledger, and* Pkg *data. It exposes no host truth-value object or unlogged internal predicate.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposSubobjectClassifierLedger exactness`

Proof. Project the subobject-classifier coordinate. It is stored as a finite row in the same packet as the finite-limit and exponential coordinates.

The dependency route is visible: the category and sheaf certificates provide provenance, while the continuation ledger carries the classifier row to the public readback. Componentwise hsame transport preserves this route.

No row in the carrier names a host truth-value object or external predicate semantics, so the subobject-classifier readback is exactly the displayed ledger entry. □

Theorem 183.5 (Topos subobject-classifier pullback boundary)**.** *Any pullback read of a displayed subobject-classifier row in a* $\mathsf{Topos}^{\uparrow}$ *packet factors only through the* $\mathsf{Cat}^{\uparrow}$ *site row, the* $\mathsf{Sheaf}^{\uparrow}$ *cover/gluing row, finite-limit rows, exponential rows, the displayed subobject-classifier row, componentwise* hsame*, finite* Cont*, and* Pkg *provenance. It exposes no host truth values, ambient set semantics, or unlogged predicate extensions.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposSubobjectClassifierLedger pullback boundary`
↪ variant `BEDC.Derived.ToposUp.ToposSubobjectClassifierLedger pullback boundary certificate`
↪ variant `BEDC.Derived.ToposUp.ToposFiniteCarrier subobject classifier pullback boundary`
↪ variant `BEDC.Derived.ToposUp.ToposSubobjectClassifier pullback boundary`

Proof. Start with Definition 183.3. It confines the structural part of any pullback request to the displayed category and sheaf source rows, finite-limit rows, exponential rows, componentwise transport, continuation, and package provenance.

Combine this with Definition 183.4. The classifier row itself is a displayed finite ledger entry in the same packet and carries no host truth-value object or external predicate semantics.

Repack the pullback request as one of the finite-limit rows already present in the carrier, with the displayed subobject-classifier row as its classified input. The repacking uses only the visible hsame, Cont, and Pkg routes, so no ambient set semantics or unlogged predicate extension is introduced. □

Theorem 183.6 (Topos site-sheaf classifier obligation)**.** *Any subobject-classifier readback in a* $\mathsf{Topos}^{\uparrow}$ *packet factors through the displayed* $\mathsf{Cat}^{\uparrow}$ *site row, the* $\mathsf{Sheaf}^{\uparrow}$ *cover/gluing row, finite-limit and exponential rows, componentwise* hsame*, finite* Cont*, and* Pkg *provenance. It exports no host truth-value object or ambient set semantics.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposFiniteCarrier site sheaf classifier obligation`

Proof. Project the carrier. The packet stores the subobject-classifier row together with the displayed category and sheaf source rows, so every classifier readback starts from those finite BHist coordinates.

Use Definition 183.3 for the structural categorical rows. The finite-limit and exponential data are already routed through the $\mathsf{Cat}^{\uparrow}$ and $\mathsf{Sheaf}^{\uparrow}$ dependencies, componentwise hsame, finite Cont, and Pkg provenance.

Use Definition 183.4 for the predicate-like classifier row. Repacking these dependency routes gives a finite BEDC obligation surface, and no remaining coordinate can supply a host truth-value object or ambient set semantics. □

Theorem 183.7 (Topos certificate boundary)**.** *Every downstream internal-logic consumer of* $\mathsf{Topos}^{\uparrow}$ *reads only the displayed finite-limit, exponential, subobject-classifier,* $\mathsf{NameCert}_{\mathsf{Cat}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and provenance rows of Definition 183.1. The certificate boundary excludes host set semantics, unlogged predicates, and any internal-language object not displayed in the packet.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposFiniteCarrier certificate boundary`
↪ variant `BEDC.Derived.ToposUp.ToposFiniteCarrier classified boundary transport`

Proof. Start from an internal-logic readback. The carrier obligation theorem confines it to the finite packet rows.

Use the finite-limit exponential theorem for the structural categorical coordinates and the subobject-classifier theorem for predicate-like readback. These account for the category and sheaf dependency rows, the continuation ledger, and the provenance data.

With no remaining coordinate for host semantics or an external internal-language object, the consumer can read only the displayed certificate rows. □

Theorem 183.8 (Topos NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Topos}^{\uparrow}}$ *fields determined by Definition 183.1 are exactly the displayed* $\mathsf{Cat}^{\uparrow}$ *and* $\mathsf{Sheaf}^{\uparrow}$ *source rows, finite-limit rows, exponential rows, subobject-classifier row, componentwise* hsame *transport, finite* Cont *ledger,* Pkg *provenance, and the consumer boundary of Definition 183.7. The obligation surface excludes host set semantics, an ambient universe, unlogged predicates, and any external internal language.*

Lean4 ✓ `BEDC.Derived.ToposUp.ToposFiniteCarrier namecert obligation surface`

Proof. Project the carrier obligation. It supplies the displayed $\mathsf{Cat}^{\uparrow}$ and $\mathsf{Sheaf}^{\uparrow}$ source rows, the finite-limit and exponential rows, the subobject-classifier row, componentwise hsame transport, finite Cont, and Pkg provenance.

Apply Definition 183.3. The structural reads remain inside the finite carrier rows and cannot import an ambient complete category, an external cartesian-closed structure, or host set-theoretic semantics.

Apply Definition 183.4 and Definition 183.5. The classifier readback is the displayed finite ledger entry, and pullback access to it factors only through the same $\mathsf{Cat}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, finite-limit, exponential, hsame, Cont, and Pkg routes.

Finally apply Definition 183.7. It exhausts downstream internal-logic reads by the listed certificate rows, leaving no coordinate for host set semantics, an ambient universe, unlogged predicates, or an external internal language. □

Theorem 183.9 (Topos public certificate export)**.** *Downstream internal-logic and sheaf consumers of* $\mathsf{Topos}^{\uparrow}$ *may read exactly the finite* BHist *packet rows listed in Definition 183.8: the* $\mathsf{Cat}^{\uparrow}$ *row, the* $\mathsf{Sheaf}^{\uparrow}$ *row, finite-limit rows, exponential rows, subobject-classifier row, componentwise* hsame*, finite* Cont*,* Pkg *provenance, and the displayed provenance rows.*

The public certificate exports no host set semantics, ambient universe, unlogged predicate, or external internal-language object.

Proof. Start with Definition 183.2. It places every consumer read inside the displayed finite BHist packet with the category, sheaf, finite-limit, exponential, subobject-classifier, classifier, continuation, and package rows.

Apply Definition 183.3 for the structural rows, and apply Definition 183.4 for the predicate-like row. The pullback boundary of Definition 183.5 keeps classifier access on the same finite ledger.

Finally use Definition 183.7 and Definition 183.8. Together they repack the obligation surface as the public certificate export and leave no coordinate for host set semantics, an ambient universe, an unlogged predicate, or an external internal-language object. □

Closure status for $\mathsf{NameCert}_{\mathsf{Topos}^{\uparrow}}$**.**

Constructive story: The topos packet is a finite BHist carrier over displayed $\mathsf{Cat}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, finite-limit, exponential, subobject-classifier, classifier, continuation, and package rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Topos}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface closes the displayed $\mathsf{Cat}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, finite-limit, exponential, subobject-classifier, BHist, hsame, Cont, Pkg, provenance, and consumer-boundary rows of the topos packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Topos}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ToposUp.ToposFiniteCarrier\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host set semantics, full internal-language semantics, ambient universe assumptions, or a standard bridge.

Upgrade path: The paper-side mature treatment is closed by the displayed carrier, classifier, public export, and consumer-boundary rows; the remaining work is bridge checking.

Chapter 184

A Concrete Naming Certificate for $\mathsf{ProbSpace}^{\uparrow}$

The probability-space interface $\mathsf{ProbSpace}^{\uparrow}$ packages a measure space whose total measure is the unit. It depends on $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92) and $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$ (chapter 38).

184.1 Carrier definition

184.2 The certificate

Theorem 184.1 (ProbSpace complement mass additivity)**.** *For a* $\mathsf{ProbSpace}^{\uparrow}$ *carrier as in section 184.1, write* Ω *for its total event,* $\mathcal{A}$ *for the designated* σ*-algebra inherited from the underlying* $\mathsf{Measure}^{\uparrow}$ *carrier,* μ *for its* $\mathsf{Real}^{\uparrow}$*-valued measure map,* 1_R *for the probability unit selected by the* $\mathsf{ProbSpace}^{\uparrow}$ *total-mass row, and* $x \sim_R y$ *for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9. Let* $A, A^{\complement} \in \mathcal{A}$ *be disjoint measurable events whose measurable binary union is the total event* Ω*. Suppose* $\varnothing \in \mathcal{A}$*, the underlying* $\mathsf{Measure}^{\uparrow}$ *certificate supplies* σ*-additivity for every pairwise-disjoint measurable sequence, classifier-stable head-tail readback and pointwise classifier stability for the resulting countable* $\mathsf{Real}^{\uparrow}$ *sums, and the target* $\mathsf{Real}^{\uparrow}$ *addition is carried by its additive* $\mathsf{AbGroup}^{\uparrow}$ *row with zero* 0_R*. If the* $\mathsf{ProbSpace}^{\uparrow}$ *total-mass row gives*

$$\mu(\Omega) \sim_R 1_R,$$

then

$$\mu(A) + \mu(A^{\complement}) \sim_R 1_R.$$

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceComplementMass additive readback`

Proof. Let $U := A \cup A^{\complement}$ be the measurable binary union supplied by the σ-algebra row. By hypothesis, $U = \Omega$. Applying Definition 92.26 to the disjoint pair $A, A^{\complement}$ gives

$$\mu(U) \sim_R \mu(A) + \mu(A^{\complement}).$$

Reading U as Ω gives

$$\mu(\Omega) \sim_R \mu(A) + \mu(A^{\complement}).$$

The probability-space total-mass row gives

$$\mu(\Omega) \sim_R 1_R.$$

The classifier $\sim_R$ is the $\mathsf{Real}^\uparrow$ classifier, so its symmetry and transitivity fields compose these two comparisons. Symmetry of the finite-additivity comparison gives

$$\mu(A) + \mu(A^{\complement}) \sim_R \mu(\Omega),$$

and transitivity with the total-mass comparison yields

$$\mu(A) + \mu(A^{\complement}) \sim_R 1_R.$$

□

Theorem 184.2 (ProbSpace complement mass as one minus event mass)**.** *For a* $\mathsf{ProbSpace}^\uparrow$ *carrier as in section 184.1, write* Ω *for its total event,* $\mathcal{A}$ *for the designated* σ*-algebra inherited from the underlying* $\mathsf{Measure}^\uparrow$ *carrier,* μ *for its* $\mathsf{Real}^\uparrow$*-valued measure map,* 1_R *for the probability unit selected by the* $\mathsf{ProbSpace}^\uparrow$ *total-mass row, and* $x \sim_R y$ *for the* $\mathsf{Real}^\uparrow$ *classifier of Definition 38.9. Let* $A, A^{\complement} \in \mathcal{A}$ *be disjoint measurable events whose measurable binary union is the total event* Ω*. Suppose* $\varnothing \in \mathcal{A}$*, the underlying* $\mathsf{Measure}^\uparrow$ *certificate supplies* σ*-additivity for every pairwise-disjoint measurable sequence, classifier-stable head-tail readback and pointwise classifier stability for the resulting countable* $\mathsf{Real}^\uparrow$ *sums, and the target* $\mathsf{Real}^\uparrow$ *addition is carried by its additive* $\mathsf{AbGroup}^\uparrow$ *row with zero* 0_R *and inverse operation* $-$*. If the* $\mathsf{ProbSpace}^\uparrow$ *total-mass row gives*

$$\mu(\Omega) \sim_R 1_R,$$

then

$$\mu(A^{\complement}) \sim_R 1_R + (-\mu(A)).$$

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceComplementMass right solution`
↪ variant `BEDC.Derived.ProbSpaceUp.ProbSpaceComplementMass one minus singleton`

Proof. By Definition 184.1 applied to the displayed pair and these hypotheses,

$$\mu(A) + \mu(A^{\complement}) \sim_R 1_R.$$

The additive $\mathsf{AbGroup}^\uparrow$ row of Definition 42.1 contains the same carrier classifier $\sim_R$, the same addition $+$, the zero 0_R, the inverse operation $-$, addition congruence, and commutativity. By Definition 42.33, omitting the commutativity field leaves a $\mathsf{Group}^\uparrow$ row for the same data.

Use the commutativity field to exchange the two summands:

$$\mu(A^{\complement}) + \mu(A) \sim_R \mu(A) + \mu(A^{\complement}).$$

Transitivity with the complement-additivity comparison gives the right-multiplication equation

$$\mu(A^{\complement}) + \mu(A) \sim_R 1_R.$$

Now read Definition 41.68 in the retained additive group, with multiplication written as $+$, inverse written as $-$, $x = \mu(A^{\complement})$, $a = \mu(A)$, and $b = 1_R$. It solves the displayed equation as

$$\mu(A^{\complement}) \sim_R 1_R + (-\mu(A)).$$

□

Theorem 184.3 (ProbSpace monotone event bounds)**.** *For a* $\mathsf{ProbSpace}^{\uparrow}$ *carrier obtained from the probability substrate of Definition 92.71, write* Ω *for its total event,* $\mathcal{A}$ *for the displayed measurable-event family inherited from the underlying* $\mathsf{Measure}^{\uparrow}$ *carrier,* μ *for its* $\mathsf{Real}^{\uparrow}$*-valued measure map,* 1_R *for the endpoint selected by the total-mass row, and* $x \sim_R y$ *for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9. Let* $A, B \in \mathcal{A}$ *be displayed events in the same carried fiber, and suppose the public event readback displays*

$$A \subseteq B \subseteq \Omega.$$

Assume the inherited complement/relative-difference rows give the two measurable decompositions required by Definition 92.99, and that the target RealAlgOrder order row is stable under $\sim_R$ *and transitive. If the total-mass row gives*

$$\mu(\Omega) \sim_R 1_R,$$

then

$$\mu(A) \leq_R \mu(B), \qquad \mu(B) \leq_R 1_R, \qquad \mu(A) \leq_R 1_R.$$

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceMonotoneEvent bounds`

Proof. By Definition 92.71, the $\mathsf{ProbSpace}^{\uparrow}$ consumer reads the same displayed measurable events, relative-difference rows, finite-additivity rows, nonnegative value rows, and RealAlgOrder additive order rows as the underlying $\mathsf{Measure}^{\uparrow}$ package, with the total-event row and unit endpoint added by the probability surface. The total-mass comparison is the normalization row isolated in Definition 92.59.

Apply the inherited complement/relative-difference row of Definition 92.16 to the displayed inclusion $A \subseteq B$. It supplies a measurable event $B \setminus A$, disjointness from A, and a binary-union readback classifying $A \cup (B \setminus A)$ as B. These are exactly the decomposition inputs for Definition 92.99, so the inherited MeasureUp monotonicity row gives

$$\mu(A) \leq_R \mu(B).$$

Apply the same row to the displayed inclusion $B \subseteq \Omega$. It supplies $\Omega \setminus B$ and a disjoint decomposition of Ω with first summand B. A second application of Definition 92.99 gives

$$\mu(B) \leq_R \mu(\Omega).$$

The total-mass row gives $\mu(\Omega) \sim_R 1_R$. Stability of the RealAlgOrder order row under the $\mathsf{Real}^{\uparrow}$ classifier transports the right endpoint of the last comparison across this classifier equality, yielding

$$\mu(B) \leq_R 1_R.$$

Finally, transitivity of the same order row composes $\mu(A) \leq_R \mu(B)$ with $\mu(B) \leq_R 1_R$, and gives

$$\mu(A) \leq_R 1_R.$$

□

Definition 184.4 (ProbSpace public event packet)**.** *For a* $\mathsf{ProbSpace}^{\uparrow}$ *carrier obtained from the probability substrate of Definition 92.71, the public event packet is the tuple whose carrier entries are the* $\mathsf{Measure}^{\uparrow}$ *measurable-event family* $\mathcal{A}$*, the total event* Ω*, the* $\mathsf{Real}^{\uparrow}$*-valued measure map* μ*, and the selected endpoint* 1_R*. Its classifier entries are the displayed measurable-event readback classifier inherited from* $\mathsf{Measure}^{\uparrow}$*, the* $\mathsf{Real}^{\uparrow}$ *classifier* $\sim_R$*, the RealAlgOrder comparison row* $\leq_R$*, and the classifier-stability fields for addition, order, complement, and relative difference. Its ledger*

entries are the underlying BHist *histories, the carried package row* Pkg*, the* $\mathsf{NameCert}_{\mathsf{Measure}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Real}^\uparrow}$ *rows read by the probability substrate, and the* $\mathsf{NameCert}_{\mathsf{ProbSpace}^\uparrow}$ *row that records the total-mass comparison*

$$\mu(\Omega) \sim_R 1_R.$$

The packet is public when these entries are exposed as named BEDC rows, with no appeal to a host probability-space axiom outside the displayed BHist*,* Pkg*, and* NameCert *ledger.*

Lean4 (definition) `BEDC.Derived.ProbSpaceUp.ProbSpacePublicEventPacket`

Theorem 184.5 (ProbSpace total event normalization row)**.** *For the public event packet of Definition 184.4, the displayed total-mass comparison*

$$\mu(\Omega) \sim_R 1_R$$

is exported as a $\mathsf{ProbSpace}^\uparrow$ *BEDC row. It is a row of the carried certificate surface, not an assertion that the ambient host theory supplies probability normalization for arbitrary outside measures.*

Proof. Project the total-mass entry from the $\mathsf{NameCert}_{\mathsf{ProbSpace}^\uparrow}$ ledger in Definition 184.4. The projected row has left endpoint $\mu(\Omega)$, right endpoint 1_R, and classifier $\sim_R$.

The classifier is the same $\mathsf{Real}^\uparrow$ classifier used in Definition 38.9. Hence the row is read as the BEDC comparison $\mu(\Omega) \sim_R 1_R$ inside the carried package, and no host normalization principle is introduced. □

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpacePublicEventPacket normalization bounds`

Theorem 184.6 (ProbSpace event classifier transport row)**.** *For the public event packet of Definition 184.4, measurable-event readback transport together with* $\mathsf{Real}^\uparrow$ *classifier transport preserves the measure endpoint, the complement packet, and the relative-difference rows used by Definition 184.3. In particular, if displayed events A and B are transported along the inherited event readback classifier and their measured endpoints are transported along $\sim_R$, then the rows presenting $A^\complement$, $B \setminus A$, $\mu(A)$, $\mu(B)$, $\mu(A^\complement)$, and $\mu(B \setminus A)$ remain rows of the same public packet.*

Proof. Start with the MeasureUp complement and relative-difference row of Definition 92.16. It is one of the inherited entries of the public event packet, so event readback transport keeps the displayed complement and relative-difference events in the same measurable-event family $\mathcal{A}$.

The measured endpoints are carried by the $\mathsf{Real}^\uparrow$-valued measure map μ. Apply the same $\mathsf{Real}^\uparrow$ classifier transport used in Definition 184.3; it transports endpoint comparisons without changing the named packet entries.

Combining these two transports preserves the complement packet, the relative-difference packet, and the RealAlgOrder rows used for monotonicity. Thus the transported rows remain available on the public $\mathsf{ProbSpace}^\uparrow$ surface. □

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpacePublicEventPacket transport rows`

Theorem 184.7 (ProbSpace public certificate export)**.** *The public event packet of Definition 184.4 exports the probability-space certificate surface* $\mathsf{NameCert}_{\mathsf{ProbSpace}^\uparrow}$*. The exported surface contains the complement-mass additivity row of Definition 184.1, the one-minus complement row of Definition 184.2, the monotone event-bounds row of Definition 184.3, the total event normalization row of Definition 184.5, and the event classifier transport row of Definition 184.6. Consequently, downstream* $\mathsf{RandomVar}^\uparrow$*,* $\mathsf{Distribution}^\uparrow$*,* $\mathsf{Independence}^\uparrow$*, and* $\mathsf{CondExp}^\uparrow$ *objects may cite this single* $\mathsf{NameCert}_{\mathsf{ProbSpace}^\uparrow}$ *surface for probability-space rows rather than reconstructing those rows from separate consequences.*

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpacePublicEventPacket public certificate export`

Proof. The packet already carries the $\mathsf{Measure}^{\uparrow}$ measurable-event family, complement and relative-difference rows, the $\mathsf{Real}^{\uparrow}$ classifier and order rows, the total event, the measure map, and the unit endpoint. By Definition 184.5, its total-mass comparison is a named certificate row.

Add the three scoped consequences already proved in this section. The complement-mass additivity row comes from Definition 184.1; the one-minus row comes from Definition 184.2; and the monotone event-bounds row comes from Definition 184.3.

It remains to make these rows stable under the event and endpoint classifiers read by downstream objects. This is exactly Definition 184.6, so the rows assemble into one public $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ surface. □

Theorem 184.8 (ProbSpace MeasureUp dependency route)**.** *Every public* $\mathsf{ProbSpace}^{\uparrow}$ *read that consumes a probability-specific event bound first exposes the underlying* $\mathsf{Measure}^{\uparrow}$ *surface of chapter 92. Concretely, the consumer must read the measurable-event family* $\mathcal{A}$*, the total event* Ω*, the* $\mathsf{Real}^{\uparrow}$*-valued measure row* μ*, the complement and relative-difference rows used by Definition 184.1 and Definition 184.3, and the total-mass normalization row of Definition 184.5 before it may consume the public certificate export of Definition 184.7.*

Proof. Start from the public event packet of Definition 184.4. Its first carrier entries are the $\mathsf{Measure}^{\uparrow}$ measurable-event family, total event, measure row, complement and relative-difference rows, event classifier transport, and $\mathsf{Real}^{\uparrow}$ endpoint classifier. These are inherited rows, not probability-specific consequences.

The probability surface adds the unit endpoint and the total-mass normalization row. By Definition 184.5, that row is the displayed comparison $\mu(\Omega) \sim_R 1_R$ inside the carried packet.

Now read any event bound through Definition 184.7. The exported complement, one-minus, and monotone-bound rows cite the inherited complement and relative-difference rows together with the normalization row. Therefore a downstream $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Distribution}^{\uparrow}$, $\mathsf{Independence}^{\uparrow}$, or $\mathsf{CondExp}^{\uparrow}$ consumer reaches probability-specific bounds only after the $\mathsf{Measure}^{\uparrow}$ event surface and total-mass row have already been exposed. □

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceMeasureDependencyRoute`

Closure status for $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$**.**

Constructive story: A probability space is obtained by taking a carried $\mathsf{Measure}^{\uparrow}$ packet, keeping its measurable-event family $\mathcal{A}$, total event Ω, and $\mathsf{Real}^{\uparrow}$-valued measure row μ, and then adding the displayed normalization row that classifies $\mu(\Omega)$ with the selected unit endpoint 1_R. The carrier admits only those event packets whose measure, complement, relative-difference, order, and additive rows are already visible through the $\mathsf{Measure}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{AbGroup}^{\uparrow}$ surfaces; two packets are the same when the inherited event readback classifier and the $\mathsf{Real}^{\uparrow}$ classifier transport all measured endpoints, order comparisons, complements, and differences to matching rows. The source therefore covers the public event packet, the pattern records total-mass normalization, complement additivity, one-minus readback, and monotone bounds, and the ledger keeps the raw BHist histories, Pkg provenance, and consumed NameCert rows aligned with the visible probability rows. Since the underlying measure and real classifiers are equivalence relations and the transported event packet keeps the same carrier entries, an admitted normalized packet supplies the nonempty witness, reflexive, symmetric, and transitive classifier comparisons, and carrier closure under classifier replacement. A history packet h lies in the signature gap of a $\mathsf{ProbSpace}^{\uparrow}$ token p when the source-domain accepts the displayed event-and-measure packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; unfolded, this says that h is exactly the normalized MeasureUp packet whose total event has mass 1_R, with the same complement, difference, and order rows that p exposes. The paper bridge is conservative: it reads the ordinary probability-space surface only through the displayed event classifier and $\mathsf{Real}^{\uparrow}$ endpoint comparisons, never through a host probability-space axiom. The chapter registers this normalized-measure construction under the name $\mathsf{ProbSpace}^{\uparrow}$; probability is the MeasureUp ledger plus one total-mass row, with no independent random-variable, distribution, conditional-expectation, or standard-space primitive introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public packet of Definition 184.7 exports the MeasureUp event rows, RealUp classifier and order transport, AbGroupUp additive inverse rows, BHist histories, hsame transport, Pkg provenance, and NameCert ledger rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{ProbSpace}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.ProbSpaceUp.ProbSpaceMonotoneEvent\_bounds`

Bridge status: paperBridge

Not claimed: This obligation packet does not close random variables, distributions, independence, conditional expectation, martingales, standard probability spaces, or any standard bridge.

Upgrade path: No further theory-axis upgrade remains; standard bridge checking remains a separate formal-axis matter.

Obligation binders invoked by the following definition.

1. **closure: RESOLVED.** The displayed binary-union, intersection, and relative-difference event rows are the finite-event closure rows of the Measure$^\uparrow$ surface, specifically the finite disjoint event envelope of Chapter 94.15 and the event-value closure surface of Chapter 94.16.

2. **coverage: RESOLVED.** The outside-piece decomposition is the public relative-difference coverage row of Theorem 94.100, read through the same event classifier rather than through host event equality.

3. **bridge: RESOLVED.** The ProbSpace$^\uparrow$ consumer inherits the finite Measure$^\uparrow$ event surface by the probability-substrate row of Theorem 94.70.

Definition 184.9 (Binary cover-difference ledger)**.** *Let P be a* ProbSpace$^\uparrow$ *carrier obtained from the probability substrate of a* Measure$^\uparrow$ *carrier. Write $\mathcal{A}$ for the displayed measurable-event family inherited from the underlying* Measure$^\uparrow$ *carrier, write μ for the* $\mathsf{Real}^\uparrow$*-valued measure map, and write $E \sim_{\mathcal{A}} F$ for the public measurable-event classifier. For displayed events $A, B \in \mathcal{A}$, a binary cover-difference ledger for (A, B) consists of displayed events*

$$U, I, D \in \mathcal{A}$$

and public rows saying that U is the displayed binary union of A and B, I is the displayed binary intersection of A and B, and D is the displayed outside-A part of B, together with the two disjoint cover readbacks

$$A \perp D, \qquad A \cup D \sim_{\mathcal{A}} U,$$

and

$$I \perp D, \qquad I \cup D \sim_{\mathcal{A}} B.$$

The ledger is a BEDC *event-surface object: it records measurable closure, disjointness, and classifier readback rows, and it does not add host set subtraction or quotient equality of events.*

Obligation binders invoked by the following theorem.

1. **closure: RESOLVED.** The measurable union and value-transport steps are supplied by the Measure$^\uparrow$ finite disjoint event envelope of Chapter 94.15, the event-value closure surface of Chapter 94.16, and the finite disjoint-union additivity row of Theorem 94.26.

2. **coverage: RESOLVED.** The two cover decompositions consumed in the proof are exactly the two cover rows packaged in Definition 184.9, whose outside-piece source is the relative-difference disjoint decomposition of Theorem 94.100.

3. **bridge: RESOLVED.** The use of these Measure$^\uparrow$ rows inside a ProbSpace$^\uparrow$ carrier is discharged by Theorem 94.70, which states that the probability consumer adds only the total-event and unit-mass rows on top of the inherited measure substrate.

Theorem 184.10 (ProbSpace binary inclusion-exclusion identity)**.** *Let P be a* ProbSpace$^{\uparrow}$ *carrier obtained from the probability substrate of a* Measure$^{\uparrow}$ *carrier. Write $\mathcal{A}$ for its displayed measurable-event family, write μ for its* $\mathsf{Real}^{\uparrow}$*-valued measure map, and write $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier. Let $A, B \in \mathcal{A}$ be displayed events in one carried fiber. Suppose that (A, B) has a binary cover-difference ledger with displayed events U, I, D in the sense of Definition 184.9. Suppose also that the finite disjoint-union additivity row applies to the disjoint pairs (A, D) and (I, D), and that the target* $\mathsf{Real}^{\uparrow}$ *addition is carried by its additive* $\mathsf{AbGroup}^{\uparrow}$ *row. Then*

$$\mu(U) + \mu(I) \sim_R \mu(A) + \mu(B).$$

Consequently, when the public notation $A \cup B$ names the displayed event U and the public notation $A \cap B$ names the displayed event I, one obtains

$$\mu(A \cup B) + \mu(A \cap B) \sim_R \mu(A) + \mu(B).$$

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceBinaryCoverDifferenceLedger inclusion exclusion identity`

Proof. The first disjoint cover row in the ledger gives $A \perp D$ and

$$A \cup D \sim_{\mathcal{A}} U.$$

Apply the finite disjoint-union additivity row to the displayed disjoint pair (A, D). This gives

$$\mu(A \cup D) \sim_R \mu(A) + \mu(D).$$

The event-value transport row carries the event classifier comparison $A \cup D \sim_{\mathcal{A}} U$ to the $\mathsf{Real}^{\uparrow}$ endpoint classifier. Composing that transport with the displayed finite-additivity comparison gives

$$\mu(U) \sim_R \mu(A) + \mu(D).$$

The second disjoint cover row in the ledger gives $I \perp D$ and

$$I \cup D \sim_{\mathcal{A}} B.$$

Apply the same finite disjoint-union additivity row to the displayed disjoint pair (I, D). This gives

$$\mu(I \cup D) \sim_R \mu(I) + \mu(D).$$

Transporting the left endpoint through $I \cup D \sim_{\mathcal{A}} B$ and composing in the $\mathsf{Real}^{\uparrow}$ classifier gives

$$\mu(B) \sim_R \mu(I) + \mu(D).$$

Now compute in the additive $\mathsf{AbGroup}^{\uparrow}$ row carried by the target $\mathsf{Real}^{\uparrow}$ endpoint surface. Addition congruence applied to the comparison

$$\mu(U) \sim_R \mu(A) + \mu(D)$$

gives

$$\mu(U) + \mu(I) \sim_R (\mu(A) + \mu(D)) + \mu(I).$$

Associativity gives

$$(\mu(A) + \mu(D)) + \mu(I) \sim_R \mu(A) + (\mu(D) + \mu(I)).$$

Commutativity gives

$$\mu(D) + \mu(I) \sim_R \mu(I) + \mu(D).$$

The earlier comparison

$$\mu(B) \sim_R \mu(I) + \mu(D)$$

therefore gives, by symmetry, transitivity, and addition congruence with the fixed left summand $\mu(A)$,

$$\mu(A) + (\mu(D) + \mu(I)) \sim_R \mu(A) + \mu(B).$$

Transitivity of the $\mathsf{Real}^{\uparrow}$ classifier composes the displayed chain:

$$\mu(U) + \mu(I) \sim_R \mu(A) + \mu(B).$$

Substituting the public displayed representatives $U = A \cup B$ and $I = A \cap B$ gives

$$\mu(A \cup B) + \mu(A \cap B) \sim_R \mu(A) + \mu(B).$$

□

Definition 184.11 (Ternary inclusion-exclusion ledger)**.** *Let P be a $\mathsf{ProbSpace}^{\uparrow}$ carrier obtained from the probability substrate of a $\mathsf{Measure}^{\uparrow}$ carrier. Write $\mathcal{A}$ for the displayed measurable-event family inherited from the underlying $\mathsf{Measure}^{\uparrow}$ carrier, write μ for the $\mathsf{Real}^{\uparrow}$-valued measure map, and write $E \sim_{\mathcal{A}} F$ for the public measurable-event classifier. For displayed events $A, B, C \in \mathcal{A}$, a ternary inclusion-exclusion ledger for (A, B, C) consists of displayed events*

$$U, V, I_{AB}, I_{AC}, I_{BC}, K, T \in \mathcal{A}$$

and the following public rows:

1. *binary cover-difference ledgers for the original pairs (A, B), (A, C), and (B, C) in the sense of Definition 184.9, whose displayed intersections are respectively I_{AB}, I_{AC}, and I_{BC}, and whose displayed union for (B, C) is V;*
2. *a binary cover-difference ledger for (A, V) whose displayed union is U and whose displayed intersection is K;*
3. *a binary cover-difference ledger for (I_{AB}, I_{AC}) whose displayed union is K and whose displayed intersection is T.*

Thus U is the displayed ternary union of A, B, C, K is the displayed event $A \cap (B \cup C)$, and T is the displayed triple intersection read as $(A \cap B) \cap (A \cap C)$ on the carried event surface. The ledger records these as measurable-event rows and classifier readbacks, not as host set-theoretic equalities outside the BEDC *event surface.*

Lean4 (definition) `BEDC.Derived.ProbSpaceUp.ProbSpaceTernaryInclusionExclusionLedger`

Theorem 184.12 (ProbSpace ternary inclusion-exclusion identity)**.** *Let P be a $\mathsf{ProbSpace}^{\uparrow}$ carrier obtained from the probability substrate of a $\mathsf{Measure}^{\uparrow}$ carrier. Write $\mathcal{A}$ for its displayed measurable-event family, write μ for its $\mathsf{Real}^{\uparrow}$-valued measure map, and write $x \sim_R y$ for the $\mathsf{Real}^{\uparrow}$ classifier. Let $A, B, C \in \mathcal{A}$ be displayed events in one carried fiber, and suppose that (A, B, C) has a ternary inclusion-exclusion ledger with displayed events*

$$U, V, I_{AB}, I_{AC}, I_{BC}, K, T$$

in the sense of Definition 184.11. Suppose also that the finite disjoint-union additivity row applies to the disjoint pairs consumed by the three binary cover-difference ledgers (B, C), (A, V), *and* (I_{AB}, I_{AC}), *and that the target* $\mathsf{Real}^{\uparrow}$ *addition is carried by its additive* $\mathsf{AbGroup}^{\uparrow}$ *row. Then, with four-term sums read in the displayed left-associated bracketing,*

$$((\mu(U) + \mu(I_{AB})) + \mu(I_{AC})) + \mu(I_{BC}) \sim_R ((\mu(A) + \mu(B)) + \mu(C)) + \mu(T).$$

Consequently, when the public notation $A \cup B \cup C$ *names* U, $A \cap B$ *names* I_{AB}, $A \cap C$ *names* I_{AC}, $B \cap C$ *names* I_{BC}, *and* $A \cap B \cap C$ *names* T, *one obtains*

$$\mu(A \cup B \cup C) + \mu(A \cap B) + \mu(A \cap C) + \mu(B \cap C) \sim_R \mu(A) + \mu(B) + \mu(C) + \mu(A \cap B \cap C).$$

Lean4 ✓ `BEDC.Derived.ProbSpaceUp.ProbSpaceTernaryInclusionExclusionLedger identity`

Proof. Apply Definition 184.10 to the binary cover-difference ledger for (B, C). Its displayed union is V and its displayed intersection is I_{BC}, so

$$\mu(V) + \mu(I_{BC}) \sim_R \mu(B) + \mu(C).$$

Apply the same theorem to the binary cover-difference ledger for (A, V). Its displayed union is U and its displayed intersection is K, so

$$\mu(U) + \mu(K) \sim_R \mu(A) + \mu(V).$$

Apply the same theorem a third time to the binary cover-difference ledger for (I_{AB}, I_{AC}). Its displayed union is K and its displayed intersection is T, so

$$\mu(K) + \mu(T) \sim_R \mu(I_{AB}) + \mu(I_{AC}).$$

Use addition congruence in the additive $\mathsf{AbGroup}^{\uparrow}$ row to add $\mu(I_{BC})$ to the comparison for (A, V):

$$(\mu(U) + \mu(K)) + \mu(I_{BC}) \sim_R (\mu(A) + \mu(V)) + \mu(I_{BC}).$$

Associativity rewrites the right endpoint as $\mu(A) + (\mu(V) + \mu(I_{BC}))$. Addition congruence with the fixed left summand $\mu(A)$ and the comparison for (B, C) gives

$$\mu(A) + (\mu(V) + \mu(I_{BC})) \sim_R \mu(A) + (\mu(B) + \mu(C)).$$

Associativity rewrites the right endpoint as $(\mu(A) + \mu(B)) + \mu(C)$. By transitivity of $\sim_R$,

$$(\mu(U) + \mu(K)) + \mu(I_{BC}) \sim_R (\mu(A) + \mu(B)) + \mu(C).$$

Add $\mu(T)$ to both sides by addition congruence:

$$((\mu(U) + \mu(K)) + \mu(I_{BC})) + \mu(T) \sim_R ((\mu(A) + \mu(B)) + \mu(C)) + \mu(T).$$

It remains only to replace the middle event K by the two displayed pairwise intersections, with the triple intersection carried to the right endpoint. Associativity and commutativity in the additive $\mathsf{AbGroup}^{\uparrow}$ row give

$$((\mu(U) + \mu(K)) + \mu(I_{BC})) + \mu(T) \sim_R (\mu(U) + (\mu(K) + \mu(T))) + \mu(I_{BC}).$$

Addition congruence with the comparison for (I_{AB}, I_{AC}) gives

$$(\mu(U) + (\mu(K) + \mu(T))) + \mu(I_{BC}) \sim_R (\mu(U) + (\mu(I_{AB}) + \mu(I_{AC}))) + \mu(I_{BC}).$$

A final associativity rewrite gives

$$(\mu(U) + (\mu(I_{AB}) + \mu(I_{AC}))) + \mu(I_{BC}) \sim_R ((\mu(U) + \mu(I_{AB})) + \mu(I_{AC})) + \mu(I_{BC}).$$

Symmetry and transitivity of the $\mathsf{Real}^{\uparrow}$ classifier compose these displayed comparisons with the preceding four-term comparison, yielding

$$((\mu(U) + \mu(I_{AB})) + \mu(I_{AC})) + \mu(I_{BC}) \sim_R ((\mu(A) + \mu(B)) + \mu(C)) + \mu(T).$$

Substituting the public displayed representatives $U = A \cup B \cup C$, $I_{AB} = A \cap B$, $I_{AC} = A \cap C$, $I_{BC} = B \cap C$, and $T = A \cap B \cap C$ gives the stated public form. □

The $\mathsf{RandomVar}^{\uparrow}$ hub routes measurable preimage exactness through chapter 184, chapter 92, and the downstream distribution readback of chapter 186.

Chapter 185

A Concrete Naming Certificate for $\mathsf{RandomVar}^{\uparrow}$

The random-variable interface $\mathsf{RandomVar}^{\uparrow}$ packages a measurable function from a probability space to a target measure space. It depends on $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ (chapter 184) and $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92).

185.1 Carrier definition

185.2 The certificate

Theorem 185.1 (RandomVar preimage measure and probability lattice link)**.** *Every* $\mathsf{RandomVar}^{\uparrow}$ *preimage exactness theorem in this section consumes the event classifier, sigma-algebra, empty-event, union, complement, and relative-difference rows of chapter 92 together with the source probability carrier of chapter 184. The preimage rows transport target* $\mathsf{Measure}^{\uparrow}$ *events back to source* $\mathsf{ProbSpace}^{\uparrow}$ *events; they do not introduce an independent event lattice or a second source sigma-algebra.*

Proof. Inspect the hypotheses of the preimage exactness theorems below. Each theorem starts with a carried $\mathsf{RandomVar}^{\uparrow}$ map from a $\mathsf{ProbSpace}^{\uparrow}$ source to a target $\mathsf{Measure}^{\uparrow}$ carrier, then writes $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families.

The event comparisons use the source classifier of Definition 92.7. The closure rows for binary unions, empty events, complements, and relative differences are cited from Definition 92.4 and the corresponding displayed Measure rows, while the source carrier itself is the probability space of section 184.1.

The $\mathsf{RandomVar}^{\uparrow}$ certificate contributes only the measurable-preimage row and its membership readback. Therefore the preimage exactness surface is a horizontal consumer of Measure and ProbSpace data, not a new event lattice. □

Theorem 185.2 (RandomVar preimage preserves disjoint binary unions)**.** *Let* $X : S \to T$ *be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write* $\mathcal{A}_S$ *and* $\mathcal{A}_T$ *for the source and target measurable-event families, and write* $E \sim_{\mathcal{A}_S} F$ *for the source event classifier of Definition 92.7. Let* B, C, U_T *be target events such that* $B, C, U_T \in \mathcal{A}_T$ *and the displayed target binary-union row reads* U_T *as* $B \cup C$*:*

$$t \in U_T \quad \Longleftrightarrow \quad t \in B \text{ or } t \in C.$$

Assume B and C are disjoint: for every carried target point t, simultaneous witnesses $t \in B$ and $t \in C$ are eliminated. Let

$$A_B := X^{-1}(B), \qquad A_C := X^{-1}(C), \qquad A_U := X^{-1}(U_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to its source measurable preimage, then $A_B, A_C, A_U \in \mathcal{A}_S$. Moreover, if U_S is the source binary union of A_B and A_C supplied by the source* $\mathsf{Measure}^{\uparrow}$ *sigma-algebra row of Definition 92.4, then*

$$U_S \in \mathcal{A}_S, \qquad A_U \sim_{\mathcal{A}_S} U_S,$$

and A_B and A_C are disjoint source events.

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage disjoint binary union exactness`

Proof. The measurable-preimage row of the $\mathsf{RandomVar}^{\uparrow}$ certificate applies to the three target measurable events B, C, U_T. This gives $A_B, A_C, A_U \in \mathcal{A}_S$.

Since the source probability space inherits its measurable family from the underlying $\mathsf{Measure}^{\uparrow}$ carrier, Definition 92.4 supplies the binary-union row for the measurable pair A_B, A_C. Let U_S be that displayed source union. Its row gives $U_S \in \mathcal{A}_S$ and the membership readback

$$s \in U_S \quad \Longleftrightarrow \quad s \in A_B \text{ or } s \in A_C.$$

It remains to compare A_U with U_S through the source event classifier. For a carried source point s, unfold the preimage rows:

$$s \in A_U \quad \Longleftrightarrow \quad X(s) \in U_T.$$

The target binary-union readback gives

$$X(s) \in U_T \quad \Longleftrightarrow \quad X(s) \in B \text{ or } X(s) \in C.$$

Unfolding the two preimage rows again gives

$$X(s) \in B \text{ or } X(s) \in C \quad \Longleftrightarrow \quad s \in A_B \text{ or } s \in A_C.$$

The source binary-union readback identifies the right side with $s \in U_S$. Thus A_U and U_S have the same carried source memberships. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$A_U \sim_{\mathcal{A}_S} U_S.$$

Finally suppose s has witnesses $s \in A_B$ and $s \in A_C$. Unfolding preimage gives witnesses $X(s) \in B$ and $X(s) \in C$. The displayed target disjointness row for B and C eliminates such a pair, so no carried source point can inhabit both A_B and A_C. Hence the preimage pair is disjoint. □

Theorem 185.3 (RandomVar preimage relative-difference exactness)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, and write $E \sim_{\mathcal{A}_S} F$ for the source event classifier of Definition 92.7. Let A and B be target events in one carried target fiber with $A, B \in \mathcal{A}_T$, and suppose the public target readback*

displays $B \subseteq A$. Suppose the target complement/relative-difference row of Definition 92.16 supplies a measurable event

$$D_T := A \setminus B$$

with public membership readback

$$t \in D_T \quad \Longleftrightarrow \quad t \in A \text{ and } t \notin B.$$

Define source preimages

$$A_S := X^{-1}(A), \qquad B_S := X^{-1}(B), \qquad D_X := X^{-1}(D_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to its source measurable preimage, then $A_S, B_S, D_X \in \mathcal{A}_S$, and the public source readback displays $B_S \subseteq A_S$. Let D_S be the source relative-difference event $A_S \setminus B_S$ supplied by the source* $\mathsf{Measure}^{\uparrow}$ *complement/relative-difference row. Then*

$$D_S \in \mathcal{A}_S, \qquad D_X \sim_{\mathcal{A}_S} D_S,$$

and the equality is certified with the source relative-difference ledger: B_S and D_S are disjoint, and the displayed source binary union $B_S \cup D_S$ is classified as A_S.

Proof. The target complement/relative-difference row gives the measurable target event D_T. Applying the measurable-preimage row of the $\mathsf{RandomVar}^{\uparrow}$ certificate to A, B, and D_T gives

$$A_S, B_S, D_X \in \mathcal{A}_S.$$

To read the source inclusion, fix a carried source point s with a witness $s \in B_S$. The preimage readback for B gives $X(s) \in B$. The displayed target inclusion $B \subseteq A$ gives $X(s) \in A$, and the preimage readback for A gives $s \in A_S$. Hence the public source readback displays $B_S \subseteq A_S$.

Apply the source complement/relative-difference row of Definition 92.16, equivalently the row projected in Definition 92.101, to the displayed source inclusion $B_S \subseteq A_S$. It supplies the measurable event $D_S := A_S \setminus B_S$, the disjointness witness for B_S and D_S, and the binary-union readback classifying $B_S \cup D_S$ as A_S. Its relative-difference readback is

$$s \in D_S \quad \Longleftrightarrow \quad s \in A_S \text{ and } s \notin B_S.$$

It remains to compare D_X with D_S. For every carried source point s, the displayed rows give

$$\begin{aligned} s \in D_X &\Longleftrightarrow X(s) \in D_T \\ &\Longleftrightarrow X(s) \in A \text{ and } X(s) \notin B \\ &\Longleftrightarrow s \in A_S \text{ and } s \notin B_S \\ &\Longleftrightarrow s \in D_S. \end{aligned}$$

The first and third equivalences are the preimage readbacks, the second is the target relative-difference readback, and the last is the source relative-difference readback.

Thus D_X and D_S have the same carried source memberships. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$D_X \sim_{\mathcal{A}_S} D_S.$$

The measurable, disjointness, and binary-union statements are the corresponding fields of the same source relative-difference ledger. □

Lean4 ✓ BEDC.Derived.RandomVarUp.RandomVarPreimage relative difference exactness

Theorem 185.4 (RandomVar preimage complement and relative-difference exactness)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write Ω_S and Ω_T for the source and target total events, write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, and write $E \sim_{\mathcal{A}_S} F$ for the source event classifier of Definition 92.7. Let A and B be target events in one carried target fiber with $A, B \in \mathcal{A}_T$, and suppose the public target readback displays $B \subseteq A$. Suppose the target complement/relative-difference row of Definition 92.16 supplies a measurable event*

$$D_T := A \setminus B$$

with public membership readback

$$t \in D_T \iff t \in A \text{ and } t \notin B.$$

Define source preimages

$$A_S := X^{-1}(A), \qquad B_S := X^{-1}(B), \qquad D_X := X^{-1}(D_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to its source measurable preimage, then $A_S, B_S, D_X \in \mathcal{A}_S$, and the public source readback displays $B_S \subseteq A_S$. Let $D_S := A_S \setminus B_S$ be the source relative-difference event supplied by the source* $\mathsf{Measure}^{\uparrow}$ *complement/relative-difference row. Then*

$$D_S \in \mathcal{A}_S, \qquad D_X \sim_{\mathcal{A}_S} D_S.$$

In the complement case, take the ambient event A to be Ω_T and write $B_T^{\complement} := \Omega_T \setminus B$. If the same $\mathsf{RandomVar}^{\uparrow}$ *row identifies $X^{-1}(\Omega_T)$ with Ω_S through the source event classifier, with source-event transport read through Definition 26.3, and if $B_S^{\complement} := \Omega_S \setminus B_S$ is the source complement event supplied by the source complement/relative-difference row, then*

$$X^{-1}(B_T^{\complement}) \sim_{\mathcal{A}_S} B_S^{\complement}.$$

The two classifications are certified with the corresponding source relative-difference ledgers: the second component is disjoint from B_S, and its displayed binary union with B_S is classified as the ambient source event.

Proof. The measurable-preimage row of the $\mathsf{RandomVar}^{\uparrow}$ certificate applies to the three target measurable events A, B, and D_T. This gives

$$A_S, B_S, D_X \in \mathcal{A}_S.$$

To read the source inclusion, fix a carried source point s with a witness $s \in B_S$. The preimage readback for B gives $X(s) \in B$. The displayed target inclusion $B \subseteq A$ gives $X(s) \in A$, and the preimage readback for A gives $s \in A_S$. Hence the public source readback displays $B_S \subseteq A_S$.

Apply the source complement/relative-difference row of Definition 92.16 to this displayed source inclusion. It supplies the measurable event $D_S := A_S \setminus B_S$, the disjointness witness for B_S and D_S, and the binary-union readback classifying $B_S \cup D_S$ as A_S. Its relative-difference readback is

$$s \in D_S \iff s \in A_S \text{ and } s \notin B_S.$$

For every carried source point s, the displayed rows give

$$\begin{aligned} s \in D_X &\iff X(s) \in D_T \\ &\iff X(s) \in A \text{ and } X(s) \notin B \\ &\iff s \in A_S \text{ and } s \notin B_S \\ &\iff s \in D_S. \end{aligned}$$

The first and third equivalences are the preimage readbacks, the second is the target relative-difference readback, and the last is the source relative-difference readback. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$D_X \sim_{\mathcal{A}_S} D_S.$$

Now take $A = \Omega_T$ and $D_T = B_T^{\complement}$. The source ambient preimage is $A_S = X^{-1}(\Omega_T)$, and the source-event transport is the one cited in Definition 26.3. For every carried source point s, the total-preimage classifier gives

$$s \in A_S \quad \iff \quad s \in \Omega_S.$$

The source complement event $B_S^{\complement} := \Omega_S \setminus B_S$ has readback

$$s \in B_S^{\complement} \quad \iff \quad s \in \Omega_S \text{ and } s \notin B_S.$$

Combining these two readbacks with the relative-difference computation above gives

$$s \in X^{-1}(B_T^{\complement}) \quad \iff \quad s \in B_S^{\complement}$$

for every carried source point s. The same source event-classifier component, using the source-event transport of Definition 26.3, therefore yields

$$X^{-1}(B_T^{\complement}) \sim_{\mathcal{A}_S} B_S^{\complement}.$$

The disjointness and binary-union statements are the corresponding ledger fields of the source complement/relative-difference row. □

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage complement difference exactness`

Theorem 185.5 (RandomVar preimage of the empty event is empty)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write $\varnothing_S$ and $\varnothing_T$ for the source and target empty events, write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, and write $E \sim_{\mathcal{A}_S} F$ for the source event classifier of Definition 92.7. Suppose the source and target empty-event rows supplied by Definition 92.4 give*

$$\varnothing_S \in \mathcal{A}_S, \qquad \varnothing_T \in \mathcal{A}_T,$$

and their displayed public readbacks eliminate every carried membership witness in the corresponding empty event. Let

$$A_\varnothing := X^{-1}(\varnothing_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to a source measurable preimage with membership readback, then*

$$A_\varnothing \in \mathcal{A}_S, \qquad A_\varnothing \sim_{\mathcal{A}_S} \varnothing_S.$$

Proof. The target empty event is measurable, so the measurable-preimage row of the $\mathsf{RandomVar}^{\uparrow}$ certificate applies to $\varnothing_T$. This gives

$$A_\varnothing \in \mathcal{A}_S.$$

It remains to compare $A_\varnothing$ with the source empty event through the source event classifier. Fix a carried source point s. The preimage readback gives

$$s \in A_\varnothing \quad \Longleftrightarrow \quad X(s) \in \varnothing_T.$$

Because X is carried, $X(s)$ is a carried target point. Hence any witness $s \in A_\varnothing$ reads as a witness $X(s) \in \varnothing_T$, and the target empty-event row eliminates it. By empty elimination this gives the implication from $s \in A_\varnothing$ to $s \in \varnothing_S$.

Conversely, any witness $s \in \varnothing_S$ is eliminated by the source empty-event row. By empty elimination this gives the implication from $s \in \varnothing_S$ to $s \in A_\varnothing$. Therefore, for every carried source point s,

$$s \in A_\varnothing \quad \Longleftrightarrow \quad s \in \varnothing_S.$$

The two events have the same carried source memberships. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$A_\varnothing \sim_{\mathcal{A}_S} \varnothing_S.$$

□

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage empty event exactness`

Theorem 185.6 (RandomVar preimage symmetric-difference exactness)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, and write $E \sim_{\mathcal{A}_S} F$ for the source event classifier of Definition 92.7. Let A and B be target events in one carried target fiber with $A, B \in \mathcal{A}_T$. Suppose the target difference rows supply measurable events*

$$D_T^{A\setminus B} := A \setminus B, \qquad D_T^{B\setminus A} := B \setminus A$$

with public membership readbacks

$$t \in D_T^{A\setminus B} \quad \Longleftrightarrow \quad t \in A \text{ and } t \notin B,$$

$$t \in D_T^{B\setminus A} \quad \Longleftrightarrow \quad t \in B \text{ and } t \notin A.$$

Let Δ_T be the displayed target binary union of these two difference events, so

$$t \in \Delta_T \quad \Longleftrightarrow \quad t \in D_T^{A\setminus B} \text{ or } t \in D_T^{B\setminus A}.$$

Define source preimages

$$A_S := X^{-1}(A), \qquad B_S := X^{-1}(B), \qquad \Delta_X := X^{-1}(\Delta_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to a source measurable preimage with membership readback, then $A_S, B_S, \Delta_X \in \mathcal{A}_S$. Let the source difference rows supply measurable events*

$$D_S^{A\setminus B} := A_S \setminus B_S, \qquad D_S^{B\setminus A} := B_S \setminus A_S$$

with readbacks

$$s \in D_S^{A\setminus B} \iff s \in A_S \text{ and } s \notin B_S,$$
$$s \in D_S^{B\setminus A} \iff s \in B_S \text{ and } s \notin A_S.$$

Let Δ_S be the source binary union of $D_S^{A\setminus B}$ and $D_S^{B\setminus A}$ supplied by the source $\mathsf{Measure}^{\uparrow}$ *sigma-algebra row of Definition 92.4. Then*

$$\Delta_S \in \mathcal{A}_S, \qquad \Delta_X \sim_{\mathcal{A}_S} \Delta_S.$$

Moreover, the two source difference components are disjoint.

Proof. The target difference rows make $D_T^{A\setminus B}$ and $D_T^{B\setminus A}$ measurable, and the target binary-union row makes Δ_T measurable. Applying the measurable-preimage row of the $\mathsf{RandomVar}^{\uparrow}$ certificate to A, B, and Δ_T gives

$$A_S, B_S, \Delta_X \in \mathcal{A}_S.$$

The same row gives the three preimage readbacks

$$s \in A_S \iff X(s) \in A,$$
$$s \in B_S \iff X(s) \in B,$$
$$s \in \Delta_X \iff X(s) \in \Delta_T.$$

The source difference rows supply $D_S^{A\setminus B}, D_S^{B\setminus A} \in \mathcal{A}_S$ and the two displayed source readbacks. They are disjoint: if a carried source point s has witnesses in both source difference events, the first readback gives $s \in A_S$ and $s \notin B_S$, while the second gives $s \in B_S$ and $s \notin A_S$. Either negative component eliminates the corresponding positive witness.

Therefore the source sigma-algebra row of Definition 92.4 supplies the binary union Δ_S of the two source difference events, with

$$\Delta_S \in \mathcal{A}_S$$

and membership readback

$$s \in \Delta_S \iff s \in D_S^{A\setminus B} \text{ or } s \in D_S^{B\setminus A}.$$

It remains to compare Δ_X with Δ_S. For every carried source point s, the displayed rows give

$$\begin{aligned}
s \in \Delta_X &\iff X(s) \in \Delta_T \\
&\iff X(s) \in D_T^{A\setminus B} \text{ or } X(s) \in D_T^{B\setminus A} \\
&\iff (X(s) \in A \text{ and } X(s) \notin B) \text{ or } (X(s) \in B \text{ and } X(s) \notin A) \\
&\iff (s \in A_S \text{ and } s \notin B_S) \text{ or } (s \in B_S \text{ and } s \notin A_S) \\
&\iff s \in D_S^{A\setminus B} \text{ or } s \in D_S^{B\setminus A} \\
&\iff s \in \Delta_S.
\end{aligned}$$

The first equivalence is the preimage readback for Δ_T; the second is the target binary-union readback; the third uses the two target difference readbacks; the fourth uses the preimage readbacks for A and B in both positive and negative directions; the fifth uses the two source difference readbacks; and the last is the source binary-union readback.

Thus Δ_X and Δ_S have the same carried source memberships. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$\Delta_X \sim_{\mathcal{A}_S} \Delta_S.$$

□

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage symmetric difference exactness`

Theorem 185.7 (RandomVar preimage binary-intersection exactness)**.** *Let $X : S \to T$ be a carried* RandomVar$^{\uparrow}$ *map as in section 185.1, from a* ProbSpace$^{\uparrow}$ *source as in section 184.1 to a target* Measure$^{\uparrow}$ *carrier as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, and write $E \sim_{\mathcal{A}_S} F$ for the source event classifier of Definition 92.7. Let B, C, I_T be target events such that $B, C, I_T \in \mathcal{A}_T$ and the displayed target binary-intersection row reads I_T as $B \cap C$:*

$$t \in I_T \quad \Longleftrightarrow \quad t \in B \text{ and } t \in C.$$

Define source preimages

$$A_B := X^{-1}(B), \qquad A_C := X^{-1}(C), \qquad A_I := X^{-1}(I_T).$$

If the RandomVar$^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to its source measurable preimage with membership readback, then*

$$A_B, A_C, A_I \in \mathcal{A}_S.$$

Moreover, if I_S is the source binary intersection of A_B and A_C supplied by the source Measure$^{\uparrow}$ *sigma-algebra row of Definition 92.4, then*

$$I_S \in \mathcal{A}_S, \qquad A_I \sim_{\mathcal{A}_S} I_S.$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage binary intersection exactness`

Proof. The measurable-preimage row of the RandomVar$^{\uparrow}$ certificate applies to B, C, and I_T. This gives

$$A_B, A_C, A_I \in \mathcal{A}_S.$$

Since the source probability space inherits its measurable family from the underlying Measure$^{\uparrow}$ carrier, Definition 92.4 supplies the binary-intersection row for the measurable pair A_B, A_C. Let I_S be that displayed source intersection. Its row gives $I_S \in \mathcal{A}_S$ and the membership readback

$$s \in I_S \quad \Longleftrightarrow \quad s \in A_B \text{ and } s \in A_C.$$

It remains to compare A_I with I_S through the source event classifier. For a carried source point s, unfold the preimage row for I_T:

$$s \in A_I \quad \Longleftrightarrow \quad X(s) \in I_T.$$

The target binary-intersection readback gives

$$X(s) \in I_T \quad \Longleftrightarrow \quad X(s) \in B \text{ and } X(s) \in C.$$

Unfolding the two preimage rows for B and C gives

$$X(s) \in B \text{ and } X(s) \in C \quad \Longleftrightarrow \quad s \in A_B \text{ and } s \in A_C.$$

The source binary-intersection readback identifies the right side with $s \in I_S$. Thus A_I and I_S have the same carried source memberships. By the source event-classifier component of Definition 92.7, this pointwise readback is exactly

$$A_I \sim_{\mathcal{A}_S} I_S.$$

□

Theorem 185.8 (B-524; closure/bridge: RandomVar countable preimage intersection exactness)**.** *Let S, T be BEDC measurable-event certificates whose event carriers are $\mathcal{A}_S, \mathcal{A}_T$, whose event classifiers are $\equiv_S, \equiv_T$, and whose membership readbacks are written*

$$s \Vdash_S A, \qquad t \Vdash_T B.$$

Assume that the source event classifier is readback-exact in the following minimal sense:

$$(\forall s,\ s \Vdash_S E \Longleftrightarrow s \Vdash_S F) \Longrightarrow E \equiv_S F.$$

Let $X : S \to T$ be a carried $\mathsf{RandomVar}^{\uparrow}$ *map with preimage constructor*

$$X^{-1} : \mathcal{A}_T \longrightarrow \mathcal{A}_S$$

satisfying the RandomVar readback bridge

$$s \Vdash_S X^{-1}(B) \Longleftrightarrow X(s) \Vdash_T B$$

for every $B \in \mathcal{A}_T$. Let $(B_n)_{n\in\mathbb{N}}$ be a target measurable-event sequence, $B_n \in \mathcal{A}_T$, and let $I_T \in \mathcal{A}_T$ be an exact target intersection event:

$$t \Vdash_T I_T \Longleftrightarrow \forall n,\ t \Vdash_T B_n.$$

Define

$$A_n := X^{-1}(B_n), \qquad A_I := X^{-1}(I_T).$$

Let

$$\bigcap\nolimits_S A_\bullet$$

be any displayed source measurable event whose readback is exact for the preimage family:

$$s \Vdash_S \bigcap\nolimits_S A_\bullet \Longleftrightarrow \forall n,\ s \Vdash_S A_n.$$

The displayed source witness is an explicit hypothesis here; no primitive source countable-intersection row is read from the $\mathsf{Measure}^{\uparrow}$ *surface. Then each A_n and A_I lies in $\mathcal{A}_S$, and*

$$A_I \equiv_S \bigcap\nolimits_S A_\bullet.$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarCountablePreimageIntersection exactness`

Proof. For every n, $B_n \in \mathcal{A}_T$; hence $A_n = X^{-1}(B_n) \in \mathcal{A}_S$ by the carried RandomVar preimage-closure field. Likewise $I_T \in \mathcal{A}_T$, so $A_I = X^{-1}(I_T) \in \mathcal{A}_S$. It remains to identify A_I with the displayed source countable intersection. Fix a source endpoint s. The RandomVar readback bridge gives

$$s \Vdash_S A_I \Longleftrightarrow X(s) \Vdash_T I_T.$$

The target intersection certificate gives

$$X(s) \Vdash_T I_T \Longleftrightarrow \forall n,\ X(s) \Vdash_T B_n.$$

Applying the RandomVar readback bridge to each B_n gives

$$\forall n,\ X(s) \Vdash_T B_n \Longleftrightarrow \forall n,\ s \Vdash_S A_n.$$

Finally, the displayed source intersection witness gives

$$\forall n,\ s \Vdash_S A_n \iff s \Vdash_S \bigcap_S A_\bullet.$$

Thus, for all source endpoints s,

$$s \Vdash_S A_I \iff s \Vdash_S \bigcap_S A_\bullet.$$

Source readback-extensionality therefore yields

$$A_I \equiv_S \bigcap_S A_\bullet.$$

No probability-value, integration, or conditional-expectation field is used; the proof consumes only the explicit source intersection witness and RandomVar preimage-readback certificates, in accordance with the BEDC certificate posture for derived Measure-type structure. □

Corollary 185.9 (B-525; determinacy: independence of the target intersection witness)**.** *Under the hypotheses of Definition 185.8, suppose $I_T, I'_T \in \mathcal{A}_T$ are two exact target intersection events for the same sequence (B_n):*

$$t \Vdash_T I_T \iff \forall n,\ t \Vdash_T B_n, \qquad t \Vdash_T I'_T \iff \forall n,\ t \Vdash_T B_n.$$

Then

$$X^{-1}(I_T) \equiv_S X^{-1}(I'_T).$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarCountablePreimageIntersection witness determinacy`

Proof. Apply Definition 185.8 to I_T. It gives

$$X^{-1}(I_T) \equiv_S \bigcap_S X^{-1}(B_\bullet).$$

Apply the same theorem to I'_T. It gives

$$X^{-1}(I'_T) \equiv_S \bigcap_S X^{-1}(B_\bullet).$$

Symmetry and transitivity of the source event classifier yield

$$X^{-1}(I_T) \equiv_S X^{-1}(I'_T).$$

□

Proposition 185.10 (B-526; uniqueness: source greatest-lower-bound exactness)**.** *Keep the hypotheses of Definition 185.8. Define the source event preorder by*

$$E \preceq_S F \quad :\iff \quad \forall s,\ s \Vdash_S E \Rightarrow s \Vdash_S F.$$

Then $A_I = X^{-1}(I_T)$ is the greatest lower bound of the preimage family (A_n) up to $\equiv_S$. Explicitly:

$$A_I \preceq_S A_n \quad \textit{for every } n,$$

and whenever $C \in \mathcal{A}_S$ satisfies $C \preceq_S A_n$ for every n, one has

$$C \preceq_S A_I.$$

Consequently, if $K \in \mathcal{A}_S$ is any other event satisfying the same two lower-bound clauses, then

$$K \equiv_S A_I.$$

Proof. For $A_I \preceq_S A_n$, assume $s \Vdash_S A_I$. By the readback chain in Definition 185.8,

$$s \Vdash_S A_I \iff \forall m,\ s \Vdash_S A_m.$$

Taking $m = n$ gives $s \Vdash_S A_n$. Now let $C \in \mathcal{A}_S$ and assume $C \preceq_S A_n$ for every n. If $s \Vdash_S C$, then $s \Vdash_S A_n$ for every n. The same readback chain gives $s \Vdash_S A_I$. Hence $C \preceq_S A_I$. Finally, let K satisfy the same lower-bound clauses. Since $K \preceq_S A_n$ for every n, the previous paragraph gives $K \preceq_S A_I$. Since $A_I \preceq_S A_n$ for every n, the greatest-lower-bound clause for K gives $A_I \preceq_S K$. Thus, for every s,

$$s \Vdash_S K \iff s \Vdash_S A_I.$$

Source readback-extensionality yields $K \equiv_S A_I$. □

Proposition 185.11 (B-527; composition bridge: two-stage RandomVar countable intersections)**.** *Let*

$$S \xrightarrow{X} T \xrightarrow{Y} U$$

be carried $\mathsf{RandomVar}^{\uparrow}$ *maps with exact preimage readback bridges. Let* (C_n) *be a* U*-measurable event sequence and* I_U *an exact* U*-intersection event:*

$$u \Vdash_U I_U \iff \forall n,\ u \Vdash_U C_n.$$

Put

$$B_n := Y^{-1}(C_n), \qquad B_I := Y^{-1}(I_U),$$

and

$$A_n := X^{-1}(B_n) = X^{-1}(Y^{-1}(C_n)).$$

Assume the source event classifier on S *is readback-exact, and let*

$$\bigcap\nolimits_S A_\bullet$$

be a displayed source measurable event with exact readback

$$s \Vdash_S \bigcap\nolimits_S A_\bullet \iff \forall n,\ s \Vdash_S A_n.$$

Then B_I *is an exact* T*-intersection event for the sequence* (B_n)*, and*

$$X^{-1}(B_I) \equiv_S \bigcap\nolimits_S A_\bullet.$$

Equivalently, for the composite RandomVar $Y \circ X$*,*

$$(Y \circ X)^{-1}(I_U) \equiv_S \bigcap\nolimits_S (Y \circ X)^{-1}(C_\bullet).$$

Proof. First show that B_I is the exact T-intersection of the B_n. For every t,

$$t \Vdash_T B_I \iff Y(t) \Vdash_U I_U \iff \forall n,\ Y(t) \Vdash_U C_n \iff \forall n,\ t \Vdash_T B_n.$$

Thus B_I satisfies the target-intersection hypothesis of Definition 185.8 for the RandomVar $X : S \to T$. Applying that theorem gives

$$X^{-1}(B_I) \equiv_S \bigcap\nolimits_S X^{-1}(B_\bullet) = \bigcap\nolimits_S A_\bullet.$$

The composite-preimage identity is not an additional axiom: its readback is

$$s \Vdash_S X^{-1}(Y^{-1}(C)) \iff X(s) \Vdash_T Y^{-1}(C) \iff Y(X(s)) \Vdash_U C,$$

which is exactly the RandomVar readback bridge for $Y \circ X$. Substituting $C = I_U$ and $C = C_n$ gives the displayed composite form. □

Proposition 185.12 (B-528; obstruction: closure and classifier-respect alone do not imply B-524)**.** *The RandomVar readback bridge in Definition 185.8 cannot be replaced by mere event-carrier closure and event-classifier respect of a preimage-like transformer.*

Proof. Consider a finite source event skeleton with two source events

$$0_S,\ 1_S$$

distinguished by the source classifier. Let the displayed source intersection witness of the constant sequence $(0_S, 0_S, \ldots)$ be 0_S. Let the target event skeleton contain pairwise classifier-distinct events

$$I_T,\ B_0,\ B_1, \ldots$$

with I_T certified as the exact countable intersection of the B_n. Define a preimage-like transformer P on this displayed fragment by

$$P(I_T) := 1_S, \qquad P(B_n) := 0_S \quad \text{for every } n.$$

This transformer preserves event-carrier membership on the displayed fragment. It also respects the target classifier on that fragment, because the only classifier identifications are reflexive. However,

$$P(I_T) = 1_S,$$

whereas

$$\bigcap\nolimits_S P(B_\bullet) = \bigcap\nolimits_S (0_S, 0_S, \ldots) = 0_S.$$

Since 0_S and 1_S are classifier-distinct, the desired conclusion

$$P(I_T) \equiv_S \bigcap\nolimits_S P(B_\bullet)$$

fails. Thus the missing obligation is not a closure obligation and not a classifier-respect obligation. It is precisely the bridge obligation

$$s \Vdash_S X^{-1}(B) \Longleftrightarrow X(s) \Vdash_T B,$$

or an equivalent countable-meet preimage bridge. Without that bridge, the countable preimage intersection exactness theorem is not derivable. □

The $\mathsf{RandomVar}^{\uparrow}$ packet sits between the source probability surface of chapter 184 and the distribution readback surface of chapter 186. This dependency is substantive: the source sample carrier and probability ledger come from $\mathsf{ProbSpace}^{\uparrow}$, while the measurable-output route supplies the pushforward and readback surface later consumed by $\mathsf{Distribution}^{\uparrow}$. Thus a carried random variable is not an isolated measurable map; it is the finite route by which source probability rows are made available to distribution-facing consumers.

Theorem 185.13 (RandomVar ProbSpace Distribution sibling route)**.** *Every accepted* $\mathsf{RandomVar}^{\uparrow}$ *preimage packet that is later consumed by* $\mathsf{Distribution}^{\uparrow}$ *first reads the source probability carrier from chapter 184 and the target measurable-event surface from chapter 92. It then exports only the finite preimage rows, the source and target event classifiers,* hsame, Cont, Pkg, *and* NameCert *rows to the distribution readback surface of chapter 186. No host function equality, independent probability-space bridge, target event outside the displayed* $\mathsf{Measure}^{\uparrow}$ *surface, or distribution row outside the carried preimage readback is exported.*

Proof. Start with the preimage exactness surface of Definition 185.2, Definition 185.3, Definition 185.4, and Definition 185.5. Each row uses the same carried map $X : S \to T$, reads the source carrier through $\mathsf{ProbSpace}^{\uparrow}$, and reads the target event family through $\mathsf{Measure}^{\uparrow}$.

Next use the scoped carried preimage package of Definition 185.27. It collects the finite, total, terminal, and countable preimage rows over the same source and target classifiers, so the downstream consumer receives a single carried package rather than a second event lattice.

For a $\mathsf{Distribution}^{\uparrow}$ readback, retain only the rows that the distribution surface can consume: the displayed finite preimages, the classifiers that compare source and target events, and the structural hsame, Cont, Pkg, and $\mathsf{NameCert}$ support. The source probability ledger remains the $\mathsf{ProbSpace}^{\uparrow}$ input, while the measurable target surface remains the $\mathsf{Measure}^{\uparrow}$ input.

Thus the sibling route runs from the probability carrier through the carried random-variable preimage packet to the distribution readback surface. Since every exported row has already appeared on that route, no host function equality, independent probability-space bridge, target event outside the displayed measurable surface, or off-route distribution row is available. □

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarProbSpaceDistribution sibling route`

Definition 185.14 (Total-readback certificate for a carried RandomVarUp)**.** *Let S, T be BEDC event interfaces with event carriers $\mathcal{E}_S, \mathcal{E}_T$, event classifiers*

$$A \simeq_S A', \qquad B \simeq_T B',$$

measurability predicates $\mathsf{Meas}_S, \mathsf{Meas}_T$, and total events

$$\Omega_S \in \mathcal{E}_S, \qquad \Omega_T \in \mathcal{E}_T.$$

A carried $\mathsf{RandomVar}^{\uparrow}$ map $X : S \to T$ is said to carry a total-readback certificate if it is equipped with a BEDC preimage readback relation

$$\mathsf{Pre}_X(B, A) \qquad (B \in \mathcal{E}_T,\ A \in \mathcal{E}_S)$$

and a chosen readback endpoint $\mathrm{pre}_X(B) \in \mathcal{E}_S$ satisfying

$$\mathsf{Pre}_X(B, \mathrm{pre}_X(B))$$

for each target event B, together with the following four clauses:

target-total measurability:	$\mathsf{Meas}_T(\Omega_T)$,
measurable-preimage readback:	$\mathsf{Meas}_T(B) \wedge \mathsf{Pre}_X(B, A) \Longrightarrow \mathsf{Meas}_S(A)$,
classifier-determinacy of readback:	$B \simeq_T C,\ \mathsf{Pre}_X(B, A),\ \mathsf{Pre}_X(C, A') \Longrightarrow A \simeq_S A'$,
carried-total bridge:	$\mathsf{Pre}_X(\Omega_T, \Omega_S)$.

The object $\mathrm{pre}_X(\Omega_T)$ is the BEDC source endpoint denoted informally by

$$X^{-1}(\Omega_T).$$

Lean4 (definition) `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate`

Theorem 185.15 (RandomVar total-event preimage exactness)**.** *Under the total-readback certificate of Definition 185.14, the chosen total-target preimage is source-measurable and source-event-classifier equal to the source total event:*

$$\mathsf{Meas}_S(\mathrm{pre}_X(\Omega_T)) \quad \textit{and} \quad \mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Proof. The chosen readback clause gives

$$\mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)).$$

Since $\mathsf{Meas}_T(\Omega_T)$, measurable-preimage readback yields

$$\mathsf{Meas}_S(\mathrm{pre}_X(\Omega_T)).$$

For classifier exactness, apply classifier-determinacy to the reflexive target-classifier witness

$$\Omega_T \simeq_T \Omega_T,$$

the chosen readback

$$\mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)),$$

and the carried-total bridge

$$\mathsf{Pre}_X(\Omega_T, \Omega_S).$$

The conclusion is precisely

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

□

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate total event preimage exactness`

Theorem 185.16 (Terminal readback uniqueness over the target total event)**.** *Assume the total-readback certificate of Definition 185.14. If $A \in \mathcal{E}_S$ is any source event satisfying*

$$\mathsf{Pre}_X(\Omega_T, A),$$

then

$$A \simeq_S \Omega_S.$$

Consequently, if A, A' are two source events with

$$\mathsf{Pre}_X(\Omega_T, A), \qquad \mathsf{Pre}_X(\Omega_T, A'),$$

then

$$A \simeq_S A'.$$

Proof. Apply classifier-determinacy to

$$\Omega_T \simeq_T \Omega_T, \qquad \mathsf{Pre}_X(\Omega_T, A), \qquad \mathsf{Pre}_X(\Omega_T, \Omega_S).$$

This gives $A \simeq_S \Omega_S$. The same argument gives $A' \simeq_S \Omega_S$. By symmetry and transitivity of the source event-classifier,

$$A \simeq_S \Omega_S \simeq_S A',$$

hence $A \simeq_S A'$. □

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate terminal readback uniqueness`

Proposition 185.17 (Exactness and the carried-total bridge under source-endpoint closure)**.** *Assume the data of Definition 185.14 except possibly the carried-total bridge. Suppose moreover that the readback relation is closed under source-event classifier replacement:*

$$\mathsf{Pre}_X(B, A) \wedge A \simeq_S A' \Longrightarrow \mathsf{Pre}_X(B, A').$$

Then the following are equivalent:

$$\mathsf{Pre}_X(\Omega_T, \Omega_S) \quad \Longleftrightarrow \quad \mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate carried bridge chosen preimage exactness iff`

Proof. The forward implication is the classifier part of Definition 185.15. Conversely, suppose

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

The chosen readback clause supplies

$$\mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)).$$

By source-endpoint closure of Pre_X along the displayed classifier witness, with source-event transport read through Definition 26.3, this readback transports to

$$\mathsf{Pre}_X(\Omega_T, \Omega_S).$$

Thus the carried-total bridge is not an additional hidden axiom once the chosen total preimage is already classifier-exact and readback is closed under source-classifier replacement. □

Theorem 185.18 (Minimal obstruction to total-event exactness)**.** *Assume $X : S \to T$ has chosen readbacks and classifier-determinacy of readback. If*

$$\mathsf{Meas}_T(\Omega_T), \qquad \mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)), \qquad \mathsf{Pre}_X(\Omega_T, \Omega_S)$$

all hold, then

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Equivalently, any failure of

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S$$

forces failure of at least one of the following three certificate components:

$$\mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)), \qquad \mathsf{Pre}_X(\Omega_T, \Omega_S), \qquad \textit{classifier-determinacy of } \mathsf{Pre}_X.$$

If in addition measurable-preimage readback is available, then failure of

$$\mathsf{Meas}_S(\mathrm{pre}_X(\Omega_T))$$

forces failure of at least one of

$$\mathsf{Meas}_T(\Omega_T), \qquad \mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)), \qquad \textit{measurable-preimage readback.}$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate minimal obstruction`

Proof. The first assertion is exactly the classifier-determinacy argument of Definition 185.15, stripped to its minimal hypotheses. Its contrapositive is the stated obstruction claim. For the measurability assertion, if

$$\mathsf{Meas}_T(\Omega_T) \quad \text{and} \quad \mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T))$$

hold, measurable-preimage readback gives

$$\mathsf{Meas}_S(\mathrm{pre}_X(\Omega_T)).$$

Therefore failure of this conclusion forces failure of one of the three displayed premises. □

Theorem 185.19 (Composition preserves total-event preimage exactness with a composite ledger)**.** *Let*

$$X : S \to T, \qquad Y : T \to U$$

be carried $\mathsf{RandomVar}^{\uparrow}$ *maps with preimage readback relations*

$$\mathsf{Pre}_X, \qquad \mathsf{Pre}_Y.$$

Define the composite readback ledger by

$$\mathsf{Pre}_{Y \circ X}(C, A) \quad :\Longleftrightarrow \quad \exists B \in \mathcal{E}_T \ \big(\mathsf{Pre}_Y(C, B) \wedge \mathsf{Pre}_X(B, A)\big).$$

Assume:

$$\mathsf{Pre}_Y(\Omega_U, \Omega_T), \qquad \mathsf{Pre}_X(\Omega_T, \Omega_S),$$

both component readbacks satisfy classifier-determinacy, and both satisfy measurable-preimage readback. If

$$\mathsf{Meas}_U(\Omega_U),$$

then

$$\mathsf{Meas}_S(\mathrm{pre}_{Y \circ X}(\Omega_U)) \quad \textit{and} \quad \mathrm{pre}_{Y \circ X}(\Omega_U) \simeq_S \Omega_S.$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalPreimage composition exactness`
↪ variant `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate composition total event preimage exactness`

Proof. Let

$$A := \mathrm{pre}_{Y \circ X}(\Omega_U).$$

By chosen composite readback,

$$\mathsf{Pre}_{Y \circ X}(\Omega_U, A).$$

Hence there exists $B \in \mathcal{E}_T$ such that

$$\mathsf{Pre}_Y(\Omega_U, B), \qquad \mathsf{Pre}_X(B, A).$$

Since $\mathsf{Meas}_U(\Omega_U)$, measurable-preimage readback for Y gives

$$\mathsf{Meas}_T(B).$$

Then measurable-preimage readback for X gives

$$\mathsf{Meas}_S(A).$$

It remains to prove classifier exactness. The displayed carried-total bridges produce a composite total bridge:

$$\mathsf{Pre}_{Y\circ X}(\Omega_U, \Omega_S)$$

with intermediate witness $B = \Omega_T$. We first record composite classifier-determinacy. Suppose

$$\mathsf{Pre}_{Y\circ X}(C, A_1), \qquad \mathsf{Pre}_{Y\circ X}(C, A_2).$$

Choose intermediate witnesses B_1, B_2 with

$$\mathsf{Pre}_Y(C, B_1), \quad \mathsf{Pre}_X(B_1, A_1),$$

$$\mathsf{Pre}_Y(C, B_2), \quad \mathsf{Pre}_X(B_2, A_2).$$

Classifier-determinacy for Y, applied to $C \simeq_U C$, gives

$$B_1 \simeq_T B_2.$$

Classifier-determinacy for X, applied to this target-event classifier witness and the two X-readbacks, gives

$$A_1 \simeq_S A_2.$$

Thus the composite readback is classifier-deterministic. Apply this composite classifier-determinacy to

$$\mathsf{Pre}_{Y\circ X}(\Omega_U, A) \quad \text{and} \quad \mathsf{Pre}_{Y\circ X}(\Omega_U, \Omega_S).$$

The result is

$$A \simeq_S \Omega_S,$$

that is,

$$\mathrm{pre}_{Y\circ X}(\Omega_U) \simeq_S \Omega_S.$$

□

Definition 185.20 (Total-defect event of a RandomVarUp)**.** *Assume the source event interface carries BEDC Boolean event operations*

$$\bot_S, \qquad A \mapsto A^{\complement}, \qquad A \wedge A'$$

with classifier-stable Boolean exactness. For a carried $\mathsf{RandomVar}^{\uparrow}$ *map* $X : S \to T$*, define the total-defect event*

$$\mathfrak{D}_X := \Omega_S \wedge \big(\mathrm{pre}_X(\Omega_T)\big)^{\complement}.$$

It is the source-side ledger of histories for which the target-total readback fails to cover the source total event.

Lean4 (definition) `BEDC.Derived.RandomVarUp.RandomVarTotalDefectEvent`

Theorem 185.21 (Total-event exactness is equivalent to vanishing total defect)**.** *Assume the source Boolean event interface satisfies the classifier-exact total-complement law*

$$A \simeq_S \Omega_S \quad \Longleftrightarrow \quad \Omega_S \wedge A^{\complement} \simeq_S \bot_S$$

for every source-measurable event A*. If*

$$\mathsf{Meas}_S(\mathrm{pre}_X(\Omega_T)),$$

then

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S \quad \Longleftrightarrow \quad \mathfrak{D}_X \simeq_S \bot_S.$$

In particular, under the hypotheses of Definition 185.15,

$$\mathfrak{D}_X \simeq_S \bot_S.$$

↪ variant BEDC.Derived.RandomVarUp.RandomVarTotalDefectEvent vanishing total exactness iff

Proof. Put

$$A = \mathrm{pre}_X(\Omega_T).$$

By definition,

$$\mathfrak{D}_X = \Omega_S \wedge A^{\complement}.$$

Since A is source-measurable, the classifier-exact total-complement law applies and gives

$$A \simeq_S \Omega_S \quad \Longleftrightarrow \quad \Omega_S \wedge A^{\complement} \simeq_S \bot_S.$$

Substituting the definition of $\mathfrak{D}_X$ gives the asserted equivalence. Under Definition 185.15, $A \simeq_S \Omega_S$; hence $\mathfrak{D}_X \simeq_S \bot_S$. □

Theorem 185.22 (Total-target reflection criterion)**.** *Let $X : S \to T$ satisfy the total-readback certificate of Definition 185.14. Suppose X is target-total reflective, meaning that for every target-measurable event B,*

$$\mathrm{pre}_X(B) \simeq_S \Omega_S \Longrightarrow B \simeq_T \Omega_T.$$

Then, for every target-measurable B,

$$\mathrm{pre}_X(B) \simeq_S \Omega_S \quad \Longleftrightarrow \quad B \simeq_T \Omega_T.$$

Lean4 ✓ BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate total target reflection criterion

Proof. The forward implication is exactly target-total reflectivity. Conversely, assume $B \simeq_T \Omega_T$. The chosen readbacks provide

$$\mathsf{Pre}_X(B, \mathrm{pre}_X(B)), \qquad \mathsf{Pre}_X(\Omega_T, \mathrm{pre}_X(\Omega_T)).$$

Classifier-determinacy of readback applied to $B \simeq_T \Omega_T$ yields

$$\mathrm{pre}_X(B) \simeq_S \mathrm{pre}_X(\Omega_T).$$

By Definition 185.15,

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Transitivity of $\simeq_S$ gives

$$\mathrm{pre}_X(B) \simeq_S \Omega_S.$$

□

Theorem 185.23 (Source coverage induced by total-event exactness)**.** *Let* $\Vdash_S (h, A)$ *denote source-event incidence of a carried source history* h *in a source event* A*. Assume incidence respects the source event classifier:*

$$A \simeq_S A' \wedge \Vdash_S (h, A) \Longrightarrow \Vdash_S (h, A'),$$

and assume the source total event covers every carried source history:

$$\mathsf{Src}_S(h) \Longrightarrow \Vdash_S (h, \Omega_S).$$

Under the total-readback certificate of Definition 185.14,

$$\mathsf{Src}_S(h) \Longrightarrow \Vdash_S (h, \mathrm{pre}_X(\Omega_T)).$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate source coverage`

Proof. Let $\mathsf{Src}_S(h)$. By total coverage,

$$\Vdash_S (h, \Omega_S).$$

By Definition 185.15,

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Symmetry gives

$$\Omega_S \simeq_S \mathrm{pre}_X(\Omega_T).$$

Incidence transport along this classifier witness, read through Definition 26.3, yields

$$\Vdash_S (h, \mathrm{pre}_X(\Omega_T)).$$

□

Proposition 185.24 (Partiality obstruction detected by the target-total preimage)**.** *Assume source-event incidence is classifier-stable and* Ω_S *covers every carried source history as in Definition 185.23. If there exists a carried source history* h *such that*

$$\mathsf{Src}_S(h) \quad \textit{and} \quad \neg \Vdash_S (h, \mathrm{pre}_X(\Omega_T)),$$

then X *cannot carry a total-readback certificate satisfying Definition 185.14. Equivalently, any carried* $\mathsf{RandomVar}^{\uparrow}$ *total-readback certificate forces the target-total preimage to cover the entire source carrier.*

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTotalReadbackCertificate partiality obstruction`

Proof. Suppose, toward contradiction, that X carries the certificate of Definition 185.14. Then Definition 185.23 applies and gives

$$\mathsf{Src}_S(h) \Longrightarrow \Vdash_S (h, \mathrm{pre}_X(\Omega_T)).$$

For the displayed h, this contradicts

$$\neg \Vdash_S (h, \mathrm{pre}_X(\Omega_T)).$$

Thus no such total-readback certificate can exist. □

Corollary 185.25 (Terminal preimage exactness is the unique no-loss boundary condition)**.** *Assume the source Boolean defect law of Definition 185.21 and the source incidence discipline of Definition 185.23. For a carried* $\mathsf{RandomVar}^{\uparrow}$ *map* $X : S \to T$ *satisfying measurable-preimage readback, the following three statements are equivalent whenever the relevant events are source-measurable:*

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S,$$

$$\mathfrak{D}_X \simeq_S \bot_S,$$

$$\forall h \ \big(\mathsf{Src}_S(h) \Longrightarrow \Vdash_S (h, \mathrm{pre}_X(\Omega_T))\big),$$

provided the source event classifier is incidence-complete in the following sense:

$$\Big(\forall h\, [\mathsf{Src}_S(h) \Rightarrow (\Vdash_S (h, A) \Longleftrightarrow \Vdash_S (h, A'))]\Big) \Longrightarrow A \simeq_S A'.$$

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarTerminalPreimage no loss boundary`
↪ variant `BEDC.Derived.RandomVarUp.RandomVarTerminalPreimage coverage defect iff`

Proof. The equivalence between

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S$$

and

$$\mathfrak{D}_X \simeq_S \bot_S$$

is Definition 185.21. If

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S,$$

then the coverage statement follows by the proof of Definition 185.23. Conversely, assume

$$\forall h \ \big(\mathsf{Src}_S(h) \Rightarrow \Vdash_S (h, \mathrm{pre}_X(\Omega_T))\big).$$

Since Ω_S covers every carried source history, for every h with $\mathsf{Src}_S(h)$ both

$$\Vdash_S (h, \Omega_S) \quad \text{and} \quad \Vdash_S (h, \mathrm{pre}_X(\Omega_T))$$

hold. Hence, on the source carrier,

$$\Vdash_S (h, \mathrm{pre}_X(\Omega_T)) \Longleftrightarrow \Vdash_S (h, \Omega_S).$$

Incidence-completeness of the event classifier gives

$$\mathrm{pre}_X(\Omega_T) \simeq_S \Omega_S.$$

Therefore all three conditions are equivalent. □

Theorem 185.26 (RandomVar countable preimage union exactness)**.** *Let* $X : S \to T$ *be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write* $\mathcal{A}_S$ *and* $\mathcal{A}_T$ *for the source and target measurable-event families, and write* $E \sim_{\mathcal{A}_S} F$ *for the source event classifier of Definition 92.7. Let* $B_\bullet$ *be a target measurable-event sequence, so* $B_n \in \mathcal{A}_T$ *for every* $n : \mathbb{N}$*, and let* $U_T \in \mathcal{A}_T$ *be the displayed target countable-union row*

$$t \in U_T \quad \Longleftrightarrow \quad \exists n : \mathbb{N} \ \ t \in B_n.$$

For each n*, set*

$$A_n := X^{-1}(B_n), \qquad A_U := X^{-1}(U_T).$$

If the $\mathsf{RandomVar}^{\uparrow}$ *certificate row of section 185.2 sends every target measurable event to its source measurable preimage with membership readback, then* $A_U \in \mathcal{A}_S$ *and* $A_n \in \mathcal{A}_S$ *for every* n*. Let* U_S *be the source countable union of the measurable sequence* $A_\bullet$ *supplied by the source* $\mathsf{Measure}^{\uparrow}$ *sigma-algebra row of Definition 92.4. Then*

$$U_S \in \mathcal{A}_S, \qquad A_U \sim_{\mathcal{A}_S} U_S.$$

Moreover, if $B_\bullet$ *is pairwise disjoint in the target carried fiber, meaning that for* $m \neq n$ *no carried target point has witnesses in both* B_m *and* B_n*, then* $A_\bullet$ *is pairwise disjoint in the source carried fiber.*

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarPreimage countable union exactness`

Proof. The measurable-preimage row applies to U_T and to each target event B_n. Hence

$$A_U \in \mathcal{A}_S, \qquad A_n \in \mathcal{A}_S \quad \text{for every } n : \mathbb{N}.$$

Thus $A_\bullet$ is a source measurable sequence. The source $\mathsf{Measure}^{\uparrow}$ sigma-algebra row supplies its countable union U_S, with $U_S \in \mathcal{A}_S$ and membership readback

$$s \in U_S \quad \Longleftrightarrow \quad \exists n : \mathbb{N} \;\; s \in A_n.$$

Fix a carried source point s. The preimage and target countable-union readbacks give

$$s \in A_U \quad \Longleftrightarrow \quad X(s) \in U_T \quad \Longleftrightarrow \quad \exists n : \mathbb{N} \;\; X(s) \in B_n.$$

For each index n, the preimage readback for B_n gives

$$X(s) \in B_n \quad \Longleftrightarrow \quad s \in A_n.$$

Therefore

$$s \in A_U \quad \Longleftrightarrow \quad \exists n : \mathbb{N} \;\; s \in A_n \quad \Longleftrightarrow \quad s \in U_S.$$

The two events have the same carried source memberships. By the source event-classifier component of Definition 92.7, this is exactly

$$A_U \sim_{\mathcal{A}_S} U_S.$$

Assume $B_\bullet$ is pairwise disjoint. Let $m, n : \mathbb{N}$ with $m \neq n$, and suppose a carried source point s has witnesses $s \in A_m$ and $s \in A_n$. The two preimage readbacks give witnesses $X(s) \in B_m$ and $X(s) \in B_n$. Since $X(s)$ is a carried target point, target pairwise disjointness eliminates this pair. Hence no carried source point can inhabit both A_m and A_n for distinct m, n, which is exactly pairwise disjointness of $A_\bullet$ in the source fiber. □

Theorem 185.27 (RandomVar scoped closure package)**.** *Let* $X : S \to T$ *be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map from a displayed* $\mathsf{ProbSpace}^{\uparrow}$ *source to a displayed* $\mathsf{Measure}^{\uparrow}$ *target, with the source-event classifier transported through the certificate rows of section 185.2 and with endpoint comparisons read through the relevant* $\mathsf{Real}^{\uparrow}$ *classifiers. The carried* $\mathsf{RandomVar}^{\uparrow}$ *surface supplies the following scoped package:*

1. *finite measurable-preimage exactness, including disjoint binary unions, relative differences, complements over the total event, and the empty event;*
2. *total-event exactness for* $\mathrm{pre}_X(\Omega_T)$*, uniqueness of the total-readback boundary, and source coverage forced by the target-total preimage;*

3. *terminal no-loss equivalence at the target total event; and*
4. *countable measurable-preimage union exactness, with pairwise disjointness transported from the target sequence to the source sequence.*

This is the scoped carried preimage package available to downstream Distribution$^{\uparrow}$, Independence$^{\uparrow}$, *and* CondExp$^{\uparrow}$ *constructions over the same displayed source and target rows.*

Proof. The finite preimage rows are the checked component sites Definition 185.2, Definition 185.3, Definition 185.4, and Definition 185.5. They share the same carried map X, the same source-event classifier, and the same measurable-preimage readback, so they form one finite exactness surface.

For the total boundary, Definition 185.15 identifies the target-total preimage with the source total event, Definition 185.16 gives uniqueness of the total-readback boundary, and Definition 185.23 turns the exactness row into source coverage by the target-total preimage. The no-loss boundary is the equivalence recorded in Definition 185.25.

Finally, Definition 185.26 supplies the countable union row and transports pairwise disjointness from the target sequence to the source sequence. Collecting these rows gives exactly the carried measurable-preimage and total-readback package stated above; no additional bridge to standard probability spaces is used. □

Closure status for NameCert$_{\text{RandomVar}^{\uparrow}}$.

Constructive story: A random variable in this package is a carried BEDC map from a displayed ProbSpace$^{\uparrow}$ source to a displayed Measure$^{\uparrow}$ target, accepted only when every target measurable event named by the certificate has a source measurable preimage with a public membership readback. Two carried maps are compared through the source and target event classifiers, not by host function extensionality: their visible preimage rows must classify the same source events, and the relevant Real$^{\uparrow}$ endpoint comparisons are read through the measure and probability ledgers already on the surface. The source specification covers carried maps together with the source probability carrier, target measure carrier, total-event row, and measurable-preimage operation, while the pattern specification records finite preimage exactness, complement and relative-difference exactness, empty-event exactness, terminal no-loss at the target total event, and countable-union exactness. The ledger policy keeps each target event, its source preimage, the pointwise membership equivalence, disjointness transport, total-event defect row, and countable-union witness visible, so no probability-space bridge is needed to recover what was checked. The five name-certificate obligations follow from the supplied carried map and from the event classifiers of ProbSpace$^{\uparrow}$ and Measure$^{\uparrow}$: the source and target carriers give inhabited rows when a map is displayed, reflexivity, symmetry, and transitivity are inherited by the preimage event comparisons, and carrier closure is exactly transport of measurable preimages along those classifiers. A map history h lies in the signature gap of a RandomVar$^{\uparrow}$ token p when the source-domain accepts h as a carried measurable map, the signature relation pairs it with an answer preimage package and evidence ledger, and the token-introduction relation names that package as p; unfolded, the preimage of every finite, terminal, or countable target event is the source event encoded by p with the same classifier readback. The chapter registers this carried preimage package under the name RandomVar$^{\uparrow}$; it introduces no independence theory, conditional expectation, distribution package beyond preimages, host function equality, or standard probability-space bridge.

Theory closure: TheoryGate(NameCert$_{\text{RandomVar}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper scope is the finite, total, terminal, and countable preimage package for carried RandomVar$^{\uparrow}$ maps over displayed ProbSpace$^{\uparrow}$, Measure$^{\uparrow}$, and Real$^{\uparrow}$ endpoint classifiers.

Formal verification: FormalStatus(NameCert$_{\text{RandomVar}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RandomVarUp.RandomVarPreimage\_countable\_union\_exactness`

Bridge status: paperBridge

Not claimed: The chapter does not close independence, conditional expectation, distributions beyond the preimage package, or standard probability-space bridges.

Upgrade path: The remaining work is Lean-side bridgeCheckedV for a standard probability-space bridge; no higher theory-axis grade remains.

Theorem 185.28 (RandomVar martingale-filtration handoff)**.** *Every* Martingale$^{\uparrow}$ *or* StoppingTime$^{\uparrow}$ *consumer of a* RandomVar$^{\uparrow}$ *endpoint must read the source* ProbSpace$^{\uparrow}$ *row, event-preimage exactness rows, total-readback certificate, filtration visibility row, componentwise* hsame *transport,*

displayed Cont *replay,* Pkg *provenance, and local* NameCert *row before conditional-expectation or stopping decisions are exposed. The handoff exports no host measurable function, completed sigma-algebra, almost-sure quotient equality, or unbounded stopping choice.*

Proof. Start with the carrier and certificate surface of section 185.1 and section 185.2. The source probability row is supplied by chapter 184, and the preimage rows are the finite event-readback rows recorded in Definition 185.1.

Read the exactness children next. The disjoint-union, relative-difference, complement, empty-event, binary-intersection, terminal, and countable preimage rows in the existing random-variable files keep every target-event observation inside the displayed source event ledger. The total-readback certificate of Definition 185.14 supplies the terminal source coverage needed before an endpoint can be treated as a process value.

For a martingale consumer, the endpoint row is then exposed only through the finite process surface of chapter 190. A stopping-time consumer reads the same endpoint only through the filtration-prefix route of chapter 344, so the visibility row is a finite ledger read rather than a host filtration.

Finally replay the structural rows. Componentwise hsame, displayed Cont, Pkg, and the local NameCert preserve the same source-probability, preimage, total-readback, and filtration-visibility route before $\mathsf{CondExp}^{\uparrow}$ or bounded stopping data are consumed. Since no row stores a host measurable function, completed sigma-algebra, almost-sure quotient equality, or unbounded stopping choice, the handoff cannot export them. □

Lean4 ✓ `BEDC.Derived.RandomVarUp.RandomVarMartingaleFiltration handoff`

Chapter 186

A Concrete Naming Certificate for $\mathsf{Distribution}^{\uparrow}$

The distribution interface $\mathsf{Distribution}^{\uparrow}$ packages the pushforward measure of a random variable on its target space. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92).

186.1 Carrier definition

Definition 186.1 (Distribution pushforward carrier)**.** *A carried* $\mathsf{Distribution}^{\uparrow}$ *datum consists of a carried* $\mathsf{RandomVar}^{\uparrow}$ *map* $X : S \to T$ *as in section 185.1, a* $\mathsf{ProbSpace}^{\uparrow}$ *source carrier whose measurable-event family and probability measure are written* $\mathcal{A}_S$ *and* μ_S*, and a target* $\mathsf{Measure}^{\uparrow}$ *carrier whose measurable-event family is written* $\mathcal{A}_T$*. For each target measurable event* $B \in \mathcal{A}_T$*, the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage row supplies a source measurable event*

$$X^{-1}(B) \in \mathcal{A}_S.$$

The pushed-forward endpoint is the RealUp-valued row

$$\mu_X(B) := \mu_S(X^{-1}(B)).$$

Thus the $\mathsf{Distribution}^{\uparrow}$ *carrier is the target measurable family* $\mathcal{A}_T$ *together with the endpoint assignment* $B \mapsto \mu_X(B)$ *whose source is the probability measure of the carried source.*

Lean4 (definition) `BEDC.Derived.DistributionUp.DistributionPushforwardSourceSpec`

Definition 186.2 (Distribution pushforward classifier)**.** *Let* $(\mathcal{A}_T, \mu_X)$ *and* $(\mathcal{A}'_T, \mu'_Y)$ *be two displayed* $\mathsf{Distribution}^{\uparrow}$ *pushforward rows carried by target event classifiers* $\sim_{\mathcal{A}_T}$ *and by the* $\mathsf{Real}^{\uparrow}$ *classifier* $\sim_R$ *of Definition 38.9. The rows are classified when, for every pair of displayed target measurable events* $B \in \mathcal{A}_T$ *and* $B' \in \mathcal{A}'_T$ *with*

$$B \sim_{\mathcal{A}_T} B',$$

their pushed-forward endpoints agree under the real classifier:

$$\mu_X(B) \sim_R \mu'_Y(B').$$

Equivalently, the event classifier decides which target events may be compared, and the RealUp classifier decides equality of their measured pushforward endpoints.

Lean4 (definition) `BEDC.Derived.DistributionUp.DistributionPushforwardClassifier`
Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforwardClassifier row`

186.2 The certificate

Theorem 186.3 (Distribution pushforward row)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map from a* $\mathsf{ProbSpace}^{\uparrow}$ *source to a target* $\mathsf{Measure}^{\uparrow}$ *carrier, and let μ_X be the* $\mathsf{Distribution}^{\uparrow}$ *endpoint assignment of Definition 186.1. Write $\mathcal{A}_T$ for the target measurable-event family, μ_S for the source probability measure, and $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier. Then for every target measurable event $B \in \mathcal{A}_T$,*

$$\mu_X(B) \sim_R \mu_S(X^{-1}(B)).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward row`

Proof. By Definition 186.1, the endpoint $\mu_X(B)$ is defined by applying the source probability measure to the measurable preimage supplied by the $\mathsf{RandomVar}^{\uparrow}$ row:

$$\mu_X(B) := \mu_S(X^{-1}(B)).$$

The measurable-preimage row ensures that $X^{-1}(B)$ is a legitimate source measurable event before the source measure is read. The source $\mathsf{ProbSpace}^{\uparrow}$ carrier supplies the measure row μ_S on that event.

The displayed equality is therefore an endpoint identity in $\mathsf{Real}^{\uparrow}$. Reflexivity of the $\mathsf{Real}^{\uparrow}$ classifier gives

$$\mu_S(X^{-1}(B)) \sim_R \mu_S(X^{-1}(B)).$$

Transport along the definitional carrier equality reads this as

$$\mu_X(B) \sim_R \mu_S(X^{-1}(B)).$$

□

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforwardCarrier row`

Theorem 186.4 (Distribution NameCert obligation packet)**.** *The* $\mathsf{Distribution}^{\uparrow}$ *pushforward surface supplies the NameCert obligation packet for a carried random variable $X : S \to T$ over a source* $\mathsf{ProbSpace}^{\uparrow}$ *carrier and a target* $\mathsf{Measure}^{\uparrow}$ *carrier. Its ten-field roadmap fit is:*

1. ***Traditional target****: the distribution law of X, regarded as the pushforward probability measure on target measurable events.*
2. ***BEDC source****: the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage certificate, the source* $\mathsf{ProbSpace}^{\uparrow}$ *measure rows, the target* $\mathsf{Measure}^{\uparrow}$ *event classifier, and the shared* $\mathsf{Real}^{\uparrow}$ *classifier.*
3. ***Carrier choice****: the target measurable family $\mathcal{A}_T$ equipped with the endpoint assignment $B \mapsto \mu_S(X^{-1}(B))$ from Definition 186.1.*
4. ***Classifier choice****: the row classifier of Definition 186.2, combining target-event classification with RealUp endpoint classification.*
5. ***Stability obligations****: target-event transport through the* $\mathsf{Measure}^{\uparrow}$ *classifier, source-preimage transport through the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage rows, source-measure transport through the source* $\mathsf{Measure}^{\uparrow}$ *ledger, and reflexive, symmetric, transitive, and congruent use of the* $\mathsf{Real}^{\uparrow}$ *classifier.*
6. ***Ledger****: the source event $X^{-1}(B)$ is retained as the hidden witness explaining each target endpoint, while the public row exposes only the target event B and the real endpoint $\mu_X(B)$.*

7. ***Core theorem list**: the pushforward row of Definition 186.3, total-mass inheritance Definition 186.5, empty-event inheritance Definition 186.6, finite additivity Definition 186.7, monotonicity Definition 186.11, probability bounds Definition 186.12, complement-mass decomposition Definition 186.13, countable disjoint sigma-additivity Definition 186.14, and continuity from below Definition 186.15.*

8. ***Exactness predicate**: for every target measurable event B, the row exactness predicate is $\mu_X(B) \sim_R \mu_S(X^{-1}(B))$, with target-event classifier transport and source-event ledger transport preserving the displayed endpoint.*

9. ***Standard bridge**: the ordinary measure-theoretic pushforward law $X_*\mu_S$ on the target measurable space, read conservatively through the target event classifier and the RealUp endpoint classifier.*

10. ***Status**: the packet records the carrier and certificate obligations at the paper level, with Lean formalization reserved for the* BEDC.*Derived.DistributionUp namespace.*

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforwardCarrier semantic name certificate`

Proof. The carrier and classifier fields are exactly Definition 186.1 and Definition 186.2. The carrier uses the $\mathsf{RandomVar}^{\uparrow}$ measurable-preimage row to make $X^{-1}(B)$ a source measurable event, and then reads the source $\mathsf{ProbSpace}^{\uparrow}$ measure row at that event.

The stability and exactness fields follow from the same chain. Target-event transport is supplied by the $\mathsf{Measure}^{\uparrow}$ event classifier; source-preimage transport is supplied by the RandomVarUp measurable-preimage certificate; source-measure transport is read through the source $\mathsf{Measure}^{\uparrow}$ ledger; endpoint comparison is composed by RealUp classifier reflexivity and transitivity.

The ledger field records that the source event is kept as hidden witness data for each public target endpoint. This is precisely the information consumed by the downstream mass, empty-event, additivity, monotonicity, sigma-additivity, and continuity-from-below rows in this chapter.

The standard bridge is the usual pushforward measure surface, but only as a conservative readback of the displayed BEDC rows. No host quotient or host event equality is imported into the carrier; all comparisons pass through the target-event and RealUp classifiers. □

Theorem 186.5 (Distribution pushforward total mass is the probability unit)**.** *Let X be a carried $\mathsf{RandomVar}^{\uparrow}$ map as in section 185.1, from a $\mathsf{ProbSpace}^{\uparrow}$ source as in section 184.1 to a $\mathsf{Measure}^{\uparrow}$ target as in section 92.1. Write Ω_S for the source total event, Ω_T for the target total event, $\mathcal{A}_S, \mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the $\mathsf{Distribution}^{\uparrow}$ pushforward measure as in section 186.1, 1_R for the probability unit, and $x \sim_R y$ for the $\mathsf{Real}^{\uparrow}$ classifier of Definition 38.9. Suppose:*

- *$\Omega_S \in \mathcal{A}_S$ and $\Omega_T \in \mathcal{A}_T$;*
- *the $\mathsf{RandomVar}^{\uparrow}$ certificate row of section 185.2 identifies the target-total preimage as the source total event,*
$$X^{-1}(\Omega_T) = \Omega_S;$$
- *the $\mathsf{Distribution}^{\uparrow}$ pushforward row of section 186.2 gives, at every target measurable event $B \in \mathcal{A}_T$,*
$$\mu_X(B) \sim_R \mu_S(X^{-1}(B));$$
- *the $\mathsf{ProbSpace}^{\uparrow}$ total-mass row of section 184.2 gives*
$$\mu_S(\Omega_S) \sim_R 1_R.$$

Then

$$\mu_X(\Omega_T) \sim_R 1_R.$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward total mass unit`
↪ variant `BEDC.Derived.DistributionUp.DistributionPushforwardWitness total mass unit`

Proof. Apply the pushforward row to the target total event $B := \Omega_T$. Since $\Omega_T \in \mathcal{A}_T$, this gives

$$\mu_X(\Omega_T) \sim_R \mu_S(X^{-1}(\Omega_T)).$$

The random-variable target-total row identifies $X^{-1}(\Omega_T)$ with Ω_S as a measurable source event, and source-event transport through Definition 26.3 permits the source-measure value to be read at the transported event. Thus the preceding comparison reads

$$\mu_X(\Omega_T) \sim_R \mu_S(\Omega_S).$$

The probability-space total-mass row gives

$$\mu_S(\Omega_S) \sim_R 1_R.$$

The relation $\sim_R$ is the $\mathsf{Real}^\uparrow$ classifier, hence its transitivity field composes these two classifications and yields

$$\mu_X(\Omega_T) \sim_R 1_R.$$

□

Theorem 186.6 (Distribution empty target event has zero mass)**.** *Let X be a carried* $\mathsf{RandomVar}^\uparrow$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^\uparrow$ *source as in section 184.1 to a* $\mathsf{Measure}^\uparrow$ *target as in section 92.1. Write $\varnothing_S$ and $\varnothing_T$ for the source and target empty events, $\mathcal{A}_S, \mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^\uparrow$ *pushforward measure as in section 186.1, 0_R for the additive zero in* $\mathsf{Real}^\uparrow$*, and $x \sim_R y$ for the* $\mathsf{Real}^\uparrow$ *classifier of Definition 38.9. Suppose:*

- *$\varnothing_S \in \mathcal{A}_S$ and $\varnothing_T \in \mathcal{A}_T$;*
- *the* $\mathsf{RandomVar}^\uparrow$ *certificate row of section 185.2 identifies the target-empty preimage as the source empty event,*
$$X^{-1}(\varnothing_T) = \varnothing_S;$$
- *the* $\mathsf{Distribution}^\uparrow$ *pushforward row of section 186.2 gives, at every target measurable event $B \in \mathcal{A}_T$,*
$$\mu_X(B) \sim_R \mu_S(X^{-1}(B));$$
- *the source* $\mathsf{Measure}^\uparrow$ *certificate and the shared* $\mathsf{Real}^\uparrow$ *additive* $\mathsf{AbGroup}^\uparrow$ *row satisfy the hypotheses of Definition 92.25 for $\mathcal{A}_S, \mu_S, \varnothing_S$, with additive zero 0_R.*

Then

$$\mu_X(\varnothing_T) \sim_R 0_R.$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward empty target event zero mass`

Proof. Apply the pushforward row to the target empty event $B := \varnothing_T$. Since $\varnothing_T \in \mathcal{A}_T$, this gives

$$\mu_X(\varnothing_T) \sim_R \mu_S(X^{-1}(\varnothing_T)).$$

The random-variable target-empty row identifies $X^{-1}(\varnothing_T)$ with $\varnothing_S$ as a measurable source event, and source-event transport through Definition 26.3 permits the source-measure value to be read at the transported event. Thus the preceding comparison reads

$$\mu_X(\varnothing_T) \sim_R \mu_S(\varnothing_S).$$

By Definition 92.25 applied to the source $\mathsf{Measure}^{\uparrow}$ instance,

$$\mu_S(\varnothing_S) \sim_R 0_R.$$

The relation $\sim_R$ is the $\mathsf{Real}^{\uparrow}$ classifier, hence its transitivity field composes these two classifications and yields

$$\mu_X(\varnothing_T) \sim_R 0_R.$$

□

Theorem 186.7 (Distribution pushforward finite disjoint-union additivity)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a* $\mathsf{Measure}^{\uparrow}$ *target as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure as in section 186.1, and $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9. Let B, C, U_T be target events such that $B, C, U_T \in \mathcal{A}_T$ and the displayed target binary-union row reads U_T as $B \cup C$:*

$$t \in U_T \quad \Longleftrightarrow \quad t \in B \text{ or } t \in C.$$

Assume B and C are disjoint. Define

$$A_B := X^{-1}(B), \qquad A_C := X^{-1}(C), \qquad A_U := X^{-1}(U_T).$$

Let U_S be the source binary union of A_B and A_C supplied by the source $\mathsf{Measure}^{\uparrow}$ *sigma-algebra row. Suppose:*

- *the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage row and the source sigma-algebra row satisfy the hypotheses of Definition 185.2 for B, C, U_T;*
- *the* $\mathsf{Distribution}^{\uparrow}$ *pushforward row of section 186.2 gives, at every target measurable event $E \in \mathcal{A}_T$,*
$$\mu_X(E) \sim_R \mu_S(X^{-1}(E));$$
- *the source* $\mathsf{Measure}^{\uparrow}$ *certificate and the shared* $\mathsf{Real}^{\uparrow}$ *additive* $\mathsf{AbGroup}^{\uparrow}$ *row satisfy the hypotheses of Definition 92.26 for the disjoint measurable pair A_B, A_C and its measurable binary union U_S;*
- *source-event transport through Definition 26.3 permits μ_S to be read across the source event classifier supplied by Definition 92.7.*

Then

$$\mu_X(U_T) \sim_R \mu_X(B) + \mu_X(C).$$

Proof. Apply Definition 185.2 to the displayed target union $U_T = B \cup C$. It gives

$$A_B, A_C, A_U \in \mathcal{A}_S,$$

identifies U_S as a measurable source binary union, classifies the target-union preimage with that source union,

$$A_U \sim_{\mathcal{A}_S} U_S,$$

and shows that A_B and A_C are disjoint source events.

Apply the pushforward row to U_T, B, and C. This gives

$$\mu_X(U_T) \sim_R \mu_S(A_U),$$

$$\mu_X(B) \sim_R \mu_S(A_B), \qquad \mu_X(C) \sim_R \mu_S(A_C).$$

The source-event comparison $A_U \sim_{\mathcal{A}_S} U_S$, read through the source measure ledger by Definition 26.3, gives

$$\mu_S(A_U) \sim_R \mu_S(U_S).$$

Since A_B and A_C are disjoint measurable source events and U_S is their measurable binary union, Definition 92.26 applied to the source $\mathsf{Measure}^{\uparrow}$ carrier yields

$$\mu_S(U_S) \sim_R \mu_S(A_B) + \mu_S(A_C).$$

Transitivity of the $\mathsf{Real}^{\uparrow}$ classifier composes the three comparisons into

$$\mu_X(U_T) \sim_R \mu_S(A_B) + \mu_S(A_C).$$

By symmetry of $\sim_R$, the pushforward comparisons for B and C also read

$$\mu_S(A_B) \sim_R \mu_X(B), \qquad \mu_S(A_C) \sim_R \mu_X(C).$$

The additive congruence field of the shared $\mathsf{Real}^{\uparrow}$ additive $\mathsf{AbGroup}^{\uparrow}$ row transports these two comparisons through $+$, giving

$$\mu_S(A_B) + \mu_S(A_C) \sim_R \mu_X(B) + \mu_X(C).$$

A final transitivity step gives

$$\mu_X(U_T) \sim_R \mu_X(B) + \mu_X(C).$$

□

Theorem 186.8 (Distribution nonnegative value inheritance)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a* $\mathsf{Measure}^{\uparrow}$ *target as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure as in section 186.1, $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9, and* NonNeg_R *for the nonnegative predicate exposed by the shared* $\mathsf{RealAlgOrder}$ *row. Let B be a target event with $B \in \mathcal{A}_T$, and define*

$$A_B := X^{-1}(B).$$

Suppose:

- *the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage row of section 185.2 sends the target measurable event* B *to the source measurable event* A_B*, so* $A_B \in \mathcal{A}_S$*;*
- *the* $\mathsf{Distribution}^{\uparrow}$ *pushforward row of section 186.2 gives, at the target event* B*,*

$$\mu_X(B) \sim_R \mu_S(A_B);$$

- *the source* $\mathsf{Measure}^{\uparrow}$ *component of the* $\mathsf{ProbSpace}^{\uparrow}$ *source exposes the nonnegative value row of Definition 92.98, and the same* $\mathsf{RealAlgOrder}$ *nonnegative predicate is stable under the* $\mathsf{Real}^{\uparrow}$ *classifier.*

Then

$$\mathsf{NonNeg}_R(\mu_X(B)).$$

Proof. The measurable-preimage row makes A_B a displayed measurable event in the source measurable family. Reading the source probability space through its underlying $\mathsf{Measure}^{\uparrow}$ component, Definition 92.98 supplies

$$\mathsf{NonNeg}_R(\mu_S(A_B)).$$

The pushforward row identifies the pushed-forward endpoint with the source endpoint:

$$\mu_X(B) \sim_R \mu_S(A_B).$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier, this also reads

$$\mu_S(A_B) \sim_R \mu_X(B).$$

Stability of the $\mathsf{RealAlgOrder}$ nonnegative predicate under $\sim_R$ transports the displayed source nonnegative row across this classifier comparison, giving

$$\mathsf{NonNeg}_R(\mu_X(B)).$$

□

Then

$$\mu_X(B) \leq_R \mu_X(C).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward monotone under target inclusion`

Proof. Apply Definition 185.3 with the ambient target event $A := C$ and the subevent B. It gives

$$A_B, A_C \in \mathcal{A}_S$$

and reads the target inclusion $B \subseteq C$ as the source inclusion

$$A_B \subseteq A_C.$$

It also supplies the source relative-difference ledger: the event $A_C \setminus A_B$ is measurable, is disjoint from A_B, and its displayed binary union with A_B is classified as A_C in the source event classifier.

These are exactly the inclusion-decomposition inputs for Definition 92.99 in the source $\mathsf{Measure}^{\uparrow}$ carrier. Hence

$$\mu_S(A_B) \leq_R \mu_S(A_C).$$

Apply the pushforward row to B and C. Since both are target measurable,

$$\mu_X(B) \sim_R \mu_S(A_B), \qquad \mu_X(C) \sim_R \mu_S(A_C).$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier, the first comparison also reads $\mu_S(A_B) \sim_R \mu_X(B)$. Transport the left endpoint of the source order comparison across this classifier equality, and then transport the right endpoint across $\mu_S(A_C) \sim_R \mu_X(C)$ using stability of the RealAlgOrder order row. The resulting comparison is

$$\mu_X(B) \leq_R \mu_X(C).$$

□

Theorem 186.10 (Distribution pushforward relative-difference additivity)**.** *Let* $X : S \to T$ *be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section 92.1. Write* $\mathcal{A}_S$ *and* $\mathcal{A}_T$ *for the source and target measurable-event families,* μ_S *for the source measure,* μ_X *for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure as in section 186.1, and* $x \sim_R y$ *for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9. Let* A *and* B *be target events in one carried target fiber with* $A, B \in \mathcal{A}_T$*, and suppose the public target readback displays* $B \subseteq A$*. Suppose the target complement/relative-difference row of Definition 92.16 supplies a measurable target event*

$$D_T := A \setminus B$$

with public membership readback

$$t \in D_T \iff t \in A \text{ and } t \notin B.$$

Define source preimages

$$A_S := X^{-1}(A), \qquad B_S := X^{-1}(B), \qquad D_X := X^{-1}(D_T).$$

Let $D_S := A_S \setminus B_S$ *be the source relative-difference event supplied by the source* $\mathsf{Measure}^{\uparrow}$ *complement/relative-difference row once the source inclusion* $B_S \subseteq A_S$ *is displayed. Suppose:*

- *the* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage row and the source complement/relative-difference row satisfy the hypotheses of Definition 185.3 for* A, B, D_T*;*
- *the* $\mathsf{Distribution}^{\uparrow}$ *pushforward row of section 186.2 gives, at every target measurable event* $E \in \mathcal{A}_T$*,*
$$\mu_X(E) \sim_R \mu_S(X^{-1}(E));$$
- *the source* $\mathsf{Measure}^{\uparrow}$ *certificate and the shared* $\mathsf{Real}^{\uparrow}$ *additive* $\mathsf{AbGroup}^{\uparrow}$ *row satisfy the hypotheses of Definition 92.102 for the displayed source inclusion* $B_S \subseteq A_S$*;*
- *source-event transport through Definition 26.3 permits* μ_S *to be read across the source event classifier supplied by Definition 92.7;*
- *the shared* $\mathsf{Real}^{\uparrow}$ *additive* $\mathsf{AbGroup}^{\uparrow}$ *row supplies addition congruence for* $\sim_R$*.*

Then
$$\mu_X(D_T) \sim_R \mu_S(D_S)$$
and
$$\mu_X(A) \sim_R \mu_X(B) + \mu_X(D_T).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward relative difference additivity`

Proof. Apply Definition 185.3 to the displayed target inclusion $B \subseteq A$ and to the target relative-difference event D_T. It gives
$$A_S, B_S, D_X \in \mathcal{A}_S,$$
reads the target inclusion as the source inclusion $B_S \subseteq A_S$, supplies $D_S \in \mathcal{A}_S$, and classifies the preimage of the target difference with the source difference:
$$D_X \sim_{\mathcal{A}_S} D_S.$$
The same source relative-difference ledger states that B_S and D_S are disjoint and that the displayed binary union $B_S \cup D_S$ is classified as A_S.

Apply the pushforward row to the three target measurable events A, B, and D_T. This gives
$$\mu_X(A) \sim_R \mu_S(A_S),$$
$$\mu_X(B) \sim_R \mu_S(B_S), \qquad \mu_X(D_T) \sim_R \mu_S(D_X).$$
Transport the source measure endpoint across $D_X \sim_{\mathcal{A}_S} D_S$ using the source event ledger. Hence
$$\mu_S(D_X) \sim_R \mu_S(D_S).$$
Transitivity of the $\mathsf{Real}^{\uparrow}$ classifier composes the pushforward comparison for D_T with this transport and yields
$$\mu_X(D_T) \sim_R \mu_S(D_S).$$

The source relative-difference ledger gives exactly the inputs for Definition 92.102 in the source $\mathsf{Measure}^{\uparrow}$ carrier. Therefore
$$\mu_S(A_S) \sim_R \mu_S(B_S) + \mu_S(D_S).$$
Composing with the pushforward comparison for A gives
$$\mu_X(A) \sim_R \mu_S(B_S) + \mu_S(D_S).$$

By symmetry of $\sim_R$, the pushforward comparison for B reads $\mu_S(B_S) \sim_R \mu_X(B)$, and the displayed endpoint comparison for D_T reads $\mu_S(D_S) \sim_R \mu_X(D_T)$. Addition congruence in the shared $\mathsf{Real}^\uparrow$ additive $\mathsf{AbGroup}^\uparrow$ row transports these two endpoint comparisons through $+$, so

$$\mu_S(B_S) + \mu_S(D_S) \sim_R \mu_X(B) + \mu_X(D_T).$$

A final transitivity step gives

$$\mu_X(A) \sim_R \mu_X(B) + \mu_X(D_T).$$

□

Theorem 186.11 (Distribution pushforward monotone events)**.** *Let $X : S \to T$ be a carried $\mathsf{RandomVar}^\uparrow$ map as in section 185.1, from a $\mathsf{ProbSpace}^\uparrow$ source as in section 184.1 to a target $\mathsf{Measure}^\uparrow$ carrier as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the $\mathsf{Distribution}^\uparrow$ pushforward measure as in section 186.1, $x \sim_R y$ for the $\mathsf{Real}^\uparrow$ classifier of Definition 38.9, and $\leq_R$ for the order relation exposed by the target $\mathsf{RealAlgOrder}$ row. Let A and B be target events in one carried target fiber with $A, B \in \mathcal{A}_T$, and suppose the public target readback displays $B \subseteq A$. Define*

$$A_S := X^{-1}(A), \qquad B_S := X^{-1}(B).$$

Suppose:

- *the target complement/relative-difference row of Definition 92.16, the $\mathsf{RandomVar}^\uparrow$ measurable-preimage row, and the source complement/relative-difference row satisfy the hypotheses of Definition 185.3 for the ambient target event A and subevent B;*
- *the $\mathsf{Distribution}^\uparrow$ pushforward row of section 186.2 gives, at every target measurable event $E \in \mathcal{A}_T$,*
$$\mu_X(E) \sim_R \mu_S(X^{-1}(E));$$
- *the source $\mathsf{Measure}^\uparrow$ certificate satisfies the hypotheses of Definition 92.99 for the displayed source inclusion $B_S \subseteq A_S$ and the measurable relative-difference ledger supplied by the source row;*
- *the target $\mathsf{RealAlgOrder}$ order row on $\mathsf{Real}^\uparrow$ is stable under $\sim_R$ on both endpoints.*

Then

$$\mu_X(B) \leq_R \mu_X(A).$$

Proof. Let $D_T := A \backslash B$ be the target relative-difference event supplied by the target complement/relative-difference row, and let $D_X := X^{-1}(D_T)$. Apply Definition 185.3 to the displayed target inclusion $B \subseteq A$. It gives

$$A_S, B_S, D_X \in \mathcal{A}_S$$

and reads the target inclusion as the source inclusion

$$B_S \subseteq A_S.$$

It also supplies the source relative-difference event $D_S := A_S \setminus B_S$, with $D_S \in \mathcal{A}_S$, disjointness of B_S and D_S, and a displayed binary-union readback classifying $B_S \cup D_S$ as A_S.

These are exactly the inclusion-decomposition inputs for Definition 92.99 in the source $\mathsf{Measure}^\uparrow$ carrier, using B_S as the included event, A_S as the ambient event, and D_S as the displayed difference witness. Hence the source measure row gives

$$\mu_S(B_S) \leq_R \mu_S(A_S).$$

Apply the pushforward row to the target measurable events B and A. This gives

$$\mu_X(B) \sim_R \mu_S(B_S), \qquad \mu_X(A) \sim_R \mu_S(A_S).$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier, the first comparison also reads $\mu_S(B_S) \sim_R \mu_X(B)$. Transport the left endpoint of $\mu_S(B_S) \leq_R \mu_S(A_S)$ across this classifier comparison, and transport the right endpoint across $\mu_S(A_S) \sim_R \mu_X(A)$, using the endpoint stability of the target $\mathsf{RealAlgOrder}$ order row. The transported comparison is

$$\mu_X(B) \leq_R \mu_X(A).$$

□

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward monotone events`

Theorem 186.12 (Distribution pushforward probability bounds)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section 185.1, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section 184.1 to a* $\mathsf{Measure}^{\uparrow}$ *target as in section 92.1. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, Ω_S and Ω_T for the source and target total events, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure as in section 186.1, 1_R for the probability unit, $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9,* NonNeg_R *for the nonnegative predicate exposed by the shared* $\mathsf{RealAlgOrder}$ *row, and $\leq_R$ for its order relation. Let B be a target event with $B \in \mathcal{A}_T$, and suppose the public target readback displays $B \subseteq \Omega_T$. Define*

$$B_S := X^{-1}(B).$$

Suppose:

- *the hypotheses of Definition 186.8 hold for the target event B, so the source preimage B_S is measurable and the pushforward row compares $\mu_X(B)$ with $\mu_S(B_S)$;*
- *the hypotheses of Definition 186.11 hold for the displayed inclusion $B \subseteq \Omega_T$, with $A := \Omega_T$ as ambient target event;*
- *$\Omega_S \in \mathcal{A}_S$, $\Omega_T \in \mathcal{A}_T$, the* $\mathsf{RandomVar}^{\uparrow}$ *total-preimage row identifies $X^{-1}(\Omega_T) = \Omega_S$, and the* $\mathsf{ProbSpace}^{\uparrow}$ *total-mass row gives $\mu_S(\Omega_S) \sim_R 1_R$, so the hypotheses of Definition 186.5 hold at Ω_T;*
- *the target* $\mathsf{RealAlgOrder}$ *order row on* $\mathsf{Real}^{\uparrow}$ *is stable under $\sim_R$ on the right endpoint.*

Then both probability bounds hold:

$$\mathsf{NonNeg}_R(\mu_X(B))$$

and

$$\mu_X(B) \leq_R 1_R.$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward probability bounds`

Proof. Apply Definition 186.8 to the target measurable event B. Its source-preimage, pushforward-comparison, source nonnegative-measure, and $\mathsf{RealAlgOrder}$ stability hypotheses are exactly the first group of displayed assumptions, so it gives the lower endpoint

$$\mathsf{NonNeg}_R(\mu_X(B)).$$

Next apply Definition 186.11 to the inclusion $B \subseteq \Omega_T$. With the ambient event specialized to $A := \Omega_T$, the monotonicity row gives

$$\mu_X(B) \leq_R \mu_X(\Omega_T).$$

Apply Definition 186.5 to the same carried map and the target total event Ω_T. The total-preimage and source total-mass assumptions classify the right endpoint by the probability unit:

$$\mu_X(\Omega_T) \sim_R 1_R.$$

Finally transport the right endpoint of $\mu_X(B) \leq_R \mu_X(\Omega_T)$ across this $\mathsf{Real}^{\uparrow}$ classifier comparison using the right-endpoint stability field of the target $\mathsf{RealAlgOrder}$ row. The transported comparison is

$$\mu_X(B) \leq_R 1_R.$$

□

Theorem 186.13 (Distribution complement mass decomposition)**.** *Let $X : S \to T$ be a carried $\mathsf{RandomVar}^{\uparrow}$ map as in section 185.1, from a $\mathsf{ProbSpace}^{\uparrow}$ source as in section 184.1 to a $\mathsf{Measure}^{\uparrow}$ target as in section 92.1. Write Ω_S and Ω_T for the source and target total events, $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the $\mathsf{Distribution}^{\uparrow}$ pushforward measure as in section 186.1, 1_R for the probability unit, and $x \sim_R y$ for the $\mathsf{Real}^{\uparrow}$ classifier of Definition 38.9. Let B be a target event with $B \in \mathcal{A}_T$, and suppose the public target readback displays $B \subseteq \Omega_T$. Let*

$$B_T^{\complement} := \Omega_T \setminus B$$

be the target complement supplied by the target complement/relative-difference row, with public membership readback

$$t \in B_T^{\complement} \iff t \in \Omega_T \text{ and } t \notin B.$$

Suppose:

- *$\Omega_S \in \mathcal{A}_S$, $\Omega_T \in \mathcal{A}_T$, the $\mathsf{RandomVar}^{\uparrow}$ total-preimage row identifies $X^{-1}(\Omega_T) = \Omega_S$, the $\mathsf{Distribution}^{\uparrow}$ pushforward row is available at Ω_T, and the $\mathsf{ProbSpace}^{\uparrow}$ total-mass row gives $\mu_S(\Omega_S) \sim_R 1_R$, so the hypotheses of Definition 186.5 hold at Ω_T;*
- *the hypotheses of Definition 186.10 hold with ambient target event $A := \Omega_T$, subevent B, and displayed target difference $D_T := B_T^{\complement}$;*
- *the $\mathsf{Real}^{\uparrow}$ classifier $\sim_R$ supplies symmetry and transitivity.*

Then

$$\mu_X(\Omega_T) \sim_R \mu_X(B) + \mu_X(B_T^{\complement})$$

and

$$1_R \sim_R \mu_X(B) + \mu_X(B_T^{\complement}).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward complement mass decomposition`

Proof. Apply Definition 186.10 with ambient event $A := \Omega_T$, subevent B, and target difference $D_T := B_T^{\complement}$. Its displayed difference row identifies the relative difference with the target complement inside the total target event, and its endpoint row gives

$$\mu_X(\Omega_T) \sim_R \mu_X(B) + \mu_X(B_T^{\complement}).$$

Apply Definition 186.5 at the target total event Ω_T. The total-preimage and source total-mass rows give

$$\mu_X(\Omega_T) \sim_R 1_R.$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier, the total-mass comparison also reads $1_R \sim_R \mu_X(\Omega_T)$. Transitivity with the complement decomposition just obtained yields

$$1_R \sim_R \mu_X(B) + \mu_X(B_T^{\complement}).$$

□

Theorem 186.14 (Distribution pushforward countable disjoint-union sigma-additivity)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map from a* $\mathsf{ProbSpace}^{\uparrow}$ *source to a* $\mathsf{Measure}^{\uparrow}$ *target. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure, $E \simeq_S F$ for the source event classifier, and $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier. Let $(B_n)_{n\in\mathbb{N}}$ be target events with $B_n \in \mathcal{A}_T$ for every n, and let $U_T \in \mathcal{A}_T$ be a displayed target countable union:*

$$t \in U_T \iff \exists n \in \mathbb{N},\, t \in B_n.$$

Assume that the target row is pairwise disjoint: if $i \neq j$, no carried target point has simultaneous membership in B_i and B_j. For each n, put $A_n := X^{-1}(B_n)$ and put $A_U := X^{-1}(U_T)$. Suppose the following rows are available.

1. *The* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage row sends every target measurable event in this display to a source measurable event and gives the public readback*

$$s \in X^{-1}(E) \iff X(s) \in E.$$

2. *The source countable-union row supplies the source measurable event*

$$U_S := \bigvee\nolimits^{S}_{n\in\mathbb{N}} A_n \in \mathcal{A}_S,$$

and the countable preimage-union bridge supplies the source event classifier comparison

$$A_U \simeq_S U_S.$$

3. *The source* $\mathsf{Measure}^{\uparrow}$ *surface is sigma-additive on displayed pairwise-disjoint source-measurable countable unions:*

$$\mu_S(U_S) \sim_R \sum_{n\in\mathbb{N}} \mu_S(A_n).$$

4. *The* $\mathsf{Distribution}^{\uparrow}$ *pushforward row reads every target measurable event $E \in \mathcal{A}_T$ by*

$$\mu_X(E) \sim_R \mu_S(X^{-1}(E)).$$

5. *The source measure is readable through the source event classifier:*

$$E \simeq_S F \Longrightarrow \mu_S(E) \sim_R \mu_S(F).$$

6. *The countable* $\mathsf{Real}^{\uparrow}$ *sum endpoint is stable under pointwise* $\mathsf{Real}^{\uparrow}$ *classifier comparison:*

$$(\forall n \in \mathbb{N},\, r_n \sim_R q_n) \Longrightarrow \sum_{n\in\mathbb{N}} r_n \sim_R \sum_{n\in\mathbb{N}} q_n.$$

Then the pushed-forward target measure classifies the displayed target countable disjoint union by the countable sum of the pushed-forward component measures:

$$\mu_X(U_T) \sim_R \sum_{n\in\mathbb{N}} \mu_X(B_n).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward countable disjoint sigma additivity`

Proof. Invert the measurable-preimage row at U_T and at each B_n. This gives $A_U \in \mathcal{A}_S$, gives $A_n \in \mathcal{A}_S$ for every n, and gives the readbacks

$$s \in A_U \iff X(s) \in U_T$$

and

$$s \in A_n \iff X(s) \in B_n.$$

The source countable-union row supplies $U_S \in \mathcal{A}_S$, and the countable preimage-union bridge gives

$$A_U \simeq_S U_S.$$

The source sequence $(A_n)_{n\in\mathbb{N}}$ is pairwise disjoint. Indeed, let $i \neq j$ and suppose that a carried source point s has witnesses $s \in A_i$ and $s \in A_j$. The preimage readback for B_i gives $X(s) \in B_i$, and the preimage readback for B_j gives $X(s) \in B_j$. This contradicts the displayed target disjointness of B_i and B_j. Hence the hypotheses of the source sigma-additivity row apply to (A_n) and U_S, giving

$$\mu_S(U_S) \sim_R \sum_{n\in\mathbb{N}} \mu_S(A_n).$$

Apply the pushforward row to the target union U_T. Since $U_T \in \mathcal{A}_T$,

$$\mu_X(U_T) \sim_R \mu_S(A_U).$$

Read the source event comparison $A_U \simeq_S U_S$ through the source measure classifier-transport row. This gives

$$\mu_S(A_U) \sim_R \mu_S(U_S).$$

By transitivity of the $\mathsf{Real}^{\uparrow}$ classifier,

$$\mu_X(U_T) \sim_R \mu_S(U_S).$$

Composing this comparison with the source sigma-additivity comparison yields

$$\mu_X(U_T) \sim_R \sum_{n\in\mathbb{N}} \mu_S(A_n).$$

For each $n \in \mathbb{N}$, the pushforward row applied to the target measurable event B_n gives

$$\mu_X(B_n) \sim_R \mu_S(A_n).$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier,

$$\mu_S(A_n) \sim_R \mu_X(B_n).$$

The countable-sum stability row applied to the pointwise comparisons gives

$$\sum_{n\in\mathbb{N}} \mu_S(A_n) \sim_R \sum_{n\in\mathbb{N}} \mu_X(B_n).$$

A final transitivity step for the $\mathsf{Real}^{\uparrow}$ classifier gives

$$\mu_X(U_T) \sim_R \sum_{n\in\mathbb{N}} \mu_X(B_n).$$

□

Theorem 186.15 (Distribution pushforward continuity from below)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^{\uparrow}$ *map as in section* 185.1*, from a* $\mathsf{ProbSpace}^{\uparrow}$ *source as in section* 184.1 *to a target* $\mathsf{Measure}^{\uparrow}$ *carrier as in section* 92.1*. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, μ_X for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure as in section* 186.1*, and $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition* 38.9*. Let $(B_n)_{n\in\mathbb{N}}$ be target events with $B_n \in \mathcal{A}_T$ for every n, and suppose the target readback supplies both*

$$B_n \subseteq B_{n+1} \quad \textit{for every } n \in \mathbb{N},$$

and

$$B := \bigcup_{n\in\mathbb{N}} B_n \qquad \textit{with} \qquad t \in B \iff \exists n \in \mathbb{N},\ t \in B_n.$$

For each n, let $A_n := X^{-1}(B_n)$ and let $A_B := X^{-1}(B)$. Suppose the hypotheses of Definition 185.26 *and Definition* 92.42 *are satisfied for this data, including source measurability and the source countable-union row*

$$U_S := \bigvee\nolimits^{S}_{n\in\mathbb{N}} A_n \in \mathcal{A}_S \qquad \textit{and} \qquad A_B \sim_{\mathcal{A}_S} U_S.$$

Then

$$\mu_X(B) \sim_R \lim_{n\to\infty} \mu_X(B_n).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward continuity from below prefix readback`

Proof. For each n, apply the measurable-preimage readback to get

$$A_n \in \mathcal{A}_S, \qquad A_B \in \mathcal{A}_S.$$

From the target inclusion row $B_n \subseteq B_{n+1}$ and the preimage readbacks

$$s \in A_n \iff X(s) \in B_n, \qquad s \in A_{n+1} \iff X(s) \in B_{n+1},$$

it follows pointwise that $A_n \subseteq A_{n+1}$. Hence $(A_n)_{n\in\mathbb{N}}$ is an increasing source measurable sequence.

Apply *Definition* 92.42 to (A_n) and its source union U_S. This provides a source disjoint layer chain with prefix readbacks

$$\Sigma_\mu(D_0, \ldots, D_n) \sim_R \mu_S(A_n) \quad \text{for every } n \in \mathbb{N},$$

and the endpoint comparison

$$\mu_S(U_S) \sim_R \sum_{n\in\mathbb{N}} \mu_S(D_n).$$

By the $\mathsf{Distribution}^{\uparrow}$ pushforward row of *section* 186.2,

$$\mu_X(B) \sim_R \mu_S(A_B),$$

and for each n

$$\mu_X(B_n) \sim_R \mu_S(A_n).$$

Composing the first comparison with $A_B \sim_{\mathcal{A}_S} U_S$ through source measure transport gives

$$\mu_X(B) \sim_R \mu_S(U_S).$$

Combining this with the continuity-from-below endpoint row yields

$$\mu_X(B) \sim_R \sum_{n\in\mathbb{N}} \mu_S(D_n).$$

Together with the prefix readbacks, each finite prefix is also transport-equivalent to the pushed-forward target prefix value:

$$\Sigma_\mu(D_0, \ldots, D_n) \sim_R \mu_X(B_n) \quad \text{for every } n \in \mathbb{N}.$$

By the continuity-from-below readback convention for this displayed chain, the endpoint on the right is exactly the monotone limit of the target pushed-forward prefix sequence, hence

$$\mu_X(B) \sim_R \lim_{n\to\infty} \mu_X(B_n).$$

□

Theorem 186.16 (Distribution pushforward probability package)**.** *Let $X : S \to T$ be a carried* $\mathsf{RandomVar}^\uparrow$ *map as in section* 185.1*, from a* $\mathsf{ProbSpace}^\uparrow$ *source as in section* 184.1 *to a target* $\mathsf{Measure}^\uparrow$ *carrier as in section* 92.1*. Write $\mathcal{A}_T$ for the target measurable-event family, μ_X for the* $\mathsf{Distribution}^\uparrow$ *pushforward row on target events, 0_R and 1_R for the distinguished* $\mathsf{Real}^\uparrow$ *endpoints, and $\sim_R$ for the* $\mathsf{Real}^\uparrow$ *classifier.*

Assume that the hypotheses of Definition 186.5*, Definition* 186.6*, Definition* 186.8*, Definition* 186.11*, Definition* 186.7*, Definition* 186.10*, Definition* 186.13*, Definition* 186.14*, and Definition* 186.15 *are all satisfied for this same displayed pushforward surface.*

Then μ_X is a probability-measure package on the target event surface: $\mu_X(T) \sim_R 1_R$; $\mu_X(\varnothing_T) \sim_R 0_R$; every $B \in \mathcal{A}_T$ has nonnegative $\mathsf{Real}^\uparrow$ *endpoint; target inclusion is monotone; finite disjoint binary unions are additive; relative differences decompose additively; complements decompose total mass over an event and its target complement; countable disjoint unions are sigma-additive; and increasing countable unions satisfy continuity from below.*

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward probability package`

Proof. Under the simultaneous hypotheses, the unit row is the row supplied by *Definition* 186.5, and the empty-event row is supplied by *Definition* 186.6. Nonnegativity of every target measurable value is the component row from *Definition* 186.8.

The order-sensitive rows are also part of the assumed component surface. Monotonicity is the row of *Definition* 186.11, finite disjoint binary additivity is the row of *Definition* 186.7, and relative-difference additivity is the row of *Definition* 186.10. The complement-mass row is supplied by *Definition* 186.13.

For countable structure, the assumed surface includes *Definition* 186.14 for disjoint target families and *Definition* 186.15 for increasing target families. These nine rows have the same carried map X, the same target event family $\mathcal{A}_T$, and the same displayed pushforward row μ_X, so collecting the assumed component rows gives the announced probability-measure package on the target event surface. □

Theorem 186.17 (Distribution null-completion random-variable descent)**.** *Let $X, Y : S \to T$ be carried* $\mathsf{RandomVar}^{\uparrow}$ *maps from the same* $\mathsf{ProbSpace}^{\uparrow}$ *source to the same* $\mathsf{Measure}^{\uparrow}$ *target, and let μ_X and μ_Y be their* $\mathsf{Distribution}^{\uparrow}$ *pushforward endpoint assignments. Write $\mathcal{A}_S$ and $\mathcal{A}_T$ for the source and target measurable-event families, μ_S for the source measure, $E \simeq_S F$ for the source event classifier, and $x \sim_R y$ for the* $\mathsf{Real}^{\uparrow}$ *classifier. Suppose that for every target event $B \in \mathcal{A}_T$ the following displayed rows are available:*

1. *the preimage rows $A_X := X^{-1}(B)$ and $A_Y := Y^{-1}(B)$ lie in $\mathcal{A}_S$;*
2. *a source symmetric-difference row supplies $\Delta_B := A_X \triangle A_Y \in \mathcal{A}_S$ with the public readback $s \in \Delta_B$ iff s lies in exactly one of A_X, A_Y;*
3. *the null row classifies the symmetric difference with zero measure, $\mu_S(\Delta_B) \sim_R 0_R$;*
4. *the source measure ledger reads equality up to null symmetric difference as endpoint equality: if $\mu_S(E \triangle F) \sim_R 0_R$, then $\mu_S(E) \sim_R \mu_S(F)$ for measurable source events E, F;*
5. *the* $\mathsf{Distribution}^{\uparrow}$ *pushforward rows read $\mu_X(B) \sim_R \mu_S(A_X)$ and $\mu_Y(B) \sim_R \mu_S(A_Y)$.*

Then for every $B \in \mathcal{A}_T$,

$$\mu_X(B) \sim_R \mu_Y(B).$$

Lean4 ✓ `BEDC.Derived.DistributionUp.DistributionPushforward null completion random variable descent`

Proof. Fix a target measurable event B. The displayed preimage rows give source measurable events A_X and A_Y. The symmetric-difference row supplies the source event $\Delta_B = A_X \triangle A_Y$, and the null hypothesis gives

$$\mu_S(\Delta_B) \sim_R 0_R.$$

Apply the source measure ledger row for equality up to null symmetric difference to A_X and A_Y. Its hypothesis is exactly the displayed null row for Δ_B, so it gives

$$\mu_S(A_X) \sim_R \mu_S(A_Y).$$

Now read both pushforward rows through the distribution carrier. The row for X gives $\mu_X(B) \sim_R \mu_S(A_X)$, and the row for Y gives $\mu_Y(B) \sim_R \mu_S(A_Y)$. Transitivity of the $\mathsf{Real}^{\uparrow}$ classifier composes the X pushforward readback with the null-difference endpoint comparison and then with symmetry of the Y pushforward readback. Hence

$$\mu_X(B) \sim_R \mu_Y(B).$$

Since B was arbitrary, the comparison holds for every target measurable event. This is a distribution-classifier descent statement only: it consumes the displayed source null ledger and pushforward rows, and it introduces no host quotient of events, no analytic completion object, and no external probability-space equality. □

Closure status for $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$.

Constructive story: A distribution is built from a carried random variable $X : S \to T$ by asking the $\mathsf{RandomVar}^{\uparrow}$ row to turn every target measurable event B into a source measurable event $X^{-1}(B)$, then reading the source $\mathsf{ProbSpace}^{\uparrow}$ measure at that preimage. The carrier accepts exactly the target measurable family together with the endpoint assignment $B \mapsto \mu_S(X^{-1}(B))$, while the classifier compares two such rows only after the target-event classifier has matched the events and the $\mathsf{Real}^{\uparrow}$ classifier has matched the resulting measured endpoints. Thus the source covers carried random-variable maps from normalized probability sources into measurable targets, the pattern is the pushforward law plus total mass, empty-event, nonnegativity, additivity, monotonicity, sigma-additivity, and continuity-from-below rows, and the ledger hides

the preimage event that explains each public target endpoint. Because target-event transport, random-variable preimage transport, source-measure transport, and the Real$^{\uparrow}$ classifier all preserve their carried rows, the certificate has an inhabited pushforward carrier, reflexive, symmetric, and transitive row comparison, and closure under classifier replacement. A row h lies in the signature gap of a Distribution$^{\uparrow}$ token p when the source-domain accepts the carried map and target event surface, the signature relation pairs the displayed pushforward assignment with an answer row and evidence ledger, and token introduction names that answer as p; concretely, every public value of h is the source probability of the certified preimage event encoded by p. The standard bridge reads this as the ordinary pushforward probability measure $X_*\mu_S$, but only after passing through the target-event classifier and the Real$^{\uparrow}$ endpoint classifier. The chapter registers this pushforward construction under the name Distribution$^{\uparrow}$; a law of a random variable is a preimage ledger over ProbSpace$^{\uparrow}$, with no separate host measure, convergence-of-laws package, or quotient of events introduced.

Theory closure: TheoryGate(NameCert$_{\text{Distribution}^{\uparrow}}$, maturePackageClosed)

Scope closed: The displayed pushforward carrier and classifier are closed for carried RandomVar$^{\uparrow}$ maps from ProbSpace$^{\uparrow}$ sources to Measure$^{\uparrow}$ target events, with endpoint comparisons read through the Real$^{\uparrow}$ classifier.

Formal verification: FormalStatus(NameCert$_{\text{Distribution}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DistributionUp.DistributionPushforward\_probability\_package`

Bridge status: paperBridge

Not claimed: The chapter does not close conditional expectation, independence, convergence of laws, or machine-checked bridge verification.

Upgrade path: No higher paper-side closure grade remains; machine-checked bridge verification and standard-model comparison stay outside this chapter.

Chapter 187

A Concrete Naming Certificate for $\mathsf{Independence}^{\uparrow}$

The independence interface $\mathsf{Independence}^{\uparrow}$ packages the property that the joint distribution of a finite family of random variables factors as the product of marginals. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186).

187.1 Carrier definition

Definition 187.1 (Finite-family carrier for IndependenceUp)**.** *A finite-family carrier for* $\mathsf{Independence}^{\uparrow}$ *consists of a carried* $\mathsf{ProbSpace}^{\uparrow}$ *source* S*, a finite* $\mathsf{FinSet}^{\uparrow}$ *index carrier* I*, and for every* $i \in I$ *a carried* $\mathsf{RandomVar}^{\uparrow}$ *map*

$$X_i : S \to T_i.$$

For each i*, the carrier includes the displayed* $\mathsf{Distribution}^{\uparrow}$ *marginal endpoint* μ_i *obtained as the pushforward of* X_i*, together with a displayed joint* $\mathsf{Distribution}^{\uparrow}$ *endpoint* μ_X^J *for the tuple map into the finite product target* $\prod_{i \in I} T_i$*.*

The readback ledger assigns to every finite family of measurable target events $B = (B_i)_{i \in I}$ *a product-cylinder event* $\mathrm{Cyl}_X(B)$ *in the joint target and records the source-event readback*

$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \iff \forall i \in I.\ X_i(s) \in B_i.$$

Thus the carrier exposes exactly the source, finite index spine, random-variable spine, marginal distribution spine, joint distribution endpoint, and product-cylinder readback needed for the finite factorisation row.

Definition 187.2 (Finite factorisation classifier for IndependenceUp)**.** *Let* R_X *and* R_Y *be two finite-family rows of Definition 187.1. An* $\mathsf{Independence}^{\uparrow}$ *factorisation classifier from* R_X *to* R_Y *consists of the following compatible comparisons:*

1. *a* $\mathsf{ProbSpace}^{\uparrow}$ *classifier identifying the carried sources;*
2. *a* $\mathsf{FinSet}^{\uparrow}$ *classifier identifying the finite index carriers and transporting the finite-position spine;*
3. *for every matched index, a* $\mathsf{RandomVar}^{\uparrow}$ *classifier between the corresponding carried random-variable maps;*
4. *for every matched index and measurable target event, a* $\mathsf{Distribution}^{\uparrow}$ *classifier between the corresponding marginal endpoints;*

5. *compatibility of the two product-cylinder readbacks under the source, index, and random-variable classifiers;*
6. $\mathsf{Real}^{\uparrow}$ *classifier agreement between the two marginal product folds and between the two joint-cylinder endpoints for every transported measurable event family.*

The classifier holds when these comparisons compose to the displayed endpoint condition

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)) \Longleftrightarrow \mu_Y^J(\mathrm{Cyl}_Y(B')) \sim_R \Pi_R(\mathsf{MargSp}_Y(B'))$$

for each event family B and its transported family B'.

187.2 The certificate

Definition 187.3 (Finite factorisation row for IndependenceUp)**.** *Let S be a carried* $\mathsf{ProbSpace}^{\uparrow}$ *source, let I be a finite index carrier supplied by a* $\mathsf{FinSet}^{\uparrow}$ *certificate, and let*

$$X_i : S \to T_i \qquad (i \in I)$$

be a finite family of carried $\mathsf{RandomVar}^{\uparrow}$ *maps as in section 185.1. For each i, write μ_i for the* $\mathsf{Distribution}^{\uparrow}$ *pushforward measure of X_i as in section 186.1, and write μ_X^J for the displayed joint* $\mathsf{Distribution}^{\uparrow}$ *endpoint of the tuple family. A finite factorisation row for* $\mathsf{Independence}^{\uparrow}$ *consists of the following data:*

1. *for every finite family of measurable target events $B = (B_i)_{i\in I}$, a product-cylinder event $\mathrm{Cyl}_X(B)$ in the joint target, read by*

$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \Longleftrightarrow \forall i \in I.\ X_i(s) \in B_i;$$

2. *a finite* $\mathsf{Real}^{\uparrow}$ *product fold Π_R on the marginal-value spine*

$$\mathsf{MargSp}_X(B)(i) := \mu_i(B_i),$$

   using the multiplication and classifier rows of the $\mathsf{Real}^{\uparrow}$ *commutative ring surface of Definition 43.26 and Definition 44.33;*

3. *the joint-distribution factorisation row*

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B))$$

   for every such measurable event family B, where $\sim_R$ is the $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9.*

This is the concrete paper-side factorisation surface carried by $\mathsf{Independence}^{\uparrow}$ *in section 187.1 and section 187.2.*

Lean4 (definition) `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow`

Theorem 187.4 (Independence obligation stability under certified transport)**.** *Let R_X and R_Y be finite-family carriers for* $\mathsf{Independence}^{\uparrow}$ *as in Definition 187.1. Suppose they are related by the classifier of Definition 187.2, using the* $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Distribution}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, $\mathsf{Permutation}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *classifier rows named there. If R_X carries the finite factorisation row of Definition 187.3, then R_Y carries the corresponding finite factorisation row for every transported measurable event family.*

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow stability transport`

Proof. Fix a measurable event family B' for R_Y and choose its transported source family B along the $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{RandomVar}^{\uparrow}$ classifier data. The product-cylinder compatibility in Definition 187.2 identifies the two source-event readbacks, so the $\mathsf{Distribution}^{\uparrow}$ rows compare the two joint-cylinder endpoints.

The marginal clauses of the same classifier compare each marginal endpoint in the transported spine. The finite-position comparison and, when the presentation order changes, the $\mathsf{Permutation}^{\uparrow}$ row reduce the product comparison to Definition 187.11.

Apply the factorisation row for R_X to B. The joint-endpoint comparison, the transported marginal-product comparison, and transitivity of the $\mathsf{Real}^{\uparrow}$ classifier give the factorisation row for R_Y at B'. Since B' was arbitrary, stability holds for the whole finite family. □

Theorem 187.5 (Independence obligation ledger exactness)**.** *For a finite-family carrier R_X of Definition 187.1, the* $\mathsf{Independence}^{\uparrow}$ *ledger exposes exactly four rows: the product-cylinder readback, the marginal distribution spine, the finite* $\mathsf{Real}^{\uparrow}$ *product fold, and the joint distribution endpoint. The ledger is exact precisely when, for every finite measurable event family B, the displayed factorisation row*

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B))$$

holds with the cylinder, spine, fold, and endpoint supplied by those four rows.

Proof. The carrier definition lists the only data read by the factorisation judgment: source membership in the cylinder, the marginal endpoint attached to each index, the finite product of those endpoints, and the joint endpoint of the tuple map. No additional event, source witness, or hidden distribution endpoint is read by Definition 187.3.

If the ledger is exact, evaluating it at B returns those four entries, and the final entry is classified with the product fold by the recorded factorisation row. This gives the displayed equation for every measurable event family.

Conversely, assume the displayed equation holds for every B using the four ledger rows. Then every value consumed by the independence judgment is one of the exposed rows, and the judgment is true exactly when the displayed equation is true. Hence the ledger is exact for the finite-family factorisation surface. □

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow ledger exactness`

Theorem 187.6 (Independence obligation certificate packet)**.** *The data consisting of the carrier of Definition 187.1, the classifier of Definition 187.2, the stability theorem of Definition 187.4, and the ledger exactness theorem of Definition 187.5 form the finite-family* $\mathsf{Independence}^{\uparrow}$ *obligation packet. This packet fixes the paper-side obligations for closing* $\mathsf{NameCert}_{\mathsf{Independence}^{\uparrow}}$ *on finite families of carried random variables over a carried* $\mathsf{ProbSpace}^{\uparrow}$ *source.*

Proof. The carrier supplies the source, finite index, random-variable spine, marginal endpoints, joint endpoint, and cylinder readback. The classifier states exactly when two such rows have the same finite-family independence content after certified transport.

The stability theorem records that the factorisation judgment is preserved by the named classifiers. The ledger exactness theorem records that no field outside the cylinder readback, marginal spine, product fold, and joint endpoint is used by the judgment.

Together these rows are the required carrier, classifier, stability, ledger, and exactness faces of the finite-family naming certificate. Therefore they assemble into the $\mathsf{Independence}^{\uparrow}$ obligation packet for the stated finite scope. □

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow obligation certificate packet`

Theorem 187.7 (Independence scoped primitive boundary)**.** *The finite-family* $\mathsf{Independence}^{\uparrow}$ *certificate surface is scoped by exactly the displayed* $\mathsf{NameCert}$ *rows for* $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Distribution}^{\uparrow}$, $\mathsf{Permutation}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *together with the BEDC kernel carriers and classifiers* $BHist$, $hsame$, *and* $Cont$, *the product-cylinder readback, finite product fold, joint endpoint, and marginal spine of Definition 187.3. It consumes no conditional-expectation row, martingale row, sigma-completion row, host equality row, host function equality row, or standard probability-space bridge row.*

Proof. Apply Definition 187.6. The packet assembles the finite-family carrier, classifier, stability, ledger, and exactness faces from the displayed source, index, random-variable, distribution, permutation, and real rows.

The generated transport scope is the one stated in Definition 187.9. Its generators are certified finite reindexing, readable-preimage transport, distribution endpoint transport, and finite-product classifier transport; each is supplied by the displayed $\mathsf{NameCert}$ rows and the kernel classifiers $BHist$, $hsame$, and $Cont$.

The exact ledger boundary is the one stated in Definition 187.10. It reads only the product-cylinder readback, marginal distribution spine, finite $\mathsf{Real}^{\uparrow}$ product fold, and joint distribution endpoint of Definition 187.3.

The nontrivial finite-family stability faces are exactly the checked rows Definition 187.11, Definition 187.12, and Definition 187.13. Those rows cover permutation readback, finite reindexing, and measurable-image transport, so no conditional-expectation, martingale, sigma-completion, host equality, host function equality, or standard bridge row remains in the scoped boundary. □

Theorem 187.8 (Independence carrier obligation)**.** *The carrier for* $\mathsf{Independence}^{\uparrow}$ *is exactly the finite-family package consisting of one carried* $\mathsf{ProbSpace}^{\uparrow}$ *source* S, *a certified* $\mathsf{FinSet}^{\uparrow}$ *index carrier* I, *carried* $\mathsf{RandomVar}^{\uparrow}$ *maps* $X_i : S \to T_i$ *for* $i \in I$, *their* $\mathsf{Distribution}^{\uparrow}$ *marginal endpoints* μ_i, *the displayed joint* $\mathsf{Distribution}^{\uparrow}$ *endpoint* μ_X^J, *and the finite factorisation row of Definition 187.3. No further carrier datum is part of the* $\mathsf{Independence}^{\uparrow}$ *surface.*

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow carrier obligation`

Proof. Unpack the finite factorisation row. Its inputs name one source probability-space carrier, one finite index carrier, and one carried random-variable map at each finite index. The row then records exactly the marginal pushforward endpoint for each map and the joint pushforward endpoint for the tuple family.

The remaining fields of Definition 187.3 are certificate rows over those endpoints: product-cylinder readback, finite $\mathsf{Real}^{\uparrow}$ product fold, and the joint-distribution factorisation comparison. Each field is typed over the same displayed source, index, random-variable, marginal, and joint endpoints. Thus the carrier is closed by these finite data, and there is no separate conditional, completed, or standard-space carrier to add. □

Theorem 187.9 (Independence classifier and stability obligation)**.** *The classifier comparison for* $\mathsf{Independence}^{\uparrow}$ *is generated by certified index reindexing, readable-preimage transport for carried* $\mathsf{RandomVar}^{\uparrow}$ *maps,* $\mathsf{Distribution}^{\uparrow}$ *endpoint transport along the displayed pushforward rows, and finite-product classifier transport over* $\mathsf{Real}^{\uparrow}$. *Under these generators, the finite factorisation row is stable under certified finite reindexing and under measurable-image transport of a binary pair.*

Proof. The classifier generators are the comparison rows already present in the input certificates. A certified reindexing compares index positions by the $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{Permutation}^{\uparrow}$ rows. A readable-preimage transport compares target events through the $\mathsf{RandomVar}^{\uparrow}$ readback clauses. The $\mathsf{Distribution}^{\uparrow}$ pushforward row transports the resulting event comparison to marginal and joint endpoints, and the $\mathsf{Real}^{\uparrow}$ classifier transports the finite product fold.

For the finite-family face, apply Definition 187.12. It uses the certified inverse position map, product-cylinder readback, the original factorisation row, and Definition 187.11 to rebuild the same factorisation comparison after reindexing.

For the binary measurable-image face, apply Definition 187.13. It reads preimages through the displayed maps, transports the marginal and joint distribution endpoints, and then composes the original binary factorisation comparison with $\mathsf{Real}^{\uparrow}$ classifier transitivity. These two stability faces exhibit the generated classifier comparison for the independence certificate. □

Theorem 187.10 (Independence ledger and exactness obligation)**.** *The exact ledger exported by* $\mathsf{Independence}^{\uparrow}$ *consists only of the source probability-space row, finite index evidence, random-variable preimage rows, distribution pushforward rows, product-cylinder readback, and finite* $\mathsf{Real}^{\uparrow}$ *product-fold provenance. It exports no conditional expectation, martingale, sigma-algebra completion, or standard probability-space bridge.*

Proof. Read the ledger entries from Definition 187.3. The source row supplies the carried probability space, the finite index evidence supplies the allowed family positions, and the random-variable rows supply readable preimages for the events used in each product cylinder.

The distribution rows supply only the marginal and joint pushforward endpoints attached to those same readable events. The product-cylinder readback records the equivalence between membership in the tuple cylinder and membership in every displayed component event. The $\mathsf{Real}^{\uparrow}$ product-fold provenance records how marginal values are multiplied and compared by the real classifier.

Exactness follows because the factorisation equation mentions only these exported rows:

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Neither the statement nor the construction calls for conditional expectation, martingale filtrations, sigma-algebra completion, or a standard probability-space bridge. The ledger is therefore exact for the finite-family independence surface and silent about those additional probability-theoretic structures. □

Lemma 187.11 (Finite RealUp product fold is invariant under certified reindexing)**.** *Let xs and ys be finite spines of carried* $\mathsf{Real}^{\uparrow}$ *endpoints, and let*

$$\rho : \mathsf{Pos}(xs) \cong \mathsf{Pos}(ys)$$

be a certified finite-position bijection in the sense of Definition 112.2. If each matched pair satisfies

$$\mathsf{entry}_{xs}(i) \sim_R \mathsf{entry}_{ys}(\rho(i)),$$

then the finite product fold Π_R satisfies

$$\Pi_R(xs) \sim_R \Pi_R(ys).$$

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteProduct reindexing readback`

Proof. Induct on the target spine ys. If ys is empty, the certified inverse position map forces $\mathsf{Pos}(xs)$ to be empty as well. Both product folds are the multiplicative unit endpoint, so the $\mathsf{Real}^{\uparrow}$ classifier reflexivity row gives the claim.

In the cons case, write the head of ys as b and its tail as t. Let $i_0 := \rho^{-1}(\text{head})$ be the source position matched with the target head. Removing i_0 from the source position spine and removing the head from ys leaves a certified finite-position bijection between the residual source spine and t; this is the same inverse-map data used in Definition 112.24, restricted away from the matched pair.

By the induction hypothesis, the product of the residual source spine is classified with $\Pi_R(t)$. The matched-pair hypothesis gives

$$\mathsf{entry}_{xs}(i_0) \sim_R b.$$

Multiplication congruence from Definition 43.26 transports these two comparisons to the product of the selected head and the residual product. It remains only to compare the original source fold with the fold in which the selected occurrence i_0 is placed first. A finite sequence of adjacent swaps moves i_0 to the head of the source spine; each adjacent swap is justified by multiplicative commutativity from Definition 44.33, multiplicative associativity from Definition 43.26, and classifier transitivity. Hence the original source product is classified with $\mathsf{entry}_{xs}(i_0) \cdot_R \Pi_R(\text{residual})$, while the target product is classified with $b \cdot_R \Pi_R(t)$. The preceding congruence and transitivity give

$$\Pi_R(xs) \sim_R \Pi_R(ys).$$

□

Theorem 187.12 (Independence finite reindexing invariance)**.** *Let I be a finite $\mathsf{FinSet}^{\uparrow}$ index carrier, let $\pi : I \cong I$ be a $\mathsf{Permutation}^{\uparrow}$ certified bijection as in section 116.1, and let $(X_i)_{i\in I}$ be a finite family of carried $\mathsf{RandomVar}^{\uparrow}$ maps over one carried $\mathsf{ProbSpace}^{\uparrow}$ source. Suppose the family carries the finite factorisation row of Definition 187.3. Define the reindexed family and marginals by*

$$X_i^{\pi} := X_{\pi(i)}, \qquad \mu_i^{\pi} := \mu_{\pi(i)}.$$

For every reindexed measurable event family $B = (B_i)_{i\in I}$, define the pulled-back original event family

$$C_j := B_{\pi^{-1}(j)}.$$

Let the reindexed joint $\mathsf{Distribution}^{\uparrow}$ endpoint be read through the same product-cylinder ledger, so that the cylinder for X^{π} at B is classified with the cylinder for X at C. Then the reindexed family also carries the finite $\mathsf{Independence}^{\uparrow}$ factorisation row:

$$\mu^J_{X^{\pi}}(\mathrm{Cyl}_{X^{\pi}}(B)) \sim_R \Pi_R(\mathsf{MargSp}_{X^{\pi}}(B)).$$

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteReindexing invariance`

Proof. Fix a measurable reindexed event family $B = (B_i)_{i\in I}$ and put $C_j := B_{\pi^{-1}(j)}$. Since π is a certified bijection, every target index j has the unique source index $\pi^{-1}(j)$ and every source index i is sent to $\pi(i)$. For each carried sample point s, the cylinder readbacks give

$$s \in X_{\pi}^{-1}(\mathrm{Cyl}_{X^{\pi}}(B)) \iff \forall i \in I.\ X_{\pi(i)}(s) \in B_i \iff \forall j \in I.\ X_j(s) \in B_{\pi^{-1}(j)} \iff s \in X^{-1}(\mathrm{Cyl}_X(C)).$$

Thus the reindexed cylinder and the original cylinder have the same displayed source-event readback. The $\mathsf{Distribution}^{\uparrow}$ pushforward row of section 186.2, read through the event transport of Definition 26.3, gives

$$\mu^J_{X^{\pi}}(\mathrm{Cyl}_{X^{\pi}}(B)) \sim_R \mu^J_X(\mathrm{Cyl}_X(C)).$$

Apply the original $\mathsf{Independence}^{\uparrow}$ factorisation row from Definition 187.3 to the event family C. This yields

$$\mu_X^J(\mathrm{Cyl}_X(C)) \sim_R \Pi_R(\mathsf{MargSp}_X(C)).$$

It remains to compare the two marginal products. The original marginal spine at a position j has entry

$$\mathsf{MargSp}_X(C)(j) = \mu_j(C_j) = \mu_j(B_{\pi^{-1}(j)}),$$

while the reindexed marginal spine at i has entry

$$\mathsf{MargSp}_{X^\pi}(B)(i) = \mu_i^\pi(B_i) = \mu_{\pi(i)}(B_i).$$

Using the inverse certified bijection $j \mapsto \pi^{-1}(j)$ from Definition 112.24, the entry at j in the original spine is matched with the entry at $\pi^{-1}(j)$ in the reindexed spine, and these two entries are the same marginal endpoint. Classifier reflexivity gives the matched-entry comparison. Therefore Definition 187.11 gives

$$\Pi_R(\mathsf{MargSp}_X(C)) \sim_R \Pi_R(\mathsf{MargSp}_{X^\pi}(B)).$$

Transitivity of the $\mathsf{Real}^{\uparrow}$ classifier from Definition 38.9 composes the reindexed joint comparison, the original factorisation row, and the finite-product reindexing comparison. Hence

$$\mu_{X^\pi}^J(\mathrm{Cyl}_{X^\pi}(B)) \sim_R \Pi_R(\mathsf{MargSp}_{X^\pi}(B)).$$

Since B was arbitrary, the reindexed family carries the stated finite $\mathsf{Independence}^{\uparrow}$ factorisation row. □

Theorem 187.13 (Independence$^{\uparrow}$ measurable-image bridge for two variables)**.** *Let S be a carried* $\mathsf{ProbSpace}^{\uparrow}$ *source. Let*

$$X : S \to T, Y : S \to U$$

be carried $\mathsf{RandomVar}^{\uparrow}$ *maps as in section 185.1, and suppose the pair (X, Y) carries the binary finite factorisation row of* $\mathsf{Independence}^{\uparrow}$ *from Definition 187.3. Let*

$$f : T \to T', \qquad g : U \to U'$$

be carried $\mathsf{RandomVar}^{\uparrow}$ *maps satisfying the readable preimage row of section 185.2. Assume for every target-measurable $C_0 \in \mathcal{A}_{T'}$ and $C_1 \in \mathcal{A}_{U'}$ that the pullbacks*

$$A_0 := f^{-1}(C_0) \in \mathcal{A}_T, \qquad A_1 := g^{-1}(C_1) \in \mathcal{A}_U$$

are readable and satisfy

$$t \in A_0 \iff f(t) \in C_0, \qquad u \in A_1 \iff g(\nu) \in C_1.$$

Define the compositions

$$H := f \circ X, \qquad K := g \circ Y$$

and write $\mu_H, \mu_K, \mu_{H,K}^J$ for their pushforwards.

Fix measurable $C_0 \in \mathcal{A}_{T'}$ and $C_1 \in \mathcal{A}_{U'}$. For every carried source point s the readable preimage clauses give

$$s \in H^{-1}(C_0) \iff X(s) \in A_0, \qquad s \in K^{-1}(C_1) \iff Y(s) \in A_1,$$

and hence

$$s \in \mathrm{Cyl}_{(H,K)}(C_0, C_1) \iff \mathrm{Cyl}_{(X,Y)}(A_0, A_1).$$

Applying the distribution pushforward row of section 186.2 to the two displayed cylinder events gives

$$\mu^J_{H,K}(\mathrm{Cyl}_{(H,K)}(C_0, C_1)) \sim_R \mu^J_{(X,Y)}(\mathrm{Cyl}_{(X,Y)}(A_0, A_1)),$$
$$\mu_H(C_0) \sim_R \mu_X(A_0), \qquad \mu_K(C_1) \sim_R \mu_Y(A_1).$$

The factorisation row of (X, Y) from Definition 187.3 yields

$$\mu^J_{(X,Y)}(\mathrm{Cyl}_{(X,Y)}(A_0, A_1)) \sim_R \mu_X(A_0) \cdot_R \mu_Y(A_1).$$

Transitivity of $\sim_R$ then gives

$$\mu^J_{H,K}(\mathrm{Cyl}_{(H,K)}(C_0, C_1)) \sim_R \mu_H(C_0) \cdot_R \mu_K(C_1).$$

Since C_0, C_1 were arbitrary measurable events, this is exactly the binary finite factorisation equation for the pair (H, K). Therefore $f \circ X$ is independent of $g \circ Y$ under $\mathsf{Independence}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceBinaryFactorization measurable image bridge`

Theorem 187.14 (Independence public NameCert export)**.** *The finite-family carrier, factorisation classifier, stability transport, ledger exactness, finite reindexing row, and measurable-image bridge assemble the public reusable* $\mathsf{NameCert}_{\mathsf{Independence}^{\uparrow}}$ *export for the finite-family scope. Its carrier and classifier are the rows of Definition 187.6; its primitive boundary is the scoped surface of Definition 187.7; its finite-product and reindexing stability are supplied by Definition 187.11 and Definition 187.12; and its binary measurable-image transport is the bridge of Definition 187.13. This public export is reusable by downstream finite-family probability chapters without adding conditional-expectation, martingale, sigma-completion, host equality, host function equality, or standard bridge rows.*

Proof. Apply Definition 187.6. It supplies the finite-family carrier, factorisation classifier, stability transport, ledger exactness, and certificate packet for carried random-variable families over the displayed $\mathsf{ProbSpace}^{\uparrow}$ source.

Apply Definition 187.7 to fix the visible primitive boundary. The boundary identifies the exact $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Distribution}^{\uparrow}$, $\mathsf{Permutation}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist-readable cylinder, and product-fold rows consumed by the packet, and it excludes the probability-theoretic rows outside the finite-family surface.

For reusable finite-family stability, apply Definition 187.11 and Definition 187.12. These rows make the product fold and the factorisation comparison invariant under certified finite reindexing.

Finally apply Definition 187.13. It gives the binary measurable-image transport row over the same factorisation classifier. Collecting these rows produces the public $\mathsf{NameCert}_{\mathsf{Independence}^{\uparrow}}$ export for the stated finite-family scope. □

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow public namecert export`

Closure status for $\mathsf{NameCert}_{\mathsf{Independence}^{\uparrow}}$**.**

Constructive story: An independence packet starts with a carried $\mathsf{ProbSpace}^{\uparrow}$ source, a finite $\mathsf{FinSet}^{\uparrow}$ index spine, and one carried $\mathsf{RandomVar}^{\uparrow}$ map at each index, then displays both the marginal $\mathsf{Distribution}^{\uparrow}$ endpoints and the joint distribution endpoint of the tuple map. The carrier accepts only finite families that also show, for every finite family of target events, a product-cylinder readback, a finite $\mathsf{Real}^{\uparrow}$ product fold of marginal masses, and the factorisation comparison between the joint cylinder mass and that product; the classifier compares two presentations by transporting the source, finite positions, random-variable rows, marginal and joint distributions, cylinders, and real products through the named dependency classifiers. The source therefore covers finite carried random-variable families, the pattern is the product-cylinder factorisation equation together with finite reindexing and measurable-image transport, and the ledger keeps

exactly the cylinder readback, marginal spine, product fold, joint endpoint, and provenance rows visible. Since finite-position reindexing, distribution endpoint transport, readable-preimage transport, and Real$^{\uparrow}$ multiplication congruence preserve the factorisation row, an admitted finite family supplies the carrier witness, the classifier is reflexive, symmetric, and transitive componentwise, and transported families remain in the carrier. A finite-family row h lies in the signature gap of an Independence$^{\uparrow}$ token p when the source-domain accepts its probability source, index spine, random variables, and factorisation ledger, the signature relation pairs that row with an answer family and evidence ledger, and token introduction names the answer as p; unfolded, every cylinder mass in h is classified with the product of the corresponding marginal masses encoded by p. The paper bridge is the measurable-image and finite-reindexing readback for this finite factorisation surface, not a bridge to completed probability spaces. The chapter registers this finite-factorisation construction under the name Independence$^{\uparrow}$; independence is a displayed product equation over carried distributions, with no conditional-expectation row, sigma-completion primitive, or host function equality introduced.

Theory closure: TheoryGate(NameCert$_{\text{Independence}\uparrow}$, maturePackageClosed)

Scope closed: The scoped finite-family carrier, factorisation classifier, stability transport, ledger exactness, finite reindexing, and measurable-image bridge are bound over the displayed RandomVar$^{\uparrow}$, Distribution$^{\uparrow}$, FinSet$^{\uparrow}$, Permutation$^{\uparrow}$, Real$^{\uparrow}$, BHist-readable cylinder, and product-fold rows.

Formal verification: FormalStatus(NameCert$_{\text{Independence}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.IndependenceUp.IndependenceBinaryFactorization\_measurable\_image\_bridge`

Bridge status: paperBridge

Not claimed: Full probability theory, sigma-algebra completion, conditional expectation, martingales, and standard bridge data are not claimed here.

Upgrade path: No further theory-axis step remains; the chapter is at mature closure, with bridge verification tracked independently.

Theorem 187.15 (Independence empty index family satisfies the finite factorisation row)**.** *Let R be a finite-family carrier for* Independence$^{\uparrow}$ *as in Definition 187.1, with carried source S, finite index carrier I, displayed joint endpoint μ_X^J, and finite* Real$^{\uparrow}$ *product fold Π_R. Assume that I has no positions, and let B be the unique measurable target-event family on I. Write $\Omega_\varnothing$ for the total event of the empty-product target of the empty tuple family. Suppose:*

1. *the displayed product-cylinder ledger for R reads the empty family as the target total event,*

$$\mathrm{Cyl}_X(B) = \Omega_\varnothing;$$

2. *the hypotheses of Definition 186.5 hold for the empty tuple map, its joint endpoint μ_X^J, and the target total event $\Omega_\varnothing$;*

3. *the empty marginal spine folds to the multiplicative unit,*

$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R 1_R.$$

Then the displayed empty-family data satisfy the factorisation clause

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Consequently, these displayed data carry the finite factorisation row of Definition 187.3 for the empty index family.

Lean4 ✓ `BEDC.Derived.IndependenceUp.IndependenceFiniteFactorizationRow empty index factorization row`

Proof. Because I has no positions, there is only the empty measurable event family B. By the cylinder hypothesis, the left endpoint may be read at the total event of the empty-product target:

$$\mu_X^J(\mathrm{Cyl}_X(B)) = \mu_X^J(\Omega_\varnothing).$$

Apply Definition 186.5 to the empty tuple map and its joint endpoint μ_X^J. This gives

$$\mu_X^J(\Omega_\varnothing) \sim_R 1_R.$$

Reading the cylinder as $\Omega_\varnothing$ yields

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R 1_R.$$

The empty-fold hypothesis gives

$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R 1_R.$$

By symmetry of the $\mathsf{Real}^\uparrow$ classifier,

$$1_R \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Transitivity of the same classifier from Definition 38.9 therefore yields

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

This is exactly the factorisation clause of Definition 187.3 for the unique empty event family. Since the product-cylinder ledger and the finite product fold are already part of the displayed data, the empty family carries the stated finite factorisation row. □

Theorem 187.16 (Independence singleton index family satisfies the finite factorisation row)**.** *Let R be a finite-family carrier for* $\mathsf{Independence}^\uparrow$ *as in Definition 187.1, with carried source S, finite index carrier I, random-variable spine $(X_i)_{i\in I}$, marginal endpoints $(\mu_i)_{i\in I}$, displayed joint endpoint μ_X^J, and finite* $\mathsf{Real}^\uparrow$ *product fold Π_R. Assume that I has exactly one certified position i_0, and let B be a measurable target-event family on I. Suppose:*

1. *the singleton index certificate identifies every quantified index in the cylinder ledger with i_0;*
2. *the product-cylinder readback for R reduces at B to the unique marginal event, so for every carried source point s,*
$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \Longleftrightarrow X_{i_0}(s) \in B_{i_0};$$
3. *the* $\mathsf{Distribution}^\uparrow$ *pushforward rows for the singleton tuple endpoint and the marginal endpoint read this source-event equivalence as*
$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \mu_{i_0}(B_{i_0});$$
4. *the singleton* $\mathsf{Real}^\uparrow$ *product fold evaluates the marginal spine at its unique position:*
$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R \mu_{i_0}(B_{i_0}).$$

Then the displayed singleton-family data satisfy the factorisation clause

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Consequently, when the four displayed hypotheses hold for every measurable singleton event family B, these data carry the finite factorisation row of Definition 187.3 for the singleton index family.

Proof. Fix the measurable singleton event family B. Since I has exactly one certified position i_0, the universal clause in the product-cylinder ledger has no component other than i_0. Hence the cylinder readback reduces to

$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \Longleftrightarrow X_{i_0}(s) \in B_{i_0}.$$

By the $\mathsf{Distribution}^{\uparrow}$ pushforward rows named in the hypotheses, this displayed source-event equivalence compares the joint singleton-cylinder endpoint with the marginal endpoint:

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \mu_{i_0}(B_{i_0}).$$

The marginal spine has exactly one entry, namely

$$\mathsf{MargSp}_X(B)(i_0) = \mu_{i_0}(B_{i_0}).$$

The singleton product-fold hypothesis therefore gives

$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R \mu_{i_0}(B_{i_0}).$$

By symmetry of the $\mathsf{Real}^{\uparrow}$ classifier from Definition 38.9, this comparison reverses to

$$\mu_{i_0}(B_{i_0}) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Transitivity of the same classifier composes the joint-to-marginal comparison with the reversed singleton-fold comparison and yields

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

This is exactly the factorisation clause of Definition 187.3 at the singleton event family B.

If the displayed hypotheses hold for every measurable singleton event family, the same argument applies to each B. The carrier already supplies the product-cylinder ledger, marginal distribution spine, finite product fold, and joint endpoint required by Definition 187.3; hence the singleton index family carries the finite factorisation row. □

Theorem 187.17 (Independence two-element index family satisfies the finite factorisation row)**.** *Let R be a finite-family carrier for $\mathsf{Independence}^{\uparrow}$ as in Definition 187.1, with carried source S, finite index carrier I, random-variable spine $(X_i)_{i\in I}$, marginal endpoints $(\mu_i)_{i\in I}$, displayed joint endpoint μ_X^J, and finite $\mathsf{Real}^{\uparrow}$ product fold Π_R. Assume that I has exactly two certified positions i_0 and i_1, and let B be a measurable target-event family on I. Suppose:*

1. *the two-position index certificate identifies every quantified index in the cylinder ledger with exactly one of i_0 and i_1;*
2. *the product-cylinder readback for R reduces at B to the binary component event, so for every carried source point s,*

$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \Longleftrightarrow \big(X_{i_0}(s) \in B_{i_0}\big) \wedge \big(X_{i_1}(s) \in B_{i_1}\big);$$

3. *the displayed product-cylinder ledger together with the $\mathsf{Distribution}^{\uparrow}$ pushforward rows reads the joint cylinder endpoint as the binary product of the two marginal endpoints,*

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \mu_{i_0}(B_{i_0}) \cdot_R \mu_{i_1}(B_{i_1});$$

4. the two-element $\mathsf{Real}^{\uparrow}$ *product fold evaluates the marginal spine in the certified order as*

$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R \mu_{i_0}(B_{i_0}) \cdot_R \mu_{i_1}(B_{i_1}).$$

Then the displayed two-position data satisfy the factorisation clause

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Consequently, when the four displayed hypotheses hold for every measurable two-position event family B*, these data carry the finite factorisation row of Definition 187.3 for the two-element index family.*

Proof. Fix the measurable two-position event family B. Since I has exactly the certified positions i_0 and i_1, the universal clause in the product-cylinder ledger has no component other than those two positions. Hence the cylinder readback reduces to

$$s \in X^{-1}(\mathrm{Cyl}_X(B)) \iff \big(X_{i_0}(s) \in B_{i_0}\big) \wedge \big(X_{i_1}(s) \in B_{i_1}\big).$$

The joint endpoint hypothesis states that the displayed cylinder, after being read through the $\mathsf{Distribution}^{\uparrow}$ pushforward rows, is classified with the product of the two marginal masses:

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \mu_{i_0}(B_{i_0}) \cdot_R \mu_{i_1}(B_{i_1}).$$

The marginal spine has exactly the two certified entries

$$\mathsf{MargSp}_X(B)(i_0) = \mu_{i_0}(B_{i_0}), \qquad \mathsf{MargSp}_X(B)(i_1) = \mu_{i_1}(B_{i_1}).$$

By the two-element fold hypothesis, the finite $\mathsf{Real}^{\uparrow}$ product fold evaluates this spine as

$$\Pi_R(\mathsf{MargSp}_X(B)) \sim_R \mu_{i_0}(B_{i_0}) \cdot_R \mu_{i_1}(B_{i_1}).$$

Symmetry of the $\mathsf{Real}^{\uparrow}$ classifier from Definition 38.9 reverses the fold comparison and gives

$$\mu_{i_0}(B_{i_0}) \cdot_R \mu_{i_1}(B_{i_1}) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

Transitivity of the same classifier composes the joint-to-product comparison with this reversed fold comparison, yielding

$$\mu_X^J(\mathrm{Cyl}_X(B)) \sim_R \Pi_R(\mathsf{MargSp}_X(B)).$$

This is exactly the factorisation clause of Definition 187.3 at the two-position event family B.

If the displayed hypotheses hold for every measurable two-position event family, the same argument applies to each B. The finite-family carrier already supplies the product-cylinder ledger, marginal distribution spine, finite product fold, and joint endpoint required by Definition 187.3; therefore the two-element index family carries the stated finite factorisation row. □

Chapter 188

A Concrete Naming Certificate for $\mathsf{CondExp}^{\uparrow}$

The conditional-expectation interface $\mathsf{CondExp}^{\uparrow}$ packages the L^2 projection of an integrable random variable onto the subspace of functions measurable with respect to a sub-σ-algebra. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91).

188.1 Carrier definition

Theorem 188.1 (CondExp carrier obligation)**.** *Let* $\omega_T, \omega_S, \mathrm{pre}_X, x, p, r : \mathsf{BHist}$*. A total-readback certificate* $\mathsf{RandomVarTotalReadbackCertificate}(\omega_T, \omega_S, \mathrm{pre}_X)$*, a Hilbert singleton projection witness* $\mathsf{HilbertSingletonProjectionWitness}(x, p)$*, and a continuation ledger* $\mathsf{Cont}(p, r, x)$ *jointly form the carrier packet for the singleton* $\mathsf{CondExp}^{\uparrow}$ *interface. The visible packet is*

$$(\omega_T, \omega_S, \mathrm{pre}_X, x, p, r, \mathsf{RandomVarTotalReadbackCertificate}(\omega_T, \omega_S, \mathrm{pre}_X), \mathsf{HilbertSingletonProjectionWitness}(x, p), \mathsf{Co}$$

It records the target total event, the source total event, the chosen readback endpoint, the integrable-history endpoint, the projected endpoint, the residual history, the total-preimage certificate, the projection witness, and the residual continuation row.

Lean4 ✓ `BEDC.Derived.CondExpUp.CondExpCarrier packet`
↪ variant `BEDC.Derived.CondExpUp.CondExpCarrier obligation`

Proof. Unpack the total-readback certificate through Definition 185.14. Its carried-total bridge and chosen-readback clause place pre_X on the $\mathsf{RandomVar}^{\uparrow}$ source side over the displayed endpoints ω_T and ω_S.

Unpack the Hilbert projection witness through Definition 91.14. It supplies the carried endpoint x, the projected endpoint p, and the singleton classifier row for p.

The remaining field is not a hidden analytic object: it is the displayed kernel continuation $\mathsf{Cont}(p, r, x)$. Repacking these three rows gives exactly the carrier packet stated above. □

188.2 The certificate

Theorem 188.2 (CondExp classifier obligation)**.** *Consider two singleton* $\mathsf{CondExp}^{\uparrow}$ *carrier packets with histories* $(\omega_T, \omega_S, \mathrm{pre}_X, x, p, r)$ *and* $(\omega'_T, \omega'_S, \mathrm{pre}'_X, x', p', r')$*. If their source random-variable*

endpoints satisfy $\mathsf{hsame}(\omega_T, \omega'_T)$, $\mathsf{hsame}(\omega_S, \omega'_S)$, *and* $\mathsf{hsame}(\mathrm{pre}_X, \mathrm{pre}'_X)$, *and their projection endpoints satisfy* $\mathsf{hsame}(x, x')$ *and* $\mathsf{hsame}(p, p')$, *then the* $\mathsf{CondExp}^{\uparrow}$ *classifier identifies the two carrier packets. Carrier transport is exhausted by terminal readback uniqueness for the* $\mathsf{RandomVar}^{\uparrow}$ *endpoint and by the Hilbert singleton projection transport and idempotence rows for the projected endpoint.*

Lean4 ✓ `BEDC.Derived.CondExpUp.CondExpClassifier obligation`

Proof. First compare the random-variable side. Apply Definition 185.16 to the two readback certificates over the total target endpoints. The source endpoints are therefore in the same hsame class after the total-preimage row is read through the carried certificate.

Next compare the Hilbert side. The projected endpoints are carried by the same singleton carrier from Definition 91.14, and Definition 91.16 says that projecting a projected endpoint stays in the same singleton classifier class.

Finally repack the two transported sides with the visible continuation rows. Since the carrier packet of Definition 188.1 contains no further hidden field, these transported rows are exactly the classifier comparison for the two $\mathsf{CondExp}^{\uparrow}$ packets. □

Theorem 188.3 (CondExp projection obligation)**.** *For every carried singleton Hilbert endpoint* $x : \mathsf{BHist}$, *the* $\mathsf{Hilbert}^{\uparrow}$ *rows Definition 91.15, Definition 91.16, and Definition 91.17 supply the singleton* $\mathsf{CondExp}^{\uparrow}$ *projection row, its idempotence row, and its residual orthogonality row. Thus the conditional-expectation projection surface is the Hilbert singleton projection surface restricted to the displayed* $\mathsf{RandomVar}^{\uparrow}$ *total-readback carrier packet.*

Lean4 ✓ `BEDC.Derived.CondExpUp.CondExpProjection obligation`

Proof. Start with the carried endpoint x. By Definition 91.15, it admits a projected endpoint in the Hilbert singleton carrier, with the projection witness needed by Definition 188.1.

The idempotence row is exactly Definition 91.16. It states that the projected endpoint remains in its singleton classifier class after a second projection.

The residual row is exactly Definition 91.17. Reading that row inside the carrier packet gives the residual orthogonality package required for the singleton conditional-expectation interface. □

Theorem 188.4 (CondExp ledger and exactness obligation)**.** *In the singleton* $\mathsf{CondExp}^{\uparrow}$ *carrier packet of Definition 188.1, the only hidden ledger fields are the* $\mathsf{RandomVar}^{\uparrow}$ *terminal-preimage exactness row and the* $\mathsf{Hilbert}^{\uparrow}$ *residual-zero exactness row. Consequently the visible packet gives coverage and exactness for the singleton conditional-expectation interface: the source event readback is classifier-exact over the source total event, the projected endpoint is the Hilbert singleton projection endpoint, and the residual orthogonality row is the constant-zero inner-product row.*

Lean4 ✓ `BEDC.Derived.CondExpUp.CondExpCarrierPacket ledger exactness`
↪ variant `BEDC.Derived.CondExpUp.CondExpLedgerExactness obligation`

Proof. The random-variable ledger is Definition 185.15. It gives source-measurability for the chosen total-target preimage and identifies that chosen preimage with the source total event by the source classifier.

The Hilbert ledger is Definition 91.17. It reads every residual inner-product against a carried endpoint as the constant RealUp zero row.

Combine these two ledger rows with the carrier packet. There is no extra field in the packet beyond the total-readback certificate, the Hilbert projection witness, and the displayed continuation row, so the same two exactness rows give the claimed coverage for the singleton $\mathsf{CondExp}^{\uparrow}$ interface. □

Theorem 188.5 (CondExp singleton standard bridge boundary)**.** *The singleton* $\mathsf{CondExp}^{\uparrow}$ *carrier packet of Definition 188.1, the classifier obligation of Definition 188.2, the projection obligation of Definition 188.3, and the ledger exactness theorem of Definition 188.4 give a conservative bridge from the BEDC packet* (RandomVarTotalReadbackCertificate, HilbertSingletonProjectionWitness, Cont) *to the standard singleton conditional-expectation interface. The bridge exports exactly the displayed total-readback source event, Hilbert singleton projection endpoint, residual continuation row, classifier transport, and ledger exactness rows. It does not export tower properties, non-total sub-σ-algebra measurability, or full conditional-expectation theory.*

Lean4 ✓ `BEDC.Derived.CondExpUp.CondExpSingleton standard bridge boundary`

Proof. Use the carrier packet to expose the three concrete BEDC inputs: the $\mathsf{RandomVar}^{\uparrow}$ total-readback certificate, the $\mathsf{Hilbert}^{\uparrow}$ singleton projection witness, and the continuation row.

The classifier obligation transports equality of displayed carrier data into the singleton $\mathsf{CondExp}^{\uparrow}$ classifier. The projection obligation supplies the singleton projection, idempotence, and residual rows from the Hilbert singleton surface.

Finally, the ledger exactness theorem identifies the only hidden bookkeeping with the terminal-preimage exactness row and the residual-zero row. Repacking only these rows yields the standard singleton interface, while every tower, non-total measurability, and unrestricted conditional-expectation clause remains outside the bridge boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$**.**

Constructive story: A conditional expectation in this scoped chapter is the singleton packet obtained by joining three displayed rows: a $\mathsf{RandomVar}^{\uparrow}$ total-readback certificate for the source and target total events, a $\mathsf{Hilbert}^{\uparrow}$ singleton projection witness for an integrable endpoint x and projected endpoint p, and a continuation row $\mathsf{Cont}(p, r, x)$ recording the residual history. The carrier accepts only packets with those three witnesses and their six visible histories, while the classifier identifies two packets when the total-readback histories, integrable endpoints, projected endpoints, and residual rows are transported by hsame and by the consumed $\mathsf{RandomVar}^{\uparrow}$ and $\mathsf{Hilbert}^{\uparrow}$ certificates. The source therefore covers only the total-readback endpoint of a carried random variable, the pattern is Hilbert singleton projection with idempotence and residual-zero orthogonality, and the ledger keeps the terminal-preimage exactness row and the residual-zero inner-product row as the hidden explanation for the visible projection. Since terminal readback uniqueness, singleton projection transport, and history-sameness are stable under the displayed comparisons, a carried singleton packet supplies the nonempty witness, the classifier is reflexive, symmetric, and transitive, and carrier membership survives classifier replacement. A packet h lies in the signature gap of a $\mathsf{CondExp}^{\uparrow}$ token p_0 when the source-domain accepts the total-readback and projection packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p_0; after unfolding, the projected endpoint is the Hilbert singleton projection of the displayed integrable endpoint and the residual row is the constant-zero orthogonality witness. The standard bridge is deliberately narrow, exporting only this singleton conditional-expectation boundary and not tower laws or non-total sub-σ-algebra measurability. The chapter registers this singleton-projection construction under the name $\mathsf{CondExp}^{\uparrow}$; conditional expectation is a RandomVarUp readback plus a Hilbert projection ledger, with no unrestricted host conditional-expectation operator introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$, maturePackageClosed)

Scope closed: This chapter binds the carrier packet, classifier obligation, projection obligation, ledger exactness rows, and singleton standard bridge boundary as the conservative singleton $\mathsf{CondExp}^{\uparrow}$ bridge.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CondExpUp.CondExpCarrierPacket\_ledger\_exactness`

Bridge status: paperBridge

Not claimed: This chapter does not claim tower properties, sub-σ-algebra measurability beyond the total-readback endpoint, Lean-side standard-bridge verification, or full conditional-expectation theory.

Upgrade path: No further theory-axis grade is above matureClosure; bridgeChecked verification remains a separate formal-axis target.

Chapter 189

A Concrete Naming Certificate for $\mathsf{MarkovChain}^{\uparrow}$

The Markov-chain interface $\mathsf{MarkovChain}^{\uparrow}$ packages a sequence of random variables in which the conditional distribution of each step depends only on the previous step. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186).

189.1 Carrier definition

Definition 189.1 (MarkovChain BHist transition carrier)**.** *A* $\mathsf{MarkovChain}^{\uparrow}$ *carrier is a finite* BHist *transition-row packet over a source* $\mathsf{ProbSpace}^{\uparrow}$ *carrier. It consists of a unary time ledger, carried* $\mathsf{RandomVar}^{\uparrow}$ *rows* $X_n : S \to E$ *for each displayed time row,* $\mathsf{Distribution}^{\uparrow}$ *rows for the laws of those random variables, transition rows* $K_n(e, -)$ *whose endpoints are probability distributions on the next-state event family, and the visible* hsame/Cont/Pkg *provenance tying each transition row to the adjacent pair* X_n, X_{n+1}.

The packet is accepted only when the Cont *ledger records that the next-step distribution read for* X_{n+1} *is sourced from the current-state endpoint of* X_n *and the displayed transition row* K_n*. The carrier contains no host stochastic-process object, no filtration, no conditional-expectation primitive, and no standard Markov-kernel bridge; those may be named only by later certificates that consume this finite transition ledger.*

Lean4 (definition) `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier`

Theorem 189.2 (MarkovChain kernel classifier stability)**.** *Let two* $\mathsf{MarkovChain}^{\uparrow}$ *transition packets have the same displayed unary time ledger. Suppose their* $\mathsf{ProbSpace}^{\uparrow}$ *sources,* $\mathsf{RandomVar}^{\uparrow}$ *rows,* $\mathsf{Distribution}^{\uparrow}$ *law rows, and transition rows are related componentwise by* hsame*, and suppose the transition* Cont *ledgers and* Pkg *provenance rows are transported along those comparisons. Then the transported rows form an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *carrier, and the transition classifier has the same current-state to next-law shape.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainKernelClassifier stability`

Proof. Use the classifier field of the roadmap ten-field template. The source rows are the $\mathsf{ProbSpace}^{\uparrow}$ carrier, the displayed $\mathsf{RandomVar}^{\uparrow}$ sequence, and the $\mathsf{Distribution}^{\uparrow}$ law rows; the carrier row is the finite BHist packet of Definition 189.1.

Transport each source row through the displayed hsame comparison. The $\mathsf{RandomVar}^{\uparrow}$ rows keep their domain in the same probability-space packet, and the $\mathsf{Distribution}^{\uparrow}$ rows keep the law endpoints attached to the transported random-variable rows.

Finally transport the transition Cont ledger and Pkg provenance. Since acceptance asks only that the next-step law be read through the adjacent carried rows and the displayed transition row, the transported packet satisfies the same carrier predicate without importing a host stochastic-process equality. □

Theorem 189.3 (MarkovChain transition ledger exactness)**.** *For every accepted* $\mathsf{MarkovChain}^{\uparrow}$ *carrier, the transition ledger exposes exactly the* BHist *rows for the* $\mathsf{ProbSpace}^{\uparrow}$ *source, the displayed* $\mathsf{RandomVar}^{\uparrow}$ *rows, the corresponding* $\mathsf{Distribution}^{\uparrow}$ *law rows, the transition rows* K_n*, the continuation row from the random-variable and transition rows, the provenance row from the probability-space and law rows, the endpoint row from provenance and transition-continuation rows, and the package provenance. It does not expose a host Markov process, a filtration, a conditional-expectation row, or a standard kernel bridge.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket ledger exactness`

Proof. Inspect the carrier definition. Its accepted rows are precisely the source probability-space row, the displayed random-variable rows, the displayed distribution rows, the transition rows, and the provenance entries that bind adjacent time steps.

The ledger field of the ten-field template is the finite Cont display explaining how the transition-continuation row is read from the displayed random-variable row and K_n, how the provenance row is read from the probability-space and law rows, and how the endpoint is read from the provenance and transition-continuation rows. Projecting the ledger therefore returns only those named rows and their package provenance.

No constructor in the carrier produces a filtration, a conditional-expectation object, or a host stochastic-process carrier. Hence none of those external stochastic objects is exported by the transition ledger. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier transition ledger exactness`

Theorem 189.4 (MarkovChain transition-kernel row factorization)**.** *Every transition-kernel read of an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *carrier factors through the displayed finite rows of the carrier: the* $\mathsf{ProbSpace}^{\uparrow}$ *event packet, the current and next* $\mathsf{RandomVar}^{\uparrow}$ *rows, the corresponding* $\mathsf{Distribution}^{\uparrow}$ *law rows, the transition row* K_n*, the* Cont *provenance from adjacent random-variable rows to the next-law endpoint, componentwise* hsame *transport,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ *row. The row may be consumed as a finite transition-kernel datum inside the BEDC packet, but it is not a standard Markov-kernel object and does not carry a host stochastic process, filtration, conditional expectation, or standard kernel bridge.*

Proof. Start from the carrier definition Definition 189.1. It admits only the source probability-space row, displayed current and next random-variable rows, law rows, transition rows K_n, and the visible hsame/Cont/Pkg provenance tying each transition to its adjacent endpoint pair.

Apply transition ledger exactness from Definition 189.3. The ledger exposes exactly the transition BHist rows, the continuation row from the random-variable and transition rows, the provenance row from the probability-space and law rows, the endpoint row from those provenance and continuation rows, and package provenance.

Use the source-boundary theorem Definition 189.5. It keeps the probability source, random variables, and distribution laws inside the joint $\mathsf{ProbSpace}^{\uparrow}/\mathsf{RandomVar}^{\uparrow}/\mathsf{Distribution}^{\uparrow}$ packet, so

the transition row cannot replace them with external probability, random-variable, or distribution objects.

Thus every transition-kernel read factors through the displayed finite rows and their structural transport. Since none of those rows is a standard Markov-kernel object, and since the carrier contains no stochastic-process, filtration, conditional-expectation, or standard-kernel bridge coordinate, the factorized row remains a BEDC transition datum only. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionCarrier transition kernel row factorization`

Theorem 189.5 (MarkovChain probability-random-variable source boundary)**.** *The* $\mathsf{MarkovChain}^{\uparrow}$ *source boundary is the joint BEDC packet consisting of the underlying* $\mathsf{ProbSpace}^{\uparrow}$ *event-and-measure rows, the time-indexed* $\mathsf{RandomVar}^{\uparrow}$ *measurable-preimage rows, and the* $\mathsf{Distribution}^{\uparrow}$ *pushforward rows for the laws of the displayed random variables. Every transition row in an accepted carrier must read its source event through that packet, and no transition row may replace it with an external probability space, external random variable, or host distribution object.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket source boundary`
Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket semantic source boundary`

Proof. Project the source field of the ten-field template. The probability-space source is the displayed $\mathsf{ProbSpace}^{\uparrow}$ packet, and every random-variable row is carried over that same source packet.

Next project the law rows through $\mathsf{Distribution}^{\uparrow}$. Each law endpoint is a pushforward row for the corresponding $\mathsf{RandomVar}^{\uparrow}$ map, so the row remains inside the BEDC source boundary.

The transition row may consume those source, random-variable, and law rows through Cont and Pkg provenance only. This gives the stated boundary and excludes host probability spaces, host random variables, and host distribution objects. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier source boundary`
↪ variant `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier probspace randomvar source boundary`

Theorem 189.6 (MarkovChain NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ *obligation surface is the transition carrier of Definition 189.1, the componentwise kernel classifier of Definition 189.2, the transition ledger exactness row of Definition 189.3, and the probability-random-variable source boundary of Definition 189.5. The surface names only* BHist *rows,* hsame *comparisons,* Cont *transition displays, and* Pkg *provenance over* $\mathsf{ProbSpace}^{\uparrow}$*,* $\mathsf{RandomVar}^{\uparrow}$*, and* $\mathsf{Distribution}^{\uparrow}$ *dependency certificates.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionLedgerSurface semantic name certificate`
↪ variant `BEDC.Derived.MarkovChainUp.MarkovChainTransitionCarrier semantic name certificate`

Proof. Assemble the obligation surface by the roadmap ten-field template. The traditional target is a discrete-time Markov chain; the BEDC source is the probability-space, random-variable, and distribution dependency packet; the carrier is the finite transition packet.

The classifier and stability fields are supplied by Definition 189.2. The ledger and exactness fields are supplied by Definition 189.3.

The source-boundary field is Definition 189.5. Together these rows give the named $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ obligation surface while keeping host stochastic-process structure outside the certificate. □

Theorem 189.7 (MarkovChain scoped kernel dependency package)**.** *The* $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ *obligation surface of Definition 189.6 is scoped exactly by the* $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, *and* $\mathsf{Distribution}^{\uparrow}$ *dependency certificates, the finite unary time ledger, the transition rows* K_n, BHist *rows,* hsame *comparisons,* Cont *displays, and* Pkg *provenance. No filtration, conditional-expectation primitive, host stochastic process, or standard Markov kernel is read by this scoped package.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket dependency unary closure`
Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainKernelClassifier endpoint confluence`

Proof. Project the carrier row from Definition 189.1. Its constructors expose only the source probability-space packet, the carried random-variable rows, the law rows, the unary time ledger, transition rows, and the displayed provenance.

Next use Definition 189.2 and Definition 189.3. These identify the classifier transport and ledger reads with componentwise hsame, Cont, and Pkg rows over the same finite packet.

Finally apply Definition 189.5 together with Definition 189.6. The dependency rows consumed by those projections are exactly the $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, and $\mathsf{Distribution}^{\uparrow}$ certificates and the finite transition ledger, so the excluded stochastic-process, filtration, conditional-expectation, and standard-kernel objects remain outside the scoped package. □

Theorem 189.8 (MarkovChain transition-packet scope)**.** *The paper scope of* MarkovChainTransitionPacket *is the finite* BHist *packet consisting of* ProbSpacePublicEventPacket *source rows,* DistributionPushforwardSourceSpec *law rows,* RandomVarTotalReadbackCertificate *current-to-next readback rows,* Cont *provenance rows,* hsame *transport rows, and the visible* BHist *time, current-state, next-state, transition, provenance, and ledger endpoints. It introduces no host stochastic-process carrier, filtration, conditional-expectation primitive, or standard Markov-kernel object.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionCarrier transition packet scope`

Proof. Unfold the transition-packet rows. The source field is the public probability event packet, the law field is the distribution pushforward source specification, and the readback field is the random-variable total readback certificate.

The remaining rows are the two displayed Cont ledgers: one from the current state and transition row to the provenance endpoint, and one from that provenance endpoint and law row to the ledger endpoint. The only transport allowed across the packet is componentwise hsame on those displayed BHist rows, so the external stochastic objects listed above are not part of the scope. □

Theorem 189.9 (MarkovChain Lean target surface)**.** *The checked* MarkovChainTransitionPacket_kernel_classifier_ *theorem states that componentwise* hsame *transport of the source, time, current, next, law, and transition rows, together with transported* Cont *provenance and ledger rows, preserves the* MarkovChainTransitionPacket *carrier and returns* hsame *comparisons for the provenance and ledger endpoints.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket kernel classifier stability`

Proof. Read the checked theorem as the transition-packet classifier transport row. The inputs are precisely the rows isolated in Definition 189.8.

The theorem transports the probability source, unary time row, random-variable current and next endpoints, law row, and transition row by hsame. It then rebuilds the two Cont ledgers at the transported endpoints, producing both the transported carrier packet and the displayed provenance and ledger endpoint comparisons. □

Theorem 189.10 (MarkovChain scoped obligation package)**.** *The transition-packet stability theorem of Definition 189.9 supplies the scoped carrier/classifier transport row for* $\mathsf{MarkovChain}^{\uparrow}$*. Ledger exactness and the assembled* $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ *remain paper obligations until their corresponding rows are separately formalized.*

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionCarrier scoped obligation package`

Proof. Combine Definition 189.8 with Definition 189.9. The former fixes the visible carrier rows, and the latter proves that the classifier transport preserves that packet.

The remaining fields of the local name certificate are not consequences of the transport theorem alone. They require the ledger exactness row and the final assembly of the $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$ surface, so they stay as stated paper obligations. □

189.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$**.**

Constructive story: A Markov-chain packet is generated from a displayed $\mathsf{ProbSpace}^{\uparrow}$ source, a unary time ledger, carried $\mathsf{RandomVar}^{\uparrow}$ rows, $\mathsf{Distribution}^{\uparrow}$ law rows, transition rows, Cont displays, hsame transport, and Pkg provenance. The carrier accepts only finite transition ledgers whose next-law rows are sourced from the adjacent carried random-variable rows, so host stochastic-process objects, filtrations, conditional-expectation primitives, and standard kernel bridges remain outside the certificate.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public surface consists of the finite-prefix restriction, transition-concat closure, splice transport, and finite-suffix carrier rows displayed in this chapter, over the same $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Distribution}^{\uparrow}$, hsame, Cont, and Pkg transition packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.MarkovChainUp.MarkovChainTransitionCarrier\_semantic\_name\_certificate`

Bridge status: none

Not claimed: No host stochastic-process carrier, filtration, conditional-expectation construction, stationary law, martingale property, or standard kernel bridge is claimed.

Upgrade path: No paper-axis strengthening remains; stronger status is purely formal or bridge-axis work.

Definition 189.11 (MarkovChain finite-prefix restriction)**.** *Let P be a displayed* $\mathsf{MarkovChain}^{\uparrow}$ *transition packet over a unary time ledger with transition-time rows $0, \ldots, n+k-1$ and endpoint rows $0, \ldots, n+k$. The finite-prefix restriction $P_{\leq n}$ is the subpacket obtained by keeping the same* $\mathsf{ProbSpace}^{\uparrow}$ *source, the endpoint rows $X_0, \ldots, X_n$, the* $\mathsf{Distribution}^{\uparrow}$ *law rows read by the first n transitions, the transition rows $K_0, \ldots, K_{n-1}$, and exactly the* hsame/Cont/Pkg *provenance entries whose adjacent endpoints both lie in $X_0, \ldots, X_n$.*

No row with transition index at least n is copied into $P_{\leq n}$, and no row is reindexed except by the evident inclusion of the prefix ledger into the original unary ledger.

Lean4 (definition) `BEDC.Derived.MarkovChainUp.MarkovChainFinitePrefixRestriction`

Theorem 189.12 (MarkovChain finite-prefix restriction carrier)**.** *Let P be an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *transition packet in the sense of Definition 189.1. Suppose its unary time ledger has length $n+k$, with endpoint rows $X_0, \ldots, X_{n+k}$ and transition rows $K_0, \ldots, K_{n+k-1}$. Then the finite-prefix restriction $P_{\leq n}$ of Definition 189.11, consisting of the same* $\mathsf{ProbSpace}^{\uparrow}$ *source, the first $n+1$ displayed* $\mathsf{RandomVar}^{\uparrow}$ *endpoint rows, the first n next-law* $\mathsf{Distribution}^{\uparrow}$ *rows, the first n transition rows, and the inherited adjacent* hsame/Cont/Pkg *provenance, is again an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *carrier.*

Proof. The carrier predicate of Definition 189.1 is local along adjacent transition rows. It asks for a finite unary time ledger, carried $\mathsf{RandomVar}^{\uparrow}$ endpoint rows on that ledger, the displayed $\mathsf{Distribution}^{\uparrow}$ law rows read by the transition rows, and for each adjacent pair X_i, X_{i+1} a Cont ledger and Pkg provenance row recording that the next-step distribution for X_{i+1} is sourced from the current-state endpoint of X_i through the displayed transition row K_i.

The prefix ledger $0, \ldots, n$ is finite because it is obtained by induction on the first n successors of the original unary ledger. Its endpoint rows $X_0, \ldots, X_n$ are carried $\mathsf{RandomVar}^{\uparrow}$ rows because each is one of the carried endpoint rows of P. The retained next-law rows are $\mathsf{Distribution}^{\uparrow}$ rows for the same reason: each retained law row is one of the law rows already accepted in the original packet and is attached to the same adjacent transition where it is read.

It remains only to check the transition obligations. Fix a prefix transition index $i < n$. Since the original packet has length $n + k$, the same index also satisfies $i < n + k$. Acceptance of P therefore supplies the transition row K_i together with the displayed Cont ledger witnessing that the next-law row for X_{i+1} is read from the current-state endpoint of X_i through K_i, and the corresponding Pkg provenance. Both endpoints X_i and X_{i+1} lie in the retained endpoint list, and K_i lies among the retained transition rows, so this exact $\mathsf{Cont}/\mathsf{Pkg}$ entry is a well-formed adjacent transition entry of $P_{\leq n}$.

Every transition obligation of $P_{\leq n}$ is obtained in this way from a unique transition obligation of P, and the restriction introduces no additional transition row whose source, target, law, or provenance would need a separate witness. The source-boundary statement of Definition 189.5 also remains unchanged, because the restricted packet keeps the same $\mathsf{ProbSpace}^{\uparrow}$ source and only discards later rows. Thus all fields required by the MarkovChain transition carrier predicate are present in the restricted finite packet, so $P_{\leq n}$ is an accepted $\mathsf{MarkovChain}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier finite prefix restriction carrier`

Theorem 189.13 (MarkovChain transition-packet concatenation closure)**.** *Let P_1 be an accepted $\mathsf{MarkovChain}^{\uparrow}$ transition packet of length n over a unary time ledger T_1, with displayed random-variable rows*

$$X_0, X_1, \ldots, X_n$$

source law rows $\mu_0^X, \mu_1^X, \ldots, \mu_n^X$, transition rows $K_0^X, \ldots, K_{n-1}^X$, and transition provenance ledgers accepted by Definition 189.1. Let P_2 be an accepted $\mathsf{MarkovChain}^{\uparrow}$ transition packet of length m over a unary time ledger T_2, over the same displayed $\mathsf{ProbSpace}^{\uparrow}$ source, with displayed random-variable rows

$$Y_0, Y_1, \ldots, Y_m$$

source law rows $\mu_0^Y, \mu_1^Y, \ldots, \mu_m^Y$, transition rows $K_0^Y, \ldots, K_{m-1}^Y$, and accepted transition provenance ledgers. Suppose the shared endpoint is displayed by a $\mathsf{RandomVar}^{\uparrow}$ classifier row

$$\mathsf{hsame}(X_n, Y_0)$$

over that same $\mathsf{ProbSpace}^{\uparrow}$ source, and let the induced $\mathsf{Distribution}^{\uparrow}$ law comparison identify the endpoint law rows μ_n^X and μ_0^Y. If the unary ledgers are displayed with a concatenation row

$$\mathsf{Cont}(T_1, T_2, T_{12})$$

so that T_{12} is the unary ledger of length $n + m$, then the end-to-end displayed packet P_{12} is an accepted $\mathsf{MarkovChain}^{\uparrow}$ transition packet over T_{12}. Its random-variable row at time i is X_i for

$0 \le i \le n$ and Y_j for $i = n + j$ with $1 \le j \le m$; its transition rows are K_i^X for $0 \le i < n$ and the shifted rows K_j^Y for $0 \le j < m$, with the first shifted row read across the splice comparison $\mathsf{hsame}(X_n, Y_0)$.

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier transition concat closure`
Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainBHistTransitionCarrier adjacent transition transport`

Proof. Unpack the accepted carrier condition in Definition 189.1. The first packet supplies the common $\mathsf{ProbSpace}^{\uparrow}$ source, the random-variable rows X_i, the law rows μ_i^X, the transition rows K_i^X, and for every $0 \le i < n$ a displayed $\mathsf{Cont}/\mathsf{Pkg}$ provenance ledger certifying that the next-step law for X_{i+1} is read from the current-state endpoint of X_i through K_i^X. The second packet supplies the same kind of data for Y_j, μ_j^Y, and K_j^Y for $0 \le j < m$ over the same probability source.

Define the displayed concatenated row sequence by

$$Z_i := X_i \quad (0 \le i \le n), \qquad Z_{n+j} := Y_j \quad (1 \le j \le m).$$

Define its law rows by

$$\lambda_i := \mu_i^X \quad (0 \le i \le n), \qquad \lambda_{n+j} := \mu_j^Y \quad (1 \le j \le m).$$

The endpoint law at the splice is well-defined on the displayed carrier because the hypothesis $\mathsf{hsame}(X_n, Y_0)$ is a $\mathsf{RandomVar}^{\uparrow}$ comparison over the shared $\mathsf{ProbSpace}^{\uparrow}$ source, and the pushforward classifier of Definition 186.2 transports the law row of Y_0 to the law row already carried by X_n.

The transition rows of P_{12} are the visible list

$$K_0^X, \ldots, K_{n-1}^X, K_0^Y, \ldots, K_{m-1}^Y.$$

For indices $i < n$, the required adjacent provenance row from Z_i to Z_{i+1} is exactly the accepted provenance row of P_1. For indices $i = n + j$ with $1 \le j < m$, the required adjacent provenance row from $Z_{n+j} = Y_j$ to $Z_{n+j+1} = Y_{j+1}$ is exactly the accepted provenance row of P_2.

It remains to check the splice transition, the row using K_0^Y from time n to time $n + 1$. In P_2, acceptance says that the next-step law for Y_1 is read from the current-state endpoint Y_0 through K_0^Y, with its displayed $\mathsf{Cont}/\mathsf{Pkg}$ provenance. Transport the current-state endpoint and its law row along

$$\mathsf{hsame}(X_n, Y_0).$$

By Definition 189.2, this componentwise transport preserves acceptance of the transition row and preserves the current-state to next-law classifier shape. Therefore the transported splice row reads the same next-step law μ_1^Y from the concatenated current row $Z_n = X_n$ through K_0^Y.

The time ledger is finite and unary because T_1 and T_2 are unary and the displayed continuation row $\mathsf{Cont}(T_1, T_2, T_{12})$ is the finite BEDC concatenation of those two ledgers. The transition provenance ledgers concatenate in the same order: rows internal to P_1 and P_2 are inherited, and the single boundary row is the transported splice row just constructed. The carrier definition asks for no host stochastic process, filtration, conditional expectation, or standard kernel bridge; it asks only for these displayed random-variable rows, law rows, transition rows, and $\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}$ provenance. Hence the assembled packet satisfies the accepted $\mathsf{MarkovChain}^{\uparrow}$ carrier predicate over the unary ledger T_{12} of length $n + m$. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket splice transport closure`

Theorem 189.14 (MarkovChain filtered transition consumer catalogue)**.** *Every downstream finite stochastic-process consumer of an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *transition packet reads only the displayed* $\mathsf{ProbSpace}^{\uparrow}$ *source, unary time ledger, adjacent* $\mathsf{RandomVar}^{\uparrow}$ *rows,* $\mathsf{Distribution}^{\uparrow}$ *law rows, transition rows, finite-prefix restrictions, concatenation and splice rows,* hsame, Cont, *and* Pkg *provenance.*

The catalogue excludes host stochastic processes, filtrations, conditional expectation, stationary laws, martingale structure, and standard kernel bridges. A consumer may restrict to a finite window, concatenate compatible windows, or read across a transported splice, but every such read remains inside the displayed finite transition packet.

Proof. Project the accepted packet through Definition 189.1. The projection exposes only the $\mathsf{ProbSpace}^{\uparrow}$ source, the unary time ledger, adjacent $\mathsf{RandomVar}^{\uparrow}$ endpoints, $\mathsf{Distribution}^{\uparrow}$ law rows, transition rows, and the displayed hsame/Cont/Pkg provenance.

For local finite windows, apply Definition 189.12. The restriction keeps the same source row and copies only the visible endpoint, law, transition, and provenance rows whose indices lie in the chosen finite prefix.

For consumers that splice or extend windows, apply Definition 189.13 together with the adjacent transport row recorded after that theorem. These results rebuild the concatenated packet from the two displayed finite ledgers and the single transported splice row.

The semantic certificate row for $\mathsf{MarkovChain}^{\uparrow}$ is then the public boundary: it certifies that the visible carrier, classifier, stability, exactness, and provenance fields are the rows available to downstream consumers. No host stochastic process, filtration, conditional expectation, stationary law, martingale datum, or standard kernel bridge is a field of that packet. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainUp concrete to schema`

Definition 189.15 (MarkovChain finite-suffix restriction)**.** *Let P be a displayed* $\mathsf{MarkovChain}^{\uparrow}$ *transition packet over a unary time ledger with transition-time rows $0, \ldots, n+k-1$ and endpoint rows $0, \ldots, n+k$. The finite-suffix restriction $P^k_{\geq n}$ is the packet obtained by keeping the same* $\mathsf{ProbSpace}^{\uparrow}$ *source, replacing the initial endpoint by the boundary row X_n, retaining the endpoint rows*

$$X_n, X_{n+1}, \ldots, X_{n+k},$$

retaining the law rows read at those endpoints, retaining the transition rows

$$K_n, K_{n+1}, \ldots, K_{n+k-1},$$

and retaining exactly the hsame/Cont/Pkg *provenance entries whose adjacent endpoints both lie in that displayed suffix.*

The suffix ledger is the unary ledger of length k whose endpoint row j is read as the original endpoint row $n+j$ and whose transition row $j < k$ is read as the original transition row $n+j$. No transition row before n is copied into $P^k_{\geq n}$.

Theorem 189.16 (MarkovChain finite-suffix restriction carrier)**.** *Let P be an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *transition packet in the sense of Definition 189.1. Suppose its unary time ledger has length $n+k$, with endpoint rows $X_0, \ldots, X_{n+k}$ and transition rows $K_0, \ldots, K_{n+k-1}$. Then the finite-suffix restriction $P^k_{\geq n}$ of Definition 189.15, consisting of the same* $\mathsf{ProbSpace}^{\uparrow}$ *source, the displayed endpoint rows $X_n, \ldots, X_{n+k}$, the corresponding* $\mathsf{Distribution}^{\uparrow}$ *law rows, the transition rows $K_n, \ldots, K_{n+k-1}$, and the inherited adjacent* hsame/Cont/Pkg *provenance, is again an accepted* $\mathsf{MarkovChain}^{\uparrow}$ *carrier.*

Proof. The carrier predicate of Definition 189.1 is local along adjacent transition rows. It requires a finite unary ledger, carried $\mathsf{RandomVar}^{\uparrow}$ endpoint rows, law rows supplied by $\mathsf{Distribution}^{\uparrow}$, transition rows, and for each adjacent pair a displayed Cont ledger and Pkg provenance row witnessing that the next-step distribution is read from the current-state endpoint through the displayed transition row.

The suffix ledger is finite because it is the displayed block of k successive transitions beginning at the boundary endpoint X_n. Its endpoint row j is X_{n+j} for $0 \le j \le k$, and its transition row $j < k$ is K_{n+j}. Each such endpoint and transition row is already a row of the accepted packet P, so the restricted packet obtains its $\mathsf{RandomVar}^{\uparrow}$ and transition data by projection from P rather than by introducing any outside stochastic-process object.

The boundary condition at the first suffix time is the only place where a prefix argument does not directly apply. In $P^k_{\ge n}$ the initial row is X_n, not X_0. This causes no additional obligation: the MarkovChain carrier does not require a distinguished initial law supplied by the original start row. It requires only that every displayed transition row have its adjacent source and target endpoints and its next-law row. For the first suffix transition, acceptance of P at the original index n supplies exactly the row

$$X_n \xrightarrow{K_n} X_{n+1}$$

with the displayed $\mathsf{Cont}/\mathsf{Pkg}$ provenance saying that the next-step law of X_{n+1} is read from the current-state endpoint of X_n through K_n. Thus the suffix packet has the required first adjacent transition ledger.

For any remaining suffix transition $j < k$, the corresponding original index is $n + j < n + k$. Acceptance of P supplies the transition row K_{n+j}, the adjacent endpoints X_{n+j} and X_{n+j+1}, the law row for the target endpoint, and the provenance witnessing the same current-state to next-law read. These are precisely the rows displayed at suffix positions j and $j + 1$, so the original provenance is well-typed after the suffix reindexing.

Every transition obligation of $P^k_{\ge n}$ is obtained from exactly one transition obligation of P with index between n and $n + k - 1$, and the suffix construction creates no additional transition. The source boundary of Definition 189.5 is preserved because the restricted packet keeps the same $\mathsf{ProbSpace}^{\uparrow}$ source and only discards rows outside the suffix. Hence all rows required by the accepted $\mathsf{MarkovChain}^{\uparrow}$ transition carrier predicate are present in $P^k_{\ge n}$. □

Lean4 ✓ `BEDC.Derived.MarkovChainUp.MarkovChainTransitionPacket finite suffix carrier`

Chapter 190

A Concrete Naming Certificate for $\mathsf{Martingale}^{\uparrow}$

The martingale interface $\mathsf{Martingale}^{\uparrow}$ packages an adapted sequence of integrable random variables whose conditional expectation at each step is the previous value. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ (chapter 188).

190.1 Carrier definition

Definition 190.1 (Adapted BHist carrier for MartingaleUp)**.** *A* $\mathsf{Martingale}^{\uparrow}$ *packet is a finite* BHist *row package over a displayed* $\mathsf{ProbSpace}^{\uparrow}$ *source. It consists of:*

1. *a finite* UnaryHistory *time spine* T *whose entries are histories* $t : \mathsf{BHist}$*;*
2. *for each displayed time* $t \in T$*, a carried* $\mathsf{RandomVar}^{\uparrow}$ *row* $X_t : S \to R$ *with integrable* $\mathsf{Real}^{\uparrow}$ *endpoint history;*
3. *for each successor display* $t \rightsquigarrow t^+$ *in* T*, a carried* $\mathsf{CondExp}^{\uparrow}$ *row* E_t *whose source random-variable row is* X_{t^+} *and whose conditioning visibility row is the filtration row* $\mathcal{F}_t$*;*
4. *filtration visibility rows* $\mathcal{F}_t \hookrightarrow \mathcal{F}_{t^+}$ *saying that the readable events and the carried random-variable endpoint* X_t *are visible at time* t*;*
5. *a finite* Cont *ledger connecting the time row, the random-variable rows, the conditional-expectation rows, and the filtration visibility rows inside one shared* Pkg *provenance row.*

The displayed martingale row of the packet is the conditional-expectation comparison

$$E_t(X_{t^+} \mid \mathcal{F}_t) \sim_R X_t$$

for every successor display $t \rightsquigarrow t^+$ *in the finite time spine, where* $\sim_R$ *is the* $\mathsf{Real}^{\uparrow}$ *classifier read through the carried conditional-expectation endpoint.*

Definition 190.2 (Conditional-expectation classifier for MartingaleUp)**.** *Let* M *and* N *be two* $\mathsf{Martingale}^{\uparrow}$ *packets as in Definition 190.1. A conditional-expectation classifier from* M *to* N *consists of:*

1. hsame *transport between the two finite* UnaryHistory *time spines, preserving successor displays;*
2. *componentwise* hsame *transport between the matched* $\mathsf{RandomVar}^{\uparrow}$ *rows* X_t *and* Y_u*;*

3. *componentwise* hsame *transport between the matched* $\mathsf{CondExp}^{\uparrow}$ *rows* E_t *and* F_u*;*
4. *transport of filtration visibility rows along the matched time and random-variable histories;*
5. *a shared* Pkg *provenance comparison, with the finite* Cont *ledger of* M *transported to the finite* Cont *ledger of* N*.*

The classifier holds exactly when these transported rows identify the displayed conditional-expectation comparison of M *with the displayed conditional-expectation comparison of* N *at every matched successor display.*

Definition 190.3 (MartingaleUp adapted BHist stream carrier)**.** *Fix a displayed finite horizon* $N : \mathbb{N}$*. A finite adapted* $\mathsf{Martingale}^{\uparrow}$ *carrier packet is a BEDC row family indexed by unary histories* $\nu_0, \ldots, \nu_N : \mathsf{BHist}$*. For every* $n \leq N$ *the packet contains a visible value endpoint* $X_n : \mathsf{BHist}$ *and a* $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ *row witnessing that* X_n *is a carried* $\mathsf{RandomVar}^{\uparrow}$ *endpoint over the displayed source and target carriers. It also contains a filtration/provenance ledger row*

$$\mathsf{Fil}_n(\nu_n, X_n, \Gamma_n)$$

whose entries live only in BHist *and* Pkg *and record the displayed observable history* ν_n*, the value endpoint* X_n*, and the certificate package* Γ_n *consumed at that time.*

For each successor index $n < N$ *the packet contains displayed endpoints*

$$X_n, \quad X_{n+1}, \quad E_{n+1|n}, \quad R_{n+1|n} : \mathsf{BHist}$$

together with the continuation row $\mathsf{Cont}(E_{n+1|n}, R_{n+1|n}, X_n)$*. The endpoint* $E_{n+1|n}$ *is the named conditional-expectation endpoint supplied by the successor* $\mathsf{CondExp}^{\uparrow}$ *row, while* $R_{n+1|n}$ *is the residual history carried by that same row.*

Definition 190.4 (MartingaleUp conditional expectation step classifier)**.** *Two finite adapted* $\mathsf{Martingale}^{\uparrow}$ *carrier packets over the same displayed horizon are classifier-equal when their components match by the BEDC rows visible in Definition 190.3. For every index* $n \leq N$ *the observable histories, value endpoints, and provenance packages satisfy*

$$\mathsf{hsame}(\nu_n, \nu'_n), \qquad \mathsf{hsame}(X_n, X'_n), \qquad \mathsf{hsame}(\Gamma_n, \Gamma'_n).$$

The value-endpoint comparison is transported through the corresponding $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ *rows, so the classifier does not read a host-level sequence equality.*

For every successor $n < N$*, the step endpoints satisfy*

$$\mathsf{hsame}(E_{n+1|n}, E'_{n+1|n}), \qquad \mathsf{hsame}(R_{n+1|n}, R'_{n+1|n}),$$

and the displayed $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ *rows identify the transported conditional-expectation endpoint* $E_{n+1|n}$ *with the previous value endpoint* X_n *through the continuation row* $\mathsf{Cont}(E_{n+1|n}, R_{n+1|n}, X_n)$*. These componentwise comparisons are the full* $\mathsf{Martingale}^{\uparrow}$ *classifier.*

Definition 190.5 (MartingaleUp BHist adapted-sequence packet)**.** *A* $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packet is a finite BEDC tuple*

$$\mathcal{M} = (R, C, F, X, E, T, \rho, \lambda)$$

whose entries have the following roles. The row R *is the consumed* $\mathsf{RandomVar}^{\uparrow}$ *packet and the row* C *is the consumed* $\mathsf{CondExp}^{\uparrow}$ *packet. The row* F *is the displayed filtration and adaptation row. The row* X *is a finite sequence of* BHist *endpoint rows, each endpoint being a* $\mathsf{RandomVar}^{\uparrow}$ *row scoped*

by R and adapted to the displayed filtration row F. The row E is a finite sequence of $\mathsf{CondExp}^{\uparrow}$ *rows, one for each adjacent time face, whose source is the later endpoint row and whose target is the previous endpoint row. The row T is the tower-law boundary row recording compatibility of adjacent conditional-expectation faces. The row ρ records package provenance through the two consumed source packets, and λ is the finite* Cont *ledger that stores all displayed transport rows.*

The packet is accepted as a $\mathsf{Martingale}^{\uparrow}$ *carrier exactly when every row just named is present in this finite tuple, the X rows are random-variable endpoint rows over R, the E rows are conditional-expectation rows over C, and no carrier datum outside R, C, F, X, E, T, ρ, and λ is used to state the martingale condition.*

Definition 190.6 (MartingaleUp conditional-expectation ledger classifier)**.** *For two adapted-sequence packets*

$$\mathcal{M} = (R, C, F, X, E, T, \rho, \lambda) \quad \textit{and} \quad \mathcal{M}' = (R', C', F', X', E', T', \rho', \lambda'),$$

the $\mathsf{Martingale}^{\uparrow}$ *ledger classifier holds when the consumed* $\mathsf{RandomVar}^{\uparrow}$ *packets R and R' are related by the* $\mathsf{RandomVar}^{\uparrow}$ *classifier, the consumed* $\mathsf{CondExp}^{\uparrow}$ *packets C and C' are related by the* $\mathsf{CondExp}^{\uparrow}$ *classifier, and the remaining displayed rows are related componentwise by* hsame*:*

$$F\,\mathsf{hsame}\,F', \quad X\,\mathsf{hsame}\,X', \quad E\,\mathsf{hsame}\,E', \quad T\,\mathsf{hsame}\,T', \quad \rho\,\mathsf{hsame}\,\rho', \quad \lambda\,\mathsf{hsame}\,\lambda'.$$

Thus the classifier transports only the visible filtration, endpoint-sequence, conditional-expectation, tower-boundary, provenance, and ledger rows, while the two consumed dependency packets supply their own internal carrier and classifier obligations.

190.2 The certificate

Theorem 190.7 (Martingale filtration ledger exactness)**.** *For a* $\mathsf{Martingale}^{\uparrow}$ *packet of Definition 190.1, the* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *ledger exposes exactly the adaptedness rows, filtration visibility rows,* $\mathsf{RandomVar}^{\uparrow}$ *rows,* $\mathsf{CondExp}^{\uparrow}$ *rows,* $\mathsf{UnaryHistory}$ *time-index rows, shared* Pkg *provenance row, and finite* Cont *ledger listed in the carrier. The ledger is exact precisely when each successor display $t \rightsquigarrow t^{+}$ reads the displayed row*

$$E_t(X_{t^+} \mid \mathcal{F}_t) \sim_R X_t$$

from those entries and from no additional host equality, host function equality, or unlisted measurability field.

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket filtration ledger exactness`

Proof. Project the carrier packet of Definition 190.1. The time spine supplies only $\mathsf{UnaryHistory}$ indices and successor displays. The random-variable spine supplies the carried $\mathsf{RandomVar}^{\uparrow}$ rows, and the filtration part supplies exactly the visibility rows that make X_t readable at time t.

The conditional-expectation entry at a successor display is already a carried $\mathsf{CondExp}^{\uparrow}$ row over X_{t^+} and $\mathcal{F}_t$. Reading its endpoint through the shared $\mathsf{Real}^{\uparrow}$ classifier gives the displayed comparison with X_t.

The finite Cont ledger records how these rows sit in one Pkg provenance row. Since every value consumed by $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ is one of the projected carrier entries, and the theorem excludes every unlisted host field, the ledger is exact for the displayed martingale surface. □

Theorem 190.8 (Martingale conditional-expectation stability)**.** *Let M and N be* $\mathsf{Martingale}^{\uparrow}$ *packets related by the classifier of Definition 190.2. If M carries the displayed conditional-expectation comparison*

$$E_t(X_{t^+} \mid \mathcal{F}_t) \sim_R X_t$$

at a successor display $t \rightsquigarrow t^+$, then N carries the transported comparison

$$F_u(Y_{u^+} \mid \mathcal{G}_u) \sim_R Y_u$$

at the matched successor display $u \rightsquigarrow u^+$. Hence classifier-related packets preserve every displayed martingale equality row.

Proof. Use the time-spine clause of the classifier to transport the successor display $t \rightsquigarrow t^+$ to $u \rightsquigarrow u^+$. The same clause transports the filtration visibility row $\mathcal{F}_t$ to $\mathcal{G}_u$.

Transport the random-variable rows componentwise by hsame, sending X_t to Y_u and X_{t^+} to Y_{u^+}. Transport the conditional-expectation row componentwise by hsame, sending E_t to F_u over the matched source random variable and matched filtration row.

Finally use the shared Pkg provenance comparison and the transported finite Cont ledger. These rows identify the displayed conditional-expectation comparison in M with the displayed comparison in N, so the $\mathsf{Real}^{\uparrow}$ classifier row for M transports to the corresponding row for N. □

Theorem 190.9 (Martingale random-variable boundary)**.** *In every finite adapted carrier packet of Definition 190.3, each visible value row X_n is supplied by the displayed* $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ *component Γ_n. The* $\mathsf{Martingale}^{\uparrow}$ *packet never reads a host-level sequence or a host equality of values; all value comparisons are mediated by* hsame *and by the transported* $\mathsf{RandomVar}^{\uparrow}$ *classifier row recorded in Γ_n.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket randomvar boundary`

Proof. Fix an index $n \leq N$. By definition of the carrier packet, the value endpoint X_n appears only together with its package Γ_n and the ledger row $\mathsf{Fil}_n(\nu_n, X_n, \Gamma_n)$.

Unpack Γ_n through the public $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ surface of section 185.2. The measurable-preimage and endpoint classifier data used by the value row are exactly the rows carried by that certificate.

No other field of Definition 190.3 contains a function from natural numbers into host values. The only index is the displayed unary history label, and the only equality test is the componentwise hsame comparison of Definition 190.4. Thus every visible value row is supplied by $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ and no host sequence is read. □

Theorem 190.10 (Martingale conditional expectation step law)**.** *For every successor index $n < N$ in a finite adapted* $\mathsf{Martingale}^{\uparrow}$ *carrier packet, the row from X_{n+1} to X_n consumes a displayed* $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ *component whose conditional-expectation endpoint $E_{n+1|n}$ is identified with the previous value endpoint X_n. The identification is recorded inside the BEDC packet by the continuation row* $\mathsf{Cont}(E_{n+1|n}, R_{n+1|n}, X_n)$ *and by the* $\mathsf{CondExp}^{\uparrow}$ *classifier, not by an ambient analytic equality.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket condexp step law`

Proof. Fix a successor index $n < N$. The carrier packet supplies the displayed endpoints X_n, X_{n+1}, $E_{n+1|n}$, and $R_{n+1|n}$, together with the successor $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ row.

Read that row through Definition 188.1. Its visible fields are the random-variable total-readback component, the projected conditional-expectation endpoint, and the continuation ledger. In the martingale packet these fields are instantiated by X_{n+1}, $E_{n+1|n}$, $R_{n+1|n}$, and X_n.

Apply the classifier obligation of Definition 188.2. It transports the displayed endpoint comparison through hsame and the continuation row. Therefore the successor row states exactly that the conditional expectation of the next value endpoint over the displayed filtration history is classified as the previous endpoint X_n. □

Theorem 190.11 (MartingaleUp obligation closure package)**.** *The public* $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ *obligation set consists exactly of the finite time spine, the RandomVarUp endpoint rows, the CondExpUp successor rows, the filtration visibility rows, the conditional-expectation comparison rows, the shared* Pkg *provenance row, and the finite* Cont *ledger. These rows are precisely the data carried by Definition 190.3 and classified by Definition 190.4. The package exports no host sequence equality, ambient analytic equality, unlisted measurability field, or bridge status.*

Proof. Start with the adapted carrier. The definition supplies the finite time spine, the displayed value endpoints, the RandomVarUp endpoint rows, the CondExpUp successor rows, the filtration/provenance ledger rows, and the finite continuation rows.

Next attach the classifier. By Definition 190.4, comparison between two packets is only componentwise hsame transport of the finite time spine, RandomVarUp rows, CondExpUp rows, filtration visibility rows, provenance, and Cont ledger.

Use Definition 190.12 and Definition 190.9 to identify the public endpoint surface. The former packages the carrier and classifier rows as the public certificate family, while the latter says every visible value endpoint comes from the consumed RandomVarUp rows.

Finally apply Definition 190.10. It identifies each successor comparison row with the displayed CondExpUp endpoint comparison and the continuation row ending at the previous value endpoint. Combining these rows gives the listed obligation set exactly, so no host sequence equality, ambient analytic equality, unlisted measurability field, or bridge status is exported. □

Theorem 190.12 (Martingale public certificate row family)**.** *The finite adapted carrier packet of Definition 190.3, the classifier of Definition 190.4, the random-variable boundary of Definition 190.9, and the successor law of Definition 190.10 form the public* $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ *obligation family. Its exported rows are precisely the carrier rows, componentwise classifier transport, stability under* hsame *replacement, filtration/provenance ledger rows, conditional expectation exactness rows, and status rows naming the finite displayed horizon.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket public certificate row family`

Proof. Start with the carrier rows. They expose a finite family of displayed BHist endpoints, Pkg provenance entries, and $\mathsf{NameCert}_{\mathsf{RandomVar}^\uparrow}$ value packages, so the public object has a concrete BEDC carrier.

Next attach the classifier. By Definition 190.4, equality is componentwise hsame plus the transported $\mathsf{RandomVar}^\uparrow$ and $\mathsf{CondExp}^\uparrow$ classifier rows. This gives stability under replacement by displayed classifier witnesses.

The random-variable boundary theorem supplies the exact source of every visible value row. The successor law supplies the exact conditional-expectation row for every adjacent pair. Repacking these rows with the filtration/provenance ledger gives the public $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ family and leaves no unrecorded host sequence, ambient conditional expectation, or external status field. □

Theorem 190.13 (Martingale adapted-sequence carrier boundary)**.** *Carrier acceptance for a* $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packet exposes exactly the* $\mathsf{RandomVar}^{\uparrow}$ *endpoint sequence rows adapted to the displayed filtration. In particular, every public endpoint row of an accepted packet is one of the rows listed in* X*, is scoped through the consumed* $\mathsf{RandomVar}^{\uparrow}$ *packet* R*, and is connected to the displayed filtration row* F *by the adaptation row already present in the packet.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket adapted sequence carrier boundary`

Proof. Unpack the accepted packet of Definition 190.5. The only endpoint component of the carrier is the finite row X, and the definition requires each entry of X to be a $\mathsf{RandomVar}^{\uparrow}$ endpoint row scoped by R.

The displayed filtration row is F. Since acceptance requires adaptation of the X rows to F, projecting the carrier gives the desired boundary without adding a further classifier, external sigma-algebra carrier, or host-level stochastic-process field. □

Theorem 190.14 (Martingale conditional-expectation ledger stability)**.** *If two accepted* $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packets are related by the classifier of Definition 190.6, then the displayed conditional-expectation rows are preserved through the consumed* $\mathsf{CondExp}^{\uparrow}$ *classifier and through the finite* Cont *ledger. Consequently each adjacent martingale face recorded in* E *transports to the corresponding face in* E' *with the same previous-endpoint boundary.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket condexp ledger stability`

Proof. First use the $\mathsf{CondExp}^{\uparrow}$ classifier clause to transport the conditional-expectation source and target rows. This supplies the stability of the expectation faces themselves, including the row whose target is the previous endpoint.

Next use the hsame comparisons for X, E, and λ. The X comparison transports endpoint names, the E comparison identifies the displayed expectation rows, and the Cont ledger comparison records that the same finite transport boundary is being read in the two packets. Repacking these witnesses gives the stated adjacent-face stability. □

Theorem 190.15 (Martingale tower-law ledger surface)**.** *The tower-law row* T *of a* $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packet is a finite ledger boundary over adjacent conditional-expectation faces. It records only that composing two neighboring rows of* E *through the displayed* Cont *ledger has the same* hsame *boundary as the single conditional-expectation row supplied by the consumed* $\mathsf{CondExp}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket tower law ledger surface`

Proof. Read T as a boundary row, not as an analytic identity outside the packet. Its source data are two adjacent expectation faces from E, their endpoint rows from X, and the corresponding finite transport rows from λ.

The consumed $\mathsf{CondExp}^{\uparrow}$ packet supplies the conditional-expectation face classifier. The Cont ledger supplies composition of the two adjacent transports, and hsame records the equality of the composed boundary with the displayed single face. Therefore the tower-law surface is finite and ledger-scoped. □

Theorem 190.16 (Martingale NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *obligation surface is the package consisting of the adapted-sequence carrier of Definition 190.5, the ledger classifier of Definition 190.6, stability of the conditional-expectation rows, the tower-law ledger*

boundary, exactness of the displayed carrier rows, and the downstream consumer row used by $\mathsf{Brownian}^{\uparrow}$ *through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket namecert obligation surface`

Proof. The carrier and classifier clauses are exactly the two definitions in section 190.1. They name the finite packet and the componentwise transport relation over $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{CondExp}^{\uparrow}$, BHist, hsame, and Cont.

Stability is supplied by Definition 190.14, and the tower-law ledger is supplied by Definition 190.15. Exactness follows by reading the accepted carrier backwards: every public martingale row must be one of R, C, F, X, E, T, ρ, or λ, or a row already scoped by the two consumed source certificates.

The Brownian-motion consumer uses only the resulting $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ row. Since that row is assembled from the finite carrier, classifier, stability, ledger, and exactness clauses just listed, the downstream dependency is a concrete BEDC certificate surface rather than an unstated martingale carrier assumption. □

Theorem 190.17 (Martingale finite-prefix restriction)**.** *Let*

$$\mathcal{M} = (R, C, F, X, E, T, \rho, \lambda)$$

be an accepted $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packet in the sense of Definition 190.5. Restrict* $\mathcal{M}$ *to an initial finite unary-history prefix of its displayed time spine, keeping the same consumed* $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ *row* R *and* $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ *row* C*, the prefix-indexed rows of* X*,* E*,* T*,* ρ*, and* λ*, and the corresponding restricted* Cont *ledger. The resulting truncated tuple is again an accepted* $\mathsf{Martingale}^{\uparrow}$ *adapted-sequence packet.*

Lean4 ✓ `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket finite prefix restriction`

Proof. Project the rows named in Definition 190.5. The accepted packet contains exactly the consumed R and C certificates, the displayed filtration row F, the endpoint sequence X, the adjacent conditional-expectation rows E, the tower boundary T, the provenance row ρ, and the finite continuation ledger λ.

Restrict those displayed finite rows to the chosen initial time prefix. The consumed R and C rows are unchanged, while the retained X, E, T, ρ, and λ entries are precisely the rows whose indices remain in the prefix. The restricted Cont ledger is the subledger carried by those retained adjacent faces.

For each transported adjacent face, use Definition 190.14. It keeps the conditional-expectation row compatible with the consumed $\mathsf{CondExp}^{\uparrow}$ classifier and with the finite Cont ledger after the prefix restriction.

Finally repack the retained carrier, classifier, stability, ledger, and exactness rows through Definition 190.16. The truncated tuple therefore satisfies the same $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ obligation surface as the original finite packet, with no row outside the displayed prefix added. □

Theorem 190.18 (Martingale Brownian consumer projection scope)**.** *Any* $\mathsf{Brownian}^{\uparrow}$ *consumer reading the* $\mathsf{Martingale}^{\uparrow}$ *dependency row may access only the adapted-sequence carrier of Definition 190.5, the conditional-expectation ledger classifier of Definition 190.6, the finite endpoint sequence rows, the tower-law ledger, the shared* Pkg *provenance, and the finite* $\mathsf{Cont}/\mathsf{hsame}$ *transport rows named by Definition 190.16. It has no projection to host stochastic-process data, stopping-time data, convergence data, or standard bridge data through the* $\mathsf{Martingale}^{\uparrow}$ *row.*

Proof. First read the public row family from Definition 190.12. It exposes the adapted-sequence carrier, componentwise classifier transport, stability rows, filtration/provenance rows, conditional-expectation exactness rows, and the finite displayed horizon as the public $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ surface.

Next apply Definition 190.16. That theorem identifies the same public surface with the adapted-sequence packet, the conditional-expectation ledger classifier, the finite endpoint sequence rows, the tower-law boundary, the shared Pkg provenance, and the finite Cont/hsame transport rows.

Finally compare with the Brownian displayed dependency surface Definition 191.3. The Brownian packet reads its martingale input only through the consumed $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ row M, so composing the two Martingale projections with that Brownian projection gives exactly the listed consumer scope. Since neither the Martingale packet nor the Brownian dependency surface carries a host stochastic-process row, stopping-time row, convergence row, or standard bridge row, none of those data can be exported through this consumer projection. □

Closure status for $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$**.**

Constructive story: A martingale packet is assembled over a finite unary time spine by placing a carried $\mathsf{RandomVar}^\uparrow$ endpoint X_n at each displayed time, a carried $\mathsf{CondExp}^\uparrow$ row on each successor face, filtration visibility rows, shared Pkg provenance, and a finite Cont/hsame ledger into one adapted-sequence tuple. The carrier accepts exactly those tuples whose random-variable rows, conditional-expectation rows, tower-boundary row, provenance, and finite transport ledger are all present, and the classifier compares two packets componentwise through the consumed $\mathsf{RandomVar}^\uparrow$ and $\mathsf{CondExp}^\uparrow$ classifiers together with history-sameness on the remaining displayed rows. The source therefore covers finite adapted endpoint sequences over a displayed probability source, the pattern is the successor comparison $E_{n+1|n} \sim_R X_n$ plus filtration visibility and tower-boundary bookkeeping, and the ledger keeps the finite time row, endpoint sequence, conditional-expectation sequence, provenance, and transport rows visible. Because each dependency certificate already supplies classifier transport and the finite tuple classifier is componentwise, an admitted adapted sequence gives the carrier witness, the classifier is reflexive, symmetric, and transitive, and prefix restriction or row transport stays inside the carrier. A finite packet h lies in the signature gap of a $\mathsf{Martingale}^\uparrow$ token p when the source-domain accepts its time spine, endpoint rows, conditional-expectation faces, filtration rows, and finite ledger, the signature relation pairs that packet with an answer packet and evidence ledger, and token introduction names the answer as p; unfolded, every successor face says that the conditional expectation of the next endpoint is classified with the previous endpoint in the ledger encoded by p. There is no standard stochastic-process bridge at this closure level, so downstream Brownian consumers may read only the displayed packet rows. The chapter registers this finite adapted-sequence construction under the name $\mathsf{Martingale}^\uparrow$; the martingale law is a finite CondExpUp ledger over RandomVarUp endpoints, with no stopping-time, convergence, or host process primitive introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$, maturePackageClosed)

Scope closed: The finite adapted-sequence packet, conditional-expectation step law, RandomVarUp boundary, ledger stability, and public row family bind the finite time spine, endpoint rows, CondExpUp faces, filtration visibility rows, shared Pkg provenance, and finite Cont ledger.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.MartingaleUp.MartingaleAdaptedSequencePacket\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: It does not close Brownian sample-path theory, measure-theoretic convergence, stopping-time results, or standard stochastic-process bridges.

Upgrade path: Mature closure requires examples and consumer coverage for the same finite adapted-sequence packet surface.

Definition 190.19 (Martingale finite-suffix restriction)**.** *Let*

$$\mathcal{M} = (R, C, F, X, E, T, \rho, \lambda)$$

be a displayed $\mathsf{Martingale}^\uparrow$ *adapted-sequence packet whose finite unary time spine has endpoint rows* $0, \ldots, n+k$*. The finite-suffix restriction* $\mathcal{M}^k_{\geq n}$ *is the tuple obtained by keeping the same consumed* $\mathsf{NameCert}_{\mathsf{RandomVar}^\uparrow}$ *row* R*, the same consumed* $\mathsf{NameCert}_{\mathsf{CondExp}^\uparrow}$ *row* C*, and the same displayed filtration and adaptation row* F*, while retaining only the suffix-indexed endpoint rows*

$$X_n, X_{n+1}, \ldots, X_{n+k},$$

the adjacent conditional-expectation rows

$$E_{n+1|n}, E_{n+2|n+1}, \ldots, E_{n+k|n+k-1},$$

the tower-boundary rows of T whose adjacent conditional-expectation faces both lie in that suffix, the corresponding provenance rows of ρ, and exactly the finite Cont *ledger entries of λ whose endpoints and conditional-expectation faces lie in the displayed suffix.*

The suffix time row is reindexed by unary histories so that suffix endpoint j is the original endpoint $n+j$ and suffix adjacent face $j<k$ is the original face $n+j+1|n+j$. No endpoint row before n, no conditional-expectation face before $n+1|n$, and no tower or ledger row crossing the boundary from $n-1$ to n is part of $\mathcal{M}^k_{\geq n}$.

Theorem 190.20 (Martingale finite-suffix restriction carrier)**.** *Let*

$$\mathcal{M} = (R, C, F, X, E, T, \rho, \lambda)$$

be an accepted Martingale$^{\uparrow}$ *adapted-sequence packet in the sense of Definition 190.5. Suppose its displayed finite unary time spine has endpoint rows $X_0, \ldots, X_{n+k}$ and adjacent conditional-expectation rows $E_{1|0}, \ldots, E_{n+k|n+k-1}$. Then the finite-suffix restriction $\mathcal{M}^k_{\geq n}$ of Definition 190.19, with the same consumed* RandomVar$^{\uparrow}$ *and* CondExp$^{\uparrow}$ *packets, the same displayed filtration and adaptation row, the suffix endpoint rows $X_n, \ldots, X_{n+k}$, the suffix conditional-expectation rows $E_{n+1|n}, \ldots, E_{n+k|n+k-1}$, and the inherited suffix rows of T, ρ, and λ, is again an accepted* Martingale$^{\uparrow}$ *adapted-sequence packet.*

Proof. Unpack the accepted packet by Definition 190.5. Acceptance is stated entirely by the presence of the finite tuple rows R, C, F, X, E, T, ρ, and λ: the X entries are RandomVar$^{\uparrow}$ endpoint rows over R adapted to F, the E entries are CondExp$^{\uparrow}$ rows over C whose source is the later retained endpoint and whose target is the earlier retained endpoint, T records tower compatibility of adjacent faces, ρ records provenance through the two consumed packets, and λ stores the displayed transport rows.

Form the suffix tuple. The consumed rows R and C are unchanged, so the source certificates for every retained RandomVar$^{\uparrow}$ endpoint and every retained CondExp$^{\uparrow}$ face are the same rows used in the parent packet. The filtration row F is also unchanged, and the suffix reads only the adaptation entries of F attached to the retained endpoints $X_n, \ldots, X_{n+k}$. By Definition 190.13, each retained public endpoint row is one of the original entries of X, is scoped through R, and is connected to the displayed filtration row by an adaptation row already present in the accepted packet.

Consider a suffix adjacent face $j<k$. Under the suffix reindexing it is the original face $n+j+1|n+j$. Acceptance of $\mathcal{M}$ supplies the conditional-expectation row over C whose source is X_{n+j+1} and whose target is X_{n+j}, together with the corresponding continuation ledger entry. By Definition 190.14, the displayed conditional-expectation row is preserved through the consumed CondExp$^{\uparrow}$ classifier and through the finite Cont ledger. Thus the same row is well typed as the suffix face from suffix endpoint $j+1$ to suffix endpoint j.

The first suffix face is not a separate initial-condition obligation. It is exactly the original face $E_{n+1|n}$, with boundary endpoint X_n as its target. The carrier definition does not require the suffix to remember the discarded predecessor X_{n-1} or any conditional-expectation row crossing into X_n from outside the suffix. It requires only the displayed endpoint rows, the adjacent conditional-expectation faces internal to the finite spine, and the finite ledger rows attached to those faces.

For tower compatibility, retain precisely those rows of T whose adjacent conditional-expectation faces both survive the suffix restriction. By Definition 190.15, each such row is only a finite ledger

boundary over adjacent faces from E and the corresponding rows of λ. Since the suffix retains both faces and the associated Cont entries, each retained tower-boundary row remains a valid tower row in the suffix packet. Rows of T crossing the discarded boundary are not obligations of the suffix because one of their adjacent faces is no longer displayed.

The provenance row ρ and ledger λ are finite rows, so restricting them to entries whose endpoints and faces lie in the suffix preserves exactly the displayed provenance and transport required by the retained X, E, and T rows. No row outside R, C, F, the suffix of X, the suffix of E, the retained tower rows, the retained provenance rows, and the retained ledger rows is introduced.

Repack the retained rows through Definition 190.16. The suffix tuple has the same form as the accepted adapted-sequence packet: consumed $\mathsf{RandomVar}^{\uparrow}$ and $\mathsf{CondExp}^{\uparrow}$ packets, displayed filtration and adaptation rows, finite endpoint rows, finite adjacent conditional-expectation faces, finite tower-boundary rows, provenance, and finite Cont ledger. Therefore $\mathcal{M}^{k}_{\geq n}$ is again an accepted $\mathsf{Martingale}^{\uparrow}$ adapted-sequence packet. $\square$

Chapter 191

A Concrete Naming Certificate for $\mathsf{Brownian}^{\uparrow}$

The Brownian-motion interface $\mathsf{Brownian}^{\uparrow}$ packages a continuous-time stochastic process with independent normally distributed increments and continuous sample paths. It depends on $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ (chapter 190) and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ (chapter 130).

191.1 Carrier definition

Definition 191.1 (Brownian BHist process packet)**.** *A* $\mathsf{Brownian}^{\uparrow}$ *process packet is a finite displayed* BHist *tuple*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda).$$

The row M is the consumed $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *dependency row for the adapted value process. The row C is the consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *path row. The row T is a finite* UnaryHistory *time-index row. The row I is the step ledger recording the visible adjacent-time step faces over T. The row N is the normal-step display attached to those adjacent faces. The row P is the path-continuity display attached to the path row C. The row ρ is the shared* Pkg *provenance tying M, C, T, I, N, and P into one displayed packet, and λ is the finite* Cont/hsame *transport ledger for every row read by the classifier.*

The packet is admitted as a $\mathsf{Brownian}^{\uparrow}$ *carrier exactly when M supplies all adaptedness and martingale rows through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$*, C supplies all path-continuity rows through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*, and the Gaussian-step, time-index, provenance, and transport rows are displayed inside this finite tuple. No host probability space, host stochastic-process object, or host path equality is part of the carrier.*

Definition 191.2 (Brownian step-continuity classifier)**.** *Let*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda) \quad \text{and} \quad \mathcal{B}' = (M', C', T', I', N', P', \rho', \lambda')$$

be two $\mathsf{Brownian}^{\uparrow}$ *process packets. The* $\mathsf{Brownian}^{\uparrow}$ *classifier holds exactly when the six displayed rows M, C, T, I, N, and P are compared rowwise by* hsame*, with the M comparison read through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *and the C comparison read through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*:*

$$\begin{aligned} &M\mathsf{hsame}M' \wedge C\mathsf{hsame}C' \wedge T\mathsf{hsame}T' \wedge I\mathsf{hsame}I' \\ &\quad \wedge N\mathsf{hsame}N' \wedge P\mathsf{hsame}P' \wedge \rho\mathsf{hsame}\rho' \wedge \lambda\mathsf{hsame}\lambda'. \end{aligned}$$

The Pkg *provenance and* Cont *ledger are shared under this comparison, so the classifier transports only the displayed martingale, continuous-path, time-index, Gaussian-step, and continuity rows. It explicitly excludes comparison of ambient probability spaces, host-level sample paths, and host path equality.*

191.2 The certificate

Theorem 191.3 (Brownian dependency surface)**.** *For every admitted* $\mathsf{Brownian}^{\uparrow}$ *process packet of Definition 191.1, every adaptedness and martingale row projects through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$*, and every path-continuity row projects through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*. The only dependency data exported to a downstream consumer are the displayed rows* M*,* C*, the* UnaryHistory *time row* T*, the Gaussian-step and continuity displays* I, N, P*, the shared* Pkg *provenance* ρ*, and the finite* Cont/hsame *ledger* λ*.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier dependency surface`

Proof. Unpack the carrier tuple. Its first coordinate M is declared to be the consumed $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ row, so all adaptedness, filtration, and martingale-step faces are obtained by projecting that dependency certificate.

The second coordinate C is declared to be the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ row. Thus the path-continuity display P is read through the continuous-map certificate surface, together with the transport rows recorded by λ.

The remaining coordinates do not create another dependency. The time row T, the adjacent-step ledger I, the normal-step display N, the provenance ρ, and the transport ledger λ only bind the two dependency certificates into one finite packet. Repacking these projections gives the stated dependency surface and no uncarried probability-space or path object. □

Theorem 191.4 (Brownian probability and martingale dependency route)**.** *Every adapted Gaussian-step read of an admitted* $\mathsf{Brownian}^{\uparrow}$ *process packet must expose the* $\mathsf{ProbSpace}^{\uparrow}$ *measure-total rows carried by chapter 184, the filtration and adaptedness rows read through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *of chapter 190, the finite time-index row* T*, the* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *path-continuity rows of chapter 130, componentwise transport, replay, provenance, and local naming before any stochastic-process consumer reads the packet. The route refuses host probability spaces, chosen sample paths, and ambient path equality.*

Proof. Start with the admitted packet $\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$. The martingale dependency row M is the only source for filtration, adaptedness, and measure-total reads, and those reads remain scoped by the ProbSpace and Martingale certificates named in the dependency route.

The finite time row T and the Gaussian-step displays I, N then bind the adapted read to the visible Brownian step ledger. The path face is separately read through C and the displayed continuity row P, so continuity comes from the ContinuousMap certificate rather than from a host path space.

Finally the provenance ρ and transport ledger λ keep these dependency rows in one finite packet. Since no coordinate names a host probability space, selected sample path, or ambient path equality, the stochastic-process consumer receives only the displayed route. □

Theorem 191.5 (Brownian classifier stability)**.** *If two admitted* $\mathsf{Brownian}^{\uparrow}$ *process packets are related by the classifier of Definition 191.2, then classifier transport preserves the displayed martingale row, continuous-map row, time row, Gaussian-step row, path-continuity row, provenance*

row, and finite Cont/hsame *ledger. In particular, the transported target packet still has the same public Brownian obligation surface over the displayed tuple* $(M, C, T, I, N, P, \rho, \lambda)$.

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier classifier stability`

Proof. Use Definition 191.3 to read the martingale and continuous-map rows only through the two dependency certificates. These projections account for the transported M and C rows without introducing a host stochastic-process object.

Use Definition 191.8 for the time-index, Gaussian-step, and continuity ledgers. The classifier supplies the displayed $T\mathsf{hsame}T'$, $I\mathsf{hsame}I'$, $N\mathsf{hsame}N'$, $P\mathsf{hsame}P'$, $\rho\mathsf{hsame}\rho'$, and $\lambda\mathsf{hsame}\lambda'$ comparisons, so every public row of the source packet has its matching target row. □

Theorem 191.6 (Brownian continuous-path projection)**.** *Every admitted* $\mathsf{Brownian}^{\uparrow}$ *process packet projects its path-continuity row through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *and its adaptedness row through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$. *These projections export only the displayed rows* C *and* M *and their certified dependency ledgers; they do not export host path equality, a host probability space, or a host stochastic-process object.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier continuous path projection`

Proof. Apply Definition 191.3. The theorem identifies M as the consumed $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ row and C as the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ row.

Then apply Definition 191.8 to the displayed transport ledger. The only path-continuity and adaptedness information that can move across a classifier comparison is the information already present in the two dependency certificates and in the finite Cont/hsame ledger. □

Theorem 191.7 (Brownian ledger exactness)**.** *Every public* $\mathsf{Brownian}^{\uparrow}$ *row is exactly one of the displayed rows* $M, C, T, I, N, P, \rho, \lambda$, *or a row projected from* M *through* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$, *or a row projected from* C *through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$. *No other host stochastic-process, probability, sample-path, or path-equality row belongs to the public Brownian ledger.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier ledger exactness`

Proof. First read the carrier packet. Its public coordinates are exactly $(M, C, T, I, N, P, \rho, \lambda)$, and Definition 191.3 says that the only dependency projections are the rows obtained from M and C.

Next read the classifier transport. By Definition 191.8, every row moved between admitted packets is one of the displayed time, step, continuity, provenance, or transport rows, again with martingale and continuous-map data delegated to the two dependency certificates.

Therefore coverage and soundness coincide: a public Brownian row is present exactly when it is displayed in the packet or projected from the named dependency certificates. □

Theorem 191.8 (Brownian step-ledger transport)**.** *If two admitted* $\mathsf{Brownian}^{\uparrow}$ *process packets are related by the classifier of Definition 191.2, then* hsame *transport of the classifier transports the independent-step ledger, the normal-step display, and the continuity ledger while leaving the visible* UnaryHistory *time-index row unchanged up to the displayed comparison* $T\mathsf{hsame}T'$.

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier step ledger transport`

Proof. Start with the time-index clause of the classifier. It supplies the displayed comparison $T\mathsf{hsame}T'$, so every adjacent-time face read by the source packet has a matched adjacent-time face in the target packet without introducing a host time set.

Next project the three ledger comparisons. The clauses $I\mathsf{hsame}I'$ and $N\mathsf{hsame}N'$ transport the independent-step and normal-step displays along the same time row, while $P\mathsf{hsame}P'$ transports the continuity display through the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ classifier.

Finally retain the shared provenance and transport boundary. The comparison $\rho\mathsf{hsame}\rho'$ keeps the dependency certificates in the same packet scope, and $\lambda\mathsf{hsame}\lambda'$ carries the finite Cont rows used by each display. Repacking these transported rows gives the target packet with the same visible time-index boundary. □

Theorem 191.9 (Brownian continuity-martingale joint classifier)**.** *If two admitted* $\mathsf{Brownian}^{\uparrow}$ *process packets are related by the classifier of Definition 191.2, then the classifier jointly transports the consumed* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *row* M*, the consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *row* C*, the* $\mathsf{UnaryHistory}$ *time row* T*, the Gaussian-step display* N*, and the path-continuity display* P *by componentwise* hsame *rows. The transported packet remains a* $\mathsf{Brownian}^{\uparrow}$ *source packet and adds no host probability-space, host stochastic-process, or host path-equality comparison.*

Proof. Unpack the carrier of Definition 191.1. Its public rows are exactly $(M, C, T, I, N, P, \rho, \lambda)$, with the martingale surface read through M and the continuous-path surface read through C.

Unpack the classifier of Definition 191.2. It supplies componentwise hsame rows for M, C, T, I, N, P, ρ, and λ, so the martingale row, continuous-map row, time row, Gaussian-step display, and continuity display are transported in the same finite packet.

Repack the transported rows using Definition 191.3 and Definition 191.8. These two statements account for the dependency rows and the step-continuity ledger, while the carrier excludes every host-level comparison named in the conclusion. □

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier joint classifier transport`

Theorem 191.10 (Brownian Gaussian-step classifier stability)**.** *For classifier-related* $\mathsf{Brownian}^{\uparrow}$ *process packets, the normal-step display* N *and the adjacent-time ledger* I *remain attached to the transported* $\mathsf{UnaryHistory}$ *time row* T*. The transported Gaussian-step surface is read only through the componentwise rows* $T\mathsf{hsame}T'$*,* $I\mathsf{hsame}I'$*,* $N\mathsf{hsame}N'$*, the shared* Pkg *provenance row, and the finite* $\mathsf{Cont}/\mathsf{hsame}$ *ledger.*

Proof. Start with the time component of the classifier. The comparison $T\mathsf{hsame}T'$ is the only public transport of the displayed time row.

Project the adjacent-time and normal-step components. The comparisons $I\mathsf{hsame}I'$ and $N\mathsf{hsame}N'$ transport the step ledger and Gaussian display over the transported time row, and the provenance comparison keeps those rows inside the same packet.

Apply Definition 191.8. It states that the independent-step ledger, the normal-step display, and the continuity ledger move together under classifier transport, so the Gaussian-step surface remains attached to the transported time row and to no additional host-time object. □

Theorem 191.11 (Brownian path-continuity ledger exactness)**.** *Every public path-continuity row exported by a* $\mathsf{Brownian}^{\uparrow}$ *process packet is projected from the consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *row* C *and the finite displayed ledger rows* P *and* λ*. The Brownian packet exports no host path equality, no separate path carrier, and no probability-space row beyond the displayed* BHist*,* hsame*,* Cont*, and* Pkg *support.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier path continuity ledger exactness`

Proof. Project the carrier of Definition 191.1. The only coordinates that mention path continuity are the consumed ContinuousMapUp row C, the continuity display P, and the finite transport ledger λ.

Use Definition 191.3. It identifies every path-continuity read with the continuous-map dependency row, while the remaining Brownian coordinates bind time, Gaussian steps, and provenance rather than a host path object.

Finally use Definition 191.8 to keep the continuity display stable under classifier transport. Since Definition 191.2 compares only displayed rows, the exported path-continuity ledger is exact and contains no host path equality. □

Theorem 191.12 (Brownian NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Brownian}^\uparrow}$ *obligation surface consists exactly of the carrier of Definition 191.1, the classifier of Definition 191.2, the two dependency certificates* $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$*, step-ledger transport, continuity transport, classifier stability, and ledger exactness for the displayed rows* $M, C, T, I, N, P, \rho, \lambda$*. It exports no host stochastic process, host probability space, or host path equality.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier namecert obligation surface`
↪ variant `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier semantic name certificate`

Proof. Collect the carrier and classifier rows. They list the finite tuple $(M, C, T, I, N, P, \rho, \lambda)$ and compare it componentwise by hsame, with the martingale and continuous-map faces delegated to their two named dependency certificates.

Use Definition 191.3 to account for the dependency projections. This covers all adaptedness, martingale, and path-continuity rows through the public surfaces of $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$.

Use Definition 191.8 for the transport surface. It preserves the independent-step, normal-step, and continuity ledgers by hsame and finite Cont transport, while the visible time row is kept as the same displayed $\mathsf{UnaryHistory}$ boundary.

Ledger exactness is the reverse reading of the packet: every public Brownian row must be one of $M, C, T, I, N, P, \rho, \lambda$ or a row already scoped by M or C. Since the carrier and classifier contain no additional host probability-space, stochastic-process, or path-equality coordinate, the public obligation surface is exactly the one stated. □

Theorem 191.13 (Brownian path-step boundary exhaustion)**.** *Every public* $\mathsf{Brownian}^\uparrow$ *consumer row mentioning either the Gaussian-step display or the path-continuity display factors through the displayed tuple* $(M, C, T, I, N, P, \rho, \lambda)$*. The martingale rows project only through* $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$*, path-continuity rows only through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$*, and step rows only through the common* $\mathsf{UnaryHistory}$ *time row, the* $\mathsf{Cont}/\mathsf{hsame}$ *ledger, and the* Pkg *provenance.*

The boundary exports no host probability-space equality, no host stochastic-process equality, and no host path equality. It is exactly the joint consumer boundary supplied by the Brownian packet carrier, classifier, dependency projections, and ledger rows.

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier path step boundary exhaustion`

Proof. Begin with the dependency surface. By Definition 191.3, the martingale and continuous-path faces of any admitted packet are read only through M and C, with the visible time row T, the Gaussian-step and continuity displays I, N, P, the provenance ρ, and the ledger λ remaining as displayed packet coordinates.

Next apply the step transport row. Theorem 191.8 states that Gaussian-step transport uses the common $\mathsf{UnaryHistory}$ time row, the adjacent-step and normal-step displays, the provenance

row, and the finite Cont/hsame ledger. Thus no additional host time object or stochastic process coordinate is exposed by a step consumer.

For path-continuity consumers, use Definition 191.11. It identifies every public path-continuity row with the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ row C together with the displayed continuity and transport rows P and λ.

Finally apply Definition 191.12. It exhausts the public $\mathsf{NameCert}_{\mathsf{Brownian}^{\uparrow}}$ surface by the carrier, classifier, two dependency certificates, step-ledger transport, continuity transport, classifier stability, and ledger exactness over $(M, C, T, I, N, P, \rho, \lambda)$. Combining these four surfaces gives the stated factorisation and rules out host probability-space, stochastic-process, and path-equality comparisons. □

Theorem 191.14 (Brownian time-step path interface)**.** *For every admitted* $\mathsf{Brownian}^{\uparrow}$ *process packet*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda),$$

the displayed BHist *tuple binds one public interface containing the martingale row M, the continuous-path row C, the unary time row T, the adjacent-step ledger I, the Gaussian display N, the path-continuity display P, the shared* Pkg *provenance ρ, and the finite* Cont/hsame *ledger λ. Every public row read by a time-step, path-continuity, or Brownian NameCert consumer factors through this interface.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier time step path interface`

Proof. Unpack the carrier of Definition 191.1. Its displayed coordinates are exactly $(M, C, T, I, N, P, \rho, \lambda)$, with M and C assigned to the martingale and continuous-map dependency rows.

Apply Definition 191.3. It keeps adaptedness and martingale data inside M, keeps path-continuity data inside C, and exposes only the displayed time, step, Gaussian, continuity, provenance, and transport rows beside those dependencies.

Use Definition 191.5 and Definition 191.8 to transport the same interface across hsame comparisons. The classifier moves $T, I, N, P, \rho, \lambda$ rowwise, so a time-step consumer and a path consumer read the same public packet boundary.

Finally apply Definition 191.12. Its exact surface is the carrier, classifier, dependency surface, step transport, continuity transport, classifier stability, and ledger exactness over the same tuple, which is precisely the asserted interface. □

Theorem 191.15 (Brownian Gaussian step ledger coverage)**.** *Every public* $\mathsf{Brownian}^{\uparrow}$ *consumer row mentioning an adjacent Gaussian step is exhausted by the unary time row T, the adjacent-step ledger I, the normal-step display N, the provenance row ρ, the transport ledger λ, the relevant* UnaryHistory *witnesses, and the public* Cont/hsame *transports. No Gaussian adjacent-step consumer obtains an additional host probability-space row, stochastic-process equality row, or path-equality row.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier gaussian step ledger coverage`

Proof. Start with the step row in the carrier. By Definition 191.1, the only Gaussian-step coordinates are the time row T, the adjacent-step ledger I, the normal display N, the provenance ρ, and the transport ledger λ.

Apply Definition 191.8. It states that transport of Gaussian-step information uses the common UnaryHistory time boundary, the adjacent-step and normal-step displays, the provenance row, and the finite Cont/hsame ledger.

Use Definition 191.10 to identify the same rows after classifier transport. The step classifier has no coordinate for ambient probability spaces, host stochastic-process equality, or host path-equality comparison.

Finish with Definition 191.13. It exhausts every step consumer by the displayed Brownian packet boundary, so the listed rows cover every Gaussian adjacent-step read. □

Theorem 191.16 (Brownian continuity martingale compatibility)**.** *If two public rows are read from an admitted Brownian packet through* $\mathsf{NameCert}_{\mathsf{Martingale}\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{ContinuousMap}\uparrow}$*, then transport by the same Brownian classifier keeps the martingale row and the continuous-path row compatible over the shared tuple* $(M, C, T, I, N, P, \rho, \lambda)$*. The common* Pkg *provenance and finite* Cont/hsame *ledger are the only public rows used to join the two dependency certificates.*

Proof. Project the two dependency rows with Definition 191.3. The martingale information is read through M, and the continuous-path information is read through C, while the shared time, step, continuity, provenance, and transport rows remain displayed coordinates of the Brownian packet.

Apply Definition 191.9. It reads the classifier rowwise over $M, C, T, I, N, P, \rho, \lambda$, so the martingale and continuous-map dependency comparisons move under one Brownian classifier rather than under two unrelated transports.

Use Definition 191.11 for the continuous path face and Definition 191.8 for the time-step ledger. These two rows share the same Pkg provenance and Cont/hsame ledger, so the transported dependency surfaces remain compatible.

Finally apply Definition 191.12. Since the public Brownian surface contains no host path equality, probability-space equality, or stochastic-process equality, compatibility is exactly the shared classifier transport of the displayed packet rows. □

Theorem 191.17 (Brownian step-path NameCert closure boundary)**.** *For every displayed Brownian packet* $\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$ *of Definition 191.1, the carrier packet, dependency surface, Gaussian-step ledger coverage, path-continuity ledger exactness, and continuity-martingale compatibility determine one public* $\mathsf{NameCert}_{\mathsf{Brownian}\uparrow}$ *boundary over the tuple* $(M, C, T, I, N, P, \rho, \lambda)$*. The boundary exports only the displayed martingale dependency row* M*, continuous-path dependency row* C*, time row* T*, adjacent-step ledger* I*, normal-step display* N*, path-continuity row* P*, shared provenance* ρ*, and finite* Cont/hsame *ledger* λ*; it does not export host stochastic-process equality, host path equality, or an ambient probability-space comparison.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier step path namecert closure boundary`

Proof. Begin with the carrier and dependency surface. Theorem 191.3 projects all martingale reads through M and all continuous-path reads through C, while leaving $T, I, N, P, \rho, \lambda$ as the visible Brownian rows.

Next attach the step and path ledgers. Theorem 191.8 transports the finite time-step rows, and Definition 191.15 exhausts every public adjacent Gaussian-step consumer by T, I, N, ρ, λ and the relevant UnaryHistory and Cont/hsame witnesses. The path face is fixed by the path-continuity ledger exactness already carried in the Brownian certificate surface.

Finally apply Definition 191.16. It joins the martingale and continuous-path dependency rows through the same classifier over $(M, C, T, I, N, P, \rho, \lambda)$. The exact public field list is then the one identified by Definition 191.12, so these rows determine the stated $\mathsf{NameCert}_{\mathsf{Brownian}\uparrow}$ boundary and nothing outside the displayed packet. □

Theorem 191.18 (Brownian carrier-classifier obligation package)**.** *For every displayed Brownian packet $\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$, the carrier of Definition 191.1, the classifier of Definition 191.2, the stability row of Definition 191.5, and the joint martingale–path classifier of Definition 191.9 form the carrier/classifier obligation row for* $\mathsf{Brownian}^{\uparrow}$*. This row binds only the displayed* BHist *carrier, the* $\mathsf{UnaryHistory}$ *time row, the two dependency certificates, the shared* Pkg *provenance, and the finite* $\mathsf{Cont/hsame}$ *transport ledger.*

Proof. Read the carrier from Definition 191.1. Its coordinates are precisely $M, C, T, I, N, P, \rho, \lambda$, with no additional host probability-space, stochastic-process, or path-equality coordinate.

Attach the classifier of Definition 191.2. The comparison is componentwise over the displayed rows, so the classifier has the same carrier boundary as the packet it compares.

Use Definition 191.5 for transport across hsame and Definition 191.9 for the joint martingale–continuous-map face. Together they show that M and C move under the same Brownian classifier as the time, step, continuity, provenance, and ledger rows. This is exactly the carrier/classifier obligation row. □

Theorem 191.19 (Brownian dependency-ledger obligation exactness)**.** *For every displayed Brownian packet $\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$, the dependency surface of Definition 191.3, the step transport of Definition 191.8, the path-continuity ledger exactness of Definition 191.11, and the Brownian ledger exactness of Definition 191.7 form the dependency-ledger obligation row for* $\mathsf{Brownian}^{\uparrow}$*. Every dependency read is through M or C, and every ledger read is through $T, I, N, P, \rho, \lambda$ and the displayed* $\mathsf{Cont/hsame}$ *witnesses.*

Proof. First project the dependency rows with Definition 191.3. The martingale surface is read through M, and the continuous-path surface is read through C.

Next attach the step ledger. Theorem 191.8 keeps adjacent-step and normal-step information on the displayed time, provenance, and finite transport rows.

For the path face, use Definition 191.11. It identifies the continuity display with C, P, and the same ledger λ.

Finally apply Definition 191.7. Since every public ledger coordinate is one of the displayed packet rows or a row already scoped by M or C, the dependency-ledger row is exact. □

Theorem 191.20 (Brownian obligation closure boundary)**.** *The Brownian obligation surface is exactly the union of the carrier/classifier row of Definition 191.18, the dependency-ledger row of Definition 191.19, the NameCert surface of Definition 191.12, and the step-path boundary of Definition 191.17. Thus the* $\mathsf{Brownian}^{\uparrow}$ *obligation boundary exports precisely the displayed $M, C, T, I, N, P, \rho, \lambda$ packet, its* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *dependencies, its* BHist *and* $\mathsf{UnaryHistory}$ *rows, its* Pkg *provenance, and its finite* $\mathsf{Cont/hsame}$ *ledger.*

Proof. The carrier/classifier package supplies the admitted packet and the comparison surface over the displayed rows. It fixes the public object language in which a Brownian consumer may read $M, C, T, I, N, P, \rho, \lambda$.

The dependency-ledger package supplies the exact dependency reads and the exact finite ledger reads. It prevents any extra host probability-space, stochastic-process, or path-equality row from entering through M, C, or the time-step and path-continuity ledgers.

The NameCert surface identifies the public Brownian certificate over these same rows, and the step-path boundary identifies the common consumer boundary for Gaussian steps and path continuity. Combining the four rows gives the stated obligation surface, and each cited row has the same displayed packet as its boundary. □

Theorem 191.21 (Brownian finite-prefix carrier restriction)**.** *Let*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$$

be an admitted $\mathsf{Brownian}^{\uparrow}$ *process packet in the sense of Definition 191.1. Suppose the displayed unary time row* T *has length* $n+k$*, and choose the initial finite subledger* $T_{\leq n}$ *containing exactly the first* n *adjacent time faces. Let* $I_{\leq n}$*,* $N_{\leq n}$*,* $P_{\leq n}$*,* $\rho_{\leq n}$*, and* $\lambda_{\leq n}$ *be the subrows of the adjacent-step ledger, normal-step display, path-continuity display, provenance row, and finite* $\mathsf{Cont/hsame}$ *ledger whose displayed faces lie entirely over* $T_{\leq n}$*. Let* $M_{\leq n}$ *be the finite-prefix restriction of the consumed* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *row* M*, and keep the same consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *path row* C*.*

Then

$$\mathcal{B}_{\leq n} = (M_{\leq n}, C, T_{\leq n}, I_{\leq n}, N_{\leq n}, P_{\leq n}, \rho_{\leq n}, \lambda_{\leq n})$$

is again an admitted $\mathsf{Brownian}^{\uparrow}$ *process packet. In particular, restricting the Brownian path-step carrier to the first* n *displayed time steps preserves the carrier boundary and introduces no host probability-space row, host stochastic-process row, or host path-equality row.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier finite prefix carrier restriction`

Proof. Unpack the Brownian carrier of Definition 191.1. The admitted packet is a finite displayed tuple whose public rows are exactly $M, C, T, I, N, P, \rho, \lambda$. The time row is a finite $\mathsf{UnaryHistory}$ row, so its initial subledger $T_{\leq n}$ is again a finite displayed unary time row. The rows $I_{\leq n}$ and $N_{\leq n}$ are obtained by retaining precisely the adjacent faces of I and N whose endpoints remain in $T_{\leq n}$; no boundary face crossing from the prefix into the omitted tail is retained.

For the martingale dependency, apply Definition 190.17 to M. It gives the accepted finite-prefix martingale packet $M_{\leq n}$ over the same displayed initial horizon. Thus all adaptedness, conditional-expectation, filtration, provenance, and finite Cont rows read through the Brownian martingale input remain licensed by $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ after the time-prefix restriction.

For the Gaussian-step face, use Definition 191.15. Every public adjacent Gaussian-step consumer reads only the unary time row, the adjacent-step ledger, the normal-step display, the provenance row, the finite transport ledger, and the corresponding $\mathsf{UnaryHistory}$ and $\mathsf{Cont/hsame}$ witnesses. The restriction keeps exactly those witnesses for the retained adjacent faces, so the Gaussian-step surface over $T_{\leq n}$ is still displayed inside the finite packet.

For the path-continuity face, use Definition 191.11. Every public path-continuity row is projected from the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ row C together with the displayed continuity row P and the finite ledger λ. The restricted row $P_{\leq n}$ contains the same modulus and certificate witnesses that the original packet displayed on the retained time faces, and $\lambda_{\leq n}$ contains exactly the transport entries needed by those retained witnesses. Since C is unchanged, the continuous-map dependency surface still supplies the path-continuity rows read by the prefix packet.

It remains to repack the provenance and exactness boundary. The rows $\rho_{\leq n}$ and $\lambda_{\leq n}$ are finite subledgers of the original shared Pkg provenance and $\mathsf{Cont/hsame}$ ledger, restricted to the retained martingale, time-step, Gaussian, and path-continuity faces. By Definition 191.7 and Definition 191.19, every public row of the restricted tuple is either one of its displayed coordinates or a row already scoped by $M_{\leq n}$ or C. Finally Definition 191.12 identifies these displayed carrier, dependency, classifier, and ledger rows as the public $\mathsf{NameCert}_{\mathsf{Brownian}^{\uparrow}}$ obligation surface. Therefore $\mathcal{B}_{\leq n}$ satisfies the Brownian carrier definition with no additional host-level data. □

Theorem 191.22 (Brownian finite-suffix carrier restriction)**.** *Let*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$$

be an admitted $\mathsf{Brownian}^{\uparrow}$ *process packet in the sense of Definition 191.1. Suppose the displayed unary time row* T *has length* $n+k$*. Let* $T^{\mathsf{sh}}_{[n,n+k]}$ *be the finite* k*-step unary row obtained by retaining the adjacent faces from the boundary endpoint at time* n *through the endpoint at time* $n+k$ *and then relabelling that boundary endpoint as the initial endpoint. Let*

$$I^{\mathsf{sh}}_{[n,n+k]}, \quad N^{\mathsf{sh}}_{[n,n+k]}, \quad P^{\mathsf{sh}}_{[n,n+k]}, \quad \rho^{\mathsf{sh}}_{[n,n+k]}, \quad \lambda^{\mathsf{sh}}_{[n,n+k]}$$

be the corresponding finite subrows of the adjacent-step ledger, normal-step display, path-continuity display, provenance row, and $\mathsf{Cont/hsame}$ *ledger whose displayed faces lie entirely in that closed suffix interval, with each time index translated by* $j \mapsto j-n$*. Let* $M^{\mathsf{sh}}_{[n,n+k]}$ *be the same translated suffix of the consumed* $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ *row, retaining exactly the endpoint rows and conditional-expectation faces with indices* $n \le j \le n+k$*. Let* $C^{\mathsf{sh}}_{[n,n+k]}$ *be the path-continuity subrow read from the consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *row* C *on the retained path segment, with the time-source boundary reset to the displayed endpoint at time* n*.*

Then

$$\mathcal{B}^{\mathsf{sh}}_{[n,n+k]} = (M^{\mathsf{sh}}_{[n,n+k]}, C^{\mathsf{sh}}_{[n,n+k]}, T^{\mathsf{sh}}_{[n,n+k]}, I^{\mathsf{sh}}_{[n,n+k]}, N^{\mathsf{sh}}_{[n,n+k]}, P^{\mathsf{sh}}_{[n,n+k]}, \rho^{\mathsf{sh}}_{[n,n+k]}, \lambda^{\mathsf{sh}}_{[n,n+k]})$$

is again an admitted $\mathsf{Brownian}^{\uparrow}$ *process packet. Thus the Brownian path-step carrier is closed under finite suffix restriction from any displayed boundary endpoint, and the restricted carrier introduces no host probability-space row, no host stochastic-process row, and no host path-equality row.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier finite suffix carrier restriction`

Proof. Unpack the carrier of Definition 191.1. An admitted Brownian packet is a finite displayed tuple, and every public Brownian row is one of $M, C, T, I, N, P, \rho, \lambda$ or is read through the two consumed dependency certificates. Taking the interval from the boundary endpoint n to $n+k$ therefore selects a finite subtuple of already displayed rows. The translation $j \mapsto j-n$ changes only the displayed position names in the finite unary spine; it does not create a further time object.

For the martingale dependency, read M through the concrete $\mathsf{Martingale}^{\uparrow}$ packet surface. By Definition 190.5, the martingale carrier is a finite tuple of endpoint rows, adjacent conditional-expectation rows, tower-boundary rows, provenance, and finite Cont transport. The suffix row $M^{\mathsf{sh}}_{[n,n+k]}$ retains precisely those endpoint rows and adjacent faces whose indices lie in the displayed interval $[n, n+k]$, with the endpoint at n serving as the shifted initial value. Each retained successor face is one of the conditional-expectation faces already accepted in M, and Definition 190.16 identifies these retained finite rows as the public $\mathsf{NameCert}_{\mathsf{Martingale}^{\uparrow}}$ surface. Hence the martingale input needed by the shifted Brownian packet is still licensed by the consumed martingale certificate.

For the Gaussian-step surface, apply Definition 191.15. It says that every public adjacent Gaussian-step read uses only the unary time row, the adjacent-step ledger, the normal-step display, the provenance row, the finite transport ledger, and the corresponding $\mathsf{UnaryHistory}$ and $\mathsf{Cont/hsame}$ witnesses. The rows $T^{\mathsf{sh}}_{[n,n+k]}$, $I^{\mathsf{sh}}_{[n,n+k]}$, $N^{\mathsf{sh}}_{[n,n+k]}$, $\rho^{\mathsf{sh}}_{[n,n+k]}$, and $\lambda^{\mathsf{sh}}_{[n,n+k]}$ keep exactly those witnesses for the retained adjacent faces. No step crossing the cut between $n-1$ and n is retained, so the shifted packet has a closed k-step Gaussian ledger over its reset time boundary.

For the path-continuity surface, use Definition 191.11. Every public path-continuity row of a Brownian packet is projected from the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ row together with the displayed continuity row P and the finite ledger λ. The row $C^{\mathsf{sh}}_{[n,n+k]}$ is the retained continuous-map certificate read on the same path segment, while $P^{\mathsf{sh}}_{[n,n+k]}$ and $\lambda^{\mathsf{sh}}_{[n,n+k]}$ keep exactly the modulus, continuity, and transport entries whose source and target faces lie in the suffix interval. Resetting

the source boundary to the endpoint at time n is therefore a ledger relabelling inside the displayed segment, not a host path equality.

It remains to repack the exact public boundary. By Definition 191.3, the shifted martingale and path rows are still read only through the two dependency certificates, and the time, Gaussian-step, continuity, provenance, and transport rows remain displayed packet coordinates. By Definition 191.7 and Definition 191.19, every public row of the shifted tuple is either one of its displayed coordinates or a row scoped by the shifted martingale dependency or the shifted continuous-map dependency. Finally Definition 191.12 identifies exactly such a displayed carrier, dependency, classifier, and finite-ledger package as the $\mathsf{NameCert}_{\mathsf{Brownian}^\uparrow}$ obligation surface. Therefore $\mathcal{B}^{\mathsf{sh}}_{[n,n+k]}$ is an admitted Brownian process packet, with no added host-level probability, stochastic-process, or path-equality data. □

Theorem 191.23 (Brownian finite prefix suffix bridge boundary)**.** *The finite-prefix restriction of Definition 191.24 and the finite-suffix restriction of Definition 191.25 form the explicit* $\mathsf{Brownian}^\uparrow$ *bridge boundary over the consumed* $\mathsf{Martingale}^\uparrow$ *and* $\mathsf{ContinuousMap}^\uparrow$ *rows, the displayed* BHist *and* UnaryHistory *rows, the shared* Pkg *provenance, the finite* Cont *transport, and the* hsame *classifier rows. A downstream bridge read of the Brownian packet therefore factors through these finite prefix and suffix surfaces, and no host probability-space row, stochastic-process row, or path equality is added to the public boundary.*

Proof. The prefix theorem identifies the Brownian carrier after an initial finite time cut. Its retained rows are the consumed martingale prefix, the unchanged continuous-map dependency, the initial UnaryHistory time row, the retained Gaussian-step and continuity displays, the shared Pkg provenance, and the finite Cont/hsame transport ledger.

The suffix theorem identifies the same carrier after a finite shifted suffix cut. It resets the displayed boundary endpoint by relabelling the finite unary spine and retains only those martingale, continuous-map, Gaussian, provenance, and transport faces whose source and target lie in the closed suffix interval.

Together these two restrictions cover the bridge-facing boundary: every consumer read of a Brownian finite segment is either a prefix read from the initial endpoint or a suffix read from a displayed boundary endpoint. The dependency reads are still mediated by $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$, while the remaining rows are exactly the displayed BHist, UnaryHistory, Pkg, Cont, and hsame rows. Thus the bridge boundary is finite and visible, with no ambient stochastic object beyond the displayed packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{Brownian}^\uparrow}$**.**

Constructive story: A Brownian packet is not a host path space; it is the finite displayed tuple $(M, C, T, I, N, P, \rho, \lambda)$ whose martingale row M is read through $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$, whose path-continuity row C is read through $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$, and whose time, adjacent-step, normal-step, provenance, and transport rows are all BHist data. The carrier accepts exactly those tuples for which the martingale dependency supplies adaptedness and step rows, the continuous-map dependency supplies path-continuity rows, and the normal-step and adjacent-time ledgers are displayed, while the classifier transports $M, C, T, I, N, P, \rho, \lambda$ rowwise by the two dependency certificates and by hsame. The source therefore covers only this finite step-continuity packet, the pattern is martingale adaptedness plus Gaussian adjacent-step data and continuous-path readback, and the ledger keeps every public coordinate either as one of the displayed tuple rows or as a row projected from M or C. Since the two dependency classifiers are equivalence relations and the remaining fields use componentwise history-sameness, an admitted Brownian packet supplies the carrier witness, the classifier is reflexive, symmetric, and transitive, and transported packets keep the same obligation surface. A packet h lies in the signature gap of a $\mathsf{Brownian}^\uparrow$ token p when the source-domain accepts its martingale row, continuous-path row, time spine, step ledger, normal-step display, and provenance, the signature relation pairs that tuple with an answer tuple and evidence ledger, and token introduction names the answer as p; unfolded, the token records exactly those adapted, continuous, Gaussian-step rows. The finite prefix and suffix restriction boundary exports the visible bridge surface over MartingaleUp, ContinuousMapUp, BHist, UnaryHistory, Pkg, Cont, and hsame rows. The chapter registers this finite step-continuity construction under

the name Brownian$^{\uparrow}$; Brownian motion is represented by dependency certificates and displayed ledgers, with no Gaussian measure construction, path-space completeness, stochastic calculus, or host stochastic-process object introduced.

Theory closure: TheoryGate(NameCert$_{\text{Brownian}\uparrow}$, maturePackageClosed)

Scope closed: The obligation scope binds the Brownian step-continuity packet to the MartingaleUp dependency row, ContinuousMapUp path row, time/path rows, normal-step row, shared provenance, finite ledger BHist rows, and the finite prefix and suffix restriction bridge surface already displayed for Brownian readers.

Formal verification: FormalStatus(NameCert$_{\text{Brownian}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: No standard Brownian motion, Gaussian measure construction, stochastic calculus, path-space completeness, or probability-space completeness theorem is claimed here.

Upgrade path: No further paper theory-axis upgrade is recorded for this Brownian surface; bridgeChecked remains a separate formal-axis matter.

Theorem 191.24 (Brownian finite-prefix carrier restriction)**.** *Let*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$$

be an admitted Brownian$^{\uparrow}$ *process packet in the sense of Definition 191.1. Suppose the displayed unary time row T has length $n+k$, and choose the initial finite subledger $T_{\leq n}$ containing exactly the first n adjacent time faces. Let $I_{\leq n}$, $N_{\leq n}$, $P_{\leq n}$, $\rho_{\leq n}$, and $\lambda_{\leq n}$ be the subrows of the adjacent-step ledger, normal-step display, path-continuity display, provenance row, and finite* Cont/hsame *ledger whose displayed faces lie entirely over $T_{\leq n}$. Let $M_{\leq n}$ be the finite-prefix restriction of the consumed* NameCert$_{\text{Martingale}\uparrow}$ *row M, and keep the same consumed* NameCert$_{\text{ContinuousMap}\uparrow}$ *path row C.*

Then

$$\mathcal{B}_{\leq n} = (M_{\leq n}, C, T_{\leq n}, I_{\leq n}, N_{\leq n}, P_{\leq n}, \rho_{\leq n}, \lambda_{\leq n})$$

is again an admitted Brownian$^{\uparrow}$ *process packet. In particular, restricting the Brownian path-step carrier to the first n displayed time steps preserves the carrier boundary and introduces no host probability-space row, host stochastic-process row, or host path-equality row.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier finite prefix carrier restriction`

Proof. Unpack the Brownian carrier of Definition 191.1. The admitted packet is a finite displayed tuple whose public rows are exactly $M, C, T, I, N, P, \rho, \lambda$. The time row is a finite UnaryHistory row, so its initial subledger $T_{\leq n}$ is again a finite displayed unary time row. The rows $I_{\leq n}$ and $N_{\leq n}$ are obtained by retaining precisely the adjacent faces of I and N whose endpoints remain in $T_{\leq n}$; no boundary face crossing from the prefix into the omitted tail is retained.

For the martingale dependency, apply Definition 190.17 to M. It gives the accepted finite-prefix martingale packet $M_{\leq n}$ over the same displayed initial horizon. Thus all adaptedness, conditional-expectation, filtration, provenance, and finite Cont rows read through the Brownian martingale input remain licensed by NameCert$_{\text{Martingale}\uparrow}$ after the time-prefix restriction.

For the Gaussian-step face, use Definition 191.15. Every public adjacent Gaussian-step consumer reads only the unary time row, the adjacent-step ledger, the normal-step display, the provenance row, the finite transport ledger, and the corresponding UnaryHistory and Cont/hsame witnesses. The restriction keeps exactly those witnesses for the retained adjacent faces, so the Gaussian-step surface over $T_{\leq n}$ is still displayed inside the finite packet.

For the path-continuity face, use Definition 191.11. Every public path-continuity row is projected from the consumed NameCert$_{\text{ContinuousMap}\uparrow}$ row C together with the displayed continuity row P and the finite ledger λ. The restricted row $P_{\leq n}$ contains the same modulus and certificate witnesses that the original packet displayed on the retained time faces, and $\lambda_{\leq n}$ contains exactly the

transport entries needed by those retained witnesses. Since C is unchanged, the continuous-map dependency surface still supplies the path-continuity rows read by the prefix packet.

It remains to repack the provenance and exactness boundary. The rows $\rho_{\le n}$ and $\lambda_{\le n}$ are finite subledgers of the original shared Pkg provenance and $\mathsf{Cont/hsame}$ ledger, restricted to the retained martingale, time-step, Gaussian, and path-continuity faces. By Definition 191.7 and Definition 191.19, every public row of the restricted tuple is either one of its displayed coordinates or a row already scoped by $M_{\le n}$ or C. Finally Definition 191.12 identifies these displayed carrier, dependency, classifier, and ledger rows as the public $\mathsf{NameCert}_{\mathsf{Brownian}^\uparrow}$ obligation surface. Therefore $\mathcal{B}_{\le n}$ satisfies the Brownian carrier definition with no additional host-level data. □

Theorem 191.25 (Brownian finite-suffix carrier restriction)**.** *Let*

$$\mathcal{B} = (M, C, T, I, N, P, \rho, \lambda)$$

be an admitted $\mathsf{Brownian}^\uparrow$ *process packet in the sense of Definition 191.1. Suppose the displayed unary time row T has length $n+k$. Let $T^{\mathsf{sh}}_{[n,n+k]}$ be the finite k-step unary row obtained by retaining the adjacent faces from the boundary endpoint at time n through the endpoint at time $n+k$ and then relabelling that boundary endpoint as the initial endpoint. Let*

$$I^{\mathsf{sh}}_{[n,n+k]}, \quad N^{\mathsf{sh}}_{[n,n+k]}, \quad P^{\mathsf{sh}}_{[n,n+k]}, \quad \rho^{\mathsf{sh}}_{[n,n+k]}, \quad \lambda^{\mathsf{sh}}_{[n,n+k]}$$

be the corresponding finite subrows of the adjacent-step ledger, normal-step display, path-continuity display, provenance row, and $\mathsf{Cont/hsame}$ *ledger whose displayed faces lie entirely in that closed suffix interval, with each time index translated by $j \mapsto j-n$. Let $M^{\mathsf{sh}}_{[n,n+k]}$ be the same translated suffix of the consumed* $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ *row, retaining exactly the endpoint rows and conditional-expectation faces with indices $n \le j \le n+k$. Let $C^{\mathsf{sh}}_{[n,n+k]}$ be the path-continuity subrow read from the consumed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ *row C on the retained path segment, with the time-source boundary reset to the displayed endpoint at time n.*

Then

$$\mathcal{B}^{\mathsf{sh}}_{[n,n+k]} = (M^{\mathsf{sh}}_{[n,n+k]}, C^{\mathsf{sh}}_{[n,n+k]}, T^{\mathsf{sh}}_{[n,n+k]}, I^{\mathsf{sh}}_{[n,n+k]}, N^{\mathsf{sh}}_{[n,n+k]}, P^{\mathsf{sh}}_{[n,n+k]}, \rho^{\mathsf{sh}}_{[n,n+k]}, \lambda^{\mathsf{sh}}_{[n,n+k]})$$

is again an admitted $\mathsf{Brownian}^\uparrow$ *process packet. Thus the Brownian path-step carrier is closed under finite suffix restriction from any displayed boundary endpoint, and the restricted carrier introduces no host probability-space row, no host stochastic-process row, and no host path-equality row.*

Lean4 ✓ `BEDC.Derived.BrownianUp.BrownianStepContinuityClassifier finite suffix carrier restriction`

Proof. Unpack the carrier of Definition 191.1. An admitted Brownian packet is a finite displayed tuple, and every public Brownian row is one of $M, C, T, I, N, P, \rho, \lambda$ or is read through the two consumed dependency certificates. Taking the interval from the boundary endpoint n to $n+k$ therefore selects a finite subtuple of already displayed rows. The translation $j \mapsto j-n$ changes only the displayed position names in the finite unary spine; it does not create a further time object.

For the martingale dependency, read M through the concrete $\mathsf{Martingale}^\uparrow$ packet surface. By Definition 190.5, the martingale carrier is a finite tuple of endpoint rows, adjacent conditional-expectation rows, tower-boundary rows, provenance, and finite Cont transport. The suffix row $M^{\mathsf{sh}}_{[n,n+k]}$ retains precisely those endpoint rows and adjacent faces whose indices lie in the displayed interval $[n, n+k]$, with the endpoint at n serving as the shifted initial value. Each retained successor face is one of the conditional-expectation faces already accepted in M, and Definition 190.16

identifies these retained finite rows as the public $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ surface. Hence the martingale input needed by the shifted Brownian packet is still licensed by the consumed martingale certificate.

For the Gaussian-step surface, apply Definition 191.15. It says that every public adjacent Gaussian-step read uses only the unary time row, the adjacent-step ledger, the normal-step display, the provenance row, the finite transport ledger, and the corresponding UnaryHistory and Cont/hsame witnesses. The rows $T^{\mathsf{sh}}_{[n,n+k]}$, $I^{\mathsf{sh}}_{[n,n+k]}$, $N^{\mathsf{sh}}_{[n,n+k]}$, $\rho^{\mathsf{sh}}_{[n,n+k]}$, and $\lambda^{\mathsf{sh}}_{[n,n+k]}$ keep exactly those witnesses for the retained adjacent faces. No step crossing the cut between $n-1$ and n is retained, so the shifted packet has a closed k-step Gaussian ledger over its reset time boundary.

For the path-continuity surface, use Definition 191.11. Every public path-continuity row of a Brownian packet is projected from the consumed $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ row together with the displayed continuity row P and the finite ledger λ. The row $C^{\mathsf{sh}}_{[n,n+k]}$ is the retained continuous-map certificate read on the same path segment, while $P^{\mathsf{sh}}_{[n,n+k]}$ and $\lambda^{\mathsf{sh}}_{[n,n+k]}$ keep exactly the modulus, continuity, and transport entries whose source and target faces lie in the suffix interval. Resetting the source boundary to the endpoint at time n is therefore a ledger relabelling inside the displayed segment, not a host path equality.

It remains to repack the exact public boundary. By Definition 191.3, the shifted martingale and path rows are still read only through the two dependency certificates, and the time, Gaussian-step, continuity, provenance, and transport rows remain displayed packet coordinates. By Definition 191.7 and Definition 191.19, every public row of the shifted tuple is either one of its displayed coordinates or a row scoped by the shifted martingale dependency or the shifted continuous-map dependency. Finally Definition 191.12 identifies exactly such a displayed carrier, dependency, classifier, and finite-ledger package as the $\mathsf{NameCert}_{\mathsf{Brownian}^\uparrow}$ obligation surface. Therefore $\mathcal{B}^{\mathsf{sh}}_{[n,n+k]}$ is an admitted Brownian process packet, with no added host-level probability, stochastic-process, or path-equality data. □

Theorem 191.26 (Brownian finite prefix suffix bridge boundary)**.** *The finite-prefix restriction of Definition 191.24 and the finite-suffix restriction of Definition 191.25 form the explicit* $\mathsf{Brownian}^\uparrow$ *bridge boundary over the consumed* $\mathsf{Martingale}^\uparrow$ *and* $\mathsf{ContinuousMap}^\uparrow$ *rows, the displayed* BHist *and* UnaryHistory *rows, the shared* Pkg *provenance, the finite* Cont *transport, and the* hsame *classifier rows. A downstream bridge read of the Brownian packet therefore factors through these finite prefix and suffix surfaces, and no host probability-space row, stochastic-process row, or path equality is added to the public boundary.*

Proof. The prefix theorem identifies the Brownian carrier after an initial finite time cut. Its retained rows are the consumed martingale prefix, the unchanged continuous-map dependency, the initial UnaryHistory time row, the retained Gaussian-step and continuity displays, the shared Pkg provenance, and the finite Cont/hsame transport ledger.

The suffix theorem identifies the same carrier after a finite shifted suffix cut. It resets the displayed boundary endpoint by relabelling the finite unary spine and retains only those martingale, continuous-map, Gaussian, provenance, and transport faces whose source and target lie in the closed suffix interval.

Together these two restrictions cover the bridge-facing boundary: every consumer read of a Brownian finite segment is either a prefix read from the initial endpoint or a suffix read from a displayed boundary endpoint. The dependency reads are still mediated by $\mathsf{NameCert}_{\mathsf{Martingale}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$, while the remaining rows are exactly the displayed BHist, UnaryHistory, Pkg, Cont, and hsame rows. Thus the bridge boundary is finite and visible, with no ambient stochastic object beyond the displayed packet. □

The Brownian process packet consumes chapter 190, chapter 184, and chapter 130 before its finite time row, Gaussian-step row, path-continuity row, provenance row, and transport rows are readable. The finite-prefix consumer Definition 191.24, the finite-suffix consumer Definition 191.25, and the combined boundary Definition 191.26 name the exposed restriction surface for martingale, probspace, and continuousmap siblings; the route refuses a host probability space, chosen sample paths, and ambient path equality.

Chapter 192

A Concrete Naming Certificate for $\mathsf{Entropy}^{\uparrow}$

The entropy interface $\mathsf{Entropy}^{\uparrow}$ packages the Shannon entropy $-\sum p_i \log p_i$ of a discrete distribution and the differential entropy $-\int f \log f$ of a continuous one. It depends on $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186) and $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$ (chapter 123).

192.1 Carrier definition

Definition 192.1 (EntropyUp BHist measure source surface)**.** *An* $\mathsf{Entropy}^{\uparrow}$ *BHist measure source surface consists of a* $\mathsf{Distribution}^{\uparrow}$ *pushforward row, an* $\mathsf{Integral}^{\uparrow}$ *finite or integral readback row, a log-weight observation row treated as a certified BHist endpoint,* hsame *transport rows for the distribution, integral, and log-weight endpoints,* Cont *ledger rows connecting the displayed observations, and* Pkg *provenance for the whole package.*

Lean4 (definition) `BEDC.Derived.EntropyUp.EntropySourceSurface`

Definition 192.2 (EntropyUp log-partition BHist carrier)**.** *An* $\mathsf{Entropy}^{\uparrow}$ *log-partition BHist carrier is a finite source packet* $\mathcal{E}_{\log Z}$ *consisting of a* $\mathsf{Distribution}^{\uparrow}$ *pushforward row, a finite partition observation row, a log-weight endpoint row, an* $\mathsf{Integral}^{\uparrow}$ *or finite-sum readback row for the displayed partition, componentwise* hsame *transports for the distribution, partition, log-weight, and readback rows, finite* Cont *ledger routes connecting the observations, and* Pkg *provenance for the packet. A consumer reads a log-partition boundary only through these rows.*

Lean4 (definition) `BEDC.Derived.EntropyUp.EntropyLogPartitionBHistCarrier`
Lean4 (definition) `BEDC.Derived.EntropyUp.EntropyLogPartitionCarrier`

Theorem 192.3 (Entropy log-partition consumer exhaustion)**.** *Every accepted consumer of the carrier* $\mathcal{E}_{\log Z}$ *in Definition 192.2 reads exactly the* $\mathsf{Distribution}^{\uparrow}$ *pushforward row, the finite partition observation row, the log-weight endpoint row, the* $\mathsf{Integral}^{\uparrow}$ *or finite-sum readback row, the componentwise* hsame *transports, the finite* Cont *ledger routes, and the* Pkg *provenance. It reads no analytic convergence row, no measure-completion row, and no host-level entropy equality.*

Proof. Project the finite carrier packet to its distribution, partition, log-weight, and readback coordinates. These are the only numeric observation rows displayed by the log-partition source.

Next project the componentwise hsame transports and finite Cont routes. Repacking those finite rows through Pkg supplies the consumer boundary and exhausts the visible carrier fields.

The packet has no field for analytic convergence, completed measures, or a host entropy identity. Such claims therefore cannot be read by a BEDC consumer of the log-partition carrier. □

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyLogPartitionCarrier consumer exhaustion`

Theorem 192.4 (Entropy log-partition transport closure)**.** *Let $\mathcal{E}_{\log Z}$ and $\mathcal{E}'_{\log Z}$ be two accepted* Entropy$^{\uparrow}$ *log-partition BHist carriers. If their* Distribution$^{\uparrow}$ *pushforward rows, finite partition rows, log-weight endpoint rows, and* Integral$^{\uparrow}$ *or finite-sum readback rows are related componentwise by the displayed* hsame *transports, then the transported packet exposes the same log-partition consumer boundary: the same partition readback, the same log-weight endpoint, the same finite* Cont *ledger routes, and the same* Pkg *provenance up to the displayed transport rows.*

The transport closure does not assert analytic convergence, measure completion, or host-level equality of entropy values.

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyLogPartitionBHistCarrier transport closure`

Proof. Begin with the exhaustion theorem for each accepted carrier. It reduces both consumer surfaces to the finite distribution, partition, log-weight, readback, transport, ledger, and provenance rows.

Use the displayed hsame rows component by component. They transport the distribution source, the partition observation, the log-weight endpoint, and the readback row without changing the finite ledger shape.

Finally repack the transported rows through the same Pkg provenance surface. Since analytic convergence, measure completion, and host entropy equality were excluded from the exhausted boundary, the transported packet is closed exactly at the finite log-partition surface. □

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyLogPartitionCarrier transport closure`

Theorem 192.5 (Entropy distribution-integral boundary)**.** *Consumers of the* Entropy$^{\uparrow}$ *source surface read exactly the* Distribution$^{\uparrow}$ *pushforward row, the* Integral$^{\uparrow}$ *readback row, the log-weight endpoint, the* hsame *transport rows, the* Cont *ledger rows, and the* Pkg *provenance from Definition 192.1. Analytic convergence, measure-theoretic completeness, and host-level entropy equality are not part of this boundary.*

Proof. Project the distribution row, integral readback row, and log-weight endpoint from the displayed BHist source surface. These are the only numerical observation rows exported by the package.

Next project the hsame transport rows and the Cont ledger rows. Repacking these rows through Pkg gives the consumer boundary, and no analytic completion claim can be derived without additional convergence or measure-theoretic rows. □

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyBHistMeasureSourceSurface distribution integral boundary`

192.2 The certificate

Theorem 192.6 (EntropyUp NameCert obligation surface)**.** *The* Entropy$^{\uparrow}$ *NameCert obligation surface for Definition 192.1 is the package containing the* Distribution$^{\uparrow}$ *pushforward row, the* Integral$^{\uparrow}$ *readback row, the certified log-weight endpoint, the* hsame *transport rows, the* Cont *ledger rows, and the* Pkg *provenance. It certifies the displayed BEDC source package without asserting analytic convergence or measure-theoretic completeness.*

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropySourceSurface namecert obligation surface`

Proof. Use Definition 192.5 to obtain the exact rows that consumers may inspect. The carrier field is the displayed log-weight BHist endpoint over the distribution and integral sources.

The dependency fields are the $\mathsf{Distribution}^{\uparrow}$ and $\mathsf{Integral}^{\uparrow}$ rows, the stability fields are the hsame transports, and the ledger fields are the Cont rows with their Pkg provenance. Repacking these finite rows supplies the NameCert obligation surface and leaves stronger analytic claims outside the certificate. □

Theorem 192.7 (Entropy log-weight transport determinacy)**.** *Let E and E' be two accepted* $\mathsf{Entropy}^{\uparrow}$ *source surfaces of the form displayed in Definition 192.1. If E and E' share the same* $\mathsf{Distribution}^{\uparrow}$ *pushforward row, the same* $\mathsf{Integral}^{\uparrow}$ *readback row, and the same transported log-weight endpoint through the displayed* hsame *rows, then every entropy consumer reads the same log-weight endpoint,* Cont *ledger rows, and* Pkg *provenance from E and E'.*

No entropy equality theorem, convergence theorem, measure completion, or host-level integral identity can distinguish the two packages within the displayed BEDC boundary.

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropySourceSurface log weight transport determinacy`

Proof. First project both packages through Definition 192.5. The only observable numerical rows are the shared $\mathsf{Distribution}^{\uparrow}$ pushforward row, the shared $\mathsf{Integral}^{\uparrow}$ readback row, and the transported log-weight endpoint carried by the displayed hsame rows.

Next project the certificate surface with Definition 192.6. Since the accepted surfaces have the same distribution, integral, and log-weight endpoints, the certificate can repack only the corresponding Cont ledger rows and the same Pkg provenance for the accepted source package.

Finally use the exclusions in the two boundary theorems. Analytic convergence, measure-theoretic completion, entropy equality, and host integral identity are not rows of the accepted $\mathsf{Entropy}^{\uparrow}$ surface. They therefore cannot supply a second consumer read or separate the two transported log-weight packages. □

Definition 192.8 (Entropy obligation inventory packet)**.** *The* $\mathsf{Entropy}^{\uparrow}$ *obligation inventory packet is the finite* BHist *packet consisting of the* $\mathsf{Distribution}^{\uparrow}$ *pushforward row, the* $\mathsf{Integral}^{\uparrow}$ *readback row, the certified log-weight endpoint, the componentwise* hsame *transports for those three rows, the finite* Cont *ledgers carrying the displayed observations, and the* Pkg *provenance for the accepted entropy source. The carrier row is the accepted source surface of Definition 192.1; the classifier row is the componentwise comparison of the displayed distribution, integral, and log-weight endpoints; the stability and ledger rows are exactly the displayed* hsame, Cont, *and* Pkg *data.*

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyUpTasteGate single carrier alignment`

Theorem 192.9 (Entropy carrier-classifier obligation)**.** *Every accepted inventory packet of Definition 192.8 supplies the* $\mathsf{Entropy}^{\uparrow}$ *carrier row and the componentwise classifier obligations for the displayed* $\mathsf{Distribution}^{\uparrow}$ *pushforward row,* $\mathsf{Integral}^{\uparrow}$ *readback row, and certified log-weight endpoint. No analytic convergence row, measure-completion row, or host entropy equality participates in the carrier or classifier obligation.*

Proof. Project the inventory packet to its carrier row. By definition this row is the accepted source surface of Definition 192.1.

Next project the classifier coordinates. They are exactly the componentwise hsame transports on the distribution pushforward, integral readback, and log-weight endpoint, so they supply the classifier obligations named by the packet.

The remaining rows are continuation and provenance data. Since the inventory has no field for convergence, completed measures, or host entropy equality, those claims cannot enter the carrier-classifier obligation. □

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropyObligationInventoryPacket carrier classifier obligation`

Theorem 192.10 (Entropy ledger stability obligation)**.** *If an accepted* Entropy$^{\uparrow}$ *obligation inventory packet is transported componentwise along its displayed* hsame *rows, then the transported log-weight endpoint and transported* Integral$^{\uparrow}$ *readback row remain inside the same finite* Cont *ledger and* Pkg *provenance package. The transported package is again an* Entropy$^{\uparrow}$ *obligation inventory packet.*

Proof. Begin with Definition 192.7. It shows that transported packages with the same distribution, integral, and log-weight endpoints expose the same log-weight consumer boundary and provenance.

Apply Definition 192.6 to read the finite ledger rows of the transported package. The Cont rows and Pkg provenance are precisely the ledger fields listed in Definition 192.8.

Repack the transported distribution, integral, log-weight, hsame, Cont, and Pkg rows. This gives another accepted obligation inventory packet and keeps analytic convergence, measure completion, and host entropy equality outside the ledger. □

Lean4 ✓ `BEDC.Derived.EntropyUp.EntropySourceSurface ledger stability obligation`

Closure status for NameCert$_{\text{Entropy}^{\uparrow}}$.

Constructive story: An entropy source is assembled as a finite BHist packet whose displayed faces are a Distribution$^{\uparrow}$ pushforward row, an Integral$^{\uparrow}$ readback row, a certified log-weight endpoint, componentwise hsame transports, finite Cont ledgers, and Pkg provenance. The chapter binds these rows as the Entropy$^{\uparrow}$ obligation inventory while leaving analytic convergence, measure completion, and host entropy equality outside the packet.

Theory closure: TheoryGate(NameCert$_{\text{Entropy}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 192.11 and Definition 192.12 bind the exported entropy readback bridge through the displayed BHist carrier, log-partition rows, transported log-weight and integral rows, componentwise classifier obligations, Cont ledgers, Pkg provenance, and consumer-exact boundary visible in this chapter.

Formal verification: FormalStatus(NameCert$_{\text{Entropy}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.EntropyUp.EntropySourceSurface\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: This chapter does not close convergence, measure completion, or host entropy equality.

Upgrade path: No further paper-axis theory closure remains; bridge verification remains separate if a machine bridge is later supplied.

Definition 192.11 (Entropy public readback bridge surface)**.** *The* Entropy$^{\uparrow}$ *public readback bridge surface is the conservative paper bridge whose BEDC side is the accepted source surface of Definition 192.1 together with the accepted log-partition carrier of Definition 192.2. Its bridge rows are exactly the displayed* Distribution$^{\uparrow}$ *pushforward row, finite partition observation row, transported log-weight endpoint row,* Integral$^{\uparrow}$ *or finite-sum readback row, componentwise* hsame *transport rows, finite* Cont *ledger rows,* Pkg *provenance, and the consumer-exact boundary supplied by Definition 192.3 and Definition 192.5.*

Theorem 192.12 (Entropy public readback bridge boundary)**.** *Let B be an* Entropy$^{\uparrow}$ *public readback bridge surface in the sense of Definition 192.11. Every conservative paper read through B factors through the displayed source carrier, the log-partition rows, the transported log-weight endpoint, the* Integral$^{\uparrow}$ *readback row, the* Cont *ledger rows, the* Pkg *provenance, and the consumer-exact boundary named in Definition 192.3 and Definition 192.5. Therefore B cannot import analytic convergence, measure completion, host entropy equality, or host integral equality.*

Proof. Project the source side of B. By Definition 192.11, this projection is the accepted source surface of Definition 192.1. Applying Definition 192.5 exhausts its public reads: a consumer sees only the $\mathsf{Distribution}^{\uparrow}$ pushforward row, the $\mathsf{Integral}^{\uparrow}$ readback row, the log-weight endpoint, the hsame transport rows, the Cont ledger rows, and the Pkg provenance.

Project the log-partition side of B. The same definition identifies this projection with the accepted carrier of Definition 192.2. Applying Definition 192.3 exhausts that side as the $\mathsf{Distribution}^{\uparrow}$ pushforward row, finite partition observation row, log-weight endpoint row, $\mathsf{Integral}^{\uparrow}$ or finite-sum readback row, componentwise hsame transports, finite Cont ledger routes, and Pkg provenance. Applying Definition 192.4 keeps those rows stable under the displayed componentwise transports and adds no analytic row.

It remains to check that the bridge has no second channel. The definition of the bridge surface lists its bridge rows as the union of the two exhausted consumer boundaries, with the transported log-weight and readback rows included only through their displayed hsame, Cont, and Pkg provenance. Thus any conservative paper read through B first lands in one of the rows already named by the source or log-partition exhaustion theorem, and reverse admission can accept only a package carrying those same rows.

Analytic convergence and measure completion are excluded by both the source boundary and the log-partition exhaustion. Host entropy equality is excluded by Definition 192.3, Definition 192.4, and Definition 192.5. Host integral equality is also excluded: the only integral information admitted by the bridge is the public $\mathsf{Integral}^{\uparrow}$ readback row, and Definition 123.4 keeps host function equality and hidden convergence choices outside the public $\mathsf{Integral}^{\uparrow}$ surface. Consequently the bridge boundary is exactly the displayed entropy readback surface and cannot import any of the four excluded host claims. □

Chapter 193

A Concrete Naming Certificate for $\mathsf{Ode}^{\uparrow}$

The ordinary-differential-equation interface $\mathsf{Ode}^{\uparrow}$ packages a system $\dot{x} = F(t, x)$ together with the local existence and uniqueness data on Lipschitz vector fields. It depends on $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ (chapter 122) and $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ (chapter 90).

193.1 Carrier definition

Definition 193.1 (OdeUp BHist local-flow source)**.** *An* $\mathsf{Ode}^{\uparrow}$ *BHist local-flow source is a time-state carrier over the* $\mathsf{Banach}^{\uparrow}$ *carrier supplied by* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$*. Its points are pairs of histories* $(t, x) : \mathsf{BHist} \times \mathsf{BHist}$ *whose time component is carried by the scalar surface used by* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *and whose state component is carried by the Banach carrier. The vector-field row is a displayed operation*

$$F : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{BHist}$$

whose value $F(t, x)$ *is again a Banach-carried state history after transport along the time and state classifiers.*

A local-flow row consists of an initial time cell t_0*, an initial state cell* x_0*, an endpoint time cell* t_1*, an endpoint state cell* x_1*, a vector-field evaluation ledger* v*, a Picard-step history* p*, and a limit witness* ℓ *such that the step and limit are linked by displayed continuations*

$$\mathsf{Cont}(t_0, x_0, p), \qquad \mathsf{Cont}(p, v, \ell), \qquad \mathsf{Cont}(t_1, \ell, x_1).$$

The classifier is inherited from the Banach and derivative surfaces: two rows are equivalent when their time cells are identified by the derivative scalar classifier, their state cells by the Banach carrier classifier, and their displayed ledgers by hsame *transport through the same* NameCert *rows. The ledger records the time cell, state cell, vector-field evaluation, Picard-step continuation route, and limit witness. It does not assert equality in any host function space.*

Lean4 (definition) `BEDC.Derived.OdeUp.OdeLocalFlowRow`

193.2 The certificate

Theorem 193.2 (OdeUp root vector-field carrier stability)**.** *For an* $\mathsf{Ode}^{\uparrow}$ *BHist local-flow source, if* t *is carried by the derivative scalar surface and* x *is carried by the Banach state carrier, then*

the displayed vector-field value $F(t,x)$ is carried by the same Banach state carrier. This assignment is stable under classifier transport: replacing t and x by t' and x' with the corresponding $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *classifier witnesses gives* $F(t,x)\mathsf{hsame}F(t',x')$ *in the endpoint classifier recorded by* NameCert.

Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlowSource vector field carrier stability`

Proof. Unpack the local-flow source. The time cell is read through $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$, and the state cell is read through $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$. The vector-field row is part of the source data, so its evaluation ledger records a Banach-carried output whenever both input cells are carried.

For transport, move first along the derivative classifier on the time cell and then along the Banach carrier classifier on the state cell. The displayed evaluation ledger is functorial for these two classifier moves because it is stored as a NameCert row rather than as host equality. Repacking the transported output row gives the required Banach-carried value and its hsame endpoint classifier. □

Theorem 193.3 (OdeUp root Picard continuation scope)**.** *In an* $\mathsf{Ode}^{\uparrow}$ *BHist local-flow source, Picard-step packages compose inside the scope generated by* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$, *and* hsame *transport. If two adjacent Picard ledgers expose* $\mathsf{Cont}(t_0,x_0,p)$, $\mathsf{Cont}(p,v,\ell)$, *and* $\mathsf{Cont}(t_1,\ell,x_1)$ *together with a second compatible step from x_1 to x_2, then associativity of* Cont *builds the composite continuation route from (t_0,x_0) to (t_2,x_2) without adding any carrier outside those two certificate surfaces.*

Proof. Read the first Picard package as a chain of displayed continuations from the initial time-state cell to its limit witness and then to its endpoint. Read the second package in the same way, with the endpoint state of the first row as the carried input state of the second.

Use Cont associativity to reassociate the terminal continuation of the first package with the initial continuation of the second package. Whenever a shared endpoint is represented by a classifier-equal history rather than by the same syntax, transport across hsame using the Banach and derivative rows of $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$.

The resulting chain is again a list of BHist continuations whose endpoints are classified by the same NameCert surfaces. Thus the composite Picard route remains scoped to Banach states, derivative time cells, and hsame transport; no ambient function-space carrier is introduced. □

Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlowSource picard continuation scope`
Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlowRow picard continuation scope`

Theorem 193.4 (OdeUp root local-uniqueness classifier)**.** *For an* $\mathsf{Ode}^{\uparrow}$ *BHist local-flow source, two local-flow witnesses with the same initial time cell, the same initial state cell, and the same Lipschitz ledger are classified by the same endpoint classifier. Concretely, if their vector-field evaluation rows, Picard-step rows, and limit witnesses are transported through the shared* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, Cont, *and* hsame *ledgers, then their endpoint state histories are related by the Banach classifier recorded in* NameCert.

Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlow endpoint classifier deterministic`

Proof. Unpack the two local-flow witnesses into their common initial time-state cell, their vector-field evaluation ledgers, Picard-step histories, limit witnesses, and endpoint histories. The shared Lipschitz ledger classifies the vector-field rows through the derivative and Banach input classifiers, so the two Picard steps have the same continuation data up to hsame.

Transport the second Picard chain along these hsame witnesses and use determinism of the displayed Cont result at each continuation stage. This identifies the two limit witnesses in the classifier inherited from the Banach carrier.

Finally transport through the endpoint continuation rows $\mathsf{Cont}(t_1, \ell, x_1)$ and $\mathsf{Cont}(t_1, \ell', x_1')$. Since the time endpoint is the same cell and the limit witnesses have just been classified together, the Banach endpoint classifier relates x_1 and x_1'. This is precisely the endpoint classifier exposed by the $\mathsf{Ode}^{\uparrow}$ source through $\mathsf{NameCert}$. □

Theorem 193.5 (OdeUp local-flow concatenation endpoint determinacy)**.** *Let R_{01} and R_{12} be $\mathsf{Ode}^{\uparrow}$ BHist local-flow rows over the same $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ surfaces:*

$$R_{01} = (t_0, x_0, t_1, x_1; v_{01}, p_{01}, \ell_{01}), \qquad R_{12} = (t_1, x_1, t_2, x_2; v_{12}, p_{12}, \ell_{12}).$$

Assume the terminal time-state cell of R_{01} is the initial time-state cell of R_{12} in the derivative and Banach classifiers, so Definition 193.3 supplies a composite Picard route. Write the resulting composite local-flow row as

$$R_{02}^{\circ} = (t_0, x_0, t_2, x_2; v_{02}^{\circ}, p_{02}^{\circ}, \ell_{02}^{\circ}).$$

If

$$D_{02} = (t_0, x_0, t_2, y; v_{02}, p_{02}, \ell_{02})$$

is any direct $\mathsf{Ode}^{\uparrow}$ local-flow row whose Lipschitz vector-field ledger is classified with the composite ledger,

$$v_{02}^{\circ} \mathsf{hsame} v_{02},$$

then the concatenated endpoint and the direct endpoint are related by the Banach endpoint classifier:

$$x_2 \sim_{\mathsf{Banach}^{\uparrow}} y,$$

where $\sim_{\mathsf{Banach}^{\uparrow}}$ denotes the classifier supplied by $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlowSource concatenation route scope`

Proof. By Definition 193.3, the two adjacent Picard ledgers compose through the shared middle time-state cell inside the same $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ surfaces. Thus the composite row R_{02}° is a local-flow witness from the initial data (t_0, x_0) to the endpoint state x_2 at time t_2.

Unpacking Definition 193.1, the composite row exposes

$$\mathsf{Cont}(t_0, x_0, p_{02}^{\circ}), \qquad \mathsf{Cont}(p_{02}^{\circ}, v_{02}^{\circ}, \ell_{02}^{\circ}), \qquad \mathsf{Cont}(t_2, \ell_{02}^{\circ}, x_2).$$

The direct row exposes the parallel chain

$$\mathsf{Cont}(t_0, x_0, p_{02}), \qquad \mathsf{Cont}(p_{02}, v_{02}, \ell_{02}), \qquad \mathsf{Cont}(t_2, \ell_{02}, y).$$

The two witnesses have the same initial time cell, the same initial state cell, the same endpoint time cell, and the displayed Lipschitz vector-field ledger comparison $v_{02}^{\circ} \mathsf{hsame} v_{02}$. Therefore Definition 193.4 applies to the composite row and the direct row. It classifies their endpoint state histories by the Banach classifier carried by $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$. Those endpoint histories are exactly x_2 and y, giving $x_2 \sim_{\mathsf{Banach}^{\uparrow}} y$. □

Lean4 ✓ `BEDC.Derived.OdeUp.OdeLocalFlowRow concatenation endpoint determinacy`

Theorem 193.6 (OdeUp local-flow concatenation associativity)**.** *Let*

$$R_{01} = (t_0, x_0, t_1, x_1; v_{01}, p_{01}, \ell_{01}), \qquad R_{12} = (t_1, x_1, t_2, x_2; v_{12}, p_{12}, \ell_{12}), \qquad R_{23} = (t_2, x_2, t_3, x_3; v_{23}, p_{23}, \ell_{23})$$

be $\mathsf{Ode}^{\uparrow}$ *BHist local-flow rows over the same* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *surfaces. Assume the terminal time-state cell of* R_{01} *is classified with the initial time-state cell of* R_{12}*, and the terminal time-state cell of* R_{12} *is classified with the initial time-state cell of* R_{23}*, in the derivative and Banach classifiers. Let*

$$R^{\circ}_{02} = (t_0, x_0, t_2, y_{02}; v^{\circ}_{02}, p^{\circ}_{02}, \ell^{\circ}_{02}), \qquad R^{\circ}_{13} = (t_1, x_1, t_3, y_{13}; v^{\circ}_{13}, p^{\circ}_{13}, \ell^{\circ}_{13})$$

be the binary composites supplied by Definition 193.3. Let

$$L^{\circ}_{03} = (t_0, x_0, t_3, z_L; v_L, p_L, \ell_L)$$

be the composite of R°_{02} *with* R_{23} *supplied by the same theorem, and let*

$$R^{\circ}_{03} = (t_0, x_0, t_3, z_R; v_R, p_R, \ell_R)$$

be the composite of R_{01} *with* R°_{13} *supplied by the same theorem. Then the two grouped composites have Banach-classified endpoint state histories:*

$$z_L \sim_{\mathsf{Banach}^{\uparrow}} z_R.$$

Proof. Apply Definition 193.3 first to R_{01} and R_{12} and separately to R_{12} and R_{23}. This produces the two binary rows R°_{02} and R°_{13} inside the same $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ surfaces. Applying the same theorem again to the adjacent pairs (R°_{02}, R_{23}) and (R_{01}, R°_{13}) produces the two grouped rows L°_{03} and R°_{03}, both read as local-flow witnesses from the same initial time-state cell (t_0, x_0) to the same terminal time cell t_3.

Unpack Definition 193.1. Each grouped row is built from exactly the three displayed local-flow packages of R_{01}, R_{12}, and R_{23} together with the two classifier transports at the shared interfaces. The only difference is the parenthesization of the continuation chain. By Definition 4.56, reassociating the left-grouped chain and the right-grouped chain does not change the resulting continuation witness up to hsame. Therefore the direct row R°_{03} has its Lipschitz vector-field ledger classified with the outer composite ledger of L°_{03}:

$$v_L \mathsf{hsame} v_R.$$

Now apply Definition 193.5 to the adjacent pair R°_{02}, R_{23}, taking R°_{03} as the direct row from (t_0, x_0) to time t_3. Its hypotheses are exactly the shared initial data, the certified outer concatenation route, and the displayed ledger comparison $v_L \mathsf{hsame} v_R$. The conclusion of that theorem is precisely that the endpoint state history of the grouped composite $(R_{01} \circ R_{12}) \circ R_{23}$ is related by the Banach endpoint classifier to the endpoint state history of the grouped composite $R_{01} \circ (R_{12} \circ R_{23})$. Hence

$$z_L \sim_{\mathsf{Banach}^{\uparrow}} z_R.$$

□

Closure status for $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$**.**

Constructive story: An ordinary differential equation local-flow row is carried by a time-state source over $\mathsf{Derivative}^{\uparrow}$ and $\mathsf{Banach}^{\uparrow}$: a time cell, state cell, vector-field evaluation, Picard-step history, limit witness, and endpoint state are tied together by three displayed continuation rows. A row is admitted only when the time component is carried by the

derivative scalar surface, the state and vector-field value are carried by the Banach surface, and the Picard and limit ledgers are present; equality in a host function space, global flow data, and Banach fixed-point theory are not carrier fields. Two local-flow rows are classified by transporting time cells through the derivative classifier, state cells through the Banach classifier, and Picard, vector-field, limit, and endpoint ledgers through hsame and Cont determinacy, rather than by comparing host solutions. The source covers the local time-state carrier, vector-field row, Picard continuations, limit witness, endpoint row, and Lipschitz ledger; the pattern records vector-field carrier stability, Picard route composition, local endpoint determinacy, and concatenation endpoint comparison; the ledger keeps the three continuation routes and their classifier transports visible. The five name-certificate obligations are obligation-level rows here: upstream derivative and Banach certificates supply carried endpoints, hsame gives reflexive, symmetric, and transitive movement, and Picard continuation scope repacks transported or concatenated routes as the same kind of local-flow row. A history h lies in the signature gap of an $\mathsf{Ode}^{\uparrow}$ token p when the source-domain accepts this local-flow package, the signature relation pairs it with an answer flow row and evidence ledger, and token introduction names that answer as p; unfolded, the initial time-state cell, vector-field ledger, Picard chain, limit witness, endpoint time, and Banach-classified endpoint are the data encoded by p. The chapter registers this local Picard-continuation construction under the name $\mathsf{Ode}^{\uparrow}$; it records a scoped obligation boundary and does not introduce global existence, smooth flow groups, host solution-space equality, standard ODE models, or bridge verification.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature local-flow composition treatment records the BHist local-flow source carrier of Definition 193.1, the Picard continuation scope of Definition 193.3, endpoint classifier determinacy from Definition 193.4, concatenation route scope from Definition 193.5, endpoint determinacy for composed rows over the derivative and Banach NameCert surfaces, and the associativity theorem Definition 193.6.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.OdeUp.OdeLocalFlowRow\_concatenation\_endpoint\_determinacy`

Bridge status: paperBridge

Not claimed: This obligation boundary does not close global existence, Banach fixed-point theory, smooth flow groups, standard ODE models, or bridge verification.

Upgrade path: The remaining formal step is bridgeCheckedV when a machine-checked standard bridge is present.

Chapter 194

A Concrete Naming Certificate for $\mathsf{Pde}^{\uparrow}$

The partial-differential-equation interface $\mathsf{Pde}^{\uparrow}$ packages a relation among partial derivatives of a function on a manifold carrier together with classification by order, type, and boundary data. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ (chapter 122).

194.1 Carrier definition

Definition 194.1 (PdeUp carried source row)**.** *A carried source row for* $\mathsf{Pde}^{\uparrow}$ *consists of the following BEDC-facing data: a* $\mathsf{Manifold}^{\uparrow}$ *carrier row naming the underlying charted carrier; the* $\mathsf{Derivative}^{\uparrow}$ *partial-derivative observation rows whose endpoints are the named derivative observations used by the equation; a finite PDE relation row whose entries refer only to those derivative endpoints together with their order and type tags; a boundary-data classifier row over the same carrier and endpoint names; and a ledger recording hidden chart choices, coordinate choices, representative functions, and solver-side presentation data.*

The carried source row does not identify host functions, host real values, analytic solution spaces, or coordinate representatives. Those objects remain ledger entries unless they are re-expressed through the displayed $\mathsf{Manifold}^{\uparrow}$, $\mathsf{Derivative}^{\uparrow}$, *relation, and boundary rows.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow source scope`

Theorem 194.2 (PdeUp carrier obligation)**.** *A carried* $\mathsf{Pde}^{\uparrow}$ *endpoint is a* BHist *row whose visible source data are exactly the* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *source, the* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *source, the PDE relation row, the boundary-data classifier row,* Pkg *provenance, and the probe bundles used to read the relation. Chart coordinates, derivative witnesses, and boundary presentations are ledger data for the certificate rather than additional carrier-equality coordinates.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow carrier obligation surface`

Proof. Read the endpoint through the ten-field certificate template. The traditional target is a partial-differential-equation endpoint on a certified manifold, while the BEDC source is the displayed BHist package assembled from the manifold certificate, derivative certificate, relation row, boundary classifier row, provenance, and probe bundles.

The carrier field therefore projects only those visible histories. The coordinate charts and derivative witnesses enter through the stability and ledger fields: they justify that the displayed

relation and boundary rows can be transported across the selected presentations, but they are not compared as carrier coordinates.

Exactness is readback from the same package. Any accepted carrier row must be one of the displayed BHist rows, and any hidden chart, derivative order, or boundary presentation is recoverable only as ledger evidence. □

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow carrier obligation`

Theorem 194.3 (PdeUp classifier obligation)**.** *The* $\mathsf{Pde}^{\uparrow}$ *classifier compares two carried endpoints exactly when the manifold source row, derivative-tuple row, PDE relation row, and boundary-data classifier row agree under the same* hsame *discipline and the same* Pkg *provenance. It does not compare endpoints by host function equality.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeRelationClassifier visible append surface`

Proof. Project the classifier slot from the ten-field template. Its source rows are the same source, carrier, classifier, stability, ledger, theorem-list, exactness, bridge, and boundary fields used by the carrier obligation.

The source field fixes the manifold row and the derivative tuple row. The carrier and classifier fields then compare the PDE relation and boundary classifier rows by hsame and by the provenance equality recorded in Pkg. Since each comparison is a comparison of displayed BHist rows, no host-level function equality is available as an extra rule.

Conversely, if these four rows and the provenance agree under the displayed hsame witnesses, the classifier field has exactly the data it requires. Repacking those witnesses gives the carried-endpoint comparison. □

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow classifier obligation`

Theorem 194.4 (PdeUp stability ledger exactness obligation)**.** *The* $\mathsf{Pde}^{\uparrow}$ *certificate is admitted only with transport stability for the derivative relation and boundary data, ledger entries for hidden chart/order/boundary choices, exactness rows for coverage, soundness, and completeness, and dependency rows citing the* $\mathsf{Manifold}^{\uparrow}$ *and* $\mathsf{Derivative}^{\uparrow}$ *sources.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow stability ledger exactness obligation surface`
Lean4 ✓ `BEDC.Derived.PdeUp.PdeStabilityLedger relation boundary append surface`

Proof. Separate the remaining certificate fields after the carrier and classifier rows have been fixed. Stability requires transport of the derivative-relation row and the boundary-data row along the displayed hsame comparisons of the manifold and derivative sources.

The ledger field records every chart, derivative-order, and boundary presentation choice used to witness that transport. These entries are evidence rows over BHist; they do not enlarge the carrier and do not create a second classifier.

The exactness field splits into coverage, soundness, and completeness rows: every admitted endpoint has displayed source and probe data, every accepted relation or boundary row is supported by the ledger, and every required source dependency cites $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$. These rows are precisely the non-bridge obligation surface claimed here. □

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow stability ledger exactness obligation`

194.2 The certificate

Theorem 194.5 (PdeUp carrier source obligation)**.** *For any carried source row of* $\mathsf{Pde}^{\uparrow}$*, the carrier obligation is discharged exactly by the named* $\mathsf{Manifold}^{\uparrow}$ *row, the named* $\mathsf{Derivative}^{\uparrow}$ *partial-derivative observation rows, the finite PDE relation row on those derivative endpoints, and the boundary-data classifier row. No host function carrier, host coordinate equality, analytic existence predicate, or solver object is part of the carrier source.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow visible source readback`

Proof. Unpack Definition 194.1. Its source entries are the $\mathsf{Manifold}^{\uparrow}$ carrier row, the $\mathsf{Derivative}^{\uparrow}$ observation rows, the relation row, and the boundary row.

The remaining listed host objects occur only in the ledger component of the same definition. Hence they can be recorded for provenance, but they cannot act as carrier-source dependencies for the $\mathsf{Pde}^{\uparrow}$ certificate. □

Theorem 194.6 (PdeUp relation classifier obligation)**.** *Let two* $\mathsf{Pde}^{\uparrow}$ *carried source rows have* $\mathsf{Manifold}^{\uparrow}$ *carrier rows related by the supplied* $\mathsf{Manifold}^{\uparrow}$ *classifier, and let each partial-derivative endpoint appearing in their PDE relation rows be related by the supplied* $\mathsf{Derivative}^{\uparrow}$ *classifier. Then the PDE relation rows are transported by replacing each relation entry with its transported derivative endpoint, order tag, and type tag; no further host equation equality is required.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeRelationClassifier endpoint transport`

Proof. The relation row in Definition 194.1 is finite and refers only to displayed derivative endpoints with their order and type tags. Transport the carrier name by the $\mathsf{Manifold}^{\uparrow}$ classifier and transport every endpoint name by the corresponding $\mathsf{Derivative}^{\uparrow}$ classifier.

After these transports, each relation entry has the same BEDC-facing shape as before: a finite relation entry over named derivative endpoints. Since host equations and coordinate representatives are ledger entries rather than relation entries, no host equation equality is introduced. □

Theorem 194.7 (PdeUp boundary-data obligation)**.** *For any* $\mathsf{Pde}^{\uparrow}$ *carried source row, boundary-data rows are transported by the same* $\mathsf{Manifold}^{\uparrow}$ *carrier classifier and* $\mathsf{Derivative}^{\uparrow}$ *endpoint classifiers used for the PDE relation row. The boundary-data obligation adds no host boundary equality and no host trace-space equality beyond those carried classifier rows.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeBoundaryData relation transport surface`
Lean4 ✓ `BEDC.Derived.PdeUp.PdeRelationClassifier boundary transport surface`

Proof. Unpack the boundary-data classifier row from Definition 194.1. Its carrier reference is the same $\mathsf{Manifold}^{\uparrow}$ carrier row, and its derivative references are among the displayed $\mathsf{Derivative}^{\uparrow}$ endpoint rows.

Therefore the boundary row uses the same two classifier families as the relation row: carrier transport from $\mathsf{Manifold}^{\uparrow}$ and endpoint transport from $\mathsf{Derivative}^{\uparrow}$. Host boundary representatives and trace-space presentations remain ledger data, so they do not become additional equality obligations. □

Theorem 194.8 (PdeUp ledger exactness obligation)**.** *The exactness data of a* $\mathsf{Pde}^{\uparrow}$ *carried source row is precisely the pair consisting of the carried PDE relation classifier and the carried boundary-data classifier. Host functions, host real equality, analytic existence of solutions, regularity theorems, numerical solvers, and solver data are ledger-external to this exactness claim.*

Lean4 ✓ `BEDC.Derived.PdeUp.PdeCarriedSourceRow ledger exactness surface`

Proof. The only classifier rows displayed in Definition 194.1 are the finite PDE relation classifier and the boundary-data classifier. Exactness is therefore the assertion that these two rows account for all BEDC-facing relation and boundary comparisons in the certificate.

Every analytic or solver-side object named in the statement is listed in the ledger component of the carried source row. Because ledger entries record presentation choices without adding classifier rows, they remain outside the exactness pair. □

Theorem 194.9 (PdeUp public interface export)**.** *The public* $\mathsf{NameCert}_{\mathsf{Pde}^\uparrow}$ *surface is exactly the* BHist *carried source row of Definition 194.1 together with the* $\mathsf{Manifold}^\uparrow$ *carrier row, the* $\mathsf{Derivative}^\uparrow$ *partial-derivative observation rows, the* Pkg *provenance row, the* ProbeBundle *rows used to read the finite PDE relation, and the following obligation surface:*

1. *the carrier obligation of Definition 194.2;*
2. *the classifier obligation of Definition 194.3;*
3. *the stability-ledger-exactness obligation of Definition 194.4;*
4. *the carrier-source obligation of Definition 194.5;*
5. *the relation classifier obligation of Definition 194.6;*
6. *the boundary-data obligation of Definition 194.7;*
7. *the ledger exactness obligation of Definition 194.8.*

No host function equality, host coordinate equality, analytic existence theorem, solution space, solver object, host real equality, regularity theorem, or numerical solver datum is part of this public interface.

Lean4 ✓ `BEDC.Derived.PdeUp.PdePublicInterface export semantic name certificate`

Proof. Start with the carried source row of Definition 194.1. Its visible BHist entries bind the $\mathsf{Manifold}^\uparrow$ carrier row, the $\mathsf{Derivative}^\uparrow$ derivative-observation rows, the finite PDE relation row, the boundary-data classifier row, Pkg provenance, and the ProbeBundle rows used to read the relation.

Repack those entries through the ten-field certificate template. The carrier, classifier, stability, ledger, theorem-list, exactness, bridge, and boundary slots are supplied by the seven cited obligation theorems, with the standard bridge slot absent and the dependency rows pointing back to the $\mathsf{Manifold}^\uparrow$ and $\mathsf{Derivative}^\uparrow$ source certificates.

Conversely, any public $\mathsf{NameCert}_{\mathsf{Pde}^\uparrow}$ endpoint must project through the same ten fields. The carrier and classifier projections recover the named source rows, the stability and ledger projections recover only transport and presentation evidence, and the exactness projection recovers the carried relation and boundary classifiers. Therefore the displayed surface is exact.

The excluded host objects occur only as ledger-side presentation data or analytic objects outside the BEDC-facing relation and boundary rows. Since no cited obligation introduces a classifier for them, they cannot enter the public $\mathsf{NameCert}_{\mathsf{Pde}^\uparrow}$ interface. □

Theorem 194.10 (PdeUp conservative standard bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{Pde}^\uparrow}$ *surface of Definition 194.9 has a conservative standard interpretation whose source is exactly the displayed* BHist *carried source row, the* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *carrier row, the* $\mathsf{NameCert}_{\mathsf{Derivative}^\uparrow}$ *partial-derivative observation rows, the finite PDE relation row, the boundary-data classifier row, the* Pkg *provenance row, and the* ProbeBundle *read rows. Conversely, any standard PDE presentation admitted through*

precisely those displayed manifold, derivative, relation, boundary, package, and probe rows repacks to the same public BEDC surface.

This bridge adds no analytic existence theorem, solution space, solver semantics, host function equality, host coordinate equality, host real equality, or regularity theory.

Proof. Apply Definition 194.9. It exposes the carried source row and the seven obligation rows: carrier, classifier, stability-ledger-exactness, carrier-source, relation-classifier, boundary-data, and ledger exactness. The standard reading is allowed to inspect only the displayed $\mathsf{Manifold}^{\uparrow}$ carrier row, $\mathsf{Derivative}^{\uparrow}$ partial-derivative rows, finite PDE relation row, boundary-data classifier row, Pkg provenance, and $\mathsf{ProbeBundle}$ read rows.

The ledger exactness theorem Definition 194.8 keeps chart selections, derivative-order witnesses, boundary presentations, representative functions, and solver-side presentation choices as provenance. Thus the standard interpretation is conservative: it reads the ordinary PDE presentation through the visible rows and does not turn hidden ledger choices into BEDC carrier coordinates or classifier clauses.

For the converse direction, start with a standard PDE presentation admitted through exactly those displayed rows. Repack its manifold carrier, derivative observations, relation entries, boundary classifier, package provenance, and probe reads into the carried source row of Definition 194.1. The seven obligations cited by Definition 194.9 then reconstruct the same public $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$ surface.

The excluded analytic and host-level objects remain outside the bridge because no row in the exported surface supplies classifiers for them. Hence the bridge certifies only conservative readback and repacking for the displayed PDE certificate surface. □

Lean4 ✓ `BEDC.Derived.PdeUp.PdeUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$.

Constructive story: A partial differential equation is carried here as a displayed row over already certified manifold and derivative data: the manifold carrier names the charted space, the derivative rows name the partial-derivative endpoints, and a finite relation row together with a boundary-data row says which endpoints are being compared. A row is admitted only when those visible pieces, the package provenance, and the probe bundles used to read the relation are present; chart choices, coordinate representatives, derivative witnesses, solver presentations, and host functions stay in the ledger, not in the carrier. Two carried endpoints are classified by transporting the manifold row, derivative tuple, finite relation row, boundary row, and provenance through the same hsame and upstream NameCert comparisons, rather than by equality of host equations or functions. The source therefore covers exactly the displayed manifold, derivative, relation, boundary, provenance, and probe rows; the pattern is the finite PDE-and-boundary shape on those derivative endpoints, and the ledger keeps hidden chart, order, representative, and boundary presentations visible only as evidence. The five name-certificate obligations are discharged because the upstream $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{Derivative}^{\uparrow}$ rows supply admitted endpoints, hsame gives reflexive, symmetric, and transitive classifier movement, and every transported relation or boundary row repacks as the same kind of carried source row. A history h lies in the signature gap of a $\mathsf{Pde}^{\uparrow}$ token p when the source-domain accepts this displayed PDE row, the signature relation pairs it with an answer row and evidence ledger, and token introduction names that answer as p; unfolded, the finite derivative relation and boundary classifier over the certified manifold must be the data encoded by p. The conservative standard bridge reads the visible rows as an ordinary PDE presentation and reads such a presentation back only when it uses precisely those rows, so the chapter registers this construction under the name $\mathsf{Pde}^{\uparrow}$ with no analytic existence theorem, solution space, solver semantics, or host-level function equality introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public paper-side surface is Definition 194.9, and the conservative standard bridge is Definition 194.10: the carried source row, the $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ carrier row, the $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ partial-derivative observation rows, the finite PDE relation row, the boundary-data classifier row, the Pkg provenance row, the ProbeBundle rows used to read the relation, and the seven public obligation rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$, bridgeChecked)

Theorem 194.11 (PdeUp finite relation subrow projection)**.** *Let S be a carried source row for* $\mathsf{Pde}^{\uparrow}$*. Write its displayed source data as a* $\mathsf{Manifold}^{\uparrow}$ *carrier row M, a finite row D of* $\mathsf{Derivative}^{\uparrow}$ *partial-derivative endpoints, a finite PDE relation row R, a boundary-data classifier row B, a* Pkg *provenance row P, and* ProbeBundle *rows Q reading the entries of R. Let R' be a displayed finite subrow of R, obtained by selecting relation entries from R, and suppose that each selected entry names only derivative endpoints occurring in D and carries only the order tags and type tags already displayed in R. Let Q' be the displayed restriction of Q to the reads of the selected entries. Then R' is again admitted as the relation coordinate of a carried* $\mathsf{Pde}^{\uparrow}$ *source row over the same M, D, B, P, and inherited probe-source rows Q'. This projection adds no host function equality, host coordinate equality, analytic solution predicate, trace-space equality, or solver object.*

Proof. Unpack the carried source row in Definition 194.1. The relation coordinate is finite, and every one of its entries is required to refer only to displayed $\mathsf{Derivative}^{\uparrow}$ endpoints together with displayed order and type tags. Since R' is obtained by selecting entries of R, no selected relation entry is created outside the original finite row. The endpoint, order, and type conditions for R' are therefore inherited entry by entry from the corresponding entries of R.

The source coordinates M, D, B, and P are not altered by the selection. The carrier-source obligation in Definition 194.5 says that these displayed manifold, derivative, relation, and boundary rows are exactly the carrier-source data for the certificate. Replacing the relation coordinate by the selected finite subrow keeps the same manifold carrier, the same derivative endpoint list, the same boundary-data classifier row, and the same package provenance.

The relation classifier obligation in Definition 194.6 permits relation rows only through their displayed derivative endpoints, order tags, and type tags. Here the transport is the identity on the retained entries: each selected entry keeps its original endpoint names and tags. Thus the selected relation row has the same BEDC-facing relation shape as the original row, with no appeal to host equation equality.

For the boundary coordinate, Definition 194.7 uses the same $\mathsf{Manifold}^{\uparrow}$ carrier classifier and $\mathsf{Derivative}^{\uparrow}$ endpoint classifiers as the relation row. Because the selected relation entries use only endpoints already present in D, the boundary-data classifier row remains compatible with the selected relation subrow. Restricting Q to Q' similarly changes only which displayed relation reads are consumed; it introduces no new probe source.

Finally apply the public export theorem Definition 194.9. The exported surface consists only of the carried source row, the manifold row, the derivative rows, the finite relation row, the boundary row, Pkg provenance, and the probe reads. The projected packet has exactly those same kinds of rows, with R' and Q' in place of the original relation reads. Since none of the cited obligations exports host functions, host coordinates, analytic solution data, trace-space equality, or solver objects, the projected packet exports none of them either. □

Lean4 ✓ `BEDC.Derived.PdeUp.PdeTasteGate single carrier alignment`

Chapter 195

A Concrete Naming Certificate for $\mathsf{DynSystem}^{\uparrow}$

The dynamical-system interface $\mathsf{DynSystem}^{\uparrow}$ packages a one-parameter family of self-maps of a phase-space carrier satisfying the flow axioms. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ (chapter 193).

195.1 Carrier definition

Definition 195.1 (DynSystemUp BHist flow carrier)**.** *A* $\mathsf{DynSystem}^{\uparrow}$ *flow packet is a displayed finite* BHist *tuple*

$$\mathcal{D} = (\mathcal{M}, \mathcal{O}, p, t, x, y, \phi, \omega, \rho, \lambda)$$

where $\mathcal{M}$ *is a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase-space packet,* $\mathcal{O}$ *is a* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *local-flow source packet,* $p : \mathsf{BHist}$ *is the phase carrier row,* $t : \mathsf{BHist}$ *is the elapsed-time row,* $x : \mathsf{BHist}$ *is the source point row,* $y : \mathsf{BHist}$ *is the target point row,* $\phi : \mathsf{BHist}$ *is the flow endpoint row,* $\omega : \mathsf{BHist}$ *is the ODE dependency witness read from* $\mathcal{O}$*,* ρ *records the* Pkg *provenance of the manifold and ODE dependency packets, and* λ *is the finite* Cont *ledger connecting the source point, elapsed time, local-flow row, and endpoint row.*

The packet is accepted only when the phase carrier and point rows are classified by the $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *surface, the local-flow source row is classified by the* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *surface, and the endpoint row* ϕ *is reached from* (t, x) *by the displayed* Cont *ledger. Two accepted packets classify the same* $\mathsf{DynSystem}^{\uparrow}$ *flow when their phase carrier, time row, source row, target row, ODE source witness, and flow endpoint row are transported by the inherited* hsame *comparisons from* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *while retaining the same* Pkg *provenance.*

Lean4 (definition) `BEDC.Derived.DynSystemUp.DynSystemFlowPacket`

Theorem 195.2 (DynSystemUp carrier flow surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase carrier and an* $\mathsf{Ode}^{\uparrow}$ *BHist local-flow source over that carrier. A* $\mathsf{DynSystem}^{\uparrow}$ *carrier cell is a* BHist *history whose displayed rows consist of the phase-carrier cell, the starting time cell, the starting state cell, the endpoint time cell, the endpoint state cell, the vector-field evaluation ledger, the Picard ledger, and the endpoint ledger of the corresponding* $\mathsf{Ode}^{\uparrow}$ *local-flow row. Thus every visible cell of the dynamical-system surface is read from* BHist *data already carried by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$*.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket flow route readback`

Proof. Read the phase row through the $\mathsf{Manifold}^{\uparrow}$ carrier. The source may be the singleton carrier of BEDC.Derived.ManifoldUp.ManifoldSingletonCarrier or any atlas row exposed by BEDC.Derived.ManifoldUp.ManifoldA in either case the displayed phase cell is a BHist cell with a certificate classifier.

Read the flow row through the $\mathsf{Ode}^{\uparrow}$ local-flow source of Definition 193.1. Its time, state, vector-field, Picard, limit, and endpoint entries are already arranged as BHist histories linked by Cont ledgers. Repacking these entries with the phase row gives the $\mathsf{DynSystem}^{\uparrow}$ carrier surface without introducing a host-level carrier of maps or trajectories. □

Theorem 195.3 (DynSystemUp classifier flow transport)**.** *Let two* $\mathsf{DynSystem}^{\uparrow}$ *carrier cells be displayed from two* $\mathsf{Ode}^{\uparrow}$ *local-flow rows over the same* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase carrier. If the displayed time cells, state cells, Picard histories, vector-field ledgers, and endpoint ledgers are related componentwise by the* hsame *transports supplied by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$*, then the two dynamical-system flow cells are classified as the same* $\mathsf{DynSystem}^{\uparrow}$ *flow.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket classifier flow transport`

Proof. Unpack each $\mathsf{DynSystem}^{\uparrow}$ cell into its phase row and its $\mathsf{Ode}^{\uparrow}$ local-flow row. The phase components are transported by the $\mathsf{Manifold}^{\uparrow}$ classifier, so the chart carrier visible to the flow row is unchanged up to hsame.

Transport the ODE row component by component: first the displayed time cells, then the state cells, then the vector-field ledger, the Picard history, the limit witness, and the endpoint ledger. The $\mathsf{Ode}^{\uparrow}$ classifier treats these as BHist rows and compares them by hsame rather than by equality of external functions.

After transport, both carrier cells expose the same ordered ledger surface. Repacking that transported surface is exactly the $\mathsf{DynSystem}^{\uparrow}$ classifier, so the two flow cells are classified together. □

Theorem 195.4 (DynSystemUp identity flow obligation)**.** *For every* $\mathsf{DynSystem}^{\uparrow}$ *phase-state cell* x *carried by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$*, the identity flow at empty time is represented by the* Cont *unit row*

$$\mathsf{Cont}(\mathsf{BHist.Empty}, x, x).$$

Its $\mathsf{DynSystem}^{\uparrow}$ *carrier ledger has empty displayed time, unchanged displayed state, the trivial Picard route, and endpoint row* x*; this row is classified by the same phase carrier and by the endpoint classifier inherited from* $\mathsf{Ode}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket identity flow obligation`

Proof. Start with the carried phase-state cell x. The empty time cell is the distinguished BHist unit, and the identity route is the empty-time continuation from x back to x.

The Picard part of the ledger is the unit continuation route. Since no nonempty vector-field evaluation is read, the vector-field component is only the displayed empty ledger accepted by the $\mathsf{Ode}^{\uparrow}$ local-flow source.

The endpoint row is again x. The $\mathsf{Manifold}^{\uparrow}$ classifier keeps the phase cell fixed, and the $\mathsf{Ode}^{\uparrow}$ endpoint classifier reads the unit continuation as an endpoint-preserving row. Repacking these rows gives the identity $\mathsf{DynSystem}^{\uparrow}$ flow obligation. □

Theorem 195.5 (DynSystemUp composition flow obligation)**.** *Let* R_{01} *and* R_{12} *be adjacent* $\mathsf{Ode}^{\uparrow}$ *local-flow source rows over the same* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase carrier, with the endpoint time-state*

cell of R_{01} classified with the initial time-state cell of R_{12}. Then $\mathsf{DynSystem}^{\uparrow}$ *represents the composite flow by concatenating the two source rows. The concatenated route is formed by* Cont *associativity on the adjacent Picard and endpoint ledgers, and its endpoint classifier is the* $\mathsf{Ode}^{\uparrow}$ *endpoint classifier transported through the shared phase carrier.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket composition flow obligation`

Proof. Read R_{01} as a local-flow row from (t_0, x_0) to (t_1, x_1), and read R_{12} as a local-flow row from (t_1, x_1) to (t_2, x_2). The adjacency hypothesis says that the middle time-state cell is shared in the $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ classifiers.

Use the Picard continuation scope of Definition 193.3 to concatenate the two Picard routes. The reassociation step is a Cont associativity move, with any syntactic mismatch at the middle cell handled by hsame transport.

The resulting source row has initial cell (t_0, x_0) and endpoint cell (t_2, x_2). Repacking it as a $\mathsf{DynSystem}^{\uparrow}$ flow row gives the composition obligation, and the endpoint determinacy is the classifier inherited from the concatenated $\mathsf{Ode}^{\uparrow}$ row. □

Theorem 195.6 (DynSystemUp Ode generator ledger)**.** *The* $\mathsf{DynSystem}^{\uparrow}$ *generator is hidden only through the* $\mathsf{Ode}^{\uparrow}$ *vector-field row and the* $\mathsf{Manifold}^{\uparrow}$ *chart carrier. Concretely, a* $\mathsf{DynSystem}^{\uparrow}$ *flow ledger records the displayed time cell, phase-state cell, Picard history, endpoint history, the* $\mathsf{Ode}^{\uparrow}$ *vector-field evaluation row, and the* $\mathsf{Manifold}^{\uparrow}$ *chart or singleton carrier row. It contains no additional generator oracle, no external trajectory equality, and no unclassified function-space comparison.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket ode generator ledger`

Proof. Inspect the carrier surface of Definition 195.2. Every time and state entry is a BHist row supplied by the $\mathsf{Ode}^{\uparrow}$ local-flow source, while the phase carrier is supplied by $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$.

The only place where the generator is read is the vector-field evaluation row of the $\mathsf{Ode}^{\uparrow}$ source. Its inputs are the displayed time cell and phase-state cell, and its output is transported by the endpoint classifier described in Definition 195.3.

The only place where coordinates or phase charts are read is the $\mathsf{Manifold}^{\uparrow}$ chart carrier. Therefore the $\mathsf{DynSystem}^{\uparrow}$ ledger hides the generator exactly behind those two certified rows and exposes only BHist, Cont, and hsame obligations to downstream flow-system consumers. □

Theorem 195.7 (DynSystemUp flow endpoint coverage)**.** *Every accepted flow endpoint row ϕ in a packet $\mathcal{D}$ of Definition 195.1 is reached by the displayed* Cont *ledger from the phase row p, elapsed-time row t, source point row x, and Ode local-flow witness ω. Conversely, whenever rows classified by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *supply a phase row, an elapsed-time row, a source point row, a local-flow witness, and a finite* Cont *route ending at ϕ over the same* Pkg *provenance, those rows repack as a* $\mathsf{DynSystem}^{\uparrow}$ *endpoint packet.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket endpoint coverage`

Proof. Project the tuple $\mathcal{D}$ to its fields p, t, x, ϕ, ω, ρ, and λ. By Definition 195.1, the field λ is exactly the finite continuation ledger that connects the source point, elapsed-time row, Ode source witness, and endpoint row inside the accepted packet.

The carrier theorem Definition 195.2 identifies the phase and Ode entries as displayed BHist rows rather than host objects. The generator theorem Definition 195.6 identifies ω as the only generator-facing row used by that endpoint route.

For the converse direction, start with the listed ManifoldUp and OdeUp classified rows together with the shared provenance and finite Cont route. Place them in the ten displayed fields of Definition 195.1; the same route supplies λ, and the classifier transport of Definition 195.3 supplies the inherited hsame comparisons. The resulting tuple is an accepted $\mathsf{DynSystem}^{\uparrow}$ endpoint packet whose public endpoint is ϕ. □

Theorem 195.8 (DynSystemUp phase-Ode classifier exactness)**.** *Two accepted* $\mathsf{DynSystem}^{\uparrow}$ *packets classify together exactly when their ManifoldUp phase-carrier and point rows, OdeUp local-flow rows, elapsed-time rows, endpoint rows, and carried* hsame *transports agree componentwise through the same* Pkg *provenance. No classifier clause may identify two packets by ignoring a displayed phase row, Ode row, elapsed-time row, endpoint row, transport witness, or provenance field.*

Proof. For the forward reading, unpack the public classifier through Definition 195.3. Its comparison first reads the ManifoldUp phase and point rows, then reads the OdeUp local-flow and elapsed-time rows, and finally transports the endpoint and ledger rows by the carried hsame witnesses.

The provenance field is not recomputed by the classifier. It is a projected field of Definition 195.1, so a classifier comparison that keeps the same public flow packet also keeps the same Pkg source for the ManifoldUp and OdeUp dependency packets.

Conversely, assume the listed componentwise comparisons and the shared provenance are already supplied. Apply the carrier surface theorem to read the two packets as the same ordered BHist flow surface, and apply the classifier transport theorem to repack those component comparisons as the public $\mathsf{DynSystem}^{\uparrow}$ classifier. The generator ledger theorem ensures that no hidden vector-field comparison is needed beyond the OdeUp local-flow row already in the list. □

Theorem 195.9 (DynSystemUp dependency provenance exhaustion)**.** *The only dependency rows exported by* $\mathsf{DynSystem}^{\uparrow}$ *are the ManifoldUp carrier and point rows, the OdeUp local-flow source row, the finite* Cont *endpoint ledger, and the shared* Pkg *provenance. The export surface contains no host trajectory space, no external vector-field equality row, and no global existence row.*

Proof. Inspect the carrier tuple in Definition 195.1. Its dependency-facing projections are the ManifoldUp packet $\mathcal{M}$, the OdeUp packet $\mathcal{O}$, the phase and point rows, the Ode witness ω, the continuation ledger λ, and the provenance row ρ.

The surface theorem Definition 195.2 shows that these projections are exactly the displayed BHist cells made available to a flow consumer. The endpoint coverage theorem above then accounts for the only endpoint-producing route, namely the finite Cont ledger from the certified phase, time, source, and Ode witness rows.

Finally apply Definition 195.6. It confines generator access to the OdeUp vector-field evaluation row and confines phase access to the ManifoldUp chart or singleton carrier. Therefore a downstream consumer receives no trajectory-space carrier, no vector-field equality outside the OdeUp row, and no global-existence dependency beyond the displayed provenance surface. □

195.2 The certificate

Theorem 195.10 (DynSystemUp zero-time flow ledger)**.** *For a packet of Definition 195.1, the zero-time row acts as the identity flow packet exactly when the displayed* Cont *ledger begins and ends at the same manifold point row after inherited* hsame *transport. In that case the source row* x*, target row* y*, and endpoint row* ϕ *are all classified with the same* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *point row, and the* Pkg *provenance remains the original dependency provenance.*

Proof. Unpack the flow packet and specialize the elapsed-time row to the zero-time cell carried by the ODE source surface. The local-flow source packet then exposes a trivial time-state route whose initial and terminal time rows are the same certified scalar row.

Project the point component through $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$. The source point is already a carried manifold row, and the zero-time route supplies no additional point movement beyond the displayed endpoint comparison.

Use the visible Cont ledger to identify the source, target, and endpoint rows by hsame. Since the tuple projection leaves ρ unchanged, the identity packet preserves the same Pkg provenance and is therefore the unit row of the dynamical-system certificate. □

Theorem 195.11 (DynSystemUp certified flow composition ledger)**.** *Let $\mathcal{D}_{01}$ and $\mathcal{D}_{12}$ be accepted $\mathsf{DynSystem}^\uparrow$ flow packets whose terminal point and time-state rows are classified with the initial point and time-state rows of the next packet. Certified time concatenation composes their accepted flow endpoint rows by associativity of Cont, and the resulting packet preserves the shared Pkg provenance over $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$.*

Proof. Read the first packet as a finite ledger from the source point x_0 through elapsed time t_{01} to endpoint x_1. Read the second packet as a finite ledger from the classified middle point x_1 through elapsed time t_{12} to endpoint x_2.

The compatibility hypothesis supplies the hsame transport needed to pass from the terminal row of the first packet to the initial row of the second. The ODE source classifier supplies the corresponding time concatenation row, so both pieces live over the same local-flow dependency surface.

Associate the two displayed Cont chains. The composite chain has source x_0, concatenated time row, endpoint x_2, and the same dependency witnesses $\mathcal{M}$ and $\mathcal{O}$.

Finally project the provenance row. Because neither component step changes the Pkg source certificates, the composite packet retains the shared provenance and is a valid $\mathsf{DynSystem}^\uparrow$ flow packet. □

Theorem 195.12 (DynSystemUp ODE source ledger)**.** *Every accepted $\mathsf{DynSystem}^\uparrow$ flow row projects to the $\mathsf{Ode}^\uparrow$ local-flow source row carried by ω. The dynamical-system packet contributes the phase carrier, manifold point classifier, elapsed-time ledger, endpoint row, and provenance binding, but it carries no additional host vector field beyond the $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ dependency row.*

Proof. Project the tuple of Definition 195.1 to its ODE component $\mathcal{O}$ and witness row ω. By acceptance of the packet, ω is already a row of the $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ local-flow source.

The phase component contributes only the carrier and point rows read through $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$. These rows select the manifold side on which the ODE source row is interpreted; they do not define a vector-field row.

The remaining fields t, x, y, ϕ, ρ, and λ are ledger and provenance data. Thus every vector-field evaluation, Picard route, and local endpoint determinacy claim is inherited from $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$, while $\mathsf{DynSystem}^\uparrow$ records how that source is packaged as a phase-space flow. □

Theorem 195.13 (DynSystemUp NameCert obligation surface)**.** *The public $\mathsf{NameCert}_{\mathsf{DynSystem}^\uparrow}$ obligation surface consists exactly of the flow carrier of Definition 195.1, the inherited classifier mediated by hsame over $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$, the zero-time unit ledger of Definition 195.10, the certified composition ledger of Definition 195.11, the ODE-source projection ledger of Definition 195.12, the stability rows obtained by transporting those fields through the same classifiers, and the ledger-exactness condition that every public flow endpoint is reached by the displayed Cont route and Pkg provenance.*

Proof. Collect the carrier fields from Definition 195.1. They provide the phase certificate, ODE source certificate, time row, source point, target point, endpoint, dependency witness, provenance, and finite ledger.

The classifier is componentwise. Manifold carrier and point rows are compared by $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, local-flow rows and elapsed-time rows by $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$, and endpoints by the transported hsame rows recorded in the same ledger.

The unit and composition rows are exactly the first two public laws needed by a flow certificate. The source theorem above supplies the dependency projection that prevents a downstream consumer from reading an uncarried vector field into the packet.

Conversely, every listed consumer reads one of these displayed rows: units read the zero-time ledger, composition reads two compatible ledgers, ODE projection reads ω, and stability reads classifier transport. Therefore the obligation surface is exact and contains no standard bridge, global-existence theorem, or host-level flow object beyond the carried BEDC rows. □

Definition 195.14 (DynSystemUp orbit-iterate packet)**.** *A* $\mathsf{DynSystem}^\uparrow$ *orbit-iterate packet is a finite* BHist *segment*

$$\mathcal{I} = (\mathcal{M}, \mathcal{O}, \nu, \rho, (R_i)_{0\le i<n}, (\alpha_i)_{0\le i<n}, (\beta_i)_{0\le i\le n}, (\lambda_i)_{0\le i<n})$$

displayed over one $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *phase carrier* $\mathcal{M}$ *and one* $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ *source packet* $\mathcal{O}$*. The row* $\nu : \mathsf{BHist}$ *is the unary index history for the finite segment, each* R_i *is an accepted* $\mathsf{DynSystem}^\uparrow$ *flow row of Definition 195.1 over the same phase carrier and ODE source, each* α_i *is the elapsed-time row of* R_i*, each* β_i *is the endpoint row at the* i*th public phase state, and each* λ_i *is the displayed* Cont *ledger from* β_i *through* α_i *to* β_{i+1}*.*

The packet is accepted when the segment provenance ρ *is the shared* Pkg *provenance of the manifold and ODE source packets, every adjacent endpoint pair is related by the inherited* hsame *witnesses needed to read* R_i *and* R_{i+1} *over the same public state, and the unary row* ν *indexes exactly the listed flow rows. Its public data are therefore a finite BHist segment, the two source certificates, the endpoint rows, the segment provenance, and the ordered* Cont *ledger list; it carries no external sequence object beyond these displayed histories.*

Theorem 195.15 (DynSystemUp orbit-iterate carrier closure)**.** *Let* $\mathcal{I}$ *be an accepted* $\mathsf{DynSystem}^\uparrow$ *orbit-iterate packet with terminal endpoint row* β_n*. Let* R_n *be an accepted* $\mathsf{DynSystem}^\uparrow$ *flow row over the same* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *phase carrier and* $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ *source packet, whose initial point and time-state rows are classified with* β_n *by the inherited* hsame *witnesses and whose provenance is the same* ρ*. Then appending* R_n *and its displayed* Cont *ledger to* $\mathcal{I}$ *produces an accepted* $\mathsf{DynSystem}^\uparrow$ *orbit-iterate packet with endpoint row* β_{n+1} *and the same carried phase, source, and segment provenance.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemOrbitIteratePacket carrier closure`

Proof. Unpack the accepted packet $\mathcal{I}$ into its unary index row, flow rows, endpoint rows, provenance row, and ordered Cont ledger list. The terminal endpoint row β_n is already a public BHist row of the packet.

Read R_n through Definition 195.1. The compatibility hypothesis supplies the hsame transport that identifies the initial point and time-state rows of R_n with the terminal public state of $\mathcal{I}$, and the provenance hypothesis keeps the same Pkg row.

Extend the unary index row by one successor cell and append the new flow row, elapsed-time row, endpoint row, and ledger. The only composition work is the reassociation of the existing

terminal Cont chain with the ledger of R_n, which is the same associativity move used in Definition 195.11.

Repack the displayed fields in the form of Definition 195.14. All acceptance clauses are inherited from the old packet or from R_n, so the carried packet remains over the same phase carrier, ODE source, and segment provenance. □

Theorem 195.16 (DynSystemUp invariant consumer projection)**.** *Let C be a downstream consumer predicate on accepted* $\mathsf{DynSystem}^{\uparrow}$ *orbit-iterate packets whose value is read only from the projected* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase row, the projected* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *source row, the endpoint rows β_i, the displayed* Cont *ledgers λ_i, the inherited* hsame *witnesses at adjacent endpoints, and the shared* Pkg *provenance ρ. If two accepted orbit-iterate packets are related by the* $\mathsf{DynSystem}^{\uparrow}$ *classifier transport on those displayed rows, then C has the same truth value on both packets.*

Proof. Project both orbit packets to the rows named in the statement. The consumer ignores every component outside this projection, so it cannot observe the syntactic presentation of the surrounding tuple.

Use the $\mathsf{DynSystem}^{\uparrow}$ classifier transport componentwise. The phase row is transported by $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, the ODE source row by $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$, and the endpoint and ledger rows by the hsame witnesses carried in the packets.

The provenance projection is unchanged because both packets expose the same Pkg source row after classifier transport. Therefore every argument supplied to C is transported to the corresponding displayed argument of the other packet.

Since C is defined only from those projected arguments, the two evaluations are the same. This proves that consumer-visible invariants are invariants of the DynSystem classifier rather than of a particular tuple presentation. □

Theorem 195.17 (DynSystemUp flow segment exhaustion)**.** *Every public finite segment of an accepted* $\mathsf{DynSystem}^{\uparrow}$ *orbit-iterate packet is obtained from its first endpoint row by repeated use of the zero-time ledger of Definition 195.10 and the certified composition ledger of Definition 195.11. Equivalently, no additional public segment operation is needed beyond selecting a finite consecutive sublist of displayed flow rows and composing their* Cont *ledgers in order.*

Proof. Proceed by induction on the length of the selected consecutive segment. For the empty segment, use the zero-time ledger of Definition 195.10; the source and endpoint rows are the same after the packet's inherited hsame transport.

For a one-row segment, read the selected row directly as a packet of Definition 195.1. Its public endpoint is already reached by the displayed Cont ledger in the orbit-iterate packet.

For the step from a length k segment to a length $k+1$ segment, apply the induction hypothesis to the first k rows. The next row is adjacent by the acceptance condition in Definition 195.14, so the terminal endpoint of the prefix is classified with the initial endpoint of the next accepted flow row.

Compose the prefix ledger with the next row using Definition 195.11. Reassociation of the finite Cont chain gives exactly the displayed ledger of the longer segment, and the shared Pkg provenance remains unchanged.

Thus every public finite segment is exhausted by repeated zero-time and composition moves already present in the DynSystem certificate surface. □

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket segment route exhaustion`

Theorem 195.18 (DynSystemUp time reindex stability)**.** *Let F_0 and F_1 be two* $\mathsf{DynSystem}^{\uparrow}$ *flow packets over the same* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase row, source state row, endpoint row, displayed* Cont *ledger, and* Pkg *provenance row. If their elapsed-time rows are related by the* $\mathsf{Ode}^{\uparrow}$ *time classifier and every fixed field is compared by the inherited* hsame *rows of the same packet surface, then F_0 and F_1 are classified by the public* $\mathsf{DynSystem}^{\uparrow}$ *classifier.*

Proof. Project both packets to their $\mathsf{Ode}^{\uparrow}$ local-flow rows by Definition 195.12. The hypotheses keep the phase carrier, source state, endpoint row, continuation ledger, and provenance fixed, so the only moving component is the elapsed-time row read by the $\mathsf{Ode}^{\uparrow}$ source classifier.

Apply the $\mathsf{Ode}^{\uparrow}$ time transport to that projected local-flow row. The transport produces the same source ledger with the reindexed elapsed-time cell and leaves the displayed endpoint comparison on the inherited ledger.

Repack the transported row through Definition 195.3. Since all non-time fields are already compared by the fixed hsame witnesses, the repacked packets are classified by $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$. □

Theorem 195.19 (DynSystemUp endpoint determinacy surface)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase carrier, an* $\mathsf{Ode}^{\uparrow}$ *local-flow source row, an initial time-state row, a displayed* Cont *ledger, and a* Pkg *provenance row. Any two accepted* $\mathsf{DynSystem}^{\uparrow}$ *endpoint rows over that surface are compared exactly by the endpoint classifier inherited from* $\mathsf{Ode}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket endpoint determinacy surface`

Proof. Use Definition 195.12 to project both accepted endpoint rows to the same $\mathsf{Ode}^{\uparrow}$ local-flow source. The fixed phase carrier, initial time-state row, continuation ledger, and provenance ensure that the two projections have the same source ledger.

Apply the $\mathsf{Ode}^{\uparrow}$ endpoint determinacy classifier on that shared source ledger. It compares the two projected endpoint rows without adding a host-level trajectory equality or any generator field outside the carried local-flow source.

Repack the comparison as a $\mathsf{DynSystem}^{\uparrow}$ endpoint comparison. The repacking uses only the fixed $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ phase carrier and the same Pkg provenance, so the public endpoint surface is precisely the inherited $\mathsf{Ode}^{\uparrow}$ endpoint surface. □

Theorem 195.20 (DynSystemUp flow provenance exactness)**.** *Every public* $\mathsf{DynSystem}^{\uparrow}$ *flow consumer row projects to one of the* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *carrier row,* $\mathsf{Ode}^{\uparrow}$ *local-flow row, elapsed-time row, endpoint row, finite* Cont *ledger, or* Pkg *provenance fields of Definition 195.1. Conversely, those displayed rows repack as the public* $\mathsf{DynSystem}^{\uparrow}$ *flow surface.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemFlowPacket flow provenance exactness`

Proof. Inspect the carrier tuple of Definition 195.1. Its projections are exactly the manifold carrier, ODE source row, elapsed-time row, endpoint row, dependency provenance, and finite continuation ledger made available to consumers.

The zero-time and composition consumers read the same tuple through Definition 195.10 and Definition 195.11. The ODE-source consumer reads the projected local-flow row through Definition 195.12, and endpoint consumers read the inherited classifier surface from the same source ledger.

Conversely, a public surface built from those rows is repacked componentwise by the classifier transport and obligation surface of Definition 195.13. No other row is exposed as public flow provenance, so the exported provenance surface is exact. □

Theorem 195.21 (DynSystemUp public flow endpoint exactness)**.** *For every accepted packet $\mathcal{D}$ of Definition 195.1, the public flow endpoint exposed by* $\mathsf{NameCert}_{\mathsf{DynSystem}^\uparrow}$ *is exactly the row ϕ reached by the displayed route*

$$\mathsf{Cont}(t, x, \phi).$$

The route is the λ component of $\mathcal{D}$, its source and endpoint comparisons are transported only by inherited hsame *rows from* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$*, and its dependency origin is the* Pkg *provenance recorded by ρ over the projected packets $\mathcal{M}$ and $\mathcal{O}$.*

Proof. Project the accepted tuple to the fields $\mathcal{M}$, $\mathcal{O}$, ρ, and λ. The first two fields name the manifold and ODE certificates through which the source point, time row, local-flow row, and endpoint row are read.

The ledger field λ is the finite Cont route connecting the displayed source row x, elapsed-time row t, and endpoint row ϕ. Any comparison needed to align the source or terminal rows is already supplied by the inherited hsame classifiers of $\mathcal{M}$ and $\mathcal{O}$.

Finally read ρ. Since the provenance field is projected from the same packet and is not recomputed by a downstream consumer, the exposed endpoint is the carried row ϕ with its original Pkg dependency binding. □

Theorem 195.22 (DynSystemUp flow adjacency classifier)**.** *Let $\mathcal{D}_{01}$ and $\mathcal{D}_{12}$ be accepted* $\mathsf{DynSystem}^\uparrow$ *packets over the same projected* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ *dependency surface. They compose as adjacent flow packets only when the terminal time-state rows of $\mathcal{D}_{01}$ and the initial time-state rows of $\mathcal{D}_{12}$ are classified together by the ManifoldUp point classifier and the OdeUp local-flow classifier. Under that classifier hypothesis, the composite packet is the certified composition row of Definition 195.11.*

Proof. Read the two packets through Definition 195.11. Its compatibility premise is not an external equality of trajectories; it is the displayed classification of the middle point and time-state rows.

Use Definition 195.3 to identify the classifiers that supply this middle comparison. The phase component is read by $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, while the elapsed-time and local-flow rows are read by $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$.

With those two classifier readings in place, the hypotheses of the composition ledger are exactly the adjacency hypotheses. The resulting concatenated Cont route is therefore the only certified composite exposed by $\mathsf{NameCert}_{\mathsf{DynSystem}^\uparrow}$. □

Theorem 195.23 (DynSystemUp ODE phase-scope separation)**.** *In every accepted* $\mathsf{DynSystem}^\uparrow$ *flow packet, phase rows are read only through* $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$ *and generator rows are read only through* $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$*. The fields p, x, y, and the phase part of ϕ belong to the ManifoldUp reading, while ω and every vector-field or local-flow generator row belong to the OdeUp reading.*

Proof. Project the packet as in Definition 195.12. The ODE source is carried by $\mathcal{O}$ and witnessed by ω, so generator information enters the dynamical-system packet only through the $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$ local-flow source row.

Next apply Definition 195.6. It identifies the chart or singleton carrier as the ManifoldUp side and the vector-field evaluation row as the OdeUp side.

Thus the two readings have disjoint scopes inside the packet: phase classification is routed through $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, and generator classification is routed through $\mathsf{NameCert}_{\mathsf{Ode}^\uparrow}$. The packet itself only records their BHist ledger and provenance binding. □

Theorem 195.24 (DynSystemUp flow consumer projection coverage)**.** *Every downstream consumer whose output is invariant under the exposed phase rows, elapsed-time rows, source and endpoint rows, ODE-source row, displayed* Cont *ledger, inherited* hsame *transports, and* Pkg *provenance of Definition 195.13 is invariant under the whole accepted* $\mathsf{DynSystem}^{\uparrow}$ *flow packet. No additional packet field can change such a consumer.*

Proof. Project an accepted packet to the obligation surface of Definition 195.13. This yields the phase certificate, ODE source certificate, time row, source point, target point, endpoint row, dependency witness, provenance, and finite continuation ledger.

Now compare two accepted packets whose listed rows are related by the exposed classifiers. The phase, source, target, and endpoint readings are transported by $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, while the elapsed-time, local-flow, and ODE-source readings are transported by $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$.

The consumer is invariant under exactly these projections, including the Cont route, hsame transports, and Pkg provenance. Since the displayed tuple of Definition 195.1 has no further public row beyond those projections, the consumer has the same value on the whole packet. □

Theorem 195.25 (DynSystemUp public NameCert export)**.** *The public* $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$ *export surface consists of the carrier of Definition 195.1, the inherited classifier of Definition 195.3, the zero-time row of Definition 195.10, the composition row of Definition 195.11, the ODE-source row of Definition 195.12, the endpoint exactness row of Definition 195.21, the adjacency classifier of Definition 195.22, the phase-scope separation row of Definition 195.23, and the consumer projection coverage row of Definition 195.24.*

Lean4 ✓ `BEDC.Derived.DynSystemUp.DynSystemUp StdBridge`

Proof. Begin with the carrier and classifier. The carrier supplies the displayed BHist tuple, and the classifier transports each visible flow field through the ManifoldUp and OdeUp certificate surfaces.

Add the algebraic flow rows. The zero-time theorem supplies the unit packet, the composition theorem supplies certified concatenation, and the adjacency theorem identifies the classifier premise under which that concatenation is public.

Add the source and projection rows. The ODE-source theorem fixes the generator reading, the phase-scope theorem separates phase and generator access, and the endpoint exactness theorem identifies the exposed endpoint with the displayed Cont route and provenance.

The consumer coverage theorem then states that these rows exhaust the public projections of an accepted packet. Together they form the advertised $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$ export surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$**.**

Constructive story: A dynamical-system row is built by taking an already certified $\mathsf{Manifold}^{\uparrow}$ phase packet and an already certified $\mathsf{Ode}^{\uparrow}$ local-flow packet, then displaying the phase row, elapsed-time row, source and target state rows, endpoint row, ODE dependency witness, provenance, and finite Cont route in one BHist tuple. The carrier accepts exactly those tuples whose phase and point rows are admitted by the manifold certificate, whose local-flow source is admitted by the ODE certificate, and whose endpoint is reached by the displayed route; a tuple missing either dependency surface, the endpoint route, or the shared provenance stays outside the carrier. Two accepted flow packets name the same dynamical-system step when the phase, time, source, target, ODE witness, endpoint, and provenance rows are transported componentwise by the inherited hsame comparisons and by the same visible continuation ledger, rather than by equality of external maps or trajectories. The source specification is the displayed manifold-plus-ODE flow surface, the pattern specification records zero-time identity, segment composition, adjacency, endpoint exactness, and phase-generator separation, and the ledger keeps every public coordinate aligned with the raw route that produced it. The five name-certificate obligations are inherited through that finite packet: an admitted flow supplies inhabitation, componentwise hsame gives reflexivity, symmetry, and transitivity, and classifier transport repacks the transported phase and ODE rows as another admitted flow packet. A packet h lies in the signature gap of a $\mathsf{DynSystem}^{\uparrow}$ token p when the source-domain accepts the displayed phase/ODE tuple, the signature relation pairs it with an answer flow packet and evidence ledger, and

the token-introduction relation names that answer as p; unfolded, the phase carrier, elapsed time, endpoint, ODE source, and continuation route are exactly the rows encoded by p. The chapter registers this routed-flow construction under the name $\mathsf{DynSystem}^{\uparrow}$; flow laws are certified concatenations and unit rows over existing manifold and ODE certificates, with no global existence theorem, invariant-measure object, ergodic package, or independent trajectory carrier introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public export surface of Definition 195.25 covers the displayed BHist flow packet, inherited Cont routes, hsame transports, Pkg provenance, the dependency surfaces of $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$, and the finite hsame-fixed orbit-iterate row of Definition 195.27.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.DynSystemUp.DynSystemFlowPacket\_endpoint\_coverage`

Bridge status: bridgeChecked

Not claimed: This chapter does not claim global existence, uniqueness beyond the displayed OdeUp row, invariant-measure structure, or ergodic consequences.

Upgrade path: No further upgrade – chapter at top of formal axis.

Definition 195.26 (DynSystemUp hsame-fixed one-step row)**.** *Let $\mathcal{D}$ be an accepted* $\mathsf{DynSystem}^{\uparrow}$ *flow packet of Definition 195.1 over phase carrier $\mathcal{M}$, ODE source packet $\mathcal{O}$, elapsed-time row t, displayed source point row p, endpoint row ϕ, provenance row ρ, and ledger λ. The packet is* hsame*-fixed at p when its public endpoint is classified with the displayed source point,*

$$\mathsf{hsame}(\phi, p),$$

and the comparison is carried on the same $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *dependency surface as $\mathcal{D}$.*

Theorem 195.27 (DynSystemUp hsame-fixed orbit-iterate stability)**.** *Let R be an accepted* $\mathsf{DynSystem}^{\uparrow}$ *flow packet of Definition 195.1 over a fixed* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *phase carrier, a fixed* $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ *source packet, elapsed-time row t, displayed source point row p, endpoint row ϕ, provenance row ρ, and continuation ledger λ. Assume that R is* hsame*-fixed at p in the sense of Definition 195.26. Then, for every finite unary horizon ν admitted by Definition 195.14, the orbit-iterate packet obtained by reading R at each successor cell of ν is accepted, has every public endpoint row classified with p, and has an ordered* Cont *ledger list whose entries are copies of λ transported only by the supplied fixed-row comparison* $\mathsf{hsame}(\phi, p)$ *and by* Cont *associativity.*

Proof. Proceed by induction on the displayed unary horizon ν. For the empty horizon, the orbit segment has no successor flow row. Its public endpoint is the initial row p, and the required comparison with p is the reflexive inherited hsame row on the carried ManifoldUp point. The ledger list is empty, so there is no endpoint motion beyond the zero-time row of Definition 195.10.

For the successor step, assume that the prefix segment indexed by ν is an accepted orbit-iterate packet whose terminal public endpoint β_n is classified with p, and whose displayed ledger list consists of transported copies of λ. The fixed-row hypothesis supplies $\mathsf{hsame}(\phi, p)$. By symmetry and transitivity for the inherited endpoint classifier, the terminal comparison $\mathsf{hsame}(\beta_n, p)$ and the fixed comparison $\mathsf{hsame}(\phi, p)$ supply the transport needed to read another copy of R with initial point classified with β_n and terminal endpoint classified again with p.

Apply the carrier-closure theorem Definition 195.15 to append that transported copy of R to the prefix packet. The appended row has the same phase carrier, the same ODE source packet, the same elapsed-time row t, and the same provenance row ρ. Its continuation entry is the same ledger λ, with only the endpoint transports just described inserted at the boundary.

The only ledger operation introduced by the append is reassociation of the finite continuation chain, exactly as in Definition 195.11. Hence the successor packet is accepted by Definition 195.14, its terminal endpoint is classified with p, and its ledger list is the prefix list followed by one further transported copy of λ. Induction over the finite unary horizon gives the stated stability for every displayed iterate. □

Chapter 196

A Concrete Naming Certificate for $\mathsf{Ergodic}^{\uparrow}$

The ergodic-theory interface $\mathsf{Ergodic}^{\uparrow}$ packages a measure-preserving transformation together with the ergodic decomposition of its invariant subspaces. It depends on $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$ (chapter 195) and $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92).

196.1 Carrier definition

Definition 196.1 (ErgodicUp BHist source surface)**.** *An* $\mathsf{Ergodic}^{\uparrow}$ *BHist source surface is a finite package consisting of* $\mathsf{DynSystem}^{\uparrow}$ *transformation rows,* $\mathsf{Measure}^{\uparrow}$ *measure rows, invariant-subspace classifier rows,* hsame *transport rows for the displayed dynamic and measure endpoints, finite* Cont *ledger routes, and* Pkg *provenance for the whole package. A consumer reads the ergodic interface only through these displayed rows.*

Definition 196.2 (ErgodicUp measure-preserving carrier)**.** *An* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier is an accepted Definition 196.1 whose displayed* $\mathsf{DynSystem}^{\uparrow}$ *transformation preserves the displayed* $\mathsf{Measure}^{\uparrow}$ *measure row through the listed finite* hsame, Cont, *and* Pkg *ledger. The carrier records the preservation claim as a finite BEDC row, not as an ambient sigma-algebra identity.*

196.2 The certificate

Theorem 196.3 (ErgodicUp invariant-subspace classifier)**.** *For an accepted* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier, invariant-subspace comparison is read only through the displayed* $\mathsf{DynSystem}^{\uparrow}$ *transformation rows,* $\mathsf{Measure}^{\uparrow}$ *measure rows,* BHist *endpoint rows, and* hsame *transport rows of Definition 196.1. No host sigma-algebra quotient, completed invariant subspace, or external equivalence relation contributes an additional classifier row.*

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingSurface invariant subspace classifier`
Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicBHistSourceSurface invariant subspace classifier`

Proof. Project the accepted carrier to its $\mathsf{DynSystem}^{\uparrow}$ transformation and $\mathsf{Measure}^{\uparrow}$ measure coordinates. These rows supply the only source endpoints for invariant-subspace comparison.

Next project the BHist endpoint and the displayed hsame transports. Repacking these finite rows gives the invariant-subspace classifier seen by a consumer.

The source package has no field for a host sigma-algebra quotient, completed invariant subspace, or external equivalence relation. Those data therefore cannot refine the displayed classifier. □

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingCarrier invariant subspace classifier`

Theorem 196.4 (ErgodicUp decomposition ledger)**.** *Every decomposition witness exposed by an accepted* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier is exhausted by the finite invariant-row ledger of Definition 196.1: the displayed invariant-subspace classifier rows, the* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance. The witness imports no host sigma-algebra quotient.*

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingSurface decomposition ledger`

Proof. First read the carrier through Definition 196.3. This reduces every decomposition comparison to the displayed transformation, measure, BHist, and transport rows.

Then project the finite Cont routes and Pkg provenance. These rows record how each invariant-row witness is carried through the package and give the full decomposition ledger available to downstream analysis consumers.

Since the carrier boundary contains no host sigma-algebra quotient, projecting and repacking the ledger cannot introduce one. The displayed finite invariant ledger therefore exhausts the decomposition witness. □

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingCarrier decomposition ledger`

Theorem 196.5 (ErgodicUp NameCert obligation surface)**.** *The* $\mathsf{Ergodic}^{\uparrow}$ *NameCert obligation surface packages the Definition 196.2, the invariant-subspace classifier of Definition 196.3, the transport stability rows, and the decomposition ledger of Definition 196.4. It exposes exactly the displayed* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{Measure}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* Pkg *rows needed by downstream analysis consumers.*

Proof. Start with the accepted measure-preserving carrier. Its displayed preservation row supplies the carrier endpoint over the dynamic and measure source rows.

Use the invariant-subspace classifier theorem to identify the classifier rows available to a consumer, then use the decomposition ledger theorem to identify the finite witness ledger and provenance rows. These two projections supply the stability and ledger components of the NameCert obligation surface.

Finally repack the carrier, classifier, stability, and ledger rows into one finite BHist package. The package has no additional field beyond the displayed $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Measure}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows, so it is the concrete $\mathsf{Ergodic}^{\uparrow}$ obligation surface. □

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingCarrier semantic name certificate`

Definition 196.6 (ErgodicUp invariant-row subledger restriction)**.** *Let* $\mathcal{E}$ *be an accepted* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier of Definition 196.2. An invariant-row subledger restriction of* $\mathcal{E}$ *is a finite packet* $\mathcal{E}|_I$ *formed as follows. It keeps the displayed* $\mathsf{DynSystem}^{\uparrow}$ *transformation rows, the displayed* $\mathsf{Measure}^{\uparrow}$ *measure rows, the* BHist *endpoint rows, the measure-preservation row, all* hsame *transports for the dynamic and measure endpoints, all finite* Cont *routes used by the preservation row, and the same* Pkg *provenance. Its invariant-subspace classifier ledger is a displayed finite subledger* I *of the invariant-subspace classifier rows of* $\mathcal{E}$*, with each retained row carrying its original endpoint witnesses and its original transport route. No row outside* I *is readable as an invariant-subspace row of* $\mathcal{E}|_I$*.*

Theorem 196.7 (ErgodicUp invariant subledger restriction stays carried)**.** *Let $\mathcal{E}$ be an accepted* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier, and let $\mathcal{E}|_I$ be an invariant-row subledger restriction in the sense of Definition 196.6. Then $\mathcal{E}|_I$ is an accepted* $\mathsf{Ergodic}^{\uparrow}$ *measure-preserving carrier. Its public decomposition ledger is exactly the retained finite invariant-row subledger I together with the unchanged* hsame, Cont, *and* Pkg *rows; in particular, the restriction adds no host sigma-algebra quotient and no completed invariant-subspace row.*

Proof. Project $\mathcal{E}$ to the source surface of Definition 196.1. The restriction keeps the dynamic rows, measure rows, endpoint rows, transport rows, continuation routes, and package provenance unchanged, and replaces the invariant-subspace classifier ledger by the displayed finite subledger I. A finite subledger of a finite ledger is again a finite ledger, so these retained rows form an $\mathsf{Ergodic}^{\uparrow}$ BHist source surface.

The measure-preserving carrier condition of Definition 196.2 is read from the displayed $\mathsf{DynSystem}^{\uparrow}$ transformation, the displayed $\mathsf{Measure}^{\uparrow}$ measure row, and the listed finite hsame, Cont, and Pkg ledger. None of those rows is removed or altered by Definition 196.6. The same preservation row therefore witnesses the carrier condition for $\mathcal{E}|_I$.

It remains to identify the public invariant data exposed by the restricted packet. By Definition 196.3, invariant-subspace comparison for $\mathcal{E}$ is read only through the displayed invariant rows and their hsame transports. The restricted packet displays exactly the rows in I, with the same endpoint witnesses and transport routes, so its classifier has no additional invariant row to read. By Definition 196.4, every decomposition witness is exhausted by the displayed finite invariant ledger, the hsame transports, the finite Cont routes, and Pkg provenance. After restriction this exhaustion ranges precisely over I and the unchanged route and provenance rows. Since neither the original surface nor the restriction has a coordinate for a host sigma-algebra quotient or completed invariant subspace, acceptance is preserved and no outside decomposition row is introduced. □

Lean4 ✓ `BEDC.Derived.ErgodicUp.ErgodicMeasurePreservingCarrier invariant subledger restriction stays carried`

Closure status for $\mathsf{NameCert}_{\mathsf{Ergodic}^{\uparrow}}$.

Constructive story: An $\mathsf{Ergodic}^{\uparrow}$ packet is generated from DynSystemUp transformation rows, MeasureUp measure rows, invariant-subspace classifier rows, measure-preservation evidence, finite BHist endpoint rows, componentwise hsame transport, Cont ledger routes, and Pkg provenance. The classifier reads ergodic decomposition only through displayed invariant rows and their transport routes; a subledger restriction is generated by retaining a finite invariant-row subledger and the unchanged preservation, transport, route, and provenance rows. The ledger story is finite invariant accounting: decomposition data is carried as displayed rows over the dynamic and measure sources, not as a host sigma-algebra quotient or completed invariant subspace.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Ergodic}^{\uparrow}}$, scopedClosed)

Scope closed: This chapter binds the measure-preserving carrier, invariant-subspace classifier, transformation and invariant-measure rows, invariant subledger restriction, and the concrete BHist, hsame, Cont, Pkg, and NameCert rows consumed by the displayed proof routes.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Ergodic}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim host sigma-algebra quotients, completed invariant subspaces, off-ledger invariant rows, or ambient ergodic decomposition beyond the displayed finite ledger.

Upgrade path: Further closure requires a public bridge from the displayed DynSystemUp, MeasureUp, BHist, hsame, Cont, Pkg, and NameCert rows into a reusable ergodic decomposition interface.

Chapter 197

A Concrete Naming Certificate for $\mathsf{FirstOrder}^{\uparrow}$

The first-order-logic interface $\mathsf{FirstOrder}^{\uparrow}$ packages a signature of relation and function symbols, a set of formulas, and a deduction calculus together with the soundness and completeness data. It depends on $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ (chapter 111) and $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$ (chapter 119).

197.1 Carrier definition

Definition 197.1 (FirstOrderUp BHist syntax carrier)**.** *A carried* $\mathsf{FirstOrder}^{\uparrow}$ *syntax packet is a displayed* BHist *tuple* $(S, T, V, R, F, \tau, \varphi, \rho)$*. The row* S *is the* $\mathsf{Set}^{\uparrow}$ *symbol-source row,* T *is the* $\mathsf{Tree}^{\uparrow}$ *parse-tree row,* V *is the variable ledger,* R *and* F *are the relation-symbol and function-symbol rows,* τ *is the finite term/formula tree endpoint,* φ *is the displayed formula endpoint, and* ρ *records the* Pkg *provenance that ties the syntax packet to the visible naming certificate.*

Acceptance of the packet is read entirely through BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*, and the* $\mathsf{Set}^{\uparrow}$ *and* $\mathsf{Tree}^{\uparrow}$ NameCert *rows. A host grammar, a host set of strings, or an external syntax equality is not part of the carrier.*

Lean4 (definition) `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier`

Definition 197.2 (FirstOrderUp deduction ledger classifier)**.** *Two* $\mathsf{FirstOrder}^{\uparrow}$ *syntax/deduction packets agree when their symbol rows, parse-tree rows, formula endpoint rows, and deduction-step ledgers are transported by* hsame *through the same* $\mathsf{Set}^{\uparrow}$ *and* $\mathsf{Tree}^{\uparrow}$ *certificates. The comparison is rowwise: relation symbols and function symbols move through the* $\mathsf{Set}^{\uparrow}$ *source, parse subtrees and formula endpoints move through the* $\mathsf{Tree}^{\uparrow}$ *source, and every deduction step carries its premise and conclusion endpoints by the displayed* Cont *and* hsame *rows recorded in the ledger.*

197.2 The certificate

Theorem 197.3 (FirstOrderUp formula carrier obligation)**.** *Every accepted* $\mathsf{FirstOrder}^{\uparrow}$ *formula row projects to a* $\mathsf{Set}^{\uparrow}$ *symbol row, a* $\mathsf{Tree}^{\uparrow}$ *parse row, a finite* ProbeBundle *arity ledger, and a* SigRel *endpoint relation. These projections are exactly the visible carrier data of Definition 197.1; no formula is accepted by a host syntax predicate outside the displayed* BHist *packet.*

Proof. Invert the carried syntax packet of Definition 197.1. The first projections expose the $\mathsf{Set}^{\uparrow}$ symbol-source row, the $\mathsf{Tree}^{\uparrow}$ parse-tree row, the relation and function symbol rows, and the formula endpoint φ.

The arity information is read from the finite ProbeBundle ledger attached to the displayed relation and function rows. Each arity check is therefore a finite probe over the named symbol endpoints, not an inspection of an ambient syntax table.

Finally apply induction on the $\mathsf{Tree}^{\uparrow}$ syntax row. Leaf rows read variables and constants from the symbol and variable ledgers; internal rows read their subformula endpoints from the same finite tree ledger. The endpoint relation is the displayed SigRel row tying the resulting formula endpoint to the accepted packet. □

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier formula carrier obligation`

Theorem 197.4 (FirstOrderUp classifier transport obligation)**.** *Every classifier-related* $\mathsf{FirstOrder}^{\uparrow}$ *syntax and deduction packet transports its relation-symbol rows, function-symbol rows, formula endpoints, and deduction-step ledgers through the displayed* $\mathsf{Set}^{\uparrow}$, $\mathsf{Tree}^{\uparrow}$, hsame, Cont, ProbeBundle, *and* SigRel *rows of* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$. *In particular, a transported classifier packet is obtained by projecting those visible rows from the source packet and repacking them as the corresponding target packet; no host syntax equality or external classifier relation is used.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier classifier transport obligation`

Proof. Start with an accepted classifier-related packet and invert the carried BHist tuple of Definition 197.1. The projections expose the $\mathsf{Set}^{\uparrow}$ symbol-source row, the $\mathsf{Tree}^{\uparrow}$ parse-tree row, the relation-symbol and function-symbol rows, the formula endpoint, and the deduction-step ledger.

Transport the symbol rows through the displayed $\mathsf{Set}^{\uparrow}$ certificate and the parse and formula rows through the displayed $\mathsf{Tree}^{\uparrow}$ certificate. The ProbeBundle rows carry the arity checks, while the SigRel rows carry the endpoint relation that identifies the source and target formula endpoints.

It remains to repack the deduction data. Use the Cont and hsame rows attached to each ledger step to move premises and conclusions through the same provenance. The repacked rows form another displayed $\mathsf{FirstOrder}^{\uparrow}$ classifier packet, and every field of that packet has been obtained from the public certificate surface. □

Theorem 197.5 (FirstOrderUp deduction endpoint exactness)**.** *The visible* $\mathsf{FirstOrder}^{\uparrow}$ *deduction endpoints are exact. Every accepted conclusion endpoint is produced by a finite displayed deduction ledger whose premises are already accepted formula endpoints, and every such finite ledger repacks as a* $\mathsf{FirstOrder}^{\uparrow}$ *deduction endpoint with the same conclusion row.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier deduction endpoint exactness`

Proof. For coverage, invert an accepted deduction endpoint. By Definition 197.8, the endpoint is visible only through the syntax carrier, the deduction classifier, and the displayed deduction-soundness ledger. Thus its conclusion row is the final conclusion of a finite ledger over formula endpoints already carried by Definition 197.3.

For soundness, induct over the finite ledger. The empty ledger exposes only initial accepted formula endpoints. In the step case, the induction hypothesis supplies accepted endpoints for the earlier premises, and Definition 197.7 supplies the visible Cont and hsame rows for the next rule step and its conclusion.

For completeness, start with a finite displayed ledger whose premises are accepted formula endpoints and whose steps carry the required transport rows. Repack the formula endpoints by the carrier obligation, repack the rule rows by the deduction-soundness obligation, and read the last conclusion row as the displayed $\mathsf{FirstOrder}^{\uparrow}$ deduction endpoint. □

Theorem 197.6 (FirstOrderUp ModelTheory consumer boundary)**.** *A downstream* $\mathsf{ModelTheory}^{\uparrow}$ *packet may consume from* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *only the symbol source, parse-tree source, formula endpoint rows, deduction endpoint rows, classifier transport rows, and provenance rows exposed by the* $\mathsf{FirstOrder}^{\uparrow}$ *certificate. The* $\mathsf{FirstOrder}^{\uparrow}$ *certificate alone supplies no host syntax equality, external proof-system validity predicate, semantic satisfaction relation, or model carrier.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier modeltheory consumer boundary`

Proof. Project the public surface described in Definition 197.8. The available rows are the syntax carrier, the deduction classifier, the formula and deduction obligation rows, and the $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ provenance rows.

Next apply Definition 197.4. It shows that classifier transport for relation symbols, function symbols, formula endpoints, and deduction ledgers is already accounted for by the displayed hsame, Cont, ProbeBundle, and SigRel rows.

Finally apply Definition 197.5. It makes the deduction endpoint rows exact, so a consumer can read precisely the finite ledgers and their accepted conclusion endpoints. None of the projected or repacked rows contains a semantic satisfaction relation or model carrier, and none asserts an ambient proof-system validity predicate outside the displayed BEDC ledger. □

Theorem 197.7 (FirstOrderUp deduction soundness ledger obligation)**.** *A* $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledger is accepted only when every rule step consumes formula endpoints already carried by Definition 197.1 and records its premise/conclusion transport by* Cont *and* hsame*. The ledger does not validate a rule by appeal to an external proof system; validity is the finite display of named endpoint consumption and transport.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier deduction soundness ledger obligation`

Proof. Induct over the finite displayed deduction ledger.

In the empty case there is no rule step to validate. The ledger acceptance condition reduces to the visibility of the initial formula endpoints already carried by the syntax packet.

In the step case, the induction hypothesis gives accepted carried endpoints for all earlier premises. The next rule row must cite only those endpoints, record the conclusion endpoint as another displayed formula row, and attach the Cont and hsame transport rows that move premises to the conclusion inside the same $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ provenance.

Appending the checked step preserves acceptance because the new ledger tail adds one finite row whose inputs, output, and transport are all visible BEDC rows. Thus the completed deduction remains a named ledger rather than a host derivation. □

Theorem 197.8 (FirstOrderUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *surface consists exactly of the syntax carrier of Definition 197.1, the deduction classifier of Definition 197.2, the formula carrier obligation of Definition 197.3, the deduction-soundness ledger of Definition 197.7, the* $\mathsf{Set}^{\uparrow}$ *symbol provenance, the* $\mathsf{Tree}^{\uparrow}$ *syntax provenance, stability under* hsame*, and exactness of displayed formula and deduction endpoints.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier namecert obligation surface`

Proof. Collect the carrier rows first. The syntax carrier supplies the displayed BHist packet, and the formula carrier obligation projects from it the symbol source, parse source, arity ledger, and endpoint relation.

Next collect the comparison rows. The deduction classifier supplies the rowwise hsame transport through the same $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ certificates, while the deduction-soundness ledger supplies the finite rule steps that consume already carried endpoints and produce displayed conclusion endpoints.

It remains to check public coverage. Any consumer of $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ asks for a syntax endpoint, a deduction endpoint, provenance in $\mathsf{Set}^{\uparrow}$ or $\mathsf{Tree}^{\uparrow}$, transport under hsame, or exact readback of a visible formula or deduction row. Each request is one of the rows just collected, so the public surface contains no additional carrier, classifier, or proof-system field. □

Definition 197.9 (FirstOrderUp deduction ledger concatenation source)**.** *Fix one carried* $\mathsf{FirstOrder}^{\uparrow}$ *syntax packet as in Definition 197.1. Let D_1 and D_2 be accepted finite* $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledgers read through the same* $\mathsf{Set}^{\uparrow}$ *and* $\mathsf{Tree}^{\uparrow}$ *certificates. They are composable when the final conclusion endpoint row displayed by D_1 is the same formula endpoint row that appears as the initial premise row of D_2, with that shared row compared only by the* hsame *transport already admitted by Definition 197.2.*

In that situation, the concatenation $D_1 \mathbin{++} D_2$ is the finite ledger obtained by listing all rule rows of D_1 followed by all rule rows of D_2, while reading the join through the shared formula endpoint row rather than through any extra host-level formula token or external proof-tree node.

Theorem 197.10 (FirstOrderUp deduction ledger concatenation closure)**.** *Let D_1 and D_2 be accepted finite* $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledgers over one carried syntax packet from Definition 197.1, and suppose that D_1 and D_2 are composable in the sense of Definition 197.9. Then the concatenated ledger $D_1 \mathbin{++} D_2$ is again an accepted* $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledger over the same* $\mathsf{Set}^{\uparrow}$ *and* $\mathsf{Tree}^{\uparrow}$ *dependency certificates.*

Moreover, every premise row, conclusion row, and transport row appearing in $D_1 \mathbin{++} D_2$ is already one of the visible rows carried by D_1, by D_2, or by their shared endpoint formula row. No extra deduction rule, external cut formula, or ambient proof-system datum enters at the join.

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderDeductionLedgerConcatenation closure`

Proof. Proceed by induction on the second ledger D_2, read as the finite displayed deduction ledger from Definition 197.7.

If D_2 is empty, then $D_1 \mathbin{++} D_2$ is just D_1, so acceptance is the given acceptance of D_1.

For the step case, write D_2 as a shorter accepted prefix E followed by one final rule row r. By the induction hypothesis, $D_1 \mathbin{++} E$ is an accepted deduction ledger over the same $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ certificates.

It remains to append r. Because E followed by r is accepted, Definition 197.7 says that r consumes only formula endpoints already carried by the displayed ledger before it, and that its premise/conclusion transport is recorded by visible Cont and hsame rows inside the same provenance. Every premise of r that lies wholly inside E is therefore already present in the accepted prefix $D_1 \mathbin{++} E$.

The only additional possibility is a premise of r that traces back to the initial premise row of D_2. By composability from Definition 197.9, that initial premise row is the shared endpoint formula row at the join with D_1. By Definition 197.3, this shared endpoint is already a carried $\mathsf{FirstOrder}^{\uparrow}$ formula row inside the same syntax packet, so the join introduces no extra carrier data. By Definition 197.2, any comparison needed at the join is exactly the admitted hsame transport through the same $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ certificates.

Thus all inputs required by r are available in the accepted prefix $D_1 \mathbin{+\!\!+} E$, and the output row of r is recorded by the same visible conclusion and transport data it had inside D_2. Appending r therefore preserves acceptance by the same step-case criterion used in Definition 197.7.

The induction closes, so $D_1 \mathbin{+\!\!+} D_2$ is an accepted finite $\mathsf{FirstOrder}^{\uparrow}$ deduction ledger over the original $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ certificates. The final claim follows because concatenation only reorders the already displayed rows by placing the rows of D_2 after those of D_1, with the join read through the shared endpoint formula row and no further datum. □

Theorem 197.11 (FirstOrderUp hsame stability obligation)**.** *For the public* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *surface, every classifier-related syntax or deduction packet transports its visible endpoints by the displayed* hsame *data. Formula endpoints, deduction-step premise and conclusion endpoints,* $\mathsf{Set}^{\uparrow}$ *symbol rows,* $\mathsf{Tree}^{\uparrow}$ *parse rows, and* Cont *ledger rows remain accepted after transport exactly when the rows are those projected from Definition 197.1 and compared by Definition 197.2.*

Proof. Project the deduction-ledger classifier of Definition 197.2. Its comparison is rowwise, so the relation-symbol and function-symbol rows move through the $\mathsf{Set}^{\uparrow}$ source, while parse subtrees and formula endpoints move through the $\mathsf{Tree}^{\uparrow}$ source.

For a deduction step, use the same classifier row on the displayed premise and conclusion endpoints. The step is accepted only with the attached Cont row and the corresponding hsame row, so transport does not create a new rule premise or a new conclusion outside the ledger.

The carrier rows then identify the endpoints being transported. By Definition 197.1, each formula endpoint and each deduction endpoint cited by the ledger is a row of the same displayed BHist packet. Thus stability is exactly the classifier transport applied to already carried rows. □

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier hsame stability obligation`

Theorem 197.12 (FirstOrderUp endpoint exactness obligation)**.** *Every public* $\mathsf{FirstOrder}^{\uparrow}$ *formula or deduction endpoint readback is exactly one of the endpoints projected from the syntax carrier and the deduction ledger. Conversely, every projected formula endpoint, premise endpoint, conclusion endpoint, and ledger endpoint repacks into the public* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *endpoint surface described by Definition 197.8.*

Proof. For the forward direction, read a public formula endpoint through the carrier of Definition 197.1. The readback exposes the displayed formula endpoint φ, together with its $\mathsf{Set}^{\uparrow}$ symbol row, $\mathsf{Tree}^{\uparrow}$ parse row, finite arity ledger, and SigRel endpoint relation.

A public deduction endpoint is read through the deduction ledger. By Definition 197.7, every premise and conclusion consumed by a rule step is already a carried formula endpoint, and the step records its own Cont and hsame transport rows. Hence no readback endpoint lies outside the projected carrier and ledger.

For the reverse direction, start with a projected carrier or ledger endpoint. The NameCert surface theorem, Definition 197.8, collects exactly these syntax endpoints, deduction endpoints, provenance rows, transport rows, and exact readback rows. Repacking the projection through that surface gives the corresponding public endpoint, and the two constructions expose the same displayed row. □

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier endpoint exactness obligation`

Theorem 197.13 (FirstOrderUp coverage obligation)**.** *Every accepted public* $\mathsf{FirstOrder}^{\uparrow}$ *request is covered by one of the listed certificate rows:* $\mathsf{Set}^{\uparrow}$ *symbol provenance,* $\mathsf{Tree}^{\uparrow}$ *parse provenance, finite* ProbeBundle *arity data, a* SigRel *endpoint relation, a* Cont *transport row, or a* Pkg *provenance*

row. No accepted request requires an additional carrier, classifier, stability, exactness, or coverage field outside the chapter surface.

Proof. Analyze an accepted public request by the part of the $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ surface it asks to read.

1. A syntax endpoint request is covered by Definition 197.1 and Definition 197.3. The former supplies the BHist packet and Pkg provenance; the latter projects the $\mathsf{Set}^{\uparrow}$ symbol row, $\mathsf{Tree}^{\uparrow}$ parse row, finite ProbeBundle arity rows, and SigRel endpoint relation.
2. A deduction endpoint request is covered by Definition 197.7. Each rule step consumes previously carried formula endpoints and records the displayed premise, conclusion, Cont, and hsame rows.
3. A transport request is covered by Definition 197.11. The classifier transports only the already projected symbol, parse, endpoint, and ledger rows, so the request stays inside the displayed carrier and deduction surface.
4. A provenance request is covered by the $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ NameCert rows named in Definition 197.8, together with the Pkg row carried in Definition 197.1.

These cases exhaust the public request forms listed by the NameCert surface theorem. Therefore each accepted request is accounted for by an existing displayed BEDC row. □

Definition 197.14 (FirstOrderUp satisfaction BHist carrier)**.** *A carried* $\mathsf{FirstOrder}^{\uparrow}$ *satisfaction packet is a displayed* BHist *tuple over five visible rows: the* $\mathsf{Set}^{\uparrow}$ *symbol row, the* $\mathsf{Tree}^{\uparrow}$ *formula row, the assignment and environment row, the interpretation row for relation and function symbols, and the finite provenance row. The provenance row records the* Cont*,* hsame*, and* Pkg *data that connect the symbol names, formula endpoint, variable assignment, and interpretation entries to the same visible syntax packet of Definition 197.1.*

The satisfaction predicate is the row classifier of this packet. It accepts only those reads whose formula endpoint is carried by the syntax row, whose free variables are read through the assignment/environment row, whose atomic relation and function entries are read through the interpretation row, and whose recursive connective and quantifier steps are displayed by finite Cont *and* hsame *transport. No host model carrier, ambient truth relation, or unrecorded semantic equality is part of the carrier.*

Lean4 (definition) `BEDC.Derived.FirstOrderUp.FirstOrderBHistSatisfactionCarrier`

Theorem 197.15 (FirstOrderUp soundness transport row)**.** *For every accepted* $\mathsf{FirstOrder}^{\uparrow}$ *deduction step, satisfaction rows transport from the displayed premise packets to the displayed conclusion packet using only the deduction ledger,* Cont*,* hsame*,* $\mathsf{Set}^{\uparrow}$*,* $\mathsf{Tree}^{\uparrow}$*, and* NameCert *provenance recorded in Definition 197.14. Equivalently, if every premise endpoint of a rule step carries a satisfaction packet over the same symbol, assignment/environment, and interpretation rows, then the conclusion endpoint carries the satisfaction packet produced by the rule row and its displayed transport data.*

Proof. Induct over the finite deduction ledger.

In the empty ledger there is no rule step to transport. The only available reads are the carried syntax and satisfaction rows already present in the visible packet.

For a nonempty ledger, apply the induction hypothesis to the earlier rule rows. This supplies satisfaction packets for every previously accepted premise endpoint, all over the same $\mathsf{Set}^{\uparrow}$ symbol row, $\mathsf{Tree}^{\uparrow}$ formula row, assignment/environment row, interpretation row, and provenance row.

The next displayed rule step names its premise endpoints and its conclusion endpoint inside the deduction ledger. Project the accompanying Cont and hsame rows. These rows transport the premise satisfaction packets across the carried formula endpoints and repack the result as the conclusion satisfaction packet.

Appending the transported conclusion preserves the ledger invariant because the new row cites only displayed premises, the displayed rule datum, and the same $\mathsf{Set}^{\uparrow}$, $\mathsf{Tree}^{\uparrow}$, and NameCert provenance. Thus soundness is a finite row transport statement, not an appeal to an unrecorded proof system or model class. □

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSatisfactionCarrier soundness transport row`

Theorem 197.16 (FirstOrderUp completeness boundary)**.** *The* $\mathsf{FirstOrder}^{\uparrow}$ *completeness surface is a BEDC boundary: every public completeness readback exposes a carried syntax row, the satisfaction carrier row of Definition 197.14, a deduction ledger row, and the* Pkg *provenance tying those rows to* $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$*. A readback that requires a host model class, an unrecorded semantic relation, or an external proof system is outside the public* $\mathsf{FirstOrder}^{\uparrow}$ *certificate.*

Proof. Project a public completeness readback from the displayed $\mathsf{FirstOrder}^{\uparrow}$ packet. Its syntax component is one of the carried formula rows of Definition 197.1, and its derivation component is one of the finite rows of Definition 197.2.

Project the semantic component through Definition 197.14. This exposes the assignment/environment row, the interpretation row, and the finite Cont/hsame/Pkg provenance that connects semantic reads to the same displayed formula endpoint.

It remains to check that the readback is complete for the public surface and no larger. Induct over the finite deduction ledger. Initial rows are exactly the carried syntax and satisfaction packets; each rule row is handled by the transport statement of Definition 197.15; the final row is therefore a displayed conclusion packet with the same package provenance.

Any proposed readback field not obtained by these projections has no displayed BHist row, no Cont or hsame transport, and no Pkg route back to $\mathsf{NameCert}_{\mathsf{Set}^{\uparrow}}$ or $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$. Such a field is not admitted by the $\mathsf{FirstOrder}^{\uparrow}$ certificate. □

Theorem 197.17 (FirstOrderUp satisfaction endpoint soundness)**.** *A satisfaction endpoint row for a carried* $\mathsf{FirstOrder}^{\uparrow}$ *formula is sound only when the formula endpoint, the model/source row, and the semantic result row are all displayed* BHist *rows. The three rows must be transported through the same* hsame *and* Cont *ledgers, observed by finite* ProbeBundle *and* SigRel *data, and grounded in the* $\mathsf{Set}^{\uparrow}$*,* $\mathsf{Tree}^{\uparrow}$*, and* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *provenance exposed by Definition 197.8.*

Lean4 ✓ `BEDC.Derived.FirstOrderUp.FirstOrderBHistSatisfactionCarrier satisfaction endpoint soundness`

Proof. Project the carried syntax packet of Definition 197.1. The formula endpoint φ is already a displayed BHist row with $\mathsf{Set}^{\uparrow}$ symbol provenance and $\mathsf{Tree}^{\uparrow}$ parse provenance.

Next project the satisfaction packet. Its model/source row is accepted only as a named source row compatible with the same relation and function symbol rows, and its semantic result row is the endpoint reached from the formula and source rows by the displayed Cont ledger. The finite ProbeBundle probes record the arity and source observations used by that ledger, while SigRel records the endpoint relation being read.

Finally transport the three rows together by the carried hsame witnesses. Because the public surface of Definition 197.8 exports only these rows and their provenance, satisfaction soundness is exactly endpoint soundness inside the BEDC ledger and not a host-level semantic assertion. □

Theorem 197.18 (FirstOrderUp substitution transport obligation)**.** *Let a carried* $\mathsf{FirstOrder}^{\uparrow}$ *formula endpoint contain a variable row or subtree row that is replaced by another carried endpoint related by the deduction classifier of Definition 197.2. Formula acceptance and deduction-ledger acceptance are preserved precisely when every affected symbol, parse, premise, and conclusion row transports rowwise by the inherited* hsame *witnesses and the displayed* Cont *ledgers.*

Proof. Induct on the displayed $\mathsf{Tree}^{\uparrow}$ parse row of the carried formula.

In a leaf case, the replaced variable or constant endpoint is a row in the variable or symbol ledger. The classifier-related replacement supplies the same $\mathsf{Set}^{\uparrow}$ provenance and an hsame witness, so the leaf remains an accepted formula endpoint after the one-row Cont transport.

In an internal subtree case, apply the induction hypothesis to each affected child endpoint. The parent relation or function row is fixed by the $\mathsf{Set}^{\uparrow}$ classifier, and the $\mathsf{Tree}^{\uparrow}$ provenance repacks the transported children as the transported parent endpoint.

For a deduction ledger, induct over the finite rule list. Premise endpoints transport by the formula argument above, and each rule row records its conclusion through the same displayed Cont ledger. Appending the transported rule row preserves ledger acceptance because no step consumes an endpoint outside the rowwise hsame comparison supplied by the classifier. □

Theorem 197.19 (FirstOrderUp completeness boundary obligation)**.** *Any completeness datum exposed by* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *is a displayed BEDC ledger from semantic endpoint agreement back to a finite deduction ledger. It is not host model-theoretic completeness, and it is not an external proof-system oracle: the datum must begin with displayed satisfaction endpoint agreement and end with a finite deduction ledger accepted by Definition 197.7.*

Proof. Project the public surface of Definition 197.8. The available rows are the syntax carrier, the deduction classifier, the formula carrier obligation, the deduction-soundness ledger, and the $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ provenance.

Now read a completeness datum as a finite reverse ledger. Its input is not a class of all host models; it is semantic endpoint agreement between displayed satisfaction rows of Definition 197.17. Each reverse step must name the formula endpoint it consumes, the semantic row it reads, and the deduction endpoint it contributes.

Induct over this finite reverse ledger. The empty case returns the displayed initial deduction ledger. In the step case, the induction hypothesis supplies the earlier finite ledger, and the next reverse row appends one accepted deduction step with its carried premise and conclusion endpoints. The result is therefore a BEDC deduction ledger, which states the completeness boundary without importing an external model theory or proof-system oracle. □

Closure status for $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$**.**

Constructive story: A first-order-logic package is built as a displayed syntax tuple whose histories name the $\mathsf{Set}^{\uparrow}$ symbol source, the $\mathsf{Tree}^{\uparrow}$ parse-tree source, variable, relation-symbol, and function-symbol ledgers, a finite term/formula endpoint, a formula endpoint, and the package provenance tying them to the certificate. The carrier accepts only formulas and deduction endpoints that can be read through those BHist, hsame, Cont, finite probe, and signature-relation rows, while host strings, host grammar tables, external proof-system validity, and semantic model carriers are excluded. Two syntax or deduction packets are classified by rowwise transport of symbol rows through $\mathsf{Set}^{\uparrow}$, parse and formula rows through $\mathsf{Tree}^{\uparrow}$, and every premise and conclusion through the displayed continuation and history-equality ledger. The source is the set-and-tree certificate pair, the pattern records formula construction, arity probes, substitution and deduction-step transport, satisfaction endpoint boundaries, and finite proof ledgers, and the ledger keeps the symbol provenance, parse provenance, rule steps, conclusion endpoints, and package rows visible. The name-certificate obligations follow because an accepted formula packet gives a carrier witness, rowwise hsame supplies reflexive, symmetric, and transitive classification, and classifier transport repacks every transported symbol, subtree, formula, and deduction step as another accepted packet. A packet h lies in the signature gap of a $\mathsf{FirstOrder}^{\uparrow}$ token p when the source-domain accepts its symbol, parse, formula, and deduction ledgers, the signature relation pairs that endpoint with an answer formula or deduction endpoint and evidence

ledger, and the token-introduction relation names the answer as p; unfolded, p records the same displayed syntax tree and finite deduction ledger. The chapter registers this syntax-and-deduction surface under the name $\mathsf{FirstOrder}^{\uparrow}$; it introduces no host syntax equality, model-theoretic completeness theorem, or external proof oracle.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FirstOrder}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper package binds the syntax-and-deduction surface, satisfaction endpoint boundary, substitution transport, finite deduction ledger, and explicit exclusion of host syntax equality.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FirstOrder}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FirstOrderUp.FirstOrderBHistSyntaxCarrier\_formula\_carrier\_obligation`

Bridge status: paperBridge

Not claimed: Host syntax equality and ModelTheoryUp completeness are not claimed by this chapter.

Upgrade path: No further paper-axis closure is claimed here; bridgeChecked remains a separate verification-axis target.

Chapter 198

A Concrete Naming Certificate for $\mathsf{ModelTheory}^{\uparrow}$

The model-theory interface $\mathsf{ModelTheory}^{\uparrow}$ packages a structure for a first-order signature, satisfaction of formulas, elementary equivalence, and elementary substructures. It depends on $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ (chapter 197).

198.1 Carrier definition

Definition 198.1 (ModelTheoryUp BHist structure packet)**.** *A* $\mathsf{ModelTheory}^{\uparrow}$ *source packet is a finite displayed* BHist *tuple* $(S, A, \mathsf{Val}, \mathsf{Sat}, \mathsf{Elem}, \rho, \lambda)$*. The row* S *is the* $\mathsf{FirstOrder}^{\uparrow}$ *signature and formula row,* A *is the displayed structure row,* Val *records variable-assignment observations,* Sat *records the satisfaction ledgers for named formulas and assignments, and* Elem *records elementary-equivalence and elementary-substructure faces. The row* ρ *is the* Pkg *provenance tying the packet to the visible certificate, and* λ *is the* Cont *and* hsame *transport ledger.*

Acceptance of the packet exports only these displayed rows. A host satisfaction relation, an ambient model equality, or an external comparison of structures is not part of the carrier.

Definition 198.2 (ModelTheoryUp satisfaction ledger classifier)**.** *Two* $\mathsf{ModelTheory}^{\uparrow}$ *source packets classify the same row exactly when* hsame *transports their* $\mathsf{FirstOrder}^{\uparrow}$ *signature rows, displayed carrier rows, valuation rows, satisfaction ledgers, elementary-equivalence rows, and* Pkg *provenance through the same* Cont *ledger. The comparison is therefore rowwise: formula and substitution reads move through the* $\mathsf{FirstOrder}^{\uparrow}$ *source, assignments move through* Val*, truth records move through* Sat*, and elementary faces move through* Elem*.*

Definition 198.3 (ModelTheoryUp satisfaction exactness row)**.** *The satisfaction exactness row of a* $\mathsf{ModelTheory}^{\uparrow}$ *packet is the finite* BHist *readback row whose entries are triples consisting of a formula endpoint, an assignment endpoint, and a truth ledger face. Such an entry is accepted exactly when the formula endpoint is read through the* $\mathsf{FirstOrder}^{\uparrow}$ *row* S*, the assignment endpoint is read through* Val*, and the truth ledger is one of the displayed* Sat *faces carried by the same packet.*

The row is exported only with its packet provenance ρ *and its comparison ledger* λ*. It does not contain a host satisfaction predicate, a semantic evaluation function, or an equality of ambient structures.*

Theorem 198.4 (ModelTheoryUp satisfaction exactness scope)**.** *Every readback accepted by Definition 198.3 is scoped by the displayed rows* S*,* Val*,* Sat*, the packet provenance* ρ*, the transport*

ledger λ, and the available hsame *comparisons. No accepted satisfaction readback requires a host satisfaction relation.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket satisfaction exactness scope`

Proof. Project an accepted readback from the exactness row. Its first coordinate is a formula endpoint, so the packet carrier and Definition 198.7 place it in the $\mathsf{FirstOrder}^{\uparrow}$ row S rather than in an independent syntax source.

Project the second coordinate. By the defining acceptance clause it is a displayed assignment read from Val, with the same packet provenance ρ and the same comparison ledger λ.

Project the third coordinate. It is one of the displayed Sat faces, and any comparison of that face is supplied by the rowwise hsame data of Definition 198.2. Repacking these three projections gives the stated scope and leaves no place for a host satisfaction relation. □

Theorem 198.5 (ModelTheoryUp elementary ledger coverage)**.** *The elementary-equivalence and elementary-substructure requests admitted by a* $\mathsf{ModelTheory}^{\uparrow}$ *packet are covered exactly by the displayed* Elem *faces whose formula endpoints are read through S and whose satisfaction references pass through Definition 198.3. No elementary request is accepted outside those faces.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket elementary ledger coverage`

Proof. For an admitted elementary request, project the packet carrier of Definition 198.1. The request must be one of the finite Elem faces, because elementary-equivalence and elementary-substructure data are exported only by that row.

Inside that face, each formula endpoint is a read through the first-order row S. Apply Definition 198.7 to identify that endpoint with the $\mathsf{FirstOrder}^{\uparrow}$ syntax surface, and apply Definition 198.3 to the corresponding satisfaction record.

Conversely, a displayed Elem face whose formula endpoints lie in S and whose satisfaction references are accepted by the exactness row is already one of the exported elementary ledger entries of the carrier packet. Repacking the face gives the elementary request, and no further row is available from the carrier. □

Theorem 198.6 (ModelTheoryUp carrier classifier stability)**.** *Classifier transport preserves both the satisfaction exactness row and the elementary ledger. The preservation is rowwise: formula endpoints, assignment endpoints, satisfaction faces, elementary faces, provenance, and comparison ledgers are transported by* hsame*, and entrywise* Cont *comparison identifies the transported ledger entries with the displayed target entries.*

Proof. Start from the classifier relation of Definition 198.2. It gives rowwise hsame transport for S, A, Val, Sat, Elem, ρ, and the Cont ledger λ.

For a satisfaction exactness entry, transport its formula endpoint along the S comparison, its assignment endpoint along the Val comparison, and its truth face along the Sat comparison. Entrywise Cont comparison identifies the transported provenance with the target packet, so the transported triple is accepted by the target exactness row.

For an elementary ledger entry, transport the displayed Elem face and then apply the previous paragraph to every satisfaction reference inside that face. The resulting face has the same formula scope and the same entrywise ledger comparison in the target packet, so the classifier preserves the elementary ledger as well. □

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket carrier classifier stability`

198.2 The certificate

Theorem 198.7 (ModelTheoryUp FirstOrder dependency surface)**.** *Every admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packet projects its signature row, term/formula grammar row, and substitution-read rows through* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$*. The structure, valuation, satisfaction, and elementary rows may consume those projected first-order endpoints, but they do not export an independent first-order syntax source.*

Proof. Invert the carried packet of Definition 198.1. The first projection is the row S, so the available symbols, terms, formulas, and substitution reads are exactly the rows already visible from $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$.

Project the displayed structure row A and the valuation row Val. Each assignment observation names variables and formula endpoints by referring back to S, so no separate grammar or substitution operation appears in the model-theory carrier.

Finally project the satisfaction and elementary ledgers. Their formula occurrences are read through the same S row, and their provenance is the same Pkg row ρ. Repacking these projections gives the admitted $\mathsf{ModelTheory}^{\uparrow}$ packet with the first-order dependency surface unchanged. □

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket firstorder dependency surface`

Theorem 198.8 (ModelTheoryUp elementary transport)**.** *If two admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packets are related by* hsame *transport of their* $\mathsf{FirstOrder}^{\uparrow}$ *rows and satisfaction ledgers, then their elementary-equivalence and elementary-substructure rows transport as displayed* Elem *rows. This transport uses no host model equality.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket elementary transport`

Proof. Start with the classifier relation of Definition 198.2. It supplies the hsame rows for the first-order source, the displayed structure row, the valuation ledger, the satisfaction ledger, the elementary ledger, and the Pkg provenance.

Use the transported $\mathsf{FirstOrder}^{\uparrow}$ row to move formula endpoints and substitution reads. Use the transported Sat row to move each satisfaction record for the corresponding assignment observation.

The elementary-equivalence and elementary-substructure faces are finite records in Elem. Project those records from the source packet, replace each formula and satisfaction reference by the transported row just obtained, and repack them as the target Elem row. No step compares ambient carriers by a host equality; every comparison is one of the displayed hsame rows. □

Theorem 198.9 (ModelTheoryUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ *obligation surface consists exactly of the carrier of Definition 198.1, the classifier of Definition 198.2, the first-order dependency surface of Definition 198.7, the elementary transport of Definition 198.8, stability transport, the satisfaction exactness ledger, the elementary-equivalence ledger, and no additional exported field.*

Proof. Collect the carrier rows first. The finite BHist packet provides S, A, Val, Sat, Elem, ρ, and λ, while the first-order dependency theorem identifies all syntax and substitution reads as projections through $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$.

Next collect the classifier rows. The satisfaction ledger classifier gives rowwise hsame transport for the first-order source, the structure carrier, valuation observations, satisfaction records, elementary faces, and provenance. The elementary transport theorem repacks the transported satisfaction data into elementary-equivalence and elementary-substructure rows.

It remains to check public coverage. A consumer of $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ can ask for a carrier row, a classifier row, stability under hsame, exact readback of satisfaction records, or the elementary

ledger. Each request is one of the collected rows, and none exposes a host satisfaction predicate, an ambient model equality, or another public field outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket namecert obligation surface`

Definition 198.10 (ModelTheoryUp assignment observation row)**.** *A* $\mathsf{ModelTheory}^{\uparrow}$ *assignment observation row is the displayed* BHist *entry*

$$(S, \varphi, x, \mathsf{Val}_{x,\varphi}, \rho_{\mathsf{Val}}, \lambda_{\mathsf{Val}})$$

whose variable endpoint x *and formula endpoint* φ *are read only through* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$*. The valuation component* $\mathsf{Val}_{x,\varphi}$ *is the visible assignment row for that endpoint pair,* λ_{Val} *records the* Cont *and* hsame *transport available for the observation, and* ρ_{Val} *is the* Pkg *provenance tying the row back to the admitted packet of Definition 198.1.*

Theorem 198.11 (ModelTheoryUp satisfaction exactness row)**.** *Every accepted* $\mathsf{ModelTheory}^{\uparrow}$ *satisfaction record is exactly the visible* Sat *row for a formula endpoint read through* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and an assignment observation of Definition 198.10. Conversely, every such visible* Sat *row repacks as the satisfaction record for the same admitted packet. No host satisfaction predicate is exported.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket satisfaction exactness row`

Proof. Unpack the finite packet of Definition 198.1. The projections expose the first-order row S, the valuation ledger Val, the satisfaction ledger Sat, and the provenance row ρ.

The formula endpoint is read from S through $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$, while the assignment endpoint is read from the displayed valuation row described in Definition 198.10. Thus the satisfaction record has no data source other than the visible pair of endpoints and the packet provenance.

Repack those projections as the same Sat row with its Pkg, Cont, and hsame witnesses. This gives the exact readback direction, and the converse is the same repacking step starting from the displayed row. At no point is a semantic satisfaction relation outside the BHist packet introduced. □

Theorem 198.12 (ModelTheoryUp elementary substructure boundary)**.** *The elementary-equivalence and elementary-substructure faces of an admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packet are finite displayed* Elem *rows transported through the satisfaction exactness row and* hsame*. Every formula occurrence in those faces is a* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *endpoint, and every assignment occurrence is a transported valuation row.*

Proof. Begin with the classifier of Definition 198.2. It supplies the rowwise hsame transports for the first-order source, valuation ledger, satisfaction ledger, elementary ledger, and Pkg provenance.

Apply Definition 198.11 to each satisfaction record referenced by an elementary face. This replaces the record by the visible Sat row for a named formula endpoint and a named assignment observation.

It remains to move the elementary face itself. Replace every formula reference by the transported first-order row and every assignment reference by the transported Val row, then repack the finite face as the target Elem row. The boundary is therefore a displayed ledger boundary, not an ambient elementary-substructure predicate. □

Theorem 198.13 (ModelTheoryUp downstream consumer row)**.** *A downstream consumer of* $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ *can ask only for the carrier packet, the satisfaction-ledger classifier, the assignment observation row, the satisfaction exactness row, the elementary substructure boundary, stability transport, and* Pkg *provenance. Any request for a host truth predicate, an ambient model equality, or an external elementary comparison lies outside the public obligation surface.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket downstream consumer row`

Proof. Project the public surface of Definition 198.9. The visible rows are the carrier packet, the classifier, first-order dependency rows, elementary transport rows, stability transport, satisfaction readback, and provenance.

Refine the satisfaction readback by Definition 198.11. Refine the assignment input by Definition 198.10, and refine the elementary request by Definition 198.12.

These refinements exhaust the consumer-facing rows. Since each row is a projection from the displayed packet or a repacking through Cont, hsame, and Pkg, no consumer receives an operation beyond the listed certificate surface. □

Definition 198.14 (ModelTheoryUp elementary readback ledger)**.** *The elementary readback ledger of an admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packet is the finite displayed* Elem *row of Definition 198.1. Its entries record only elementary-equivalence and elementary-substructure observations whose formula endpoints are read through the transported* $\mathsf{FirstOrder}^{\uparrow}$ *source row, whose truth witnesses are entries of the displayed* Sat *row, and whose provenance is the same* Pkg *row* ρ *carried by the packet.*

Theorem 198.15 (ModelTheoryUp satisfaction exactness ledger)**.** *For any admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packet, every satisfaction record in* Sat *reads back exactly through the displayed* $\mathsf{FirstOrder}^{\uparrow}$ *formula row and the displayed valuation row* Val*. The readback exports the transported formula endpoint, the transported valuation endpoint, the recorded truth entry, and the* Pkg *provenance, and it exports no host satisfaction predicate.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket satisfaction exactness ledger`

Proof. Begin with the packet of Definition 198.1. Its displayed rows include the first-order source S, the valuation ledger Val, the satisfaction ledger Sat, and the provenance row ρ.

Apply the classifier of Definition 198.2. A satisfaction entry is classified rowwise, so its formula endpoint is transported along the $\mathsf{FirstOrder}^{\uparrow}$ row and its assignment endpoint is transported along Val.

Use Definition 198.7 to identify the formula endpoint as a projection through $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$. The truth entry is then the displayed Sat record itself, and its source provenance is the carried Pkg row.

Finally apply Definition 198.8 and Definition 198.9 only to check that this projection lies on the public obligation surface. Those theorems add no host satisfaction predicate, so the readback is exactly the displayed row data. □

Theorem 198.16 (ModelTheoryUp elementary readback boundary)**.** *For any admitted* $\mathsf{ModelTheory}^{\uparrow}$ *packet, elementary-equivalence and elementary-substructure readback is exhausted by the elementary readback ledger of Definition 198.14. In particular, the boundary of the readback consists of the transported* $\mathsf{FirstOrder}^{\uparrow}$ *formula endpoints,* Val *assignment endpoints,* Sat *truth entries,* Elem *elementary faces, and* Pkg *provenance, and it uses no host model equality.*

Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket elementary readback boundary`
Lean4 ✓ `BEDC.Derived.ModelTheoryUp.ModelTheoryElementaryReadbackLedgerSpine normalized cont`

Proof. Project the elementary row from the carrier of Definition 198.1. By definition Definition 198.14, this row is the finite displayed Elem ledger attached to the packet.

The classifier of Definition 198.2 supplies the only allowed transport data: S, A, Val, Sat, Elem, and ρ. Hence every formula occurrence is read through the $\mathsf{FirstOrder}^{\uparrow}$ source row, every assignment occurrence through Val, and every truth occurrence through Sat.

Apply Definition 198.7 for the first-order projection and Definition 198.8 for repacking the elementary-equivalence and elementary-substructure faces. The public surface theorem Definition 198.9 then rules out any additional exported comparison field.

Thus the elementary readback boundary is exactly the displayed Elem ledger together with its named source rows, and no step requires an equality of ambient host models. □

Theorem 198.17 (ModelTheoryUp downstream consumer interface)**.** *Any downstream consumer of* $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ *can consume only the first-order source row, the displayed structure row, the valuation row, the satisfaction exactness row of Definition 198.15, the elementary readback row of Definition 198.14, and the* Pkg *provenance. No downstream interface can demand a host satisfaction predicate, host model equality, or an extra carrier outside those rows.*

Proof. Start from the public obligation surface of Definition 198.9. It lists the carrier, classifier, first-order dependency surface, elementary transport, stability, satisfaction exactness, elementary ledger, and no additional exported field.

Unpack the carrier using Definition 198.1. The consumable rows are S, A, Val, Sat, Elem, ρ, and the transport ledger. The first-order theorem Definition 198.7 identifies S as the only source of formula and substitution reads.

Use the classifier of Definition 198.2 to restrict transport to the displayed rows. The satisfaction exactness theorem gives the allowed truth-record readback, while Definition 198.8 and Definition 198.14 give the allowed elementary readback.

Therefore every downstream request factors through one of the listed rows or through Pkg provenance. Since the obligation surface has no remaining field, no consumer can obtain a host satisfaction predicate, host model equality, or another carrier from $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$**.**

Constructive story: A model-theory packet is generated by taking a $\mathsf{FirstOrder}^{\uparrow}$ signature-and-formula row, a displayed structure row, valuation observations, satisfaction faces, elementary-equivalence and elementary-substructure faces, package provenance, and a continuation/history-equality transport ledger. The carrier accepts only finite BHist tuples whose formulas and substitutions are read through the first-order source and whose valuation, satisfaction, and elementary rows are displayed in the same packet; host satisfaction relations, ambient model equality, and external structure comparisons are not admitted. Two packets are classified rowwise: formula and substitution reads move through $\mathsf{FirstOrder}^{\uparrow}$, assignments through the valuation row, truth records through the satisfaction ledger, elementary faces through the elementary row, and provenance through the same Cont ledger. The source is the first-order certificate surface, the pattern records structure, valuation, satisfaction exactness, elementary readback, and consumer handoff, and the ledger keeps the first-order row, assignment endpoints, truth faces, elementary faces, Pkg provenance, and continuation comparisons visible. The five name-certificate obligations hold because any accepted structure packet gives habitation, the rowwise history classifier is reflexive, symmetric, and transitive, and carrier-classifier stability transports satisfaction exactness and elementary ledgers into a repacked target packet. A packet h lies in the signature gap of a $\mathsf{ModelTheory}^{\uparrow}$ token p when the source-domain accepts its first-order, structure, valuation, satisfaction, and elementary rows, the signature relation pairs the packet with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records exactly those displayed truth and elementary-readback faces. The chapter registers this finite satisfaction-and-elementary ledger under the name $\mathsf{ModelTheory}^{\uparrow}$; it does not introduce completeness, compactness, Lowenheim–Skolem, host model equality, or a standard bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{ModelTheory}^{\uparrow}}$, maturePackageClosed)

Scope closed: The paper bridge boundary runs from FirstOrder$^{\uparrow}$ syntax rows to the ModelTheory$^{\uparrow}$ satisfaction and elementary-equivalence ledger through valuation, readback, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{ModelTheory}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ModelTheoryUp.ModelTheoryBHistStructurePacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close compactness, Lowenheim-Skolem, host model equality, or bridgeChecked verification.

Upgrade path: BridgeChecked verification requires a checked standard bridge target.

Theorem 198.18 (ModelTheoryUp elementary-equivalence reflexivity row)**.** *Let* $(S, A, \mathsf{Val}, \mathsf{Sat}, \mathsf{Elem}, \rho, \lambda)$ *be an admitted* ModelTheory$^{\uparrow}$ *source packet in the sense of Definition 198.1. Then the displayed structure row* A *is classified with itself by the elementary-equivalence part of* Elem*. The diagonal witness is obtained by using* hsame*-reflexivity on the displayed* S*,* A*,* Val*,* Sat*,* ρ*, and* λ *rows, and by reading every formula-assignment truth comparison through Definition 198.3 with identical formula and assignment endpoints. No equality of host models is used.*

Proof. Project the admitted packet. The available rows are exactly S, A, Val, Sat, Elem, ρ, and λ by Definition 198.1; in particular, the carrier exports no ambient model equality and no host satisfaction predicate.

Use reflexivity of hsame from Definition 3.8 on each displayed row of the packet. This gives the trivial transport from S to S, from A to A, from Val to Val, from Sat to Sat, and from the provenance and comparison ledgers to themselves. Thus the two structure endpoints of the elementary-equivalence request are the same displayed row A, compared only by the packet's internal hsame ledger.

Fix any formula endpoint and assignment endpoint cited by the elementary face. Since the formula endpoint is read through S and the assignment endpoint is read through Val, the triple consisting of that formula endpoint, that assignment endpoint, and its displayed truth face is an entry of the satisfaction exactness row of Definition 198.3. Applying the same exactness row to the identical formula endpoint and identical assignment endpoint gives the matching truth readback on the other side of the diagonal comparison.

Now apply Definition 198.5. Its coverage criterion says that an elementary-equivalence request is accepted precisely through a displayed Elem face whose formula endpoints are read through S and whose satisfaction references pass through the satisfaction exactness row. The diagonal request just constructed has exactly those entries: the formula and assignment endpoints are unchanged, and each satisfaction reference is the exactness entry paired with itself.

Repacking these diagonal formula, assignment, satisfaction, provenance, and hsame rows gives the elementary-equivalence face in Elem classifying A with itself. Every component of the witness is a projected or reflexive row of the admitted packet, so the construction never invokes a host model identity. □

Chapter 199

A Concrete Naming Certificate for $\mathsf{Computable}^{\uparrow}$

The computable-function interface $\mathsf{Computable}^{\uparrow}$ packages partial functions $\mathbb{N} \to \mathbb{N}$ defined by Turing-machine simulation up to time-step bounds. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28) and $\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$ (chapter 120).

199.1 Carrier definition

199.2 The certificate

Definition 199.1 (Bounded simulation witness for $\mathsf{Computable}^{\uparrow}$)**.** *Fix a deterministic Turing-machine code P whose input and output tapes carry unary $\mathsf{Nat}^{\uparrow}$ histories. For unary histories n, B, and m, the judgment*

$$\mathsf{BoundedSim}(P, n, B, m)$$

means that there is a $\mathsf{Seq}^{\uparrow}$ trace C of configurations indexed by the unary prefixes of B such that:

1. *the zero-prefix entry is the initial configuration of P on input n;*
2. *every one-step extension in the prefix interval follows the transition relation of P, with halted configurations allowed to repeat;*
3. *the endpoint entry at bound B is halted and reads back the unary output m.*

The trace is a $\mathsf{Seq}^{\uparrow}$ object in the sense of chapter 120, while the bound and output are unary histories in the sense of Definition 28.1. Thus B is an upper bound, not an exact running time.

Definition 199.2 (Bounded $\mathsf{Computable}^{\uparrow}$ graph certificate)**.** *For a partial graph $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$, a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate consists of a deterministic machine code P_F and a $\mathsf{Seq}^{\uparrow}$ unary-bound modulus β_F such that, for all unary n and m,*

$$F(n, m) \iff \mathsf{BoundedSim}(P_F, n, \beta_F(n), m),$$

and any two bounded simulations for the same input return hsame*-classified output histories. The modulus value $\beta_F(n)$ is part of the certificate ledger, so each accepted graph value carries its displayed time-step bound.*

Lean4 (definition) `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate`

Theorem 199.3 (Computable carrier obligation)**.** *Let $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ carry a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate (P_F, β_F) in the sense of Definition 199.2. For every accepted graph row $F(n, m)$, the certificate exposes the unary source input n, the unary output m, the unary bound value $\beta_F(n)$, and a $\mathsf{Seq}^{\uparrow}$ trace carrier whose rows are configurations indexed by the unary prefixes of $\beta_F(n)$.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate carrier obligation`

Proof. Unpack the graph-equivalence clause in Definition 199.2. The accepted row $F(n, m)$ converts to a bounded simulation witness

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m).$$

Now read the witness data from Definition 199.1. Its input and endpoint clauses supply the unary source and unary output histories. Its bound argument is the displayed modulus value $\beta_F(n)$, and the witness itself is a $\mathsf{Seq}^{\uparrow}$ trace of configurations over the unary prefix interval of that bound. These are exactly the carrier rows visible at the public certificate surface. □

Theorem 199.4 (Computable classifier obligation)**.** *Let $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ carry a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate (P_F, β_F). Accepted outputs over the same unary input are classified by hsame: if $F(n, m)$ and $F(n, m')$, then $m \mathsf{hsame} m'$. Moreover, the identity graph $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$ uses exactly the unary $\mathsf{Nat}^{\uparrow}$ classifier, namely $n \mathsf{hsame} m$ between unary input and output histories.*

Proof. For the general certificate, apply Definition 199.13. It expands both accepted rows to bounded simulations at the same displayed bound and then applies the certificate's output-determinacy field, giving $m \mathsf{hsame} m'$.

For the identity graph, unfold Definition 199.14. Its graph predicate is precisely unary source membership, unary output membership, and the classifier clause $n \mathsf{hsame} m$. By Definition 28.27, this is the $\mathsf{Nat}^{\uparrow}$ unary classifier rather than host equality of history terms. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate graph output transport`

Theorem 199.5 (Computable stability obligation)**.** *The bounded $\mathsf{Computable}^{\uparrow}$ certificate interface is stable under identity and bounded-simulation composition. The identity surface is the empty-bound certificate for $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$, and two certified rows $F(n, m)$ and $G(m, k)$ compose to a bounded simulation from n to k with an explicit phase boundary.*

Proof. Identity stability is witnessed by Definition 199.17. Its graph-equivalence field is supplied by Definition 199.16, so the empty-bound halted code realizes exactly the unary classifier identity graph.

Composition stability is Definition 199.11. Given bounded simulations for $F(n, m)$ and $G(m, k)$, the proof concatenates their $\mathsf{Seq}^{\uparrow}$ traces along a displayed continuation witness and records the phase switch as part of the composite deterministic code. The resulting witness is again a bounded simulation, now from n to k. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim output hsame transport`

Theorem 199.6 (Computable ledger obligation)**.** *The visible ledger of a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate consists of the deterministic program code, the displayed unary bound value, the $\mathsf{Seq}^{\uparrow}$ trace, the phase boundary used for composition, and the empty bound used for identity.*

Proof. The deterministic program code and displayed bound are the two certificate fields (P_F, β_F) in Definition 199.2. For an accepted row $F(n, m)$, the graph-equivalence field exposes the concrete bound $\beta_F(n)$ and the bounded simulation witness at that bound.

The trace ledger is the $\mathsf{Seq}^{\uparrow}$ configuration trace named in Definition 199.1. Its zero-prefix row, transition rows, halted repetitions, and endpoint row are the observable rows carried by the witness.

For composition, Definition 199.11 records the phase machine $P_{G \circ F}$ and the boundary between the F trace and the G trace. For identity, Definition 199.15 fixes the displayed bound to $\beta_{\mathsf{id}}(n) = \mathsf{e}$, and Definition 199.17 reads that empty-bound ledger as the identity certificate. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim visible ledger rows`

Theorem 199.7 (Computable bounded graph source and observation carriers)**.** *Every bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate* (P_F, β_F) *for a partial graph* $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ *has the following carrier obligations. Its source carrier and output carrier are unary* $\mathsf{Nat}^{\uparrow}$ *histories in the sense of Definition 28.1. Its observation carrier is the* $\mathsf{Seq}^{\uparrow}$ *trace of configurations indexed by the unary prefixes of the displayed bound* $\beta_F(n)$*, as in chapter 120. Thus any accepted row* $F(n, m)$ *is represented by carrier data*

$$\mathsf{UnaryHistory}(n), \quad \mathsf{UnaryHistory}(\beta_F(n)), \quad \mathsf{SeqTrace}_{P_F}(n, \beta_F(n)), \quad \mathsf{UnaryHistory}(m).$$

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate source carrier obligation`

Proof. Unpack Definition 199.2. The certificate contains a deterministic code P_F and a displayed unary-bound modulus β_F. For a unary source history n, the modulus value $\beta_F(n)$ is a unary history, so the bound is an object of the same unary generation specified in Definition 28.1.

For an accepted row $F(n, m)$, the graph-exactness field gives the corresponding bounded simulation witness of Definition 199.1. That witness supplies a $\mathsf{Seq}^{\uparrow}$ trace of configurations over the unary prefixes of $\beta_F(n)$, with zero row, transition rows, and halted endpoint row. The endpoint readback is the output history m, so the output carrier is again unary by the same local witness and the $\mathsf{Nat}^{\uparrow}$ unary classifier. □

Theorem 199.8 (Computable bounded graph classifier stability)**.** *Let* (P_F, β_F) *be a bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate for* $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$*. If unary inputs* n *and* n' *are classified together by the* $\mathsf{Nat}^{\uparrow}$ *history classifier and* $F(n, m)$ *holds, then transporting the accepted graph row through that classifier preserves bounded simulation output classification. In particular, whenever* $F(n', m')$ *also holds, the two transported outputs satisfy*

$$m \mathsf{hsame} m'.$$

Consequently graph membership transported through the $\mathsf{Nat}^{\uparrow}$ *history classifier preserves the bounded simulation readback class and the single-valuedness of the certified graph.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate classifier stability obligation`

Proof. Convert the accepted row $F(n, m)$ to a bounded simulation by the exactness field of Definition 199.2. The source transport $n \mathsf{hsame} n'$ is a transport along the unary history classifier of Definition 28.1; the transported run uses the same deterministic code and the displayed modulus row assigned to the transported source.

If a second accepted row $F(n', m')$ is present, exactness converts it to a bounded simulation for the same certified graph over the transported source. Apply Definition 199.13 to the two accepted

rows after classifier transport. The conclusion is $m\mathsf{hsame}m'$, which is exactly stability of bounded simulation output classification rather than host equality of histories.

The same argument controls composition. When the transported row is used as a component of a composite run, Definition 199.11 composes the transported bounded trace with the next certified trace, and the output class remains governed by the same single-valuedness theorem. □

Theorem 199.9 (Computable bounded graph ledger exactness)**.** *For every bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate* (P_F, β_F) *for* $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$*, the ledger records the deterministic code* P_F*, the displayed bound modulus* β_F*, the* $\mathsf{Seq}^{\uparrow}$ *simulation trace, and the endpoint readback. Its exactness clause is the displayed equivalence*

$$F(n, m) \iff \mathsf{BoundedSim}(P_F, n, \beta_F(n), m)$$

at that bound, with continuation data recorded by Cont *whenever two certified traces are composed.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraph ledger exactness obligation`

Proof. The deterministic code and modulus are the two explicit fields of Definition 199.2. For each accepted graph row, the forward direction of the displayed equivalence gives the $\mathsf{Seq}^{\uparrow}$ trace and endpoint readback required by Definition 199.1.

Conversely, a bounded simulation at the displayed value $\beta_F(n)$ is converted back to graph membership by the reverse direction of the same equivalence. Thus ledger exactness is an iff between graph membership and bounded simulation at the displayed certificate bound, not an existential statement over hidden running times.

For composed certificates, Definition 4.10 supplies the continuation witness joining the two displayed bounds, and Definition 199.11 builds the composite trace. The endpoint readback of the composite ledger is the endpoint readback of the second trace, while single-valuedness is supplied by Definition 199.13. □

Theorem 199.10 (Computable bounded graph certificate scope)**.** *For every bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate* (P_F, β_F) *for a partial graph* $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$*, the primitive scope of the four certificate obligations is exactly the bounded graph certificate surface. The carrier obligation is scoped by the unary input history* n*, the unary output history* m*, the displayed unary bound* $\beta_F(n)$*, and the* $\mathsf{Seq}^{\uparrow}$ *simulation trace. The classifier obligation is scoped by* hsame *and the* $\mathsf{Nat}^{\uparrow}$ *unary classifier. The stability obligation is scoped by the identity certificate,* Cont *phase-boundary composition, and bounded-simulation single-valuedness. The ledger obligation is scoped by the program code* P_F*, the displayed bound value* $\beta_F(n)$*, the trace, the endpoint readback, and the continuation witness used for composed traces.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate scope`

Proof. Unpack the bounded graph certificate of Definition 199.2. Its fields are the deterministic code P_F, the unary-bound modulus β_F, the graph exactness equivalence with bounded simulation, and output determinacy. The witness format of Definition 199.1 then names the only carrier data used by an accepted row: unary source input, displayed bound, $\mathsf{Seq}^{\uparrow}$ trace, and unary endpoint readback.

The carrier and ledger clauses are therefore the obligations isolated in Definition 199.7 and Definition 199.9. They expose no hidden running-time object beyond $\beta_F(n)$ and no hidden observation object beyond the $\mathsf{Seq}^{\uparrow}$ trace and endpoint readback.

The classifier clause is Definition 199.8: transport is governed by hsame and the unary classifier of $\mathsf{Nat}^{\uparrow}$, and the accepted output class is controlled by Definition 199.13.

Finally, stability is supplied by Definition 199.17 for the identity surface and by Definition 199.11 for phase-boundary composition. Thus Cont records the continuation witness joining displayed bounds, while single-valuedness keeps each certified graph row functional up to the unary classifier. These ingredients are precisely the bounded $\mathsf{Computable}^{\uparrow}$ graph certificate scope. □

Theorem 199.11 (Computable composition by bounded simulation)**.** *Let F and G be partial $\mathsf{Nat}^{\uparrow}$ graphs carrying bounded $\mathsf{Computable}^{\uparrow}$ graph certificates (P_F, β_F) and (P_G, β_G) in the sense of Definition 199.2. Suppose $F(n, m)$ is witnessed by*

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m)$$

and $G(m, k)$ is witnessed by

$$\mathsf{BoundedSim}(P_G, m, \beta_G(m), k).$$

Then there is a unary history B and a deterministic composite machine code $P_{G\circ F}$ such that

$$\mathsf{BoundedSim}(P_{G\circ F}, n, B, k).$$

Consequently the composite graph

$$(G \circ F)(n, k) := \exists m : \mathsf{Nat}^{\uparrow},\ F(n, m) \text{ and } G(m, k)$$

has a certified bounded simulation returning k on input n.

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim composition`

Proof. Write $b_F := \beta_F(n)$ and $b_G := \beta_G(m)$. Since the two certificates are $\mathsf{Seq}^{\uparrow}$ unary-bound moduli over the $\mathsf{Nat}^{\uparrow}$ source, b_F and b_G are unary histories. Apply the continuation rules of Definition 4.10 to choose a history B with $\mathsf{Cont}(b_F, b_G, B)$. By unary closure under continuation from Definition 10.2, B is unary.

Define $P_{G\circ F}$ as the phase machine that first runs P_F on the input tape, reads the halted unary output as the next input tape, and then runs P_G. The phase boundary is exact: the endpoint row of the first bounded trace is halted with output m, which is precisely the initial input required by the second bounded trace.

Build a $\mathsf{Seq}^{\uparrow}$ trace over the unary prefixes of B by prefix recursion along the displayed continuation witness $\mathsf{Cont}(b_F, b_G, B)$. On the first segment, indexed by prefixes of b_F, use the trace supplied by $\mathsf{BoundedSim}(P_F, n, b_F, m)$. At the boundary b_F, the first trace is already halted with output m by Definition 199.1. On the second segment, indexed as the continuation of b_F by prefixes of b_G, use the trace supplied by $\mathsf{BoundedSim}(P_G, m, b_G, k)$.

The transition rows are valid in all cases. Inside the first segment they are the transition rows of P_F; inside the second segment they are the transition rows of P_G; at the boundary they are the phase switch of $P_{G\circ F}$. Halted-state repetition in Definition 199.1 permits the first bounded run to occupy its whole bound before the second phase begins. The endpoint of the composite bound corresponds to the endpoint of the G trace, so it is halted with output k. Hence the assembled trace is a witness of $\mathsf{BoundedSim}(P_{G\circ F}, n, B, k)$. □

Theorem 199.12 (Computable bounded graph certificate is functional)**.** *Let $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ be a partial graph carrying a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate (P_F, β_F) in the sense of Definition 199.2. For unary histories n, m, and m', if $F(n, m)$ and $F(n, m')$ both hold, then m and m' are classified as the same $\mathsf{Nat}^{\uparrow}$ output:*

$$m \mathsf{hsame} m'.$$

Proof. Apply the graph-equivalence clause of the bounded certificate to the first graph membership. It converts $F(n, m)$ into a bounded simulation witness

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m).$$

Apply the same clause to the second graph membership, obtaining

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m').$$

These are bounded simulations for the same deterministic machine code, the same input history, and the same displayed bound, because the bound is the certificate modulus value $\beta_F(n)$. The output-determinacy clause of Definition 199.2 therefore compares their endpoint readbacks and yields $m\mathsf{hsame}m'$. By the unary classifier specification of Definition 28.27, this is exactly sameness of the two $\mathsf{Nat}^{\uparrow}$ output classes. □

Theorem 199.13 (Computable bounded graph single-valuedness)**.** *Let $F \subseteq \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ carry a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate (P_F, β_F) in the sense of Definition 199.2. For unary histories n, m, and m', if $F(n, m)$ and $F(n, m')$ both hold, then the two accepted rows expand to bounded simulations at the same displayed certificate bound,*

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m) \quad \textit{and} \quad \mathsf{BoundedSim}(P_F, n, \beta_F(n), m'),$$

and their output histories are classified together:

$$m\mathsf{hsame}m'.$$

Thus a bounded $\mathsf{Computable}^{\uparrow}$ graph certificate makes the accepted output over each unary input single-valued up to the $\mathsf{Nat}^{\uparrow}$ history classifier.

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim same bound output deterministic`

Proof. Unpack the bounded graph certificate of Definition 199.2. Its graph-equivalence field states, for every unary input and unary output, that graph membership is equivalent to bounded simulation by the certified machine at the certified bound:

$$F(n, x) \iff \mathsf{BoundedSim}(P_F, n, \beta_F(n), x).$$

Apply this field with $x = m$ to the accepted row $F(n, m)$, obtaining

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m).$$

Apply the same field with $x = m'$ to the accepted row $F(n, m')$, obtaining

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m').$$

The two simulations now have the same deterministic code P_F, the same unary input n, and the same displayed ledger bound $\beta_F(n)$. The output-determinacy field of the same bounded graph certificate says that any two bounded simulations for one input return hsame-classified output histories. Applying that field to the two displayed simulation witnesses gives $m\mathsf{hsame}m'$. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate single valuedness`

Definition 199.14 (Unary classifier identity graph)**.** *The identity graph on* $\mathsf{Nat}^{\uparrow}$ *histories is the partial graph*

$$\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m) :\Longleftrightarrow \mathsf{UnaryHistory}(n) \wedge \mathsf{UnaryHistory}(m) \wedge n\mathsf{hsame}m.$$

Its equality content is the unary classifier of Definition 28.27, not host equality of history terms.

Lean4 (definition) `BEDC.Derived.ComputableUp.ComputableUnaryIdentityGraph`

Definition 199.15 (Halted unary identity code with empty bound)**.** *Let* P_{id} *be the one-state deterministic machine code whose unique state is halted. On unary input* n*, its initial configuration already carries* n *on the output tape. Its halted readout is the* $\mathsf{Nat}^{\uparrow}$ *classifier readout: a unary output history* m *is read at that row exactly when* $n\mathsf{hsame}m$*. The halted-state repeat row is the only transition row. Define the displayed bound modulus by*

$$\beta_{\mathsf{id}}(n) := \mathsf{e}.$$

This is the constant-empty $\mathsf{Seq}^{\uparrow}$ *unary-bound modulus, since* e *is unary by Definition 28.1.*

Lean4 (definition) `BEDC.Derived.ComputableUp.ComputableHaltedUnaryIdentityCode`

Lemma 199.16 (Identity empty-bound simulation exactness)**.** *For unary histories* n *and* m*,*

$$\mathsf{BoundedSim}(P_{\mathsf{id}}, n, \beta_{\mathsf{id}}(n), m) \Longleftrightarrow \mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m).$$

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableUnaryIdentityGraph empty bound exactness`
↪ variant `BEDC.Derived.ComputableUp.ComputableUnaryIdentityGraph empty bound simulation exactness`

Proof. Assume first $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m)$. By Definition 199.14, the histories n and m are unary and $n\mathsf{hsame}m$. Use the one-entry $\mathsf{Seq}^{\uparrow}$ trace indexed by the empty bound $\beta_{\mathsf{id}}(n) = \mathsf{e}$. Its zero-prefix entry is the initial configuration of P_{id} on n, which is already halted by Definition 199.15. There are no nontrivial one-step extensions in the empty prefix interval. The endpoint is the same halted row, and its classifier readout accepts m because $n\mathsf{hsame}m$. Hence the trace satisfies Definition 199.1.

Conversely, assume $\mathsf{BoundedSim}(P_{\mathsf{id}}, n, \beta_{\mathsf{id}}(n), m)$. Since the displayed bound is e, the endpoint row is the zero-prefix row. By Definition 199.1, that row is the initial configuration of P_{id} on n and is halted with readout m. The readout clause of Definition 199.15 gives $n\mathsf{hsame}m$, and the simulation witness supplies the unary input and unary output histories. Therefore $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m)$ by Definition 199.14. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableUnaryIdentityGraph empty bound simulation iff`

Theorem 199.17 (Computable identity bounded graph certificate)**.** *The pair* $(P_{\mathsf{id}}, \beta_{\mathsf{id}})$ *is a bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate for* $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$*. In particular, for all unary histories* n *and* m*,*

$$\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m) \Longleftrightarrow \mathsf{BoundedSim}(P_{\mathsf{id}}, n, \beta_{\mathsf{id}}(n), m),$$

and any two bounded simulations for the same unary input return hsame*-classified output histories.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableUnaryIdentityGraph empty bound certificate`

Proof. The program field is the deterministic halted code P_{id} from Definition 199.15. The bound field is the constant-empty $\mathsf{Seq}^{\uparrow}$ unary-bound modulus β_{id}; its value is part of the certificate ledger and is unary for every unary input.

The graph-equivalence field is exactly Definition 199.16, read in both directions. For output determinacy, let

$$\mathsf{BoundedSim}(P_{\mathsf{id}}, n, \beta_{\mathsf{id}}(n), m) \quad \text{and} \quad \mathsf{BoundedSim}(P_{\mathsf{id}}, n, \beta_{\mathsf{id}}(n), m')$$

be two bounded simulations for the same unary input. Applying the reverse direction of Definition 199.16 gives $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m)$ and $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}(n, m')$. Unfolding Definition 199.14 gives $n\mathsf{hsame}m$ and $n\mathsf{hsame}m'$. Symmetry and transitivity of history-sameness from Definition 3.8 yield $m\mathsf{hsame}m'$. These are precisely the fields required by Definition 199.2. □

Theorem 199.18 (Computable bounded graph identity and composition interface)**.** *Bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificates provide an identity and composition interface for partial* $\mathsf{Nat}^{\uparrow}$ *graphs. The identity object is the classifier identity graph* $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$ *of Definition 199.14, certified by Definition 199.17. If* F *and* G *carry bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificates and accepted rows* $F(n, m)$ *and* $G(m, k)$ *are displayed by their certified bounded simulations, then Definition 199.11 supplies a unary bound* B *and a deterministic composite code* $P_{G\circ F}$ *with*

$$\mathsf{BoundedSim}(P_{G\circ F}, n, B, k).$$

Moreover, Definition 199.13 ensures that each certified component graph, and hence the composite graph assembled through its certified middle row, remains single-valued up to the $\mathsf{Nat}^{\uparrow}$ *history classifier rather than becoming a multivalued relation.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim identity composition interface`

Proof. The identity row is already a bounded graph certificate: Definition 199.17 packages the halted identity code P_{id}, the empty bound modulus β_{id}, the exactness equivalence with $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$, and output determinacy. Thus $\mathsf{Id}_{\mathsf{Nat}^{\uparrow}}$ is the neutral graph available at the certificate level, with equality interpreted through $n\mathsf{hsame}m$ by Definition 199.14.

For composition, start from certified rows

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m) \quad \text{and} \quad \mathsf{BoundedSim}(P_G, m, \beta_G(m), k).$$

Apply Definition 199.11. Its construction chooses a continuation witness $\mathsf{Cont}(\beta_F(n), \beta_G(m), B)$ for the displayed bounds, concatenates the two $\mathsf{Seq}^{\uparrow}$ traces along that witness, and runs the phase code $P_{G\circ F}$ first through P_F and then through P_G. The endpoint of the concatenated bound is the endpoint of the second trace, so it reads back k.

It remains to record that the interface is still a partial graph interface. If a certified component accepts two outputs over the same unary input, Definition 199.13 expands both accepted rows to simulations at the same ledger bound and applies output determinacy, yielding hsame-classified outputs. Therefore the middle row used by the composite is determined up to the $\mathsf{Nat}^{\uparrow}$ classifier, and the resulting accepted output row is controlled by the same single-valuedness clause instead of by an unconstrained relation. □

Theorem 199.19 (Computable bounded graph composition associativity)**.** *Let* F*,* G*, and* H *be partial* $\mathsf{Nat}^{\uparrow}$ *graphs carrying bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificates* (P_F, β_F)*,* (P_G, β_G)*, and*

(P_H, β_H). *Suppose accepted rows* $F(n,m)$, $G(m,k)$, *and* $H(k,l)$ *are displayed by bounded simulations*

$$\mathsf{BoundedSim}(P_F, n, \beta_F(n), m), \quad \mathsf{BoundedSim}(P_G, m, \beta_G(m), k), \quad \mathsf{BoundedSim}(P_H, k, \beta_H(k), l).$$

Then the two iterated composite rows $((H \circ G) \circ F)(n,l)$ *and* $(H \circ (G \circ F))(n,l)$ *are represented by bounded simulations whose phase order is* P_F *then* P_G *then* P_H. *Their displayed bounds are compared by the associativity row of* Cont, *and their endpoint output histories are classified by* hsame.

Proof. For the left bracketing, first apply Definition 199.11 to the displayed F and G simulations. This gives a composite code $P_{G \circ F}$, a unary bound B_{GF}, and a continuation witness $\mathsf{Cont}(\beta_F(n), \beta_G(m), B_{GF})$. Apply Definition 199.11 again to the resulting $G \circ F$ simulation and the displayed H simulation, obtaining a code for $(H \circ G) \circ F$ and a bound B_L with $\mathsf{Cont}(B_{GF}, \beta_H(k), B_L)$.

For the right bracketing, first apply Definition 199.11 to the displayed G and H simulations. This gives a composite code $P_{H \circ G}$, a unary bound B_{HG}, and a continuation witness $\mathsf{Cont}(\beta_G(m), \beta_H(k), B_{HG})$. Apply Definition 199.11 again to the displayed F simulation and the resulting $H \circ G$ simulation, obtaining a code for $H \circ (G \circ F)$ and a bound B_R with $\mathsf{Cont}(\beta_F(n), B_{HG}, B_R)$.

Both constructions are built from the same concrete $BHist$ traces. The $\mathsf{Seq}^{\uparrow}$ carrier clauses in Definition 199.1 supply the first trace segment for P_F, the second segment for P_G, and the third segment for P_H; only the parenthesizing of the continuation witnesses changes.

The bound comparison is exactly the associativity clause for the continuation relation of Definition 4.10, together with its unit rows for the empty-bound edge cases. Thus the left and right displayed bounds present the same three-phase continuation data, with phase order P_F, then P_G, then P_H.

Finally, the endpoint row of either iterated simulation is the endpoint row of the H trace. If two representatives for the same iterated composite row are produced through different middle histories, Definition 199.13 first classifies the G endpoints over m and then the H endpoints over k, yielding hsame-classified final output histories. This is a three-certificate composition law over concrete $BHist$ traces, not transport between two abstract source presentations. □

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedSim composition associativity`

Theorem 199.20 (Computable bounded graph scoped certificate)**.** *A bounded* $\mathsf{Computable}^{\uparrow}$ *graph certificate over a partial* $\mathsf{Nat}^{\uparrow}$ *graph is scoped exactly by the BEDC primitives* BHist, UnaryHistory, hsame, *the* $\mathsf{Seq}^{\uparrow}$ *bounded-simulation trace,* ComputableBoundedSim, *the displayed bound modulus, and* Cont *phase composition. For every certificate* (P_F, β_F) *and every accepted row* $F(n,m)$, *the scoped certificate packages the following four rows at the displayed bound* $\beta_F(n)$*:*

1. *the carrier and source row of Definition 199.7:* $\mathsf{UnaryHistory}(n)$, $\mathsf{UnaryHistory}(\beta_F(n))$, $\mathsf{UnaryHistory}(m)$, *and the* $\mathsf{Seq}^{\uparrow}$ *trace used by* $\mathsf{BoundedSim}(P_F, n, \beta_F(n), m)$*;*
2. *the classifier row of Definition 199.8: source transport through* hsame *preserves accepted output classes for the certified bounded simulation;*
3. *the stability row of Definition 199.18: the empty-bound identity certificate and* Cont*-mediated phase composition provide the identity and composition interface for certified partial graphs;*
4. *the ledger and exactness row of Definition 199.9: graph membership is equivalent to* $\mathsf{BoundedSim}(P_F, n, \beta_F(n), m$ *at the displayed certificate bound.*

Lean4 ✓ `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate scoped certificate`

Proof. For the carrier row, apply Definition 199.7. It exposes the unary source, displayed bound, output history, and $\mathsf{Seq}^{\uparrow}$ configuration trace from the bounded simulation witness, all at the certificate value $\beta_F(n)$. These are the local BHist objects seen by the certificate surface.

For the classifier row, use Definition 199.8. It says that transport through the $\mathsf{Nat}^{\uparrow}$ history classifier preserves the accepted bounded-simulation readback class, and Definition 199.13 supplies the same hsame control when two accepted rows share the certified source.

For the stability row, cite Definition 199.18. The neutral graph is the empty-bound identity certificate, while the composite row is built by concatenating two $\mathsf{Seq}^{\uparrow}$ traces along a Cont phase witness and returning a bounded simulation for the composite output.

For the ledger row, apply Definition 199.9. Its two directions identify the accepted graph row with $\mathsf{BoundedSim}(P_F, n, \beta_F(n), m)$ at the displayed bound, so the program code, modulus, trace, endpoint readback, and composition boundary are all recorded inside the scoped certificate rather than left as separate obligations. □

Closure status for $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$.

Constructive story: A computable partial graph is carried by a deterministic machine code together with a displayed unary-bound modulus: for an accepted row $F(n, m)$, the input n, bound $\beta_F(n)$, and output m are unary histories, and a $\mathsf{Seq}^{\uparrow}$ trace of configurations runs along the unary prefixes of that bound. The carrier accepts exactly the bounded simulation package whose zero row is the initial configuration, whose one-step rows follow the transition relation with halted repetitions allowed, and whose endpoint is halted with unary readback m; hidden exact running times, universal machines, and external recursion-theoretic objects are not carrier fields. The classifier uses the $\mathsf{Nat}^{\uparrow}$ history classifier and hsame: accepted outputs over the same certified input and displayed bound are single-valued up to history-sameness, while the identity graph is the empty-bound halted code whose graph predicate is just unary input, unary output, and $n\mathsf{hsame}m$. The source covers unary inputs, unary bounds, unary outputs, deterministic program code, and $\mathsf{Seq}^{\uparrow}$ traces; the pattern records graph exactness, single-valuedness, identity, bounded-simulation composition, composition associativity, and classifier stability; the ledger keeps the code, modulus value, trace, endpoint readback, and Cont phase boundary visible. The five name-certificate obligations are supplied by the inhabited identity certificate, by reflexive, symmetric, and transitive hsame control on unary histories, and by transport and composition rows that repack bounded simulations after classifier movement. A history h lies in the signature gap of a $\mathsf{Computable}^{\uparrow}$ token p when the source-domain accepts the bounded graph row, the signature relation pairs it with an answer row and simulation ledger, and token introduction names that answer as p; unfolded, h is the graph value produced by the deterministic code at its displayed bound, with output matching the unary value encoded by p. The chapter registers this bounded-simulation construction under the name $\mathsf{Computable}^{\uparrow}$; computability here is an explicit time-bounded trace certificate, not a totality claim, halting decision procedure, recursion-theory library, or standard bridge.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridged scope treats the bounded graph public interface of Definition 199.2 and the single-valuedness theorem Definition 199.13 as the bridge boundary, exposing identity, composition, associativity, and the scoped certificate rows of Definition 199.20.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ComputableUp.ComputableBoundedGraphCertificate\_single\_valuedness`

Bridge status: none

Not claimed: The chapter does not close total computability, universal machines, halting decidability, recursion theory, or standard bridge claims.

Upgrade path: The bounded-graph public interface is the mature theory boundary; the remaining verification work is a checked standard bridge for that boundary.

Chapter 200

A Concrete Naming Certificate for $\mathsf{LambdaCalc}^{\uparrow}$

The lambda-calculus interface $\mathsf{LambdaCalc}^{\uparrow}$ packages the inductive carrier of λ-terms together with β-reduction, α-equivalence, and a stability classifier under capture-avoiding substitution. It depends on $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$ (chapter 119) and $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28).

200.1 Carrier definition

Definition 200.1 (LambdaCalc BHist term carrier)**.** *The LambdaCalc BHist term carrier* LambdaCalcBHistTermCa *is the* $\mathsf{Tree}^{\uparrow}$*-backed syntax row whose visible spine is a* BHist *tree with three constructor tags. A variable row has tag* lamVar *and a* $\mathsf{Nat}^{\uparrow}$ *unary variable index* i *with* $\mathsf{UnaryHistory}(i)$*. An abstraction row has tag* lamAbs*, a unary binder index, and one body subtree. An application row has tag* lamApp *and two subtrees. In each case the spine is carried by a* TreeBHistCarrier *row, constructor readback is expressed by* hsame *between the visible tag-and-subtree endpoint and the displayed* BHist *syntax row, and the classifier compares carried terms only through the corresponding* Cont *witness on these visible spines.*

Theorem 200.2 (LambdaCalc variable constructor carrier)**.** *For histories* $i, h : \mathsf{Hist}$*, if* $\mathsf{UnaryHistory}(i)$*, the visible variable constructor row for* h *is a* TreeBHistCarrier *row, and the displayed constructor endpoint satisfies*

$$\mathsf{hsame}(h, \mathsf{lamVar}(i)),$$

then $\mathsf{LambdaCalcBHistTermCarrier}(h)$*. Moreover the carried row keeps the* $\mathsf{Nat}^{\uparrow}$ *index visible: any* Cont *witness transporting* h *to* h' *along a constructor-preserving* $\mathsf{hsame}(h, h')$ *transports the same unary index row and yields* $\mathsf{LambdaCalcBHistTermCarrier}(h')$*.*

Proof. Read the variable row through the visible spine supplied by TreeBHistCarrier. The tag readback identifies the root as lamVar, and the sole payload is the unary history i.

NatUp unary index closure keeps i in the unary fragment under the displayed hsame transport. TreeUp visible-spine transport then carries the tagged endpoint from h to h', so the transported row is again a LambdaCalc carrier row of the variable form. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermCarrier variable constructor carrier`

Theorem 200.3 (LambdaCalc abstraction and application carrier closure)**.** *For histories x, b, f, g, h : Hist, suppose the displayed syntax spines for b, f, and g are $\mathsf{TreeBHistCarrier}$ rows and*

$$\mathsf{LambdaCalcBHistTermCarrier}(b), \quad \mathsf{LambdaCalcBHistTermCarrier}(f), \quad \mathsf{LambdaCalcBHistTermCarrier}(g).$$

If $\mathsf{UnaryHistory}(x)$ *and*

$$\mathsf{hsame}(h, \mathsf{lamAbs}(x, b)),$$

then $\mathsf{LambdaCalcBHistTermCarrier}(h)$*. If instead*

$$\mathsf{hsame}(h, \mathsf{lamApp}(f, g)),$$

then $\mathsf{LambdaCalcBHistTermCarrier}(h)$*. Both conclusions are stable under any constructor-preserving* Cont *transport of the displayed* BHist *spine.*

Proof. For abstraction, use the TreeUp visible-spine row to expose the lamAbs root, the unary binder payload, and the single body subtree. The body is already a LambdaCalc carrier row, and NatUp unary index closure keeps the binder inside the admitted index surface.

For application, use the same TreeUp spine readback with root lamApp and the two carried subtrees f and g. No host syntax operation is used: the two arguments are exactly the displayed BHist subtrees, and the carrier conclusion repacks them through the LambdaCalc definition.

Constructor-preserving Cont transport acts componentwise on the visible spine. It preserves the root tag and transports each carried subtree by hsame, so both constructor clauses remain inside $\mathsf{LambdaCalcBHistTermCarrier}$. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermCarrier abstraction application closure`

Theorem 200.4 (LambdaCalc substitution ledger scope)**.** *Let x, s, t, u : Hist be histories with* $\mathsf{UnaryHistory}(x)$*,* $\mathsf{LambdaCalcBHistTermCarrier}(s)$*, and* $\mathsf{LambdaCalcBHistTermCarrier}(t)$*. A LambdaCalc substitution ledger row for substituting s for the unary variable x in t is in scope only when it is presented by a* BHist *visible-spine traversal whose nodes are carried by* $\mathsf{TreeBHistCarrier}$*, whose recursive calls are connected by* Cont *witnesses, and whose output endpoint u satisfies* $\mathsf{LambdaCalcBHistTermCarrier}(u)$ *together with constructorwise* hsame *readback. The row exports no host substitution function and no unmentioned capture-avoidance primitive.*

Proof. Traverse the displayed TreeUp spine of t. In the variable case, compare the visible NatUp unary index with x and choose either the carried substituent s or the original variable row, with the choice recorded as a BEDC ledger branch rather than a host-language function.

In the abstraction and application cases, use the constructor closure theorem above after recursively transporting the displayed child rows. The Cont witnesses record the recursive route through the visible BHist spine, and every endpoint comparison is an hsame comparison between displayed constructor rows.

Thus the substitution ledger remains a scoped LambdaCalc carrier obligation: it names only BHist, $\mathsf{UnaryHistory}$, $\mathsf{TreeBHistCarrier}$, Cont, hsame, and $\mathsf{LambdaCalcBHistTermCarrier}$ rows. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier substitution ledger scope`

Definition 200.5 (LambdaCalcUp term packet carrier)**.** *A* $\mathsf{LambdaCalc}^{\uparrow}$ *term packet carrier is a finite* BHist *packet*

$$\mathcal{L} = (T, I, a, b, s, \lambda, \rho)$$

over the source rows $\mathsf{NameCert}_{\mathsf{Tree}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Nat}^\uparrow}$*. The row* T *is the displayed* $\mathsf{Tree}^\uparrow$ *syntax row for variables, abstraction nodes, and application nodes. The row* I *is the displayed* $\mathsf{Nat}^\uparrow$ *binder-index row used to name de Bruijn levels, binder depth, and free-variable positions. The row* a *is the alpha-equivalence ledger comparing syntax only through the carried tree and index rows. The row* b *is the beta-redex ledger naming application-abstraction pairs together with their substitution endpoint. The row* s *is the capture-avoidance* Cont *ledger recording renaming, binder shift, and substitution continuations. The row* λ *orders the finite term-construction and reduction steps, and* ρ *is the* Pkg *provenance row for the displayed syntax, index, alpha-equivalence, beta-redex, capture-avoidance, and continuation entries.*

200.2 The certificate

Definition 200.6 (LambdaCalc free-variable ledger packet)**.** *A LambdaCalc free-variable ledger packet is a finite* BHist *packet*

$$\mathcal{F} = (T, I, F, A, B, S, \lambda, \rho)$$

over $\mathsf{NameCert}_{\mathsf{Tree}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Nat}^\uparrow}$*. The row* T *is the TreeUp syntax spine for variables, abstraction nodes, and application nodes. The row* I *is the NatUp binder-index ledger naming de Bruijn levels and binder depth. The row* F *records the free-variable endpoint rows exposed by the syntax traversal. The row* A *records alpha-renaming comparisons, and* B *records beta-redex source and endpoint rows. The row* S *is the finite* Cont *substitution provenance for renaming, binder shift, and capture-avoiding replacement. The row* λ *orders the displayed traversal, and* ρ *is the* Pkg *provenance tying the TreeUp syntax, NatUp indices, free-variable rows, alpha rows, beta-redex rows, and substitution ledger into a single LambdaCalc certificate packet.*

Theorem 200.7 (LambdaCalc free-variable ledger coverage)**.** *Every accepted free-variable endpoint of a* $\mathsf{LambdaCalc}^\uparrow$ *term is projected from a packet of Definition 200.6. More precisely, if* $v : \mathsf{Hist}$ *is accepted as a free variable of a carried* LambdaCalcBHistTermCarrier *term* t*, then there are rows* $T, I, F, A, B, S, \lambda, \rho$ *forming* $\mathcal{F}$ *such that* t *occurs in the TreeUp spine* T*,* v *occurs in the NatUp index ledger* I*, the endpoint row is listed in* F*, and the projection is justified only by the displayed* BHist*,* Cont*,* hsame*,* NameCert*, and* Pkg *rows. No host variable set is exported.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier free variable ledger coverage`

Proof. Induct on the displayed TreeUp spine of the carried LambdaCalc term. In the variable case, the NatUp unary index row is the exposed free-variable endpoint, and the packet records it in F with the same TreeUp and NatUp provenance rows.

For an abstraction node, read the binder index from I and compare it with the free-variable row by the carried hsame ledger. The binder branch removes only the displayed endpoint row from the packet; it does not form a host set of variables.

For an application node, use the two recursive packet projections and concatenate their finite Cont provenance through λ. Repacking the two child rows with the common Pkg provenance gives exactly the accepted endpoint rows in F, so every accepted free-variable endpoint is covered by the finite packet. □

Theorem 200.8 (LambdaCalc capture-avoidance Cont closure)**.** *Let* $x, s, t, u : \mathsf{Hist}$ *be histories with* $\mathsf{UnaryHistory}(x)$*,* $\mathsf{LambdaCalcBHistTermCarrier}(s)$*, and* $\mathsf{LambdaCalcBHistTermCarrier}(t)$*. If a packet of Definition 200.6 displays a capture-avoiding substitution* Cont *ledger from* t *with substituent* s *at the unary variable* x *to endpoint* u*, then* $\mathsf{LambdaCalcBHistTermCarrier}(u)$*. The closure statement is stable under the same TreeUp and NatUp* hsame *rows recorded by the packet.*

Proof. Induct on the TreeUp spine of t. The variable branch compares the visible NatUp index with x inside the finite ledger and chooses either the carried substituent s or the original variable constructor row.

For abstraction, use the binder row in I and the alpha ledger A to rename the binder when the displayed free-variable row would otherwise be captured. The substitution provenance remains a Cont row, and the body endpoint is obtained by the induction hypothesis.

For application, run the induction hypothesis on the two displayed child spines and combine their endpoints with the application constructor closure of Definition 200.3. The resulting endpoint u is therefore a LambdaCalc BHist term carrier, transported only through the listed hsame and Cont rows. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier capture avoidance cont closure`

Theorem 200.9 (LambdaCalc alpha-beta carrier transport)**.** *Suppose two beta-redex packets in Definition 200.6 have TreeUp syntax rows and NatUp binder-index rows related by the alpha ledger A. Then the source application, abstraction body, argument, substitution endpoint, and beta-contractum endpoints transport as* LambdaCalcBHistTermCarrier *rows along the displayed TreeUp and NatUp* hsame *comparisons. Thus alpha-related beta-redex packets determine equivalent carrier endpoints without exporting quotient alpha classes.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha beta carrier transport`

Proof. Read the two beta-redex packets through the TreeUp application spine. The alpha ledger supplies constructor-preserving hsame rows for the application root, the abstraction child, the binder index, and the argument subtree.

Transport the capture-avoidance ledger S along these rows. The preceding closure theorem keeps the substitution endpoint inside LambdaCalcBHistTermCarrier after binder renaming and NatUp index transport.

Finally repack the transported source and endpoint rows as the beta-redex carrier data. Since every comparison is a displayed TreeUp or NatUp hsame row and every route is recorded in Cont, the transported endpoints are carrier-equivalent in the LambdaCalc certificate surface. □

Theorem 200.10 (LambdaCalc carrier reflexivity)**.** *Every accepted* $\mathsf{LambdaCalc}^{\uparrow}$ *term packet over a* $\mathsf{Tree}^{\uparrow}$ *syntax row and a* $\mathsf{Nat}^{\uparrow}$ *binder ledger classifies with itself. The reflexive classifier is the componentwise* hsame *row on the syntax tree, binder indices, free-variable ledger, and package provenance.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier carrier reflexive`

Proof. 1. Traditional target: reflexivity of the lambda-term equality classifier. BEDC source: an accepted LambdaCalcBHistTermCarrier packet whose visible syntax row is supplied by $\mathsf{Tree}^{\uparrow}$ and whose binder indices are supplied by $\mathsf{Nat}^{\uparrow}$.

2. Carrier: keep the same BHist term packet and the same Pkg provenance row. Classifier: use reflexive hsame on the visible TreeUp skeleton, each unary binder index, the free-variable ledger, and the package provenance.

3. Stability and ledger: the identity Cont ledger transports no constructor payload and no binder row. The carried rows are therefore read back through the same visible spine.

4. Core theorem and exactness: the accepted packet classifies with itself, and no endpoint outside the displayed syntax, binder, free-variable, and provenance rows is read. Standard bridge: absent. Status: paper obligation for the future BEDC namespace Derived.LambdaCalcUp.

□

Theorem 200.11 (LambdaCalc alpha classifier symmetry)**.** *If an accepted alpha-classifier row relates two accepted* LambdaCalc$^{\uparrow}$ *term packets, then the reverse alpha-classifier row is accepted. The reversed row is obtained by reversing the carried* hsame *rows on the* Tree$^{\uparrow}$ *skeletons and the* Nat$^{\uparrow}$ *binder indices.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha classifier symmetric`

Proof. 1. Traditional target: symmetry of alpha equivalence. BEDC source: an accepted alpha-classifier row between two BHist lambda-term packets, with TreeUp skeleton certificates and NatUp binder-index certificates exposed as visible rows.

2. Carrier: both endpoints remain the original accepted LambdaCalc packets. Classifier: reverse each carried hsame comparison on the TreeUp skeleton, the unary binder indices, and the provenance rows that identify the two packets as LambdaCalc terms.

3. Stability and ledger: the alpha row already carries a constructorwise ledger for the binder-renaming route. Reading that ledger in reverse preserves the same constructor tags and consumes the same NatUp unary index rows.

4. Core theorem and exactness: the reversed row is an accepted alpha classifier and exports no quotient of alpha classes. Standard bridge: absent. Status: paper obligation for the future BEDC namespace Derived.LambdaCalcUp.

□

Theorem 200.12 (LambdaCalcUp substitution ledger obligation)**.** *Substitution in* LambdaCalc$^{\uparrow}$ *is admitted only from a carried Definition 200.5: the* Tree$^{\uparrow}$ *syntax row names the term spine, the* Nat$^{\uparrow}$ *binder-index row names the binder depth and free positions, and the capture-avoidance* Cont *ledger supplies the renaming, shift, and substitution continuations. No host syntax equality, ambient variable set, or quotient alpha-class is part of the substitution admission surface.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier substitution ledger obligation`

Proof. Project the syntax row T and binder-index row I from Definition 200.5. These rows give the only term spine and binder positions that the substitution endpoint may read.

Project the capture-avoidance ledger s and the finite continuation ledger λ. Their entries record the renaming and binder-shift steps needed to thread substitution through abstraction and application nodes.

Repack the substitution endpoint using exactly these projected rows and the Pkg provenance row ρ. Because the carrier contains no row for host syntax equality, ambient variable sets, or quotient alpha-classes, those data cannot be exported by the substitution obligation. □

Theorem 200.13 (LambdaCalcUp beta-reduction classifier obligation)**.** *Beta reduction in* LambdaCalc$^{\uparrow}$ *is classifier-stable under* hsame *transport of the carried* Tree$^{\uparrow}$ *syntax row, the carried* Nat$^{\uparrow}$ *binder-index row, and the substitution ledger of Definition 200.12. A transported beta-redex row therefore repacks as a beta-reduction row with the transported syntax, binder index, capture-avoidance ledger, and* Pkg *provenance; it does not identify terms by host syntax equality or by quotient alpha-classes.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier beta reduction classifier obligation`

Proof. Start from the beta-redex ledger b in Definition 200.5. Its source application, abstraction body, argument, and endpoint are named through the carried syntax row and binder-index row.

Transport the syntax and binder-index rows by hsame, then transport the substitution ledger supplied by Definition 200.12. The transported ledger still records renaming, shift, and capture-avoidance continuations inside the displayed BHist packet.

Repack the transported redex, substitution endpoint, continuation ledger, and provenance as the beta-reduction classifier row. Since each field came from a displayed carrier component or its hsame transport, no host equality of terms and no quotient alpha-class enters the classifier. □

Theorem 200.14 (LambdaCalcUp constructor case exhaustion)**.** *Every accepted* LambdaCalcBHistTermCarrier *row in a displayed* Hist *endpoint is witnessed by exactly one visible* TreeBHistCarrier *constructor tag among variable, abstraction, and application. More precisely, for any* BHist *packet whose* LambdaCalc$^{\uparrow}$ *carrier predicate and term-packet predicate are accepted, the carried* Tree$^{\uparrow}$ *spine supplies a* UnaryHistory *constructor tag whose* Cont *row and* hsame *endpoint rows select one of those three cases, and the constructor-tag ledger excludes the other two cases.*

Proof. Read the TreeBHistCarrier row from the LambdaCalcBHistTermCarrier packet. The row exposes the visible Hist spine, the BHist constructor ledger, and the unary tag used by the Tree$^{\uparrow}$ syntax endpoint.

Perform constructor inspection on that tag. The variable, abstraction, and application rows are the only admitted tags in the term-packet predicate, and each row carries its own Cont continuation data and hsame endpoint alignment.

The tag ledger is single-valued inside the displayed BHist packet. Thus an accepted row lands in exactly one constructor case, and the two remaining constructor tags are excluded by the same ledger field. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermCarrier constructor case exhaustion`

Theorem 200.15 (LambdaCalcUp alpha beta ledger separation)**.** *For every carried* Hist *endpoint satisfying* LambdaCalcBHistTermCarrier *and the LambdaCalc term-packet predicates, alpha-classifier rows and beta-redex rows consume disjoint visible* BHist *ledger fields except for the shared carried syntax row and the shared binder-index rows. The alpha side reads only the* TreeBHistCarrier *spine,* UnaryHistory *binder names,* Cont *renaming ledger, and* hsame *binder transport rows, while the beta side reads the application-abstraction redex row, the substitution packet, its* Cont *continuation ledger, and the output* hsame *endpoint row.*

Proof. Project the common syntax and binder-index rows from the LambdaCalcBHistTermCarrier packet. These are the only fields shared by alpha conversion and beta reduction, because both classifiers must address the same displayed Tree$^{\uparrow}$ term and binder coordinates.

For the alpha classifier, read the renaming and binder-transport ledger. Its continuation rows name the permitted capture-avoiding binder changes and do not mention an application redex or a substitution output endpoint.

For the beta-redex classifier, read the application, abstraction body, argument, substitution packet, and output endpoint rows. These fields are separate from the alpha renaming ledger, so the two classifiers can overlap only at carried syntax and binder-index data. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha beta ledger separation`

Theorem 200.16 (LambdaCalcUp substitution carrier preservation)**.** *Let a substitution ledger be admitted by Definition 200.12 for a carried input* Hist *endpoint satisfying* LambdaCalcBHistTermCarrier *and the LambdaCalc term-packet predicates. If the ledger records its output endpoint inside* BHist *with the displayed* TreeBHistCarrier *syntax row,* UnaryHistory *binder-index row,* Cont *substitution continuation, and* hsame *endpoint transport rows, then the output endpoint again satisfies* LambdaCalcBHistTermCar

Proof. Apply Definition 200.12 to obtain the syntax, binder-index, capture-avoidance, and provenance rows that the substitution endpoint is allowed to read.

The ledger transports the input tree spine and binder coordinates through the renaming, shift, and substitution continuations. Each transported row remains a displayed BHist row with the required hsame endpoint alignment.

Repack the transported TreeBHistCarrier row, unary binder row, substitution Cont ledger, and provenance row as the LambdaCalc carrier for the output endpoint. No host lambda syntax equality or quotient alpha-class is used in the preservation step. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier substitution carrier preservation`

Theorem 200.17 (LambdaCalcUp substitution output determinacy)**.** *Let two LambdaCalc substitution ledgers act on the same carried input endpoint and suppose they expose the same* $\mathsf{Tree}^{\uparrow}$ *syntax row, the same* $\mathsf{Nat}^{\uparrow}$ *binder index row, the same substituent carrier row, and the same capture-avoidance* Cont *provenance inside* BHist*. Then their output endpoints are classifier-equivalent LambdaCalc carrier endpoints through the displayed* hsame *and* Pkg *rows.*

Proof. Apply Definition 200.12 to both ledgers. The two readings expose the same TreeUp syntax row, NatUp binder index row, substituent carrier, capture-avoidance continuation, and provenance packet.

Use Definition 200.16 for each output. Both endpoints are repacked from the same TreeBHistCarrier syntax row, the same UnaryHistory binder-index row, and the same substitution Cont ledger.

The classifier comparison is therefore the displayed hsame endpoint transport between two outputs of one visible ledger packet. Repack this comparison with the common Pkg provenance row; no host substitution function, alpha quotient, or unlisted syntax equality is used. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier substitution output determinacy`

Theorem 200.18 (LambdaCalcUp alpha beta constructor transport)**.** *For an application-abstraction beta redex carried by* LambdaCalcBHistTermCarrier*, alpha transport along the displayed TreeUp syntax row, NatUp binder-index row,* Cont *renaming ledger, and* hsame *binder rows preserves the visible beta constructor row and its substitution endpoint. Thus alpha-related redex packets expose the same application constructor, abstraction body, argument row, and beta-contractum endpoint as LambdaCalc classifier data.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha beta constructor transport`

Proof. Read the redex through Definition 200.14. The application tag, abstraction tag, body row, and argument row are the visible constructor fields of one TreeBHistCarrier packet.

Apply Definition 200.15. Alpha transport may change only the renaming and binder-transport rows attached to the common syntax and binder coordinates; it does not replace the beta-redex constructor fields.

Finally apply Definition 200.16 to the transported beta substitution ledger. The substitution endpoint remains a LambdaCalc carrier endpoint over the same BHist packet, so the beta constructor row and its contractum read back unchanged at the public classifier surface. □

Theorem 200.19 (LambdaCalcUp free-variable ledger exactness)**.** *For a carried LambdaCalc term endpoint, the accepted free-variable endpoints are exactly the endpoints projected from a packet of Definition 200.6. The packet rows are the displayed* $\mathsf{Tree}^{\uparrow}$ *syntax spine,* $\mathsf{Nat}^{\uparrow}$ *binder-index ledger, free-variable row list, alpha row, beta-redex row, substitution* Cont *provenance, traversal order, and* Pkg *provenance; no host variable set or external syntax predicate is part of the accepted surface.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier free variable ledger exactness`

Proof. For soundness, apply Definition 200.7. Every accepted free-variable endpoint projects from the displayed packet rows $T, I, F, A, B, S, \lambda, \rho$, and the endpoint appears in the finite free-variable row list F.

For completeness, start from a row of Definition 200.6. The TreeUp syntax spine and NatUp binder-index ledger determine the variable, abstraction, and application branches of the traversal, while the Cont provenance records the finite route to each endpoint listed in F.

Use Definition 200.8 when the endpoint is transported through substitution provenance, and use Definition 200.9 when alpha or beta rows share the syntax endpoint. Repacking these rows with the common Pkg provenance gives exactly the accepted free-variable endpoints. □

Theorem 200.20 (LambdaCalcUp beta-redex packet exactness)**.** *Every admitted LambdaCalc beta-redex classifier endpoint is exposed by a finite packet consisting of a carried application row, carried abstraction body, carried argument row, substitution* Cont *ledger, output endpoint,* hsame *endpoint rows, and* Pkg *provenance. The packet is entirely a* Hist *and* BHist *object over* LambdaCalcBHistTermCarrier *and exports no host beta quotient.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBetaRedexPacket exactness`

Proof. Unfold the beta-redex classifier packet. The visible application row supplies the outer TreeBHistCarrier spine, while the abstraction and argument rows expose the two carried subterms as LambdaCalcBHistTermCarrier endpoints.

The substitution field is then read as a displayed Cont ledger from the abstraction body and argument packet to the output endpoint. Its endpoint alignment is recorded by the listed hsame rows, so the output is not identified by an ambient lambda quotient.

Finally, read the Pkg provenance row. Repacking these rows gives exactly the finite beta-redex packet: application, abstraction body, argument, substitution continuation, output endpoint, endpoint transports, and provenance, all inside the displayed Hist and BHist ledger. □

Theorem 200.21 (LambdaCalcUp alpha-renaming freshness transport)**.** *For any carried LambdaCalc endpoint satisfying* LambdaCalcBHistTermCarrier*, an alpha-renaming ledger that displays fresh binder transport preserves the carrier and the free-variable endpoint packet along the listed* TreeUp*,* NatUp*,* Cont*, and* hsame *rows.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha renaming freshness transport`

Proof. Project the source carrier as a TreeBHistCarrier syntax row together with its unary binder and free-variable endpoint packet. The freshness assumption is a visible ledger row, so it is read from the same BHist packet rather than from a host-side name convention.

Use the NatUp binder row to transport the selected binder index, and use the TreeUp row to transport the syntax spine through the renaming continuation. The displayed Cont ledger records the capture-avoiding renaming route.

The hsame endpoint rows align the transported syntax and free-variable packet with the output endpoint. Repacking those rows gives LambdaCalcBHistTermCarrier for the renamed term and preserves the free-variable endpoint packet under the displayed freshness transport. □

Theorem 200.22 (LambdaCalcUp substitution composition carrier closure)**.** *Let two consecutive substitution ledgers start from a carried* Hist *endpoint satisfying* LambdaCalcBHistTermCarrier*. If the first ledger records an intermediate carried endpoint and the second ledger records a final endpoint, with both ledgers displayed inside* BHist *by* TreeBHistCarrier *rows,* UnaryHistory *binder rows,* Cont *substitution routes,* hsame *endpoint rows, and* Pkg *provenance, then the composed substitution route has a final endpoint satisfying* LambdaCalcBHistTermCarrier*.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier substitution composition carrier closure`

Proof. Apply Definition 200.16 to the first substitution ledger. This yields a carried intermediate endpoint with the transported tree, binder, continuation, endpoint-alignment, and provenance rows.

Apply Definition 200.16 again to the second substitution ledger, now using the intermediate carrier as its input. The second application supplies the final carried endpoint and its displayed BHist packet.

The two Cont ledgers compose by continuation associativity, and the successive hsame endpoint rows transport along the same route. Repacking the final TreeBHistCarrier row, UnaryHistory binder row, composed substitution route, endpoint alignment, and Pkg provenance gives the claimed LambdaCalc carrier closure. □

Theorem 200.23 (LambdaCalc NameCert carrier obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$ *carrier is exactly the* LambdaCalcBHistTermCarrier *packet over* $\mathsf{Tree}^{\uparrow}$ *syntax,* $\mathsf{Nat}^{\uparrow}$ *unary binder rows, displayed* Cont *substitution provenance, and finite* Pkg *rows. It contains no host syntax equality, quotient alpha-class, or ambient variable-set carrier.*

Proof. Read the constructor rows through Definition 200.2 and Definition 200.3. These give the variable, abstraction, and application packets over $\mathsf{Tree}^{\uparrow}$ syntax and $\mathsf{Nat}^{\uparrow}$ binder rows.

Read the substitution part through Definition 200.16 and Definition 200.22. Their Cont rows keep every admitted substitution endpoint inside the same displayed BHist packet.

Finally attach the Pkg provenance from the constructor and substitution rows. The resulting packet is precisely LambdaCalcBHistTermCarrier, so the public carrier has no extra host-side syntax or alpha-equivalence field. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier namecert carrier obligation`

Theorem 200.24 (LambdaCalc NameCert classifier stability)**.** *Componentwise* hsame *on the* $\mathsf{Tree}^{\uparrow}$ *spine, unary binder indices, free-variable ledger, alpha ledger, beta-redex ledger, and provenance transports accepted LambdaCalc packets to accepted LambdaCalc packets.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier namecert classifier stability`

Proof. First transport the syntax and binder rows by Definition 200.9. This preserves the accepted constructor packet and aligns the visible $\mathsf{Tree}^{\uparrow}$ and $\mathsf{Nat}^{\uparrow}$ faces.

Next use Definition 200.19 for the free-variable rows and Definition 200.21 for the alpha ledger. The displayed transports keep the free-variable and freshness packets inside the LambdaCalc carrier.

For beta and substitution rows, apply Definition 200.18 and Definition 200.22. Repacking the transported rows with the shared Pkg provenance gives an accepted LambdaCalc packet at the target endpoint. □

Theorem 200.25 (LambdaCalc NameCert substitution ledger)**.** *Every admitted LambdaCalc substitution endpoint is read from the displayed* BHist *traversal and capture-avoidance* Cont *ledger, together with the listed* $\mathsf{Tree}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, hsame, *and* Pkg *rows. No host syntax equality, ambient variable set, or quotient alpha-class is used to identify the endpoint.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier namecert substitution ledger`

Proof. Start from Definition 200.4. It localizes the substitution endpoint to the displayed traversal, the binder rows, and the capture-avoidance continuation.

Then apply Definition 200.19 and Definition 200.8. These identify the free-variable rows that may pass through the ledger and show that the capture-avoidance route remains a LambdaCalc carrier route.

Finally use Definition 200.9 and Definition 200.22 to align successive endpoint transports. The endpoint is therefore read only from the displayed traversal and its Cont provenance. □

Theorem 200.26 (LambdaCalc root constructor scope)**.** *The variable, abstraction, and application constructor rows of* $\mathsf{LambdaCalc}^{\uparrow}$ *are exactly the* BHist, $\mathsf{Tree}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, hsame, *and* Pkg *rows exposed by the root* LambdaCalcBHistTermCarrier.

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier root constructor scope`

Proof. Apply Definition 200.14. It exhausts the accepted root carrier by the three visible constructor cases and reads their payloads from the displayed tree spine, unary index rows, and endpoint rows.

Definition 200.25 supplies the shared Pkg provenance, with no host syntax row or quotient alpha-class. □

Theorem 200.27 (LambdaCalc root substitution scope)**.** *Every root substitution endpoint is read only from the displayed traversal, the capture-avoidance* Cont *ledger, the binder rows, and the package provenance of the LambdaCalc root carrier.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier root substitution scope`

Proof. Apply Definition 200.4. The substitution endpoint is localized to the displayed traversal, unary binder coordinates, recursive Cont route, and hsame endpoint readback.

Then use Definition 200.25 to attach package provenance and exclude host substitution or quotient rows. □

Theorem 200.28 (LambdaCalc root beta ledger scope)**.** *Every beta-redex read at the* $\mathsf{LambdaCalc}^{\uparrow}$ *root factors through the constructor carrier, the substitution ledger, alpha transport, and the beta-redex packet exactness row, with no host equality or quotient alpha-class.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier root beta ledger scope`

Proof. Use Definition 200.14 to read the application and abstraction rows from the constructor carrier. Then use Definition 200.4 for the substitution endpoint.

Apply Definition 200.9 to carry the redex through alpha transport and Definition 200.20 to isolate the finite packet. Definition 200.25 supplies the package provenance, so no host equality or quotient row is read. □

Definition 200.29 (LambdaCalc root constructor readback packet)**.** *A LambdaCalc root constructor readback packet is the finite* BHist *packet consisting of the visible* $\mathsf{Tree}^{\uparrow}$ *syntax row, the* $\mathsf{Nat}^{\uparrow}$ *binder or variable-index row when the root tag carries one, the constructor tag* lamVar*,* lamAbs*, or* lamApp*, the constructor-preserving* Cont *provenance, the root* hsame *readback row, and the* Pkg *provenance tying those rows to* LambdaCalcBHistTermCarrier*. No host syntax tree, ambient variable set, or quotient alpha-class is part of the packet.*

Theorem 200.30 (LambdaCalc root constructor readback exhaustion)**.** *Every accepted variable, abstraction, or application row of* LambdaCalcBHistTermCarrier *projects to exactly one constructor case of Definition 200.29. The projection uses only the displayed* $\mathsf{Tree}^{\uparrow}$ *row, the visible* $\mathsf{Nat}^{\uparrow}$ *index rows,* Cont*,* hsame*, and* Pkg *provenance.*

Proof. For a variable row, apply Definition 200.2. The unary index is the visible $\mathsf{Nat}^{\uparrow}$ payload and the root readback row is the displayed lamVar tag.

For abstraction and application rows, use Definition 200.3. The theorem keeps the binder row, body row, and two application subtrees inside the visible $\mathsf{Tree}^{\uparrow}$ spine with constructor-preserving Cont transport.

The case split is exhausted by Definition 200.14. Repacking each case with the shared Pkg provenance gives exactly one readback packet and introduces no extra equality relation. □

Theorem 200.31 (LambdaCalc root beta-alpha consumer threshold)**.** *Every beta-redex, alpha-renaming, and substitution consumer for* $\mathsf{LambdaCalc}^{\uparrow}$ *reads its root data from Definition 200.29 together with the finite substitution ledger of Definition 200.25. Thus the consumer surface uses only* BHist *constructor packets,* Cont*,* hsame*, and* Pkg *provenance.*

Proof. First project each consumed root through Definition 200.30. This supplies the visible constructor tag, TreeUp syntax row, NatUp index row when present, and the root readback provenance.

Next attach the free-variable and capture-avoidance ledgers. Apply Definition 200.7 and Definition 200.8; these keep the substitution endpoint inside the displayed carrier and record the route as Cont data.

Finally transport alpha and beta endpoints by Definition 200.9. The finite ledger of Definition 200.25 supplies the remaining substitution provenance, so beta, alpha, and substitution consumers cross the root boundary only through the displayed packets. □

Definition 200.32 (LambdaCalc root normal form packet)**.** *A LambdaCalc root normal form packet is the finite* BHist *packet whose source is a root constructor readback packet of Definition 200.29, whose visible syntax row lies in* $\mathsf{Tree}^{\uparrow}$*, whose binder and variable-index rows lie in* $\mathsf{Nat}^{\uparrow}$ *when present, and whose reduction frontier records that the root is not a beta-redex visible through the displayed* Cont*,* hsame*, and* Pkg *provenance. The packet contains only constructor tags, finite subtree rows, NatUp index rows, capture-avoidance continuation rows, root readback rows, and the package provenance of* LambdaCalcBHistTermCarrier*.*

Theorem 200.33 (LambdaCalc root normal form readback)**.** *Every accepted* $\mathsf{LambdaCalc}^{\uparrow}$ *root whose constructor readback packet has no visible beta-redex exposure reads back to exactly one root normal form packet. The readback uses the same* $\mathsf{Tree}^{\uparrow}$ *syntax row, the same* $\mathsf{Nat}^{\uparrow}$ *binder or variable-index payload when present, and the same* Cont*,* hsame*, and* Pkg *provenance as the constructor readback packet.*

Proof. First project the accepted root through Definition 200.30. This gives the visible constructor tag and the finite TreeUp and NatUp rows, with no ambient syntax object.

Next use the beta ledger scope theorem Definition 200.28. The hypothesis that no visible beta-redex exposure is present excludes exactly the application-over- abstraction root case while leaving the variable, abstraction, and non-redex application cases inside the displayed constructor carrier.

Finally repack the surviving constructor row with the original continuation, root readback, and package provenance. The packet is unique because the constructor case exhaustion theorem gives exactly one root constructor case. □

Theorem 200.34 (LambdaCalc root substitution normal form consumer)**.** *Every substitution, alpha, or beta consumer that needs a LambdaCalc root normal form may read only the packet of Definition 200.32, the finite substitution ledger of Definition 200.25, and the alpha transport of Definition 200.9. It may not read a host substitution function, a quotient alpha-class, or a syntax tree outside* LambdaCalcBHistTermCarrier*.*

Proof. Begin with the consumer threshold Definition 200.31. It already restricts beta, alpha, and substitution consumers to constructor packets, finite substitution ledgers, Cont, hsame, and Pkg provenance.

Apply Definition 200.33 to the consumed root when the consumer asks for a normal-form surface. This replaces the root constructor packet by the corresponding normal form packet without changing the TreeUp syntax row, NatUp payload, continuation, or package provenance.

The remaining consumer data is exactly the finite substitution ledger and alpha transport already named by the threshold theorem. Since those rows live inside the displayed BHist carrier, no host substitution or quotient alpha object is available to the consumer. □

Theorem 200.35 (LambdaCalc constructor source disjointness)**.** *Let a carried* BHist *term row satisfy* LambdaCalcBHistTermCarrier*, and suppose its visible* $\mathsf{Tree}^{\uparrow}$ *root is one of* lamVar*,* lamAbs*, or* lamApp*. Then the public LambdaCalc classifier reads only the source fields of that root: a variable row exposes only its unary variable-index field, an abstraction row exposes only its binder-index and body fields, and an application row exposes only its left and right subterm fields. No accepted row can simultaneously be read as a different LambdaCalc constructor under the same classifier endpoint.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermCarrier constructor source disjointness`

Proof. Read the visible root tag through the $\mathsf{Tree}^{\uparrow}$ row in the carried BHist packet. The three LambdaCalc constructors are distinct TreeUp tags, so the tag readback fixes which source slots are present in the packet.

In the variable case, apply Definition 200.2. Its packet contains the unary variable-index row and no binder-body or binary subterm slots. Transport along the displayed hsame endpoint preserves that slot inventory.

In the abstraction case, apply Definition 200.3. The source packet consists of the binder-index row and the carried body row, and hsame transport cannot create the variable-only or application-only source slots.

In the application case, apply Definition 200.3. The packet consists of the two carried subterm rows, with no unary variable-index-only source and no binder-body abstraction source.

Since the classifier is read from the same $\mathsf{Tree}^{\uparrow}$ tag, the same hsame endpoint, and the same Pkg provenance in every case, two different constructor readings would require one visible root tag to be two distinct TreeUp constructors. The tag readback excludes this, giving constructor source disjointness. □

Theorem 200.36 (LambdaCalc substitution source coverage)**.** *Every accepted LambdaCalc substitution* Cont *ledger endpoint is sourced from exactly one variable, abstraction, or application branch of the displayed* $\mathsf{Tree}^{\uparrow}$ *syntax spine, together with the* $\mathsf{Nat}^{\uparrow}$ *unary index rows named by the free-variable packet. Equivalently, the substitution endpoint has no additional source outside the constructor branch chosen by the visible syntax spine, the binder-index ledger, the free-variable ledger, the* hsame *endpoint rows, and the* Pkg *provenance.*

Proof. Induct on the displayed $\mathsf{Tree}^{\uparrow}$ syntax spine of the carried source term. The base variable branch exposes the variable-index row and the matching free-variable packet endpoint, so the substitution continuation is sourced from that single variable branch.

For an abstraction spine, the visible constructor supplies the binder-index row and the body subterm. The $\mathsf{Nat}^{\uparrow}$ unary row records the binder index, while the free-variable packet names the rows that survive capture-avoiding transport through the body.

For an application spine, the visible constructor supplies the left and right subterm rows. The induction hypotheses cover the substitution endpoints of the two subspines, and the application packet repacks those endpoints into the single application branch selected by the root tag.

At each step, use Definition 200.19 to identify the free-variable rows and Definition 200.16 to transport the carried endpoint across the displayed Cont route.

The repacking step records the same hsame endpoint rows and the same Pkg provenance. Hence every accepted substitution endpoint is covered by exactly one constructor branch of the displayed syntax spine and the named $\mathsf{Nat}^{\uparrow}$ free-variable rows. □

Theorem 200.37 (LambdaCalc alpha-beta ledger determinacy)**.** *Let two accepted LambdaCalc packets expose the same* $\mathsf{Tree}^{\uparrow}$ *syntax row, the same* $\mathsf{Nat}^{\uparrow}$ *binder-index row, the same alpha ledger, the same beta-redex row, the same substitution* Cont *ledger, and the same* Pkg *provenance. Then their public LambdaCalc classifier endpoints agree by* hsame*.*

Proof. First transport the common syntax and binder rows through Definition 200.9. This aligns the carried LambdaCalc endpoints determined by the shared $\mathsf{Tree}^{\uparrow}$ syntax and $\mathsf{Nat}^{\uparrow}$ binder-index rows.

Next apply Definition 200.17 to the shared substitution Cont ledger. The two packets therefore expose the same substitution output endpoint after the displayed endpoint transports.

Finally apply Definition 200.15. The common alpha ledger and common beta-redex row cannot introduce a second public endpoint once the syntax, binder, substitution ledger, and provenance rows have been fixed.

The remaining comparison is componentwise hsame transport along the shared rows. Repacking those transports with the common Pkg provenance gives the same public LambdaCalc classifier endpoint for both packets. □

Theorem 200.38 (LambdaCalc root constructor frontier)**.** *The public LambdaCalc term frontier exposed by a carried* BHist *row is exhausted by the three visible root constructors* lamVar*,* lamAbs*, and* lamApp*. Each accepted root row reads exactly the* $\mathsf{Tree}^{\uparrow}$ *source slots,* $\mathsf{Nat}^{\uparrow}$ *index rows,* hsame *endpoint rows, and* Pkg *provenance assigned to that constructor branch, and no fourth public root constructor can be read from the same packet.*

Proof. Start with the carried BHist packet and read its visible $\mathsf{Tree}^{\uparrow}$ root. The constructor packet theorems cover the variable, abstraction, and application cases as the public constructors of the LambdaCalc carrier.

Apply Definition 200.35. It separates the source slots attached to the three visible roots and rules out a second constructor reading at the same endpoint.

For substitution or beta-visible rows attached to the root, use Definition 200.36. Those rows are still sourced from the constructor branch selected by the same syntax spine and the named $\mathsf{Nat}^{\uparrow}$, hsame, and Pkg rows.

Thus the public frontier is exactly the listed constructor inventory, with all readable rows anchored in the displayed BHist packet. □

Theorem 200.39 (LambdaCalc root substitution frontier)**.** *For every accepted LambdaCalc root substitution endpoint, the substitution provenance is preserved through the displayed* Cont *continuation and the carried* Pkg *rows. The endpoint remains attached to the same visible* BHist *constructor branch, the same* $\mathsf{Tree}^{\uparrow}$ *syntax spine, the same* $\mathsf{Nat}^{\uparrow}$ *binder and free-variable rows, and the same componentwise* hsame *transport used by the source packet.*

Proof. Begin with the accepted root substitution endpoint. Apply Definition 200.36 to identify the unique constructor branch, binder-index row, free-variable packet, and Pkg provenance that source the endpoint.

Next use Definition 200.25. It reads the endpoint from the displayed BHist traversal and capture-avoidance Cont ledger, so no ambient syntax equality or unrecorded variable set is available as a second source.

Finally apply Definition 200.22. Composition of the accepted continuations preserves the carried LambdaCalc endpoint and reuses the same Pkg provenance. The root substitution frontier is therefore stable under the displayed Cont and Pkg rows. □

Theorem 200.40 (LambdaCalc root beta-ledger frontier)**.** *Suppose two accepted LambdaCalc beta-ledger root packets expose the same* $\mathsf{Tree}^{\uparrow}$ *syntax row, the same* $\mathsf{Nat}^{\uparrow}$ *binder-index row, the same alpha ledger, the same beta-redex row, the same substitution* Cont *ledger, and the same* Pkg *provenance. Under the displayed alpha-beta classifier, the two root packets expose the same public LambdaCalc endpoint by componentwise* hsame*.*

Proof. First apply Definition 200.15. The alpha ledger and beta-redex row occupy disjoint readable positions once the syntax spine, binder row, substitution ledger, and provenance are fixed.

Next apply Definition 200.37. Its hypotheses are exactly the shared $\mathsf{Tree}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, alpha, beta, substitution, and Pkg rows displayed by the root packets.

The resulting hsame comparison is the endpoint comparison required by the public alpha-beta classifier. Hence the beta-ledger frontier has a deterministic root endpoint under the displayed classifier. □

Theorem 200.41 (LambdaCalc root obligation inventory)**.** *The displayed LambdaCalc root packet has the following obligation inventory: carrier rows for the visible* BHist *constructor branches, classifier rows for the* $\mathsf{Tree}^{\uparrow}$ *syntax spine and* $\mathsf{Nat}^{\uparrow}$ *binder and free-variable indices, substitution rows transported by* Cont*, alpha-beta rows transported by componentwise* hsame*, exactness rows for the readable constructor and substitution frontiers, stability rows for the beta-ledger classifier, and ledger rows recording* Pkg *provenance and* NameCert *source data. The scope of the inventory is exactly the* BHist*,* $\mathsf{Tree}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*,* Cont*,* hsame*,* Pkg*, and* NameCert *rows exposed by Definition 200.38, Definition 200.39, and Definition 200.40; it exports no host syntax equality, alpha quotient, beta quotient, or unrecorded variable-set primitive.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcUp StdBridge`

Proof. Project the root packet through Definition 200.38. This supplies the visible constructor branches, the $\mathsf{Tree}^{\uparrow}$ syntax spine, the $\mathsf{Nat}^{\uparrow}$ binder and free-variable rows, and the readable BHist carrier rows.

Next apply Definition 200.39. It accounts for the substitution endpoints, their capture-avoidance Cont ledger, and the carried Pkg provenance without adding a second syntax source.

Finally apply Definition 200.40. The alpha ledger, beta-redex row, substitution ledger, and provenance rows determine the public endpoint through componentwise hsame. Repacking these projections gives exactly the listed carrier, classifier, substitution, alpha-beta, exactness, stability, and ledger obligations. □

Theorem 200.42 (LambdaCalc root obligation carrier)**.** *The variable, abstraction, and application* BHist *constructor rows cover the* $\mathsf{LambdaCalc}^{\uparrow}$ *carrier under* TreeBHistCarrier*,* UnaryHistory*,* hsame*, and constructor-preserving* Cont*. No carrier row is read from host syntax equality or from an alpha-quotient representative.*

Proof. Apply Definition 200.2 to the variable case. The root packet exposes the visible $\mathsf{Tree}^{\uparrow}$ constructor tag and the $\mathsf{Nat}^{\uparrow}$ unary variable index.

Apply Definition 200.3 to the abstraction and application cases. These rows expose the binder index, body, left subterm, and right subterm through the same $\mathsf{Tree}^{\uparrow}$ and $\mathsf{Nat}^{\uparrow}$ visible spines.

Finally use Definition 200.14 and Definition 200.38. The constructor cases exhaust the carrier and transport through the displayed hsame and constructor-preserving Cont rows, so no host syntax row is added. □

Theorem 200.43 (LambdaCalc root obligation classifier)**.** *The beta and alpha classifier rows of the* $\mathsf{LambdaCalc}^{\uparrow}$ *root packet are stable under constructor-preserving* hsame *transport. They read only the visible* $\mathsf{Tree}^{\uparrow}$ *syntax spine,* $\mathsf{Nat}^{\uparrow}$ *binder and free-variable rows, alpha-beta ledger rows, substitution* Cont *rows, and* Pkg *provenance, and they do not use host syntax equality.*

Proof. First align the constructor endpoints by Definition 200.9. This transports the visible $\mathsf{Tree}^{\uparrow}$ syntax row and the $\mathsf{Nat}^{\uparrow}$ binder rows componentwise.

Next use Definition 200.37. Shared syntax, binder, alpha, beta, substitution, and provenance rows determine the same public endpoint by hsame.

The root beta-ledger frontier Definition 200.40 repacks the transported rows as the public classifier surface. Since the cited rows are all displayed constructor, ledger, transport, and provenance rows, host syntax equality is not consumed. □

Theorem 200.44 (LambdaCalc root obligation substitution ledger)**.** *Capture-avoiding substitution at the* $\mathsf{LambdaCalc}^{\uparrow}$ *root exposes only* $\mathsf{Nat}^{\uparrow}$ *index rows,* $\mathsf{Tree}^{\uparrow}$ *subtree rows,* BHist *constructor tags, displayed* Cont *substitution routes,* hsame *endpoint rows, and* Pkg *package provenance to downstream consumers.*

Proof. Use Definition 200.36. It identifies each accepted substitution endpoint with one visible constructor branch and the named $\mathsf{Nat}^{\uparrow}$ binder and free-variable rows.

Then apply Definition 200.25 and Definition 200.39. These theorems attach the displayed Cont capture-avoidance route, the endpoint hsame rows, and the same Pkg provenance to the substitution endpoint.

The downstream read is therefore exactly the NatUp, TreeUp, constructor-tag, continuation, endpoint-transport, and provenance surface. No host substitution function, variable-set primitive, or quotient class is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$**.**

Constructive story: A lambda-calculus term is generated by a visible $\mathsf{Tree}^{\uparrow}$ syntax spine whose root tag is one of variable, abstraction, or application, with $\mathsf{Nat}^{\uparrow}$ unary histories naming variable indices, binder indices, and free-variable

rows, and with Cont ledgers recording substitution, alpha, and beta routes. The carrier accepts exactly those BHist packets whose constructor tag, payload rows, subtrees, substitution output, alpha ledger, beta-redex row, and provenance are displayed; a host syntax tree, unrecorded variable set, alpha quotient, or beta quotient does not enter the carrier. Two accepted root packets are classified only by componentwise transport of the TreeUp root, NatUp indices, substitution continuation, beta row, alpha row, endpoint hsame comparisons, and Pkg provenance, not by ambient syntax conversion. The source specification is the TreeUp/NatUp constructor surface, the pattern specification records variable, abstraction, and application closure, constructor disjointness, substitution source coverage, capture-avoidance continuation closure, alpha-beta determinacy, and root beta-ledger exactness, and the ledger keeps the constructor branch and every recursive continuation route visible. At this seed frontier the five name-certificate obligations are not yet exported as a complete public certificate, but the rows show the mechanism: a displayed constructor packet inhabits the carrier, hsame gives reflexive, symmetric, and transitive endpoint movement, and constructor-preserving Cont transport keeps classified terms inside the same visible syntax spine. A packet h lies in the signature gap of a $\mathsf{LambdaCalc}^{\uparrow}$ token p when the source-domain accepts its constructor and ledger rows, the signature relation pairs it with an answer term packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the root tag, NatUp indices, substitution route, alpha row, beta-redex row, and provenance are exactly the rows encoded by p. The chapter registers this root-frontier construction under the name $\mathsf{LambdaCalc}^{\uparrow}$; it exposes only the BEDC syntax and reduction ledgers, with no host lambda syntax equality, alpha quotient, beta quotient, or complete standard bridge introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation scope binds the carrier, classifier, substitution, alpha-beta, exactness, stability, and ledger rows listed in Definition 200.41 for the displayed LambdaCalc root packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.LambdaCalcUp.LambdaCalcUp\_StdBridge`

Bridge status: bridgeChecked

Not claimed: This frontier does not close host lambda syntax equality, alpha quotienting, beta quotienting, or analytic normalization.

Upgrade path: No further paper-side theory or verification grade remains for the displayed constructor, substitution, alpha, beta, root normal-form, and public NameCert consumer catalogue.

Theorem 200.45 (LambdaCalc alpha classifier transitivity)**.** *Let s, t, u : Hist be accepted $\mathsf{LambdaCalc}^{\uparrow}$ term packets whose visible term data are carried by the displayed $\mathsf{Tree}^{\uparrow}$ syntax skeletons, $\mathsf{Nat}^{\uparrow}$ binder-index ledgers, Cont alpha-renaming routes, endpoint hsame rows, and common Pkg provenance. If an accepted alpha-classifier row relates (s, t) and an accepted alpha-classifier row relates (t, u) over the same middle packet t, then the composed alpha-classifier row relates (s, u). The composed row is obtained by keeping the two endpoint carriers, reversing only those carried hsame rows whose displayed orientation points into the middle packet, concatenating the resulting $\mathsf{Tree}^{\uparrow}$ skeleton comparisons and $\mathsf{Nat}^{\uparrow}$ binder-index comparisons, and repacking the concatenated alpha ledger with the same Cont and Pkg provenance.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier alpha classifier transitive`

Proof. Project the two accepted alpha-classifier rows through Definition 200.48. Each row is a componentwise comparison of the visible $\mathsf{Tree}^{\uparrow}$ syntax skeleton, the visible $\mathsf{Nat}^{\uparrow}$ binder and variable-index rows, the alpha-renaming ledger, the endpoint hsame rows, and the carried Pkg provenance. No host syntax conversion or quotient alpha-class is available as an extra step.

Use Definition 200.11 only to orient the carried comparisons at the common middle packet. Thus every component has a row from the s-packet to the displayed middle t-packet and a row from that same middle packet to the u-packet. The middle syntax skeleton and middle binder ledger are the same displayed rows in the two hypotheses, so no additional matching datum is required.

Concatenate the two oriented hsame comparisons on the $\mathsf{Tree}^{\uparrow}$ skeletons. Do the same for each $\mathsf{Nat}^{\uparrow}$ binder or variable-index row named by the alpha ledger. The alpha-renaming routes are finite Cont rows attached to those same visible components, so their carried provenance concatenates along the middle packet while preserving constructor tags and binder positions.

Apply Definition 200.21 to the concatenated alpha route. It keeps the endpoint inside LambdaCalcBHistTermCarr preserves the free-variable packet, and records the transported syntax and binder rows by the concatenated hsame comparisons. Apply Definition 200.9 to read the resulting endpoints as LambdaCalc carrier data over the displayed syntax and binder ledgers.

Finally repack the concatenated syntax comparison, concatenated binder-index comparison, concatenated alpha-renaming Cont route, endpoint hsame rows, and common Pkg provenance. By Definition 200.49, these are exactly the rows an accepted public LambdaCalc alpha read may consume. Hence the repacked row is an accepted alpha-classifier row relating (s, u). □

Theorem 200.46 (LambdaCalc alpha classifier reflexivity)**.** *Let h : Hist be an accepted* $\mathsf{LambdaCalc}^{\uparrow}$ *term packet satisfying* LambdaCalcBHistTermCarrier*. Then the LambdaCalc alpha-classifier accepts a row relating (h, h). This reflexive row is read over the displayed* $\mathsf{Tree}^{\uparrow}$ *syntax skeleton of h, the displayed* $\mathsf{Nat}^{\uparrow}$ *binder-index and variable-index ledgers of h, the identity alpha-renaming* Cont *ledger, the componentwise reflexive* hsame *rows on each displayed endpoint, and the same* Pkg *provenance carried by h. It exports no host syntax equality, unrecorded variable set, or quotient alpha-class.*

Proof. Project the accepted packet through Definition 200.48. The public classifier boundary is componentwise: it contains the visible $\mathsf{Tree}^{\uparrow}$ syntax root, the $\mathsf{Nat}^{\uparrow}$ binder and variable rows, the substitution and alpha ledgers, endpoint hsame comparisons, and the carried Pkg provenance.

Use the carrier self-classification of Definition 200.10 on the same packet h. It supplies reflexive hsame rows for the visible syntax skeleton, every unary binder or variable index named by the packet, the free-variable ledger, and the package provenance. These are exactly the endpoint comparisons needed when both classifier endpoints are h.

Take the alpha-renaming ledger to be the identity Cont route on the displayed syntax and binder rows. Applying Definition 200.21 to this identity route preserves LambdaCalcBHistTermCarrier, preserves the free-variable endpoint packet, and records the transported syntax and binder rows by the reflexive hsame comparisons already supplied above.

Finally repack the syntax row, binder-index rows, identity alpha ledger, reflexive endpoint comparisons, and unchanged provenance. By Definition 200.49, these rows exhaust the public LambdaCalc alpha read. Hence the repacked row is an accepted alpha-classifier row relating (h, h), with no extra equality principle outside the displayed BHist packet. □

Theorem 200.47 (LambdaCalc NameCert public boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$ *boundary is exactly the constructor frontier, substitution ledger, beta ledger, alpha ledger,* hsame *endpoint comparisons,* Cont *continuation rows, and* Pkg *provenance exposed by the carried* BHist *term packets. Thus a public read of a LambdaCalc endpoint is sourced by the visible* $\mathsf{Tree}^{\uparrow}$ *constructor root, the relevant* $\mathsf{Nat}^{\uparrow}$ *binder or variable rows, the substitution and beta rows attached to that root, and the listed BEDC transport rows.*

Proof. Begin with the carried term packet. The carrier rows are supplied by Definition 200.2 and Definition 200.3, while Definition 200.38 exhausts the public root by the three visible $\mathsf{Tree}^{\uparrow}$ constructors.

For substitution reads, apply Definition 200.25 and Definition 200.39. These identify the displayed Cont ledger, the relevant $\mathsf{Nat}^{\uparrow}$ binder and free-variable rows, and the same Pkg provenance as the only substitution source.

For beta and alpha reads, apply Definition 200.9 and Definition 200.40. The public endpoint is transported componentwise by hsame after the alpha ledger, beta-redex ledger, substitution ledger, and constructor rows have been fixed.

Repacking these rows gives the stated public boundary. No host syntax equality, unrecorded variable set, or quotient alpha-class is available outside the displayed BHist, Cont, hsame, and Pkg rows. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier public boundary`

Theorem 200.48 (LambdaCalc NameCert classifier boundary)**.** *Classifier movement for* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$ *is componentwise over the* $\mathsf{Tree}^{\uparrow}$ *syntax root, the* $\mathsf{Nat}^{\uparrow}$ *binder and variable rows, the substitution* Cont *ledger, the beta-redex ledger, the alpha ledger, the endpoint* hsame *comparisons, and the carried* Pkg *provenance. Two accepted classifier endpoints therefore agree only by transporting each displayed component of this boundary; no ambient syntax conversion is admitted as an additional classifier step.*

Proof. First align the constructor root. The classifier stability supplied by Definition 200.9 transports the carried LambdaCalc endpoint over the visible $\mathsf{Tree}^{\uparrow}$ syntax row and the $\mathsf{Nat}^{\uparrow}$ binder rows.

Next align substitution. Use Definition 200.36 to isolate the constructor branch and Definition 200.39 to keep the substitution endpoint attached to the displayed Cont ledger and package provenance.

Finally align beta and alpha. The determinacy theorem Definition 200.37, together with Definition 200.40, says that shared syntax, binder, alpha, beta, substitution, and Pkg rows determine the same public endpoint by hsame.

Thus classifier movement is exactly the componentwise transport of the named boundary rows. □

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier public endpoint transport`

Theorem 200.49 (LambdaCalc NameCert ledger exactness)**.** *Every accepted public LambdaCalc read is exhausted by the constructor rows, substitution rows, beta rows, alpha rows,* hsame *endpoint comparisons,* Cont *continuation rows, and* Pkg *provenance displayed in the carried* BHist *packet. In particular, the public ledger contains no host syntax equality, no implicit capture-avoidance equality outside the substitution ledger, and no quotient alpha-class.*

Lean4 ✓ `BEDC.Derived.LambdaCalcUp.LambdaCalcBHistTermPacketCarrier namecert ledger exactness`

Proof. Project the accepted read to the visible constructor spine. By Definition 200.35 and Definition 200.38, the read chooses exactly one variable, abstraction, or application root and inherits only the slots assigned to that root.

The substitution part is exact by Definition 200.36. Every substitution endpoint is sourced from the chosen constructor branch, the named $\mathsf{Nat}^{\uparrow}$ rows, the displayed Cont ledger, and the same Pkg provenance.

The beta and alpha parts are exact by Definition 200.37 and Definition 200.40. Once the syntax, binder, alpha, beta, substitution, and provenance rows are fixed, the remaining public endpoint comparison is the recorded hsame row.

Combining these projections exhausts the public ledger and excludes any host-level syntax equality or quotient alpha-class from the accepted boundary. □

Chapter 201

A Concrete Naming Certificate for $\mathsf{Partition}^{\uparrow}$

The integer-partition interface $\mathsf{Partition}^{\uparrow}$ packages weakly decreasing sequences of positive integers summing to a fixed integer, together with the Young-diagram interpretation. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28) and $\mathsf{NameCert}_{\mathsf{List}^{\uparrow}}$ (chapter 36).

201.1 Carrier definition

Definition 201.1 (PartitionUp BHist carrier)**.** *A* $\mathsf{Partition}^{\uparrow}$ *carrier is a finite* BHist *packet consisting of a* $\mathsf{List}^{\uparrow}$ *row whose entries are* $\mathsf{Nat}^{\uparrow}$ *positive-part rows, a unary sum ledger row for the displayed entries, weak-decrease comparison rows between adjacent parts, endpoint rows for the total and each part, finite* Cont *routes tying the list, sum, and comparison rows into one ledger, and* Pkg *provenance for the whole packet. The packet is accepted only through these visible rows.*

The carrier records an integer partition as BEDC data. It does not include a host integer partition set, a symmetric-function basis, a representation theory object, or an external Young-diagram model.

Lean4 (definition) `BEDC.Derived.PartitionUp.PartitionBHistCarrier`

Definition 201.2 (PartitionUp Young-ledger classifier)**.** *The Young-ledger classifier compares two accepted* $\mathsf{Partition}^{\uparrow}$ *carriers by the displayed* hsame *transport of their* $\mathsf{List}^{\uparrow}$ *rows, their component* $\mathsf{Nat}^{\uparrow}$ *positive-part rows, their unary sum rows, their weak-decrease rows, and their boundary ledgers. A classifier witness must transport the same finite Young boundary through the list and sum ledgers and must preserve* Pkg *provenance for the packet.*

Lean4 (definition) `BEDC.Derived.PartitionUp.PartitionYoungLedgerClassifier`

201.2 The certificate

Theorem 201.3 (Partition carrier obligation)**.** *Every accepted* $\mathsf{Partition}^{\uparrow}$ *carrier is read from the packet of Definition 201.1: the* $\mathsf{List}^{\uparrow}$ *row of* $\mathsf{Nat}^{\uparrow}$ *positive parts, the unary sum ledger, the weak-decrease comparison rows, the Young boundary ledger, the finite* Cont *routes, and the* Pkg *provenance. No additional partition object is available to a consumer of the carrier.*

Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier obligation`

Proof. Project the finite BHist packet to its list, part, sum, comparison, boundary, route, and provenance coordinates. These are the only rows named by the carrier definition.

The $\mathsf{List}^{\uparrow}$ dependency supplies the finite row spine, and the $\mathsf{Nat}^{\uparrow}$ dependency supplies the positive unary part rows. The remaining rows are ordinary ledgers attached to that spine by Cont and packaged by Pkg.

Since the carrier has no coordinate for a host partition set or external Young-diagram model, every accepted consumer stops at the displayed ledger surface. □

Theorem 201.4 (Partition classifier stability)**.** *Let $\mathcal{P}$ and $\mathcal{P}'$ be accepted* $\mathsf{Partition}^{\uparrow}$ *carriers. If the classifier of Definition 201.2 relates their* $\mathsf{List}^{\uparrow}$ *rows, component* $\mathsf{Nat}^{\uparrow}$ *positive-part rows, unary sum rows, weak-decrease rows, and Young boundary ledgers by displayed* hsame *transport, then the transported rows repack as an accepted* $\mathsf{Partition}^{\uparrow}$ *carrier with the same finite certificate surface.*

Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier classifier stability`

Proof. Begin with the $\mathsf{List}^{\uparrow}$ row. Its classifier transports the finite spine and therefore fixes the positions at which the part rows are read.

Next transport the component $\mathsf{Nat}^{\uparrow}$ rows and the unary sum ledger along the displayed hsame witnesses. The positive-part condition and the total row remain visible because they are ledger entries, not external arithmetic objects.

Finally transport the weak-decrease and boundary rows and concatenate the finite Cont routes in the same order. The original Pkg provenance then repacks the transported rows as an accepted carrier. □

Theorem 201.5 (Partition ledger exactness)**.** *For every accepted* $\mathsf{Partition}^{\uparrow}$ *carrier, the readable ledger consists exactly of the* $\mathsf{List}^{\uparrow}$ *row, the* $\mathsf{Nat}^{\uparrow}$ *positive-part rows, the unary sum row, the weak-decrease comparison rows, the Young boundary ledger, the displayed* hsame *transports, the finite* Cont *routes, and the* Pkg *provenance. It exposes no host partition enumeration, hook formula, symmetric-function identity, or representation-theoretic datum.*

Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier ledger exactness`

Proof. Use Definition 201.3 to reduce a consumer readback to the visible packet rows.

The exactness direction is by projection: each listed row is a coordinate of the carrier packet and is therefore readable. The converse direction is by constructor inspection: the carrier definition has no constructor for any row outside the listed ledger.

The exclusions follow from the same inspection. A host enumeration, hook formula, symmetric-function identity, or representation-theoretic datum would require an additional coordinate, and none is present. □

Theorem 201.6 (Partition finite NameCert surface)**.** *The finite* $\mathsf{NameCert}_{\mathsf{Partition}^{\uparrow}}$ *surface consists of the* BHist *carrier of Definition 201.1, the Young-ledger classifier of Definition 201.2, classifier stability from Definition 201.4, ledger exactness from Definition 201.5, and the source coverage assertion that every accepted partition row is read through the displayed* $\mathsf{List}^{\uparrow}/\mathsf{Nat}^{\uparrow}$ *packet with* Cont *routes and* Pkg *provenance.*

Proof. Use the carrier as the source predicate. It displays the list spine, positive parts, sum row, weak-decrease rows, Young boundary row, route ledger, and package provenance in one finite packet.

Use the Young-ledger classifier as the comparison predicate. Its transport obligation is exactly Definition 201.4.

The exactness and coverage clauses are supplied by Definition 201.5 and Definition 201.3. These clauses cover the finite surface and exclude all host-level partition structures outside the packet. □

Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier semantic name certificate`
Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier finite namecert surface`

Theorem 201.7 (Partition Young boundary package)**.** *The Young-diagram boundary exported by* $\mathsf{Partition}^{\uparrow}$ *is the finite ledger whose rows are the positive-part list, the unary row sums, the adjacent weak-decrease comparisons, and the boundary route obtained by concatenating the displayed* Cont *rows. The boundary is stable under the classifier of Definition 201.2 and is packaged only through the carrier's* Pkg *provenance.*

Proof. Read the boundary rows from the carrier packet. The positive-part list gives the row lengths, the unary sum ledger gives the total size, and the weak-decrease comparisons give the Young boundary order.

Concatenate the displayed Cont routes from the list row to the sum row and from the comparison rows to the boundary ledger. This produces the visible boundary route without adding a host diagram.

Apply classifier stability to transport the same boundary route across hsame-related packets. The transported route is repackaged by the same Pkg provenance surface, so the exported Young boundary remains a finite BEDC ledger. □

Lean4 ✓ `BEDC.Derived.PartitionUp.PartitionBHistCarrier young boundary package`

Theorem 201.8 (Partition bridged closure route)**.** *Every public* $\mathsf{Partition}^{\uparrow}$ *consumer that reads the Young-boundary package factors through the standard Young-ledger surface: the positive-part* $\mathsf{List}^{\uparrow}$ *row, component* $\mathsf{Nat}^{\uparrow}$ *part rows, unary size ledger, weak-decrease comparisons, displayed boundary continuation, componentwise* hsame *transport, and* Pkg *provenance. The route preserves the finite* $\mathsf{NameCert}_{\mathsf{Partition}^{\uparrow}}$ *surface and exports no host partition enumeration, hook formula, symmetric-function identity, or representation-theoretic datum.*

Proof. Read the public certificate through Definition 201.6. The available surface is the finite carrier, its Young-ledger classifier, carrier obligation, classifier stability, ledger exactness, and the Young-boundary package.

Apply Definition 201.7. The exported boundary is computed from the positive-part list, unary sum rows, adjacent weak-decrease comparisons, and the displayed continuation route, then transported by the same classifier and provenance rows.

Thus every standard Young-ledger consumer receives exactly the public $\mathsf{Partition}^{\uparrow}$ NameCert rows. The absent host enumeration, hook formula, symmetric-function identity, and representation-theoretic data remain outside the bridged paper surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{Partition}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Partition}^{\uparrow}}$, maturePackageClosed)

Scope closed: The visible seed scope is the finite BHist carrier, the Young-ledger classifier, the $\mathsf{List}^{\uparrow}/\mathsf{Nat}^{\uparrow}$ source packet, and the displayed hsame, Cont, and Pkg rows.

Constructive story: A partition packet is generated from a finite list-source row, unary size rows, adjacent weak-decrease checks, displayed boundary continuations, hsame transport, and Pkg provenance; no host enumeration or representation-theoretic object is part of the carrier.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Partition}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.PartitionUp.PartitionBHistCarrier\_young\_boundary\_package`

Bridge status: paperBridge

Not claimed: No host partition enumeration, hook formula, symmetric-function identity, or representation-theoretic datum is claimed.

Upgrade path: No further paper-side theory upgrade remains short of a machine-checked standard bridge for the Young-ledger consumer surface.

Chapter 202

A Concrete Naming Certificate for $\mathsf{Matroid}^{\uparrow}$

The matroid interface $\mathsf{Matroid}^{\uparrow}$ packages a finite ground set with a family of subsets (independent sets) closed under taking subsets and satisfying the exchange axiom. It depends on $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112) and $\mathsf{NameCert}_{\mathsf{Lattice}^{\uparrow}}$ (chapter 55).

202.1 Carrier definition

202.2 The certificate

Definition 202.1 (FinSetUp subset and intersection over one ground)**.** *Fix a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. For predicates* $U, V, J : \mathsf{BHist} \to \mathsf{Prop}$*, define finite-set subset over this ground by*

$$\mathsf{FinSetSubset}_{E,\sim_E}(U, V) \iff \exists xs : \mathsf{HistSpine}.\ \mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs, U) \wedge \forall z : \mathsf{BHist}.\ U(z) \to V(z).$$

Define the $\mathsf{FinSet}^{\uparrow}$ *intersection predicate by*

$$\mathsf{FinSetIntersection}_{E,\sim_E}(J; U, V) \iff \exists zs : \mathsf{HistSpine}.\ \mathsf{FinSetSpineEnumerates}_{E,\sim_E}(zs, J) \wedge \forall z : \mathsf{BHist}.\ J(z) \iff U(z).$$

Thus the intersection row is an exact finite-spine presentation of pointwise membership conjunction in the common ground.

Definition 202.2 (MatroidUp independent-set certificate surface)**.** *A* $\mathsf{Matroid}^{\uparrow}$ *independent-set certificate over* $(E, \sim_E)$ *consists of a finite-set predicate family*

$$\mathsf{Ind}_M : (\mathsf{BHist} \to \mathsf{Prop}) \to \mathsf{Prop}$$

and the rows

$$\begin{gathered}
\mathsf{finite}_M : \forall I.\ \mathsf{Ind}_M(I) \to \exists xs : \mathsf{HistSpine}.\ \mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs, I), \\
\mathsf{ground}_M : \forall I\, z.\ \mathsf{Ind}_M(I) \to I(z) \to E(z), \\
\mathsf{empty}_M : \mathsf{Ind}_M(\lambda z.\ \bot), \\
\mathsf{hereditary}_M : \forall I\, J.\ \mathsf{Ind}_M(I) \to \mathsf{FinSetSubset}_{E,\sim_E}(J, I) \to \mathsf{Ind}_M(J).
\end{gathered}$$

The exchange row is the certified finite-spine exchange clause on these same finite predicates: independent finite sets with certified smaller cardinal admit a carried element of the larger set whose

$\mathsf{FinSet}^{\uparrow}$ *insertion into the smaller set remains independent. The hereditary row is the subset-closure field named in the* $\mathsf{Matroid}^{\uparrow}$ *certificate paragraph of section 202.2.*

Lemma 202.3 (FinSetUp intersection projects to the left factor)**.** *Fix a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. For predicates* $I, K, J : \mathsf{BHist} \to \mathsf{Prop}$*, if*

$$\mathsf{FinSetIntersection}_{E,\sim_E}(J; I, K)$$

holds, then

$$\mathsf{FinSetSubset}_{E,\sim_E}(J, I)$$

holds. This is the finite-set form of the left lower-bound role for meet in Definition 55.102, read here from the exact $\mathsf{FinSet}^{\uparrow}$ *membership row.*

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinsetIntersection left subset`
Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinSetIntersection left subset`

Proof. Unpack Definition 202.1. The intersection hypothesis supplies a finite spine zs with

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(zs, J)$$

and a pointwise equivalence

$$\forall z : \mathsf{BHist}.\ J(z) \iff I(z) \wedge K(z).$$

To prove $\mathsf{FinSetSubset}_{E,\sim_E}(J, I)$, keep the same finite spine zs as the finite-set witness for J. It remains only to prove the inclusion row. Fix $z : \mathsf{BHist}$ and assume $J(z)$. The forward half of the displayed pointwise equivalence gives $I(z) \wedge K(z)$, and projecting its first component gives $I(z)$. Thus every member of J is a member of I, with the finite-spine witness already supplied. □

Theorem 202.4 (Matroid intersection preserves independence)**.** *Fix a* $\mathsf{Matroid}^{\uparrow}$ *independent-set certificate over a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*, with independent-family row* Ind_M *as in Definition 202.2. Let* $I, K, J : \mathsf{BHist} \to \mathsf{Prop}$ *be finite-set predicates over the same ground. Suppose*

$$\mathsf{Ind}_M(I)$$

and suppose there are finite spines xs *and* ys *such that*

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs, I) \qquad \textit{and} \qquad \mathsf{FinSetSpineEnumerates}_{E,\sim_E}(ys, K).$$

If J *is the* $\mathsf{FinSet}^{\uparrow}$ *intersection of* I *with* K*,*

$$\mathsf{FinSetIntersection}_{E,\sim_E}(J; I, K),$$

then

$$\mathsf{Ind}_M(J).$$

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinsetIntersection independence preserved`
Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidIntersection preserves independence`

Proof. The finite-spine witnesses xs and ys record that I and K are finite predicates over the same ground $(E, \sim_E)$ in the sense of Definition 112.17. The independence hypothesis gives the $\mathsf{Matroid}^{\uparrow}$ independent set I.

Apply Definition 202.3 to the displayed intersection row. This gives

$$\mathsf{FinSetSubset}_{E,\sim_E}(J, I).$$

The hereditary field $\mathsf{hereditary}_M$ of the $\mathsf{Matroid}^{\uparrow}$ certificate in Definition 202.2 applies to $\mathsf{Ind}_M(I)$ and this finite-set subset row, and yields

$$\mathsf{Ind}_M(J).$$

The exchange row and all cardinal comparison data are irrelevant for this closure step; independence is preserved solely by the certified subset-closure field. □

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinSetIntersection preserves independence`

Definition 202.5 (Certified matroid restriction rows)**.** *Fix a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. For predicates* $I, I^+ : \mathsf{BHist} \to \mathsf{Prop}$ *and a history* $x : \mathsf{BHist}$*, define the certified* $\mathsf{FinSet}^{\uparrow}$ *insertion row by*

$$\mathsf{FinSetInsert}_{E,\sim_E}(I, x, I^+) \iff E(x) \wedge \exists xs^+ : \mathsf{HistSpine}.\ \mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs^+, I^+) \wedge \forall z : \mathsf{BHist}.\ I^+(z) \Longleftarrow$$

For a certified finite-cardinality comparison predicate $\mathsf{FinSetCardLt}_{E,\sim_E}$*, the ambient exchange row for a family* Ind *is*

$$\mathsf{MatroidExchangeRow}_{E,\sim_E,\mathsf{FinSetCardLt}}(\mathsf{Ind}) \iff \forall I\ J.\ \mathsf{Ind}(I) \to \mathsf{Ind}(J) \to \mathsf{FinSetCardLt}_{E,\sim_E}(I, J) \to \exists x : \mathsf{BHist}.\ \exists I^+$$

For a finite subset predicate K *of* E *and a candidate restricted family* $\mathsf{Ind}_{M|K}$*, define the restricted* $\mathsf{Matroid}^{\uparrow}$ *row package by*

$$\forall I$$

$$\forall I.\ \mathsf{Ind}_{M|}$$

$$\mathsf{MatroidRestrictionRows}_{E,\sim_E,K,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M, \mathsf{Ind}_{M|K}) \iff$$

$$\forall I\ J$$

$$\forall I\ J.\ \mathsf{Ind}_{M|K}(I) \to \mathsf{Ind}_{M|K}(J) \to \mathsf{FinSetCardLt}_{E,\sim_E}(I,$$

The rows use the same finite-spine and cardinal-comparison surface as the ambient $\mathsf{Matroid}^{\uparrow}$ *certificate of Definition 202.2, while the ground row is narrowed to* K*.*

Lemma 202.6 (Finite-spine subsets are classifier saturated)**.** *Let* $E : \mathsf{BHist} \to \mathsf{Prop}$ *have classifier* $\sim_E$*, let* $\mathsf{cert} : \mathsf{NameCert}(E, \sim_E)$*, and let* $K : \mathsf{BHist} \to \mathsf{Prop}$*. If*

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(ks, K),$$

then for all histories $x, y : \mathsf{BHist}$*,*

$$K(x) \wedge E(y) \wedge y \sim_E x \to K(y).$$

Proof. Unfold Definition 112.17. The enumeration hypothesis turns $K(x)$ into $\mathsf{EnumMem}_{E,\sim_E}(x, ks)$. Unfolding Definition 112.1, choose a position $i : \mathsf{Pos}(ks)$ with $E(\mathsf{entry}_{ks}(i))$ and

$$x \sim_E \mathsf{entry}_{ks}(i).$$

The transitivity field of cert from Definition 9.7, applied to $y \sim_E x$ and the displayed comparison, gives

$$y \sim_E \mathsf{entry}_{ks}(i).$$

Together with $E(y)$ and the same position i, this repacks as $\mathsf{EnumMem}_{E,\sim_E}(y, ks)$. The forward half of the enumeration equivalence for y yields $K(y)$. □

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinSetSpineEnumerates classifier saturation`

Theorem 202.7 (Matroid restriction certificate)**.** *Fix a* $\mathsf{Matroid}^{\uparrow}$ *independent-set certificate over a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$ *and naming certificate* $\mathsf{cert} : \mathsf{NameCert}(E, \sim_E)$*. Let* Ind_M *be its independent-family row, with fields* finite_M*,* ground_M*,* empty_M*, and* $\mathsf{hereditary}_M$ *as in Definition 202.2. Assume also the ambient exchange row*

$$\mathsf{MatroidExchangeRow}_{E,\sim_E,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M).$$

Let $K : \mathsf{BHist} \to \mathsf{Prop}$ *be a* $\mathsf{FinSet}^{\uparrow}$ *subset of* E*:*

$$\mathsf{FinSetSubset}_{E,\sim_E}(K, E).$$

If a family $\mathsf{Ind}_{M|K}$ *is exactly the family of ambient independent predicates contained in* K*,*

$$\forall I.\ \mathsf{Ind}_{M|K}(I) \iff \mathsf{Ind}_M(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, K),$$

then it satisfies the restricted $\mathsf{Matroid}^{\uparrow}$ *row package over* K*:*

$$\mathsf{MatroidRestrictionRows}_{E,\sim_E,K,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M, \mathsf{Ind}_{M|K}).$$

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidRestrictionRows certificate`
Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidRestrictionRows exchange support boundary`

Proof. Unpack the displayed K-subset row using Definition 202.1. Choose a finite spine ks with

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(ks, K),$$

and keep the inclusion row $K(z) \to E(z)$. Unfold Definition 202.5. The defining equivalence row for $\mathsf{Ind}_{M|K}$ is exactly the displayed hypothesis.

For the finite row, assume $\mathsf{Ind}_{M|K}(I)$. The defining equivalence gives $\mathsf{Ind}_M(I)$, so finite_M supplies a finite spine enumerating I over $(E, \sim_E)$.

For the ground row over K, assume $\mathsf{Ind}_{M|K}(I)$ and $I(z)$. The defining equivalence gives $\mathsf{FinSetSubset}_{E,\sim_E}(I, K)$. Unpacking that subset row gives the inclusion $I(z) \to K(z)$, hence $K(z)$.

For the empty row, empty_M gives $\mathsf{Ind}_M(\lambda z.\ \bot)$. Applying finite_M to this ambient independent set gives a finite spine enumerating the empty predicate. Pair that spine with the vacuous inclusion $(\lambda z.\ \bot)(z) \to K(z)$ to obtain

$$\mathsf{FinSetSubset}_{E,\sim_E}(\lambda z.\ \bot, K).$$

The defining equivalence for $\mathsf{Ind}_{M|K}$ then gives $\mathsf{Ind}_{M|K}(\lambda z.\ \bot)$.

For hereditary closure, assume $\mathsf{Ind}_{M|K}(I)$ and $\mathsf{FinSetSubset}_{E,\sim_E}(J, I)$. The defining equivalence gives $\mathsf{Ind}_M(I)$ and $\mathsf{FinSetSubset}_{E,\sim_E}(I, K)$. The ambient hereditary row gives $\mathsf{Ind}_M(J)$. Unpack the two subset rows: the row from J to I supplies a finite spine enumerating J and an inclusion $J(z) \to I(z)$, while the row from I to K supplies an inclusion $I(z) \to K(z)$. Composing the inclusions and keeping the finite spine for J gives

$$\mathsf{FinSetSubset}_{E,\sim_E}(J, K).$$

The defining equivalence repacks these two facts as $\mathsf{Ind}_{M|K}(J)$.

For exchange, assume $\mathsf{Ind}_{M|K}(I)$, $\mathsf{Ind}_{M|K}(J)$, and $\mathsf{FinSetCardLt}_{E,\sim_E}(I, J)$. The defining equivalence gives ambient independence of both I and J, plus subset rows

$$\mathsf{FinSetSubset}_{E,\sim_E}(I, K) \qquad \text{and} \qquad \mathsf{FinSetSubset}_{E,\sim_E}(J, K).$$

Apply the ambient exchange row to obtain histories x and I^+ such that

$$J(x) \wedge \neg I(x) \wedge \mathsf{FinSetInsert}_{E,\sim_E}(I, x, I^+) \wedge \mathsf{Ind}_M(I^+).$$

Unpacking the subset row from J to K gives the inclusion $\forall z : \mathsf{BHist}.\ J(z) \to K(z)$; applying this inclusion at x to the witness $J(x)$ gives $K(x)$. Unpack the insertion row: it supplies a finite spine enumerating I^+ and the pointwise law

$$I^+(z) \iff I(z) \vee (E(z) \wedge z \sim_E x).$$

To prove $\mathsf{FinSetSubset}_{E,\sim_E}(I^+, K)$, keep the finite spine from the insertion row. If $I^+(z)$ holds, the displayed pointwise law gives either $I(z)$ or $E(z) \wedge z \sim_E x$. In the first case, the subset row from I to K gives $K(z)$. In the second case, apply Definition 202.6 to the finite spine ks, the witness $K(x)$, the carried witness $E(z)$, and the comparison $z \sim_E x$; this gives $K(z)$. Thus I^+ is a finite subset of K.

Pair $\mathsf{Ind}_M(I^+)$ with this subset row and apply the defining equivalence for $\mathsf{Ind}_{M|K}$ to obtain $\mathsf{Ind}_{M|K}(I^+)$. The selected x, the predicate I^+, the witnesses $J(x)$, $\neg I(x)$, $K(x)$, the insertion row, and the restricted independence of I^+ are exactly the restricted exchange row. □

Lemma 202.8 (FinSetUp subset rows compose over one ground)**.** *Fix a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. For predicates* $A, B, C : \mathsf{BHist} \to \mathsf{Prop}$*, if*

$$\mathsf{FinSetSubset}_{E,\sim_E}(A, B) \qquad \textit{and} \qquad \mathsf{FinSetSubset}_{E,\sim_E}(B, C)$$

hold, then

$$\mathsf{FinSetSubset}_{E,\sim_E}(A, C)$$

holds.

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinsetSubset row composition`

Proof. Unpack Definition 202.1. The first subset row supplies a finite spine as with

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(as, A)$$

and an inclusion $A(z) \to B(z)$ for every $z : \mathsf{BHist}$. The second subset row supplies an inclusion $B(z) \to C(z)$ for every $z : \mathsf{BHist}$. Keep the same finite spine as as the enumeration witness for A. For the inclusion row, fix z and assume $A(z)$. The first inclusion gives $B(z)$, and the second gives $C(z)$. This is exactly $\mathsf{FinSetSubset}_{E,\sim_E}(A, C)$. □

Theorem 202.9 (Matroid restrictions compose to direct restriction)**.** *Fix a* $\mathsf{Matroid}^{\uparrow}$ *independent-set certificate over a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$ *and naming certificate* $\mathsf{cert} : \mathsf{NameCert}(E, \sim_E)$*. Let* Ind_M *be its independent-family row, with fields* finite_M*,* empty_M*, and* $\mathsf{hereditary}_M$ *as in Definition 202.2. Assume also the ambient exchange row*

$$\mathsf{MatroidExchangeRow}_{E,\sim_E,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M).$$

Let $K, L : \mathsf{BHist} \to \mathsf{Prop}$ *satisfy*

$$\mathsf{FinSetSubset}_{E,\sim_E}(K, E) \qquad \textit{and} \qquad \mathsf{FinSetSubset}_{E,\sim_E}(L, K).$$

Let $\mathsf{Ind}_{M|K}$ *and* $\mathsf{Ind}_{(M|K)|L}$ *be predicate families such that*

$$\forall I.\ \mathsf{Ind}_{M|K}(I) \iff \mathsf{Ind}_M(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, K)$$

and

$$\forall I.\ \mathsf{Ind}_{(M|K)|L}(I) \iff \mathsf{Ind}_{M|K}(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, L).$$

Then, for every predicate $I : \mathsf{BHist} \to \mathsf{Prop}$*,*

$$\mathsf{Ind}_{(M|K)|L}(I) \iff \mathsf{Ind}_M(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, L),$$

and the iterated restriction satisfies the direct restricted row package

$$\mathsf{MatroidRestrictionRows}_{E,\sim_E,L,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M, \mathsf{Ind}_{(M|K)|L}).$$

Proof. By Definition 202.8, the displayed subset rows for $L \subseteq K$ and $K \subseteq E$ compose to

$$\mathsf{FinSetSubset}_{E,\sim_E}(L, E).$$

Fix $I : \mathsf{BHist} \to \mathsf{Prop}$. For the forward implication, assume $\mathsf{Ind}_{(M|K)|L}(I)$. The second displayed defining equivalence gives

$$\mathsf{Ind}_{M|K}(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, L).$$

Applying the first displayed defining equivalence to the first component gives $\mathsf{Ind}_M(I)$. Pairing this ambient independence with the retained subset row $\mathsf{FinSetSubset}_{E,\sim_E}(I, L)$ gives the direct restriction condition.

For the reverse implication, assume

$$\mathsf{Ind}_M(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, L).$$

The subset row $\mathsf{FinSetSubset}_{E,\sim_E}(I, L)$ composes with $\mathsf{FinSetSubset}_{E,\sim_E}(L, K)$ by Definition 202.8, giving

$$\mathsf{FinSetSubset}_{E,\sim_E}(I, K).$$

The first defining equivalence therefore gives $\mathsf{Ind}_{M|K}(I)$ from $\mathsf{Ind}_M(I)$ and this subset row. Pairing $\mathsf{Ind}_{M|K}(I)$ with the original subset row $\mathsf{FinSetSubset}_{E,\sim_E}(I, L)$ and applying the second defining equivalence gives $\mathsf{Ind}_{(M|K)|L}(I)$.

Thus the displayed direct equivalence holds for every I. Apply Definition 202.7 with L as the finite restriction predicate, using the composed row $\mathsf{FinSetSubset}_{E,\sim_E}(L, E)$ and the direct equivalence just proved. The result is exactly

$$\mathsf{MatroidRestrictionRows}_{E,\sim_E,L,\mathsf{FinSetCardLt}}(\mathsf{Ind}_M, \mathsf{Ind}_{(M|K)|L}).$$

□

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidRestrictions compose direct restriction`

Lemma 202.10 (FinSetUp intersection projects to the right factor)**.** *Fix a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. For predicates* $I, K, J : \mathsf{BHist} \to \mathsf{Prop}$*, if*

$$\mathsf{FinSetIntersection}_{E,\sim_E}(J; I, K)$$

holds, then

$$\mathsf{FinSetSubset}_{E,\sim_E}(J, K)$$

holds. This is the finite-set form of the right lower-bound role for intersection over the common $\mathsf{FinSet}^{\uparrow}$ *ground, read from the exact membership row in Definition 202.1.*

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidFinsetIntersection right subset`

Proof. Unpack Definition 202.1. The intersection hypothesis supplies a finite spine zs with

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(zs, J)$$

and a pointwise equivalence

$$\forall z : \mathsf{BHist}.\ J(z) \iff I(z) \wedge K(z).$$

To prove $\mathsf{FinSetSubset}_{E,\sim_E}(J, K)$, keep the same finite spine zs as the finite-set witness for J. It remains only to prove the inclusion row. Fix $z : \mathsf{BHist}$ and assume $J(z)$. The forward half of the displayed pointwise equivalence gives $I(z) \wedge K(z)$, and projecting its second component gives $K(z)$. Thus every member of J is a member of K, with the finite-spine witness already supplied. □

Theorem 202.11 (Matroid restriction to the empty subset is singleton)**.** *Fix a* $\mathsf{Matroid}^{\uparrow}$ *independent-set certificate over a ground predicate* $E : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_E$*. Let* Ind_M *be its independent-family row, with fields* finite_M*,* empty_M*, and* $\mathsf{hereditary}_M$ *as in Definition 202.2. Let* $\mathsf{Ind}_{M|\varnothing}$ *be the restriction family defined by the empty restriction predicate:*

$$\forall I.\ \mathsf{Ind}_{M|\varnothing}(I) \iff \mathsf{Ind}_M(I) \wedge \mathsf{FinSetSubset}_{E,\sim_E}(I, \lambda z.\ \bot).$$

Then, for every predicate $I : \mathsf{BHist} \to \mathsf{Prop}$*,*

$$\mathsf{Ind}_{M|\varnothing}(I) \iff \forall z : \mathsf{BHist}.\ I(z) \iff \bot.$$

Thus the empty restriction accepts exactly the pointwise empty independent predicate.

Lean4 ✓ `BEDC.Derived.MatroidUp.MatroidRestriction empty singleton independent family`

Proof. Fix $I : \mathsf{BHist} \to \mathsf{Prop}$. For the forward implication, assume $\mathsf{Ind}_{M|\varnothing}(I)$. The displayed defining equivalence gives

$$\mathsf{FinSetSubset}_{E,\sim_E}(I, \lambda z.\ \bot).$$

Unpacking Definition 202.1, this subset row contains the inclusion

$$\forall z : \mathsf{BHist}.\ I(z) \to \bot.$$

For each z, this inclusion is the forward half of $I(z) \iff \bot$, while the reverse half follows from elimination of $\bot$. Hence I is pointwise empty.

For the reverse implication, assume

$$\forall z : \mathsf{BHist}.\ I(z) \iff \bot.$$

The ambient empty row gives $\mathsf{Ind}_M(\lambda z.\ \bot)$. Applying finite_M to this row chooses a finite spine xs with

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs, \lambda z.\ \bot).$$

Use this same finite spine as the ledger for I. By Definition 112.17, the enumeration row for the empty predicate says that, for every z,

$$\mathsf{EnumMem}_{E,\sim_E}(z, xs) \iff \bot.$$

Combining this equivalence with the assumed pointwise equivalence $I(z) \iff \bot$ gives

$$\mathsf{FinSetSpineEnumerates}_{E,\sim_E}(xs, I).$$

The assumed pointwise equivalence also gives the inclusion $I(z) \to \bot$ for every z. Therefore, by Definition 202.1, the same finite spine xs proves

$$\mathsf{FinSetSubset}_{E,\sim_E}(I, \lambda z.\ \bot).$$

The hereditary row $\mathsf{hereditary}_M$ applies to the ambient empty independent set and this finite-subset row, yielding $\mathsf{Ind}_M(I)$. Pairing $\mathsf{Ind}_M(I)$ with the displayed subset row and applying the defining equivalence for $\mathsf{Ind}_{M|\varnothing}$ gives

$$\mathsf{Ind}_{M|\varnothing}(I).$$

The two implications prove the claimed equivalence. □

Theorem 202.12 (Matroid finite bridge package)**.** *The displayed* $\mathsf{FinSet}^{\uparrow}$ *subset and intersection rows together with the* $\mathsf{Lattice}^{\uparrow}$ *dependency rows export the finite* $\mathsf{Matroid}^{\uparrow}$ *public interface as a paper-level bridge package. The bridge source is the finite ground row, the independent-set certificate of Definition 202.2, the restriction rows, the intersection rows, and the empty-restriction singleton row; its target reads the same finite matroid interface through subset, intersection, hereditary, and exchange data, with no host matroid oracle or off-ledger independence predicate.*

Proof. Start with the finite subset and intersection rows. The left and right subset theorems, the intersection-preservation theorems, and the subset-composition theorem expose the public finite-set operations only through $\mathsf{FinSet}^{\uparrow}$ rows over the displayed ground predicate.

Read the dependency rows through $\mathsf{Lattice}^{\uparrow}$. The restriction and composed-restriction theorems keep every retained-ground and empty-restriction read inside the same finite dependency surface, while the classifier-saturation row keeps the independent-family classifier tied to those displayed rows.

The bridge package is therefore the tuple of source, target, encode, decode, theorem-preservation, and no-host-leak data supplied by those finite rows. Encoding sends an accepted $\mathsf{Matroid}^{\uparrow}$ packet to its displayed finite ground, subset, intersection, hereditary, exchange, and restriction rows; decoding repacks the same rows as the public finite matroid interface. The preservation and no-host-leak fields are exactly the nonescape clauses already stated in the carrier and restriction proofs: a consumer receives only finite $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{Lattice}^{\uparrow}$ dependency data, not a host independence oracle. □

Closure status for $\mathsf{NameCert}_{\mathsf{Matroid}^{\uparrow}}$.

Constructive story: A $\mathsf{Matroid}^{\uparrow}$ packet is generated from a finite ground-set row, displayed subset rows over that ground, independent-set certificate rows, restriction rows, intersection rows, singleton empty-restriction rows, componentwise hsame transport, finite Cont readbacks, package provenance, and local naming. The classifier reads independence only through the finite subset and certificate surface; restriction is generated by projecting to retained ground elements and repacking the same independence witnesses over the restricted carrier. The ledger story is finite matroid accounting: intersections, restrictions, composed restrictions, and the empty restriction are all produced from explicit FinSetUp rows and their transport routes, not from a host matroid object or off-ledger independence oracle.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Matroid}^{\uparrow}}, \mathsf{bridgedClosed})$

Scope closed: This chapter exports the public carrier route from finite independence, subset, intersection, restriction, classifier-saturation, and exchange rows to the downstream $\mathsf{Matroid}^{\uparrow}$ restriction surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Matroid}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim host matroid equality, infinite ground sets, unlisted rank or closure operators, or independence data outside the displayed finite certificate rows.

Upgrade path: Bridge closure requires Lean verification and a standard bridge for the public finite-independence carrier route exposed here.

Chapter 203

A Concrete Naming Certificate for $\mathsf{Ramsey}^{\uparrow}$

The Ramsey-theory interface $\mathsf{Ramsey}^{\uparrow}$ packages, for every finite colouring of the r-element subsets of a sufficiently large finite set, a monochromatic subset of bounded size. It depends on $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112) and $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118).

203.1 Carrier definition

Definition 203.1 (Ramsey monochrome witness carrier)**.** *The Ramsey monochrome witness carrier is the finite* BHist *packet whose readable rows are the* $\mathsf{FinSet}^{\uparrow}$ *vertex spine, the displayed subset spine, the colour endpoint rows indexed by that subset spine, the chosen witness subset row, the component* hsame *transports, the finite* Cont *lookup routes from displayed subsets to colour endpoints, and the shared* Pkg *provenance for the packet. The carrier accepts a downstream witness only when each row is read through these finite packet coordinates and through the dependency certificates* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *where those projections are requested.*

Lean4 (definition) `BEDC.Derived.RamseyUp.RamseyMonochromeWitnessCarrier`

203.2 The certificate

Theorem 203.2 (Ramsey colouring carrier obligation)**.** *A carried* $\mathsf{Ramsey}^{\uparrow}$ *colouring row over a displayed* $\mathsf{FinSet}^{\uparrow}$ *source is a finite* BHist *packet consisting of the certified finite vertex spine, the certified r-subset spine read through* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$*, one colour endpoint row for each displayed subset, finite* Cont *routes tying the subset rows to their colour endpoints, and shared* Pkg *provenance for the table. The carrier accepts only these finite colouring rows.*

The carrier does not read a host finite-set enumeration, a host function from subsets to colours, or an ambient combinatorial universe. All subset and colour reads pass through the displayed BHist *rows and the finite ledger.*

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier obligation surface`

Proof. Project the $\mathsf{Ramsey}^{\uparrow}$ row to the finite vertex spine supplied by $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ and to the displayed subset spine built over it. The colour table is then a finite family of endpoint rows indexed by that subset spine, with each lookup routed by a visible Cont row and packaged by the same Pkg provenance.

Since the packet has no coordinate for a host enumeration or a host colouring function, a consumer can only read the listed BHist rows. Repacking those rows gives the stated carrier surface. □

Theorem 203.3 (Ramsey public projection package)**.** *The checked rows Definition 203.2, Definition 203.4, Definition 203.5, and Definition 203.6 assemble a public projection package for* $\mathsf{Ramsey}^{\uparrow}$*. FinSetUp and GraphUp consumers receive only the vertex spine, subset spine, colour endpoint rows, witness rows, component* hsame *transports, finite* Cont *lookup routes, and shared* Pkg *provenance displayed by the finite* BHist *ledger.*

The package exports no host finite-set enumeration, no host colouring function, no graph equality primitive, and no ambient graph object.

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier public projection package`

Proof. Project first through the carrier rows of Definition 203.2. This identifies the public source available to a FinSetUp or GraphUp consumer with the displayed vertex spine, subset spine, colour table, witness rows, finite lookup routes, transport rows, and provenance rows.

Apply the classifier stability row of Definition 203.4 to transport the monochrome classifier across component hsame witnesses. The transported classifier still reads the same finite colour endpoints through the same Cont routes.

Use the witness scope row Definition 203.5 for every downstream dependency read. It restricts finset and graph consumers to the displayed dependency certificates and prevents any read from leaving the finite packet.

Finally combine ledger exactness from Definition 203.6 with the downstream boundary of Definition 203.8. Together they give both inclusions: all exported public rows are the listed ledger rows, and the excluded host enumeration, colouring function, graph equality primitive, and ambient graph object have no carrier coordinate to project. □

Theorem 203.4 (Ramsey monochrome classifier stability)**.** *Let* $\mathcal{C}$ *and* $\mathcal{C}'$ *be carried* $\mathsf{Ramsey}^{\uparrow}$ *colouring rows over the same displayed* $\mathsf{FinSet}^{\uparrow}$ *source. If their vertex spines, subset spines, colour endpoint rows, finite* Cont *routes, and* Pkg *provenance are related componentwise by* hsame*, then the monochrome-subset classifier transports from* $\mathcal{C}$ *to* $\mathcal{C}'$*. In particular, any displayed witness subset whose* r*-subsets have one colour in* $\mathcal{C}$ *is carried to a displayed witness subset with the same classified colour in* $\mathcal{C}'$*.*

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier classifier stability`

Proof. Begin with the subset witness. The $\mathsf{FinSet}^{\uparrow}$ classifier transports the finite vertex entries and the displayed subset spine, so every r-subset read from the witness in $\mathcal{C}$ has a corresponding transported row in $\mathcal{C}'$.

Next transport the colour endpoints along the displayed hsame rows. The finite Cont routes preserve which table entry is read by each subset, and the shared Pkg provenance keeps the transported reads inside the same colouring packet.

The monochrome condition is pointwise equality through the colour classifier on the transported endpoint rows. Thus all transported r-subsets retain the same classified colour, and the witness subset remains monochrome without choosing a host subset representative. □

Theorem 203.5 (Ramsey monochrome witness scope)**.** *Every monochrome witness consumed downstream from the* $\mathsf{Ramsey}^{\uparrow}$ *surface is read only through the carrier of Definition 203.1, together with the* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *projections already exposed by the displayed packet.*

No downstream clause reads a host subset iterator, a host colouring function, or an ambient graph object outside those packet rows.

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier monochrome witness scope`

Proof. First project the witness to the finite packet of Definition 203.1. This gives the vertex spine, subset spine, colour endpoint rows, chosen witness subset, component hsame transports, finite lookup routes, and shared provenance as explicit BHist rows.

Next apply Definition 203.2. It identifies the accepted colouring surface with the same finite packet, so every colour read used by the witness is routed through a displayed Cont lookup rather than through a host colouring function.

The witness classifier is stable under the transported rows by Definition 203.4. The finite ledger exactness theorem then says that the readable rows are exactly the displayed carrier, lookup, transport, and provenance rows, with any finset or graph consumer receiving only the corresponding $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ or $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ projection.

Thus the downstream witness has no remaining coordinate from which a host subset iterator, host colouring function, or ambient graph object could be read. □

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier witness scope`

Theorem 203.6 (Ramsey finite ledger exactness)**.** *For every accepted* $\mathsf{Ramsey}^{\uparrow}$ *colouring row, the readable ledger consists exactly of the* $\mathsf{FinSet}^{\uparrow}$ *vertex spine, the finite* r*-subset spine, the colour endpoint table, the displayed monochrome witness subset rows, the component* hsame *transports, the finite* Cont *lookup routes, and the shared* Pkg *provenance. It exposes no host finite-set enumeration, host subset iterator, off-ledger colour function, or graph object beyond the displayed dependency rows.*

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier finite ledger exactness`

Proof. Use Definition 203.2 to reduce any consumer read to the carrier packet. Each listed ledger row is a coordinate of that packet or a finite lookup route attached to it.

For the reverse containment, inspect the carrier surface: every vertex, subset, colour, witness, transport, lookup, and provenance row appears in the finite ledger. The packet has no constructor for host enumeration, host subset iteration, or off-ledger colouring functions.

If a graph consumer is present, it can only receive the dependency rows already certified by $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ and the displayed finite ledger. No extra graph object is generated by the Ramsey ledger itself. □

Theorem 203.7 (Ramsey NameCert obligation assembly)**.** *The public* $\mathsf{NameCert}_{\mathsf{Ramsey}^{\uparrow}}$ *obligation surface is assembled from the finite colouring carrier of Definition 203.2, the monochrome-subset classifier stability of Definition 203.4, the ledger exactness of Definition 203.6, and the dependency certificates* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *when graph-shaped consumers read the same finite rows. The assembled surface binds carrier, classifier, stability, exactness, and source coverage over* BHist*,* hsame*,* Cont*, and* Pkg*.*

No clause of the assembled surface treats host finite-set enumeration, host function equality, or an ambient graph object as a primitive.

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier namecert obligation assembly`

Proof. Use the carried colouring row as the source predicate. Its finite vertex spine, subset spine, colour table, lookup routes, and provenance are exactly the carrier rows isolated in Definition 203.2.

Use the monochrome-subset classifier as the comparison predicate. Stability under transported vertex, subset, colour, route, and provenance rows is precisely Definition 203.4.

The exactness and source-coverage clauses are supplied by Definition 203.6. The $\mathsf{FinSet}^{\uparrow}$ dependency accounts for all finite spines, and the $\mathsf{Graph}^{\uparrow}$ dependency is only a consumer boundary for graph-shaped readings of those rows, so the assembled certificate remains a finite BHist ledger. □

Theorem 203.8 (Ramsey downstream boundary)**.** *Every graph, finset, or combinatorial consumer of the* $\mathsf{Ramsey}^{\uparrow}$ *surface reads only the assembled* $\mathsf{NameCert}_{\mathsf{Ramsey}^{\uparrow}}$ *rows of Definition 203.7: the displayed* $\mathsf{FinSet}^{\uparrow}$ *vertex spine, the finite subset spine, the colour endpoint table, the monochrome witness rows, the* hsame *transports, the finite* Cont *lookup routes, and the shared* Pkg *provenance. A consumer may project these rows into* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *or* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *interfaces, but it cannot read a host finite-set enumeration, host subset iterator, host colouring function, or graph equality primitive from* $\mathsf{Ramsey}^{\uparrow}$ *itself.*

Lean4 ✓ `BEDC.Derived.RamseyUp.RamseyColouringCarrier downstream boundary`

Proof. First reduce the consumer read to the assembled certificate surface by Definition 203.7. This fixes the carrier, classifier, stability, ledger, and source-coverage rows over the finite BHist packet.

For a finset consumer, project the vertex and subset spines through $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$. The projection preserves the displayed hsame transports and finite lookup routes, and it does not expose a host enumeration.

For a graph-shaped consumer, use $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ only on rows already present in the finite ledger. The graph interface receives carried vertex, edge, or incidence rows as projections, while the Ramsey table and witness remain the same Cont-routed finite packet.

Thus every downstream boundary is a projection of the public Ramsey ledger, not an additional primitive surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{Ramsey}^{\uparrow}}$**.**

Constructive story: A $\mathsf{Ramsey}^{\uparrow}$ packet is generated from a finite vertex spine, colour endpoint rows, monochrome-witness rows, dependency projections to FinSetUp and GraphUp, componentwise hsame transport, finite Cont lookup routes, package provenance, and local naming. The classifier reads monochromaticity only through the displayed finite colouring ledger and the transported colour endpoints for each listed subset. The ledger story is finite Ramsey projection: public consumers receive vertex, edge, subset, colour, witness, route, and provenance rows already present in the BHist packet, while host enumeration, off-ledger colouring functions, and graph objects beyond the displayed dependency certificates are not generated.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Ramsey}^{\uparrow}}$, obligation)

Scope closed: This chapter binds the Ramsey witness carrier and the colouring-carrier, public-projection, classifier-stability, witness-scope, finite-ledger-exactness, NameCert-assembly, and downstream-boundary theorems for $\mathsf{Ramsey}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Ramsey}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim host finite-set enumeration, host colouring functions, off-ledger subset iteration, or graph data beyond the displayed FinSetUp and GraphUp projections.

Upgrade path: Scoped closure requires binding the finite Ramsey ledger obligations to FinSetUp, GraphUp, BHist, hsame, Cont, Pkg, and NameCert scope.

Chapter 204

A Concrete Naming Certificate for $\mathsf{TopGroup}^{\uparrow}$

The topological-group interface $\mathsf{TopGroup}^{\uparrow}$ packages a group carrier with a topology making multiplication and inversion continuous. It depends on $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88).

204.1 Carrier definition

Definition 204.1 (TopGroupUp BHist carrier)**.** *A* $\mathsf{TopGroup}^{\uparrow}$ BHist *carrier is a finite packet*

$$\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$$

over the displayed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source rows. The row G is the group carrier and classifier surface. The row T is the topology carrier containing the public open-neighbourhood rows. The row m is the multiplication graph row, with endpoints read in G and neighbourhoods read in T. The row i is the inversion graph row with the same carrier and neighbourhood interface. The row n records the open neighbourhood transport rows used by multiplication and inversion. The row λ is the finite* Cont *ledger for continuity transport, and ρ is the* Pkg *provenance row for the group, topology, operation, neighbourhood, continuity, and ledger entries.*

The classifier between two carriers compares the G, T, m, i, n, and ρ rows by hsame *and compares the continuation ledgers by* Cont*. No external topological group object is part of the carrier.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupBHistCarrier`

204.2 The certificate

Theorem 204.2 (TopGroupUp multiplication continuity carrier)**.** *Let $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ be a* $\mathsf{TopGroup}^{\uparrow}$ BHist *carrier. If x and y are carried by the group row G, and if an open-neighbourhood row of T is displayed around the product endpoint $m(x, y)$, then the multiplication graph row keeps $m(x, y)$ in the topology carrier. Transporting x, y, the product row, and the target neighbourhood by the classifier uses only the displayed* hsame *rows and the finite* Cont *continuity ledger.*

Proof. Project the group row, topology row, multiplication graph row, neighbourhood row, continuation ledger, and provenance row from Definition 204.1. These projections name both operation endpoints and the target open-neighbourhood row.

The classifier transports the two group endpoints and the multiplication graph componentwise by hsame. It also transports the relevant open-neighbourhood row in T and records the continuity step in the finite Cont ledger.

Repack the transported multiplication graph with the same topology carrier and provenance row. The resulting product endpoint is still read through T, so the multiplication continuity row remains inside the $\mathsf{TopGroup}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage multiplication continuity carrier`

Theorem 204.3 (TopGroupUp inversion continuity carrier)**.** *Let $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ be a $\mathsf{TopGroup}^{\uparrow}$ BHist carrier. If x is carried by the group row G, and if an open-neighbourhood row of T is displayed around the inverse endpoint $i(x)$, then the inversion graph row keeps $i(x)$ in the topology carrier. Transporting x, its inverse row, and the target neighbourhood by the classifier uses only the displayed* hsame *rows and the same finite* Cont *continuity ledger.*

Proof. Project the inversion graph row from Definition 204.1, together with the group carrier, topology carrier, neighbourhood row, continuation ledger, and provenance row.

The endpoint transport is componentwise: x is transported inside G, the inverse graph row is transported by hsame, and the target neighbourhood is transported inside T. The continuity entry is recorded in the finite Cont ledger already carried by $\mathcal{G}$.

Repack these rows with the unchanged source certificates. Since the carrier contains no additional neighbourhood object or external topology, the inverse endpoint remains in the displayed $\mathsf{TopGroup}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage inversion continuity carrier`

Theorem 204.4 (TopGroupUp NameCert obligation surface)**.** *The public $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ obligation surface consists exactly of the* BHist *carrier of Definition 204.1, its componentwise classifier, the inherited $\mathsf{Group}^{\uparrow}$ operation rows, the $\mathsf{Topology}^{\uparrow}$ open-neighbourhood rows, the multiplication and inversion continuity rows, and the finite* Cont/Pkg *ledger scope. It exports no group-topology data beyond those displayed BEDC rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage namecert obligation surface`

Proof. Unpack the carrier packet. The projections expose the group source, topology source, multiplication graph, inversion graph, open-neighbourhood transport, continuation ledger, and provenance row.

Apply Definition 204.2 for the product continuity row and Definition 204.3 for the inverse continuity row. Both results use only the componentwise classifier and the finite Cont ledger.

Repack the projected rows as the public certificate surface. The source rows are the displayed $\mathsf{Group}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ certificates, while every operation and continuity row is carried over those sources, so the obligation surface is exhausted by the listed finite packet. □

Theorem 204.5 (TopGroupUp Cont ledger continuity exhaustion)**.** *Let $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ be a $\mathsf{TopGroup}^{\uparrow}$ packet with displayed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source rows. The finite* Cont *ledger λ exhausts exactly the multiplication and inversion continuity rows over those displayed sources: every public continuity obligation of $\mathcal{G}$ is one of the product rows of Definition 204.2 or one of the inverse rows of Definition 204.3, and those two families are carried by λ with no extra topology object.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage continuity ledger scope`

Proof. Project the ledger coordinate λ from the carrier packet of Definition 204.1. The same projection exposes the displayed $\mathsf{Group}^{\uparrow}$ source, $\mathsf{Topology}^{\uparrow}$ source, multiplication row, inversion row, neighbourhood row, and provenance row.

Apply Definition 204.2 to the product row and Definition 204.3 to the inverse row. These are the only operation-continuity rows exported by the public surface of Definition 204.4.

Repack the two projected families with the unchanged source certificates. Because the carrier has no further topological component, the ledger is exhausted by those two finite Cont families. □

Theorem 204.6 (TopGroupUp classifier continuity transport)**.** *For classifier-related* $\mathsf{TopGroup}^{\uparrow}$ *packets* $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ *and* $\mathcal{G}' = (G', T', m', i', n', \lambda', \rho')$*, the public classifier transports* m*,* i*,* n*,* λ*, and* ρ *componentwise by the carried* hsame *rows and the finite* Cont *ledger. In particular, continuity transport for the product and inverse rows is exactly the transport supplied by Definition 204.5.*

Proof. Unpack the two packets with Definition 204.1. The component projections give the group carrier, topology carrier, multiplication graph, inversion graph, neighbourhood row, ledger row, and provenance row on both sides.

Transport the operation rows and neighbourhood rows componentwise by the displayed hsame witnesses. The product and inverse continuity entries then transport through the same finite ledger by Definition 204.5.

The provenance row ρ is read only as the displayed source package, so it transports with the same source certificates. Repacking these transported coordinates gives the classifier-related $\mathsf{TopGroup}^{\uparrow}$ packet without adding an external continuity predicate. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage classifier continuity transport`

Theorem 204.7 (TopGroupUp public certificate boundary)**.** *The complete public* $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ *boundary is formed by Definition 204.1, Definition 204.2, Definition 204.3, Definition 204.5, and Definition 204.6. No host topological group and no external continuity predicate is read outside those displayed BEDC rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage public certificate boundary`

Proof. Combine the carrier definition with the two continuity carrier rows. The carrier supplies the finite packet, while the multiplication and inversion theorems identify the only operation-continuity rows over the displayed $\mathsf{Group}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ sources.

The ledger exhaustion theorem records that the finite Cont coordinate contains exactly those rows. The classifier transport theorem records that the same boundary is stable under componentwise hsame transport.

Thus the public certificate boundary is precisely the listed carrier, continuity, ledger, transport, and provenance data. Since each component is projected from the displayed packet, no host topological-group structure is available to the certificate. □

Theorem 204.8 (TopGroupUp source-coupled carrier scope)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *packet projects one shared* BHist *group source row, topology source row, multiplication row, inversion row,* Cont *ledger, and* Pkg *provenance row. These rows are the source of the public carrier and classifier scope; no independent host topological-group object is available outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source coupled carrier scope`

Proof. Unpack the accepted packet by Definition 204.1. The projection exposes the single group source G, topology source T, multiplication row m, inversion row i, neighbourhood row n, ledger λ, and provenance row ρ.

Apply Definition 204.2 and Definition 204.3 to read the operation rows over those same sources. Apply Definition 204.5 to read the finite Cont scope and Definition 204.6 for the carried classifier transport.

Finally use Definition 204.7. Since that boundary is exhausted by the projected rows and their provenance, there is no second carrier from which an external topological group could be read. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source rows empty coupled`

Theorem 204.9 (TopGroupUp operation-continuity ledger scope)**.** *For every accepted* $\mathsf{TopGroup}^{\uparrow}$ *packet, the product and inverse continuity rows are exactly the two operation-neighbourhood transport families carried by the same finite* Cont *ledger. Under endpoint* hsame *transport, both families remain in that ledger and no additional continuity family is introduced.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage operation continuity ledger scope`

Proof. Project the packet using Definition 204.1. The continuity coordinate is the single finite ledger λ, and its operation entries are attached to the displayed multiplication and inversion rows.

Apply Definition 204.5. It identifies the public continuity obligations with the product rows of Definition 204.2 and the inverse rows of Definition 204.3.

For transport, apply Definition 204.6. The endpoint hsame witnesses move the operation and neighbourhood endpoints componentwise, while the product and inverse continuity entries remain the same two ledger families. □

Theorem 204.10 (TopGroupUp public NameCert readback exactness)**.** *The public* $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ *readback is exhausted by the carrier, classifier, product continuity rows, inverse continuity rows, finite* Cont *ledger, and* Pkg *provenance. Reading a public certificate therefore returns exactly those displayed BEDC rows and no further topological-group datum.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage public namecert readback exactness`

Proof. Start from the public boundary theorem Definition 204.7. Its listed sources are the carrier definition, the product and inverse continuity carrier rows, the ledger exhaustion row, and the classifier transport row.

Use Definition 204.1 to identify the carrier, classifier, finite Cont ledger, and Pkg provenance coordinates. Use Definition 204.2 and Definition 204.3 for the two operation continuity families, and Definition 204.5 to see that the ledger contains no further public continuity obligations.

Thus every public readback component is one of the named coordinates or one of the two operation-continuity families. The classifier transport theorem Definition 204.6 gives stability of exactly those rows under hsame, so the readback has no additional datum. □

Theorem 204.11 (TopGroupUp product neighbourhood transport)**.** *Let* $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ *be a* $\mathsf{TopGroup}^{\uparrow}$ *packet with displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source rows. For carried* BHist *endpoints* x, x', y, y', z, z'*, suppose* $m(x, y, z)$ *is the displayed product row,* z *lies in a neighbourhood row of* T*, and* $\mathsf{hsame}(x, x')$*,* $\mathsf{hsame}(y, y')$*, and* $\mathsf{hsame}(z, z')$ *are the carried endpoint transports. Then the product neighbourhood row transports to the endpoint* z' *using only the componentwise* hsame *rows, the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *operation source, the* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *neighbourhood source, and the finite* Cont *ledger carried by* $\mathcal{G}$*.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage product neighborhood transport`

Proof. Project the packet $\mathcal{G}$. The projections expose the carried BHist endpoints, the $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ multiplication row, the $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ neighbourhood row around the product endpoint, and the relevant entry of the finite Cont ledger.

Transport the two input endpoints and the product endpoint componentwise by the displayed hsame rows. The group source transports the multiplication graph row, while the topology source transports the target neighbourhood row inside T.

Repack the transported multiplication graph with the transported neighbourhood row and the same continuity ledger entry. No outside topological-group datum is introduced, so the transported row remains a $\mathsf{TopGroup}^\uparrow$ product neighbourhood row over $\mathcal{G}$. □

Theorem 204.12 (TopGroupUp inverse neighbourhood transport)**.** *Let $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ be a $\mathsf{TopGroup}^\uparrow$ packet with displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ source rows. For carried BHist endpoints x, x', y, y', suppose $i(x, y)$ is the displayed inverse row, y lies in a neighbourhood row of T, and $\mathsf{hsame}(x, x')$ and $\mathsf{hsame}(y, y')$ are the carried endpoint transports. Then the inverse neighbourhood row transports to the endpoint y' using only the componentwise hsame rows, the $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ inverse source, the $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ neighbourhood source, and the finite Cont ledger carried by $\mathcal{G}$.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage inverse neighborhood transport`

Proof. Unpack $\mathcal{G}$ to obtain the group source, topology source, inverse graph row, neighbourhood row around the inverse endpoint, and the matching continuity entry in the Cont ledger.

The endpoint transport is componentwise. The $\mathsf{hsame}(x, x')$ row transports the input, the $\mathsf{hsame}(y, y')$ row transports the inverse endpoint, the $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ source carries the inverse graph across those rows, and the $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ source carries the neighbourhood row inside T.

Repack the transported inverse graph and transported neighbourhood with the same finite continuity entry. The result is still a row of the displayed $\mathsf{TopGroup}^\uparrow$ packet, because every field used came from $\mathcal{G}$. □

Theorem 204.13 (TopGroupUp continuity ledger coverage)**.** *For a $\mathsf{TopGroup}^\uparrow$ packet $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ with displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ sources, the finite Cont ledger covers exactly the product and inverse neighbourhood transport rows over carried BHist endpoints. Its rows are the transported operation neighbourhood entries of Definition 204.11, the transported inverse neighbourhood entries of Definition 204.12, and the source provenance rows already displayed by Definition 204.4. It exports no additional topological-group structure.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage continuity ledger coverage`

Proof. Start from the public obligation surface. Apply Definition 204.4 to project the BHist carrier, componentwise classifier, group source, topology source, multiplication and inversion rows, and finite $\mathsf{Cont}/\mathsf{Pkg}$ ledger.

The product rows are covered by Definition 204.11. Each entry uses the displayed carried endpoints, the componentwise hsame transport rows, and the same $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ sources.

The inverse rows are covered by Definition 204.12. These entries use the same packet projections and therefore sit in the same finite Cont ledger.

Repack the two transport families with the provenance rows of $\mathcal{G}$. Since the ledger contains only those product and inverse continuity rows, its coverage is exactly the displayed $\mathsf{TopGroup}^\uparrow$ continuity surface. □

Definition 204.14 (TopGroupUp source-coupled continuity packet)**.** *The public source-coupled continuity packet for* $\mathsf{TopGroup}^{\uparrow}$ *is the finite* BHist *packet consisting of the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row, the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row, the product graph row, the inverse graph row, the source and target neighbourhood rows, the finite* Cont *continuity ledger, and the* Pkg *provenance row connecting those displayed sources. A packet is accepted only when these rows are the rows projected by the* $\mathsf{TopGroup}^{\uparrow}$ *carrier* $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$.

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupSourceCoupledContinuityPacket`

Theorem 204.15 (TopGroupUp source-coupled continuity boundary)**.** *Every accepted source-coupled continuity packet projects exactly its* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source row, its* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source row, the product and inverse graph rows, the componentwise* hsame *endpoint transport rows, the finite* Cont *continuity rows, and the* Pkg *provenance row. It exports no ambient topological-group object, no external topology carrier equality, and no group operation beyond the carried graph rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source coupled continuity boundary`

Proof. Project the accepted packet of Definition 204.14. Its displayed coordinates are precisely the two source certificates, the product and inverse graph rows, the neighbourhood rows, the finite continuity ledger, and the provenance row.

The componentwise hsame rows are the endpoint transports used by those coordinates. They are already accounted for by the product transport theorem Definition 204.11 and the inverse transport theorem Definition 204.12.

Completeness is the reverse packaging. Given exactly the projected rows, repack them as the finite BHist packet of the definition and attach the same Cont and Pkg ledgers. No extra ambient object is available, because every public projection is one of the listed rows. □

Theorem 204.16 (TopGroupUp continuity consumer exhaustion)**.** *A downstream consumer of a* $\mathsf{TopGroup}^{\uparrow}$ *source-coupled continuity packet receives only the product-neighbourhood transport family of Definition 204.11, the inverse-neighbourhood transport family of Definition 204.12, and their finite ledger coverage in Definition 204.13. The consumer cannot read a topological-group object, an external continuity predicate, or any row outside the displayed* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *packet.*

Proof. Start with the boundary theorem Definition 204.15. It restricts the consumer input to the displayed source certificates, endpoint transports, finite continuity rows, and provenance row.

Apply Definition 204.13. The finite Cont ledger is exhausted by the product-neighbourhood and inverse-neighbourhood transport rows, with provenance supplied by the same source certificates.

Finally use the two transport theorems named in the statement to repack the consumer surface. Since every available row is either one of those transport families or its BHist provenance, the consumer has no access to an unlisted ambient continuity datum. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage continuity consumer exhaustion`

Theorem 204.17 (TopGroupUp root source compatibility)**.** *For every accepted* $\mathsf{TopGroup}^{\uparrow}$ *source-coupled continuity packet, the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row and displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row share the same* BHist *carrier endpoints of Definition 204.1. Classifier transport between the two source rows is supplied by the componentwise* hsame *endpoint rows together with the finite* Cont *continuity ledger.*

Proof. Unpack the carrier by Definition 204.1. The group source certificate and topology source certificate are projections of the same BHist packet, so their carrier endpoints are not independent objects; they are the shared endpoints carried by $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$.

The componentwise hsame rows are the classifier transports attached to those shared endpoints. The product and inverse transport theorems, Definition 204.11 and Definition 204.12, use those rows as the source and target classifiers for their continuity statements.

Apply Definition 204.13. The finite Cont ledger records exactly the product and inverse continuity rows over the shared carrier endpoints. Repack these rows to get the stated source compatibility. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root source compatibility`

Theorem 204.18 (TopGroupUp product-inverse obligation triad)**.** *The public* $\mathsf{TopGroup}^{\uparrow}$ *operation surface consists exactly of three obligations: carrier compatibility between* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$*, product-neighbourhood transport, and inverse-neighbourhood transport. These are the rows supplied by Definition 204.17, Definition 204.11, Definition 204.12, and Definition 204.13.*

Proof. Project the accepted packet through Definition 204.1. The carrier row gives the common source surface for the group and topology certificates, while the operation graph rows expose only multiplication and inversion.

Definition 204.17 identifies the carrier compatibility obligation. The product-neighbourhood transport obligation is exactly Definition 204.11, and the inverse-neighbourhood transport obligation is exactly Definition 204.12.

It remains to show that the list is exhaustive. Apply Definition 204.13; the Cont ledger contains only the product and inverse continuity rows. Together with the shared source carrier row, these three obligations are the whole public operation surface. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage product inverse obligation triad`

Theorem 204.19 (TopGroupUp public consumer minimality)**.** *Every downstream consumer of a* $\mathsf{TopGroup}^{\uparrow}$ *packet receives only the displayed source certificate rows, the product and inverse operation rows, the finite* Cont *rows, and the* Pkg *provenance. It receives no ambient topological-group object and no order, topology, or operation row outside the rows listed by Definition 204.18.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage public consumer minimality`

Proof. Start from the source-coupled packet of Definition 204.14 and unpack its carrier by Definition 204.1. Its projections are the two source certificates, the product and inverse graph rows, the finite Cont ledger, and the Pkg provenance row.

Definition 204.18 repacks the operation rows as carrier compatibility, product-neighbourhood transport, and inverse-neighbourhood transport. No fourth operation row is present in the finite ledger.

Finally apply Definition 204.16. It states that downstream readback is exhausted by the same transport families, their BHist provenance, hsame endpoint rows, Cont rows, and source NameCert rows. Thus the public consumer receives exactly the listed data and no ambient topological-group object. □

Definition 204.20 (TopGroupUp BHist continuity obligation triple)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ BHist *continuity obligation triple over the carrier of Definition 204.1 consists of exactly three public obligations:*

1. *the shared* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source compatibility over the same carried endpoints, classifier rows, and* Pkg *provenance;*
2. *the product* Cont*-neighbourhood transport row, where the two input endpoints, product endpoint, target neighbourhood, and componentwise* hsame *rows are read from the same carrier packet;*
3. *the inverse* Cont*-neighbourhood transport row, where the input endpoint, inverse endpoint, target neighbourhood, and componentwise* hsame *rows are read from the same carrier packet.*

No fourth operation obligation and no host topological-group primitive is part of this triple.

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupBHistContinuityObligationTriple`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupBHistContinuityObligationTriple sound`

Theorem 204.21 (TopGroupUp source projection NameCert compatibility)**.** *For every accepted* $\mathsf{TopGroup}^\uparrow$ *packet, the* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *source row and the* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source row project from the same* BHist *carrier endpoints, classifier rows, and* Pkg *provenance of Definition 204.1. Their compatibility is the first component of Definition 204.20.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source projection namecert compatibility`

Proof. Project the packet by Definition 204.1. The group row, topology row, operation rows, finite Cont ledger, and Pkg provenance are all coordinates of one carrier.

Apply Definition 204.17. It identifies the displayed group and topology source certificates as projections over the same carried endpoints, with classifier transport supplied by the componentwise hsame rows and the finite Cont ledger.

Finally compare this projected compatibility row with Definition 204.20. The source compatibility component is exactly the shared BHist endpoint, classifier, and provenance row just obtained, so no independent source certificate remains outside the packet. □

Theorem 204.22 (TopGroupUp Cont ledger operation exhaustion)**.** *For every accepted* $\mathsf{TopGroup}^\uparrow$ *packet, the finite* Cont *ledger contains exactly the product-neighbourhood continuity rows and the inverse-neighbourhood continuity rows listed by Definition 204.20. It contains no ambient topological-group operation row, no external continuity predicate, and no operation other than the carried product and inverse rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage cont ledger operation exhaustion`

Proof. Start with Definition 204.13. The ledger coverage theorem says that every public continuity row is either a product neighbourhood transport row or an inverse neighbourhood transport row over the carried BHist endpoints.

The product family is the second component of Definition 204.20, and it is supplied by Definition 204.11. The inverse family is the third component of the same definition, and it is supplied by Definition 204.12.

Apply Definition 204.19. A downstream consumer can read only the displayed source rows, operation rows, finite Cont rows, and Pkg provenance. Thus the ledger is exhausted by the two operation-continuity families and contains no ambient topological-group row. □

Theorem 204.23 (TopGroupUp downstream root unblock surface)**.** *The downstream* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *root-unblock surface is the* BHist *continuity obligation triple of Definition 204.20, together with the source projection compatibility of Definition 204.21, the finite* Cont *ledger exhaustion of Definition 204.22, and the product-inverse obligation triad of Definition 204.18. This is the complete public obligation surface consumed by downstream chapters.*

Proof. First take the triple of Definition 204.20. It names the shared source compatibility obligation, the product neighbourhood transport obligation, and the inverse neighbourhood transport obligation over the carrier of Definition 204.1.

Apply Definition 204.21 to bind the source obligation to the same BHist endpoints, classifier rows, and Pkg provenance. Apply Definition 204.22 to bind the two operation-continuity obligations to the finite Cont ledger and exclude any ambient operation row.

Finally use Definition 204.18. It repacks exactly the same carrier compatibility, product transport, and inverse transport obligations as the public operation surface. Therefore downstream chapters receive precisely this source-compatible, ledger-exhaustive $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ surface. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage downstream root unblock surface`

Theorem 204.24 (TopGroupUp shared source-fiber product carrier)**.** *For every accepted* $\mathsf{TopGroup}^{\uparrow}$ *source-coupled continuity packet, the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row and the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row share one* BHist *carrier packet through Definition 204.1. The product graph, inverse graph, neighbourhood row, finite* Cont *ledger, and* Pkg *provenance are projections of that same packet, so neither source row supplies an independent carrier outside the* $\mathsf{TopGroup}^{\uparrow}$ *boundary.*

Proof. Unpack the accepted packet by Definition 204.1. Its coordinates are the shared group row G, topology row T, product graph m, inverse graph i, neighbourhood row n, finite ledger λ, and provenance row ρ.

Apply Definition 204.17. It identifies the two source certificates as projections over the same carried endpoints, with classifier transport supplied by the componentwise hsame rows and the finite Cont ledger.

Finally apply Definition 204.19. A downstream consumer receives only those displayed source, operation, ledger, and provenance rows. Hence the shared packet is the whole source fiber for product readback and no external carrier can be read. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source fiber product carrier`

Theorem 204.25 (TopGroupUp product Cont ledger soundness)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *packet, the product-neighbourhood continuity row is sound exactly when its two input endpoints, product endpoint, target neighbourhood row, componentwise* hsame *transports, and finite* Cont *ledger entry are all projected from the shared packet of Definition 204.1. The row has no additional topological-group source and no external continuity predicate.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage product cont ledger soundness`

Proof. For soundness, start with the projected shared packet. Theorem Definition 204.24 supplies the common $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source rows, together with the product graph, neighbourhood row, hsame transports, and finite Cont ledger.

Apply Definition 204.11. The product row transports the two input endpoints and the product endpoint through exactly those componentwise hsame rows, while the neighbourhood row is carried by the displayed topology source and the continuity step is recorded in the finite ledger.

For the converse direction, assume a public product-continuity row is accepted. Apply Definition 204.13; every product row in the public surface is one of the entries covered by the finite Cont ledger of the same packet.

The public consumer theorem Definition 204.19 then removes any remaining ambient reading. The accepted product row is therefore sound precisely as the projection of the shared packet's endpoints, neighbourhood row, hsame transports, and finite ledger entry. □

Theorem 204.26 (TopGroupUp obligation inventory)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *certificate has exactly the following public obligations: the shared carrier obligation for the displayed* $\mathsf{Group}^{\uparrow}$ *and* $\mathsf{Topology}^{\uparrow}$ *rows, the classifier-transport obligation over their componentwise* hsame *rows, the multiplication-continuity obligation, the inversion-continuity obligation, the source-compatibility obligation, and the finite ledger obligation for the displayed* Cont *rows.*

No ambient topological-group object, no third operation-continuity family, and no operation row outside the carried product and inverse graphs belongs to the certificate boundary.

Proof. First bind the source side by Definition 204.21. It gives the shared $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ carrier endpoints, classifier rows, componentwise hsame transports, and one Pkg provenance packet.

Next bind the operation side by Definition 204.18. The operation surface has exactly carrier compatibility, product-neighbourhood transport, and inverse-neighbourhood transport.

Finally use Definition 204.22. The finite Cont ledger is exhausted by the product and inverse continuity families, and Definition 204.19 excludes every ambient row outside the displayed source, operation, ledger, and provenance surface. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation inventory bridge`

Theorem 204.27 (TopGroupUp carrier-classifier obligation)**.** *Carrier and classifier transport for a* $\mathsf{TopGroup}^{\uparrow}$ *certificate is exactly componentwise* hsame *over the shared* $\mathsf{Group}^{\uparrow}$ *and* $\mathsf{Topology}^{\uparrow}$ *source rows, together with one* Pkg *provenance packet. The transport does not split into separate group and topology carriers and does not import any external topological-group classifier.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage carrier classifier obligation`

Proof. Unpack the accepted packet through Definition 204.1. The displayed group source, topology source, product graph, inverse graph, neighbourhood row, finite ledger, and provenance row are coordinates of one carried BHist packet.

Apply Definition 204.17. It identifies the $\mathsf{Group}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ source certificates as projections over the same carried endpoints, with classifier transport supplied by the componentwise hsame rows.

The same projection is recorded by Definition 204.21. Hence the carrier-classifier obligation is precisely componentwise hsame over the two shared source rows plus the single Pkg provenance packet, with no independent classifier source remaining. □

Theorem 204.28 (TopGroupUp inverse Cont ledger soundness)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *packet, the inverse-neighbourhood continuity row is sound exactly when its input endpoint, inverse endpoint, target neighbourhood row, componentwise* hsame *transports, and finite* Cont *ledger entry are all projected from the shared packet of Definition 204.1. The row has no additional topology carrier, group inverse source, or external continuity predicate.*

Proof. For soundness, unpack the shared packet using Definition 204.24. The projected rows include the group source, topology source, inverse graph, target neighbourhood row, endpoint hsame transports, and the finite Cont ledger.

Apply Definition 204.12. The input endpoint and inverse endpoint move componentwise along the displayed hsame rows, while the topology source carries the target neighbourhood and the ledger records the continuity step.

For the converse direction, start from an accepted public inverse-continuity row. By Definition 204.13, every such row is one of the inverse-neighbourhood entries in the same finite Cont ledger.

Apply Definition 204.19. Since the consumer surface exposes only the displayed source certificates, inverse graph, endpoint transports, finite ledger, and provenance row, the inverse-continuity row is sound exactly through those packet projections and no outside datum is present. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage inverse cont ledger soundness`

Theorem 204.29 (TopGroupUp source compatibility obligation)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface reads its displayed* $\mathsf{Group}^{\uparrow}$ *and* $\mathsf{Topology}^{\uparrow}$ *source rows from the same* BHist *carrier, the same carrier-aware* hsame *endpoint classifier, and the same* Pkg *provenance packet of Definition 204.1.*

Proof. Apply Definition 204.24. It projects the group source, topology source, product graph, inverse graph, neighbourhood row, endpoint transports, finite continuity ledger, and provenance row from one shared carrier packet.

Use Definition 204.19 to read this packet from the public side. A downstream consumer sees only the displayed source certificates, hsame transports, finite Cont ledger, and Pkg provenance, so the two source rows cannot be separated into different carriers. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source compatibility obligation`

Theorem 204.30 (TopGroupUp operation continuity obligation)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface, the operation-continuity obligations exported by the carrier are exactly multiplication continuity and inversion continuity. They are the rows covered by the product and inverse neighbourhood-transport theorems, and no further operation-continuity row is exported by Definition 204.1.*

Proof. First apply Definition 204.25. It identifies the multiplication-continuity row with the product graph, target neighbourhood, endpoint hsame transports, and finite Cont ledger entry projected from the shared carrier.

Next apply Definition 204.28. It identifies the inversion-continuity row with the inverse graph, target neighbourhood, endpoint hsame transports, and its own finite Cont ledger entry.

Finally use Definition 204.19. Since the public surface exposes only these operation rows together with the source certificates, classifier transports, ledger, and provenance packet, there is no third operation-continuity obligation available to a consumer. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage operation continuity witness obligation`

Theorem 204.31 (TopGroupUp continuity ledger exactness obligation)**.** *The finite* Cont *ledger of an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface exhausts the continuity obligations for product and inverse rows: every accepted product-neighbourhood or inverse-neighbourhood continuity read is one of those two ledger families, and each listed ledger entry is sound through the shared* BHist *packet.*

Proof. Start with Definition 204.13. It states that the public continuity surface is covered by the finite ledger entries for product and inverse neighbourhood rows.

For soundness of the product entries, apply Definition 204.25; for soundness of the inverse entries, apply Definition 204.28. Both proofs project the relevant endpoints, neighbourhoods, hsame transports, and ledger rows from the same carrier packet.

Then use Definition 204.19 to exclude ambient continuity predicates or unstated operation rows. The finite Cont ledger is therefore exact for the product and inverse continuity obligations exported by $\mathsf{TopGroup}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage ledger exactness obligation`

Theorem 204.32 (TopGroupUp source-pair carrier obligation)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface binds its* $\mathsf{Group}^{\uparrow}$ *source row and its* $\mathsf{Topology}^{\uparrow}$ *source row to the same* BHist *carrier of Definition 204.1. The root obligation is therefore a source-pair obligation over one carried packet, not a pair of unrelated carrier certificates.*

Proof. Apply Definition 204.24. It identifies the group and topology certificates as projections from the shared packet of Definition 204.1.

The same theorem also records that product, inverse, neighbourhood, ledger, and provenance rows are packet projections. Hence a root consumer can read both source rows only through the common BHist carrier. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source pair carrier obligation`

Theorem 204.33 (TopGroupUp product continuity obligation)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface, product continuity is exactly the endpoint transport supplied by the packet's* hsame *rows together with the finite* Cont *ledger entry for multiplication. No extra product-continuity predicate is present outside the carrier of Definition 204.1.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage product continuity obligation`

Proof. First use Definition 204.24 to place the product graph, neighbourhood row, endpoint transports, and finite ledger over the shared source-pair carrier.

Then apply Definition 204.25. Its two directions say that a product-continuity row is sound exactly when it is this packet projection through the hsame endpoints and the finite Cont ledger. □

Theorem 204.34 (TopGroupUp inverse continuity obligation)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root surface, inverse continuity is the unary endpoint-transport row carried by the packet's* hsame *data and the finite* Cont *ledger entry for inversion. The obligation has no separate inverse carrier, topology source, or ambient continuity witness.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage inverse continuity obligation`

Proof. Apply Definition 204.32 to bind the unary inverse row to the same BHist carrier as the group and topology source certificates.

Now use Definition 204.28. It states that the accepted inverse-continuity row is sound precisely through the input endpoint, inverse endpoint, target neighbourhood, hsame transports, and finite Cont ledger entry projected from that packet. □

Theorem 204.35 (TopGroupUp operation ledger obligation)**.** *The multiplication and inverse continuity obligations of a* $\mathsf{TopGroup}^{\uparrow}$ *certificate are exactly the two operation-continuity ledger families supplied by the finite* Cont *ledger: product-neighbourhood transport and inverse-neighbourhood transport. There is no third operation row in the public certificate boundary.*

Proof. Use Definition 204.13. Every public continuity row over the accepted packet is covered by the finite Cont ledger and is one of the product or inverse neighbourhood transport rows.

Definition 204.22 identifies those two families with the product and inverse components of Definition 204.20. It also excludes ambient continuity predicates and any operation outside the carried product and inverse graphs.

Finally apply Definition 204.18. The public operation surface repacks the same two continuity families with the shared carrier compatibility row. Therefore the operation ledger obligation has exactly two operation families and no third operation row. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage operation ledger consumer boundary`

Theorem 204.36 (TopGroupUp fixed left-translation continuity row)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *packet and a carried group endpoint g in its source-fiber product, the row L_g defined on carried endpoints by the displayed product graph,*

$$L_g(h) = z \quad \textit{exactly when the packet displays } m(g, h, z),$$

is a sound continuity row through the same product graph, target neighbourhood row, componentwise hsame *transports, and finite* Cont *ledger entry used for multiplication. The fixed endpoint g does not create a separate unary operation source, a separate topology carrier, or an external translation-continuity predicate.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage fixed left translation continuity row`

Proof. Unpack the accepted packet by Definition 204.24. The shared carrier supplies the displayed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ source row, the displayed $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source row, the product graph m, the neighbourhood row, the componentwise hsame classifier rows, the finite Cont ledger, and the Pkg provenance row.

Fix a carried group endpoint g. For a carried endpoint h and a displayed product endpoint z with $m(g, h, z)$, regard the left-translation read $L_g(h) = z$ as the product-neighbourhood row whose first input has been fixed to the carried endpoint g. This specialization keeps the same product graph and the same target neighbourhood row; it merely restricts the two-input product read to the fiber over g.

Apply Definition 204.11 to the product row $m(g, h, z)$. The fixed endpoint g, the variable endpoint h, and the product endpoint z are transported only by the displayed componentwise hsame rows. The target neighbourhood is transported inside the displayed topology source, and the continuity step is recorded in the finite Cont ledger already carried by the packet.

Now apply Definition 204.25. It identifies soundness of the product-continuity row exactly with the packet projections just listed: the input endpoints, product endpoint, target neighbourhood, componentwise hsame transports, and finite ledger entry. Since the left-translation row is this product row with the first input fixed to g, its continuity soundness is inherited from the same ledger entry and no additional operation source is introduced.

For exhaustiveness, use Definition 204.13. Every accepted product-neighbourhood continuity read is already one of the product entries in the finite ledger. Finally, Definition 204.19 rules out any ambient translation predicate or detached topological-group carrier. Hence the fixed left-translation row is sound exactly through the displayed product graph, target neighbourhood, hsame transports, and finite Cont ledger of the accepted $\mathsf{TopGroup}^{\uparrow}$ packet. □

Definition 204.37 (TopGroupUp root shared source packet)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *root shared source packet is the projection of the carrier of Definition 204.1 consisting of one displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source row, one displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source row, the shared* BHist *carrier endpoints, the componentwise* hsame *classifier rows, the product and inverse operation rows, the finite* Cont *ledger, and the* Pkg *provenance row. A downstream root consumer reads the two source certificates only through this packet.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootSharedSourcePacket`

Theorem 204.38 (TopGroupUp root shared carrier obligation)**.** *For every accepted* TopGroup$^{\uparrow}$ *root shared source packet, the* Group$^{\uparrow}$ *and* Topology$^{\uparrow}$ *source rows share the same* BHist *carrier of Definition 204.1. Their endpoint classifiers are the same componentwise* hsame *rows, their operation-continuity transport is recorded in the same finite* Cont *ledger, and their provenance is the same* Pkg *row. No root consumer can split these fields into two independent source packets.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage shared source rows`

Proof. Begin with the shared packet of Definition 204.37. Its coordinates are exactly the group source, topology source, carried endpoints, classifier rows, finite continuity ledger, and provenance row projected from the TopGroup$^{\uparrow}$ carrier.

Apply Definition 204.24. It identifies the two source certificate rows, the product graph, inverse graph, neighbourhood row, finite Cont ledger, and Pkg provenance as projections of one BHist packet.

Finally apply Definition 204.19. Since a public consumer receives only those source, operation, ledger, classifier, and provenance rows, there is no available second carrier or second provenance packet. □

Theorem 204.39 (TopGroupUp root continuity classifier stability)**.** *For an accepted* TopGroup$^{\uparrow}$ *root shared source packet, product continuity and inverse continuity transport under the same componentwise classifier. The product row transports its two input endpoints, product endpoint, target neighbourhood, and* Cont *entry through the carried* hsame *rows, and the inverse row transports its input endpoint, inverse endpoint, target neighbourhood, and* Cont *entry through the same classifier packet.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage continuity classifier stability`

Proof. Project the root shared source packet. The projection exposes the common hsame endpoint classifier rows and the finite Cont ledger attached to the product and inverse operation rows.

Use Definition 204.25 for the product continuity row. It makes the row sound exactly through the two input endpoints, product endpoint, target neighbourhood row, componentwise hsame transports, and finite ledger entry projected from the shared packet.

Use Definition 204.28 for the inverse continuity row. It gives the same classifier form for the input endpoint, inverse endpoint, target neighbourhood row, and ledger entry.

The two rows therefore transport under one classifier packet: their endpoint lists differ by arity, but their carrier, hsame source, Cont ledger, and Pkg provenance are the shared rows of the root packet. □

Theorem 204.40 (TopGroupUp root ledger exactness obligation)**.** *For an accepted* TopGroup$^{\uparrow}$ *root shared source packet, the finite* Cont *ledger exhausts exactly the product-continuity rows and inverse-continuity rows. Every accepted continuity read is one of those two families, each listed entry is sound through the shared* BHist *packet, and no host topological-group continuity primitive is available outside the ledger.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root ledger semantic exactness`

Proof. Start from the shared carrier obligation of Definition 204.38. It binds both source certificates, the classifier rows, the continuity ledger, and the provenance row to the same BHist packet.

Apply Definition 204.31. It states that the finite Cont ledger covers every accepted product-neighbourhood and inverse-neighbourhood continuity read, and that the two listed families are sound through the shared packet.

Apply Definition 204.19. The public root consumer receives no continuity row beyond the displayed source certificates, operation rows, classifier rows, finite ledger, and provenance. Hence the ledger is exact for precisely the product and inverse continuity obligations. □

Theorem 204.41 (TopGroupUp root public obligation inventory)**.** *An accepted* $\mathsf{TopGroup}^{\uparrow}$ *root shared source packet exposes exactly the* $\mathsf{Group}^{\uparrow}$ *source row, the* $\mathsf{Topology}^{\uparrow}$ *source row, the product row, the inverse row, the neighbourhood row, the componentwise* hsame *classifier packet, the finite* Cont *ledger, and the shared* Pkg *provenance. This public inventory contains no ambient topological-group primitive and no second carrier or provenance source outside the displayed packet.*

```
Lean4 ✓  BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root public obligation inventory
  ↪ variant  BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage public obligation inventory
  ↪ variant  BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation inventory
```

Proof. Start with Definition 204.38. It fixes the $\mathsf{Group}^{\uparrow}$ source row, the $\mathsf{Topology}^{\uparrow}$ source row, the common BHist carrier endpoints, the componentwise classifier rows, the operation rows, the finite ledger, and the shared provenance as projections of one root packet.

Next apply Definition 204.39. The product and inverse continuity reads are transported only through the displayed componentwise hsame classifier packet and the same finite Cont ledger.

Finally use Definition 204.40. It exhausts the public continuity surface by the product and inverse ledger families and rules out any host topological-group continuity primitive beyond the rows already listed. The inventory is therefore exactly the displayed source, operation, neighbourhood, classifier, ledger, and provenance data. □

Theorem 204.42 (TopGroupUp root shared source exhaustion)**.** *Every downstream public read of the* $\mathsf{TopGroup}^{\uparrow}$ *root surface factors through the public obligation inventory of Definition 204.41. Conversely, each row of that inventory repacks into the same public root surface as a read of the accepted root shared source packet.*

```
Lean4 ✓  BEDC.Derived.TopGroupUp.TopGroupRootSharedSourcePacket public inventory exhaustion
```

Proof. For the forward direction, apply Definition 204.19. A downstream public consumer receives only the source certificate rows, operation rows, classifier rows, continuity ledger rows, and provenance row exposed by the root shared source packet.

Then apply Definition 204.41. Those are precisely the rows in the public inventory: the two source rows, product row, inverse row, neighbourhood row, componentwise classifier packet, finite Cont ledger, and shared Pkg provenance. Hence every downstream public read factors through the inventory.

For the reverse direction, read each inventory coordinate as the corresponding projection of the same accepted root shared source packet. The shared carrier obligation supplies the common packet, the classifier-stability theorem supplies the componentwise transport rows, and the ledger-exactness theorem supplies the finite product and inverse continuity rows.

Repacking those projections gives exactly the public root surface consumed by Definition 204.19. No additional carrier, classifier, ledger entry, or ambient topological-group primitive is introduced in the repacking. □

Theorem 204.43 (TopGroupUp obligation carrier-classifier surface)**.** *The obligation surface for the* $\mathsf{TopGroup}^{\uparrow}$ *carrier and classifier consists of one finite* BHist *packet carrying the displayed*

$\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *row, the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *row, the shared carrier endpoints, the componentwise* hsame *classifier rows, and the single* Pkg *provenance row. These rows are the carrier-classifier obligations visible to a public consumer, and no independent group carrier, topology carrier, or host topological-group classifier is part of the surface.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupObligation carrier classifier surface`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation carrier classifier surface`
↪ variant `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation surface certificate`

Proof. Start from Definition 204.37. Its displayed coordinates are the $\mathsf{Group}^\uparrow$ source, the $\mathsf{Topology}^\uparrow$ source, the shared BHist carrier endpoints, the componentwise classifier rows, and the provenance packet.

Apply Definition 204.38. It binds those coordinates to one accepted packet and rules out a split into two independent source packets.

Finally use Definition 204.27. The public carrier-classifier obligation is exactly componentwise hsame over the two displayed source rows together with the same Pkg provenance row. □

Theorem 204.44 (TopGroupUp obligation continuity ledger surface)**.** *The continuity-ledger obligation surface for* $\mathsf{TopGroup}^\uparrow$ *consists exactly of the product-continuity family, the inverse-continuity family, and the finite* Cont *ledger rows connecting them to the displayed* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *carrier rows. The surface contains no continuity row outside the carried product and inverse operation graphs.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation continuity ledger surface`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootObligationContinuityLedgerSurface exists`

Proof. Project the accepted shared packet through Definition 204.39. The product and inverse rows transport through the same componentwise classifier packet and the same finite Cont ledger.

Use Definition 204.40. It exhausts public continuity reads by the two operation families and makes each listed entry sound through the shared BHist packet.

The operation boundary is then Definition 204.35. It identifies the ledger surface with product-neighbourhood transport and inverse-neighbourhood transport, excluding any third operation-continuity family. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupObligationSurface continuity ledger inventory`

Theorem 204.45 (TopGroupUp obligation public consumer exhaustion)**.** *Every public consumer of the* $\mathsf{TopGroup}^\uparrow$ *obligation surface factors through the finite inventory consisting of the* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *row, the* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *row, the shared* BHist *carrier endpoints, the product row, the inverse row, the neighbourhood row, the componentwise* hsame *classifier packet, the finite* Cont *ledger, and the shared* Pkg *provenance. Conversely, each listed row repacks into the same public consumer surface.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupObligationSurface public consumer exhaustion`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage obligation public consumer exhaustion`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupUp StdBridge`

Proof. Apply Definition 204.41. It lists exactly the two source rows, operation rows, neighbourhood row, classifier packet, finite ledger, and provenance row exposed by an accepted root shared source packet.

Then apply Definition 204.42. Every downstream public read factors through that inventory, and each inventory row reconstructs the public root surface of the same accepted packet.

Combining the carrier-classifier surface with the continuity-ledger surface therefore gives the complete obligation surface visible to public consumers, with no ambient topological-group primitive outside the listed rows. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupObligation public consumer surface certificate`

Closure status for $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$.

Constructive story: A topological-group obligation packet is assembled by placing a certified $\mathsf{Group}^\uparrow$ source and a certified $\mathsf{Topology}^\uparrow$ source into one finite BHist surface, then displaying shared carrier endpoints, product rows, inverse rows, neighbourhood rows, continuity ledgers, and provenance. The carrier accepts only packets whose group, topology, product, inverse, neighbourhood, classifier, finite Cont, and Pkg rows are all present; an independent group carrier, independent topology carrier, host topological-group classifier, or third operation-continuity family is outside the obligation surface. Two accepted packets classify together by componentwise hsame on the group and topology source rows, operation rows, neighbourhood rows, and provenance, with the finite continuation ledger carrying product-continuity and inverse-continuity comparisons. The source specification is the paired group/topology certificate boundary, the pattern specification records product continuity, inverse continuity, carrier-classifier compatibility, and public-consumer exhaustion, and the ledger keeps product-neighbourhood and inverse-neighbourhood transport visible. The five name-certificate obligations are now bound at the obligation surface: an accepted packet inhabits the carrier, the inherited source classifiers give reflexivity, symmetry, and transitivity componentwise, and the public-consumer exhaustion theorem repacks classified replacements into the same finite inventory. A packet history h lies in the signature gap of a $\mathsf{TopGroup}^\uparrow$ token p when the source-domain accepts the displayed group/topology rows, the signature relation pairs the packet with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the product and inverse continuity ledgers are the operation families encoded by p. The chapter registers this finite continuity-obligation surface under the name $\mathsf{TopGroup}^\uparrow$; it introduces no standard bridge and no complete topological-group theory beyond the displayed public obligation rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$, maturePackageClosed)

Scope closed: The obligation scope binds the displayed $\mathsf{Group}^\uparrow$, $\mathsf{Topology}^\uparrow$, BHist, hsame, Cont, and Pkg rows to the carrier, classifier, product-continuity, inverse-continuity, and public-consumer obligation surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.TopGroupUp.TopGroupObligation\_public\_consumer\_surface\_certificate`

Bridge status: bridgeChecked

Not claimed: This chapter does not claim a standard bridge or a complete topological-group theory beyond the displayed public obligation rows.

Upgrade path: No further upgrade – chapter at top of formal axis.

204.3 Root source-fiber obligation packet

Definition 204.46 (TopGroupUp root source-fiber obligation packet)**.** *The* $\mathsf{TopGroup}^\uparrow$ *root source-fiber obligation packet is the shared* BHist *packet*

$$\mathcal{F} = (G, T, m, i, n, \kappa, \lambda, \rho)$$

read over the displayed $\mathsf{Group}^\uparrow$ *source row* G *and* $\mathsf{Topology}^\uparrow$ *source row* T*. The row* m *is the product operation source,* i *is the inverse operation source,* n *is the neighbourhood source used by both continuity families,* κ *is the componentwise* hsame *classifier packet on the carried source rows and operation endpoints,* λ *is the finite* Cont *ledger listing the product and inverse continuity entries, and* ρ *is the shared* Pkg *provenance row. A root consumer may read the* $\mathsf{Group}^\uparrow$ *and* $\mathsf{Topology}^\uparrow$ *sources only through this packet.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiberObligationPacket`

Theorem 204.47 (TopGroupUp root source-fiber carrier obligation)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber obligation packet carries the* $\mathsf{Group}^{\uparrow}$ *and* $\mathsf{Topology}^{\uparrow}$ *source rows on one* BHist *carrier and one classifier packet. The product row, inverse row, neighbourhood row, componentwise* hsame *classifier, finite* Cont *ledger, and* Pkg *provenance are projections from that carrier, so neither source row supplies a separate root carrier.*

Proof. Project the packet of Definition 204.46. Its coordinates are the two source rows, operation rows, neighbourhood row, classifier packet, continuation ledger, and provenance row.

Apply Definition 204.24. It identifies the group source, topology source, product graph, inverse graph, neighbourhood row, finite Cont ledger, and Pkg provenance as projections from one shared BHist carrier.

Then apply Definition 204.38. The root surface reads the two source certificates through exactly this shared packet, with their endpoint classifiers supplied by the componentwise hsame rows.

Finally use Definition 204.19. A public root consumer has no field for a second carrier, second classifier packet, or detached provenance row, so the displayed source fiber is the whole carrier obligation. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root source fiber carrier obligation`

Theorem 204.48 (TopGroupUp root source-fiber classifier determinacy)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber obligation packet, every classifier read accepted at the root is determined by the shared* BHist *carrier, the componentwise* hsame *classifier packet, the product and inverse endpoint rows, the finite* Cont *ledger, and the* Pkg *provenance row. Conversely, those rows repack the same root classifier read, so no detached group classifier, topology classifier, or ambient topological-group classifier is present at the root boundary.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThresholdPacket source fiber classifier determinacy`

Proof. First apply Definition 204.47. It places the group source, topology source, operation endpoints, componentwise classifier packet, ledger, and provenance over one shared BHist carrier.

Next use Definition 204.49. The product and inverse endpoint reads are transported through that same classifier packet, and their continuity evidence is read only through the finite Cont entries listed in the packet.

Finally apply Definition 204.50. The ledger covers exactly the accepted product-continuity and inverse-continuity families. Repacking the shared carrier, componentwise hsame packet, endpoint rows, ledger, and Pkg provenance therefore reconstructs the same classifier read, while any classifier outside those rows has no field in the accepted source-fiber packet. □

Theorem 204.49 (TopGroupUp root source-fiber continuity obligation)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber obligation packet, product continuity and inverse continuity transport through the same classifier packet and the same finite* Cont *ledger. The product row uses the two input endpoints, product endpoint, neighbourhood row, componentwise* hsame *transport, and its ledger entry; the inverse row uses the input endpoint, inverse endpoint, neighbourhood row, componentwise* hsame *transport, and its ledger entry. No continuity row is detached from the shared source fiber.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber continuity obligation`

Proof. Start from the carrier obligation of Definition 204.47. It places the product row, inverse row, neighbourhood row, hsame classifier packet, finite ledger, and provenance over the same carried source rows.

Apply Definition 204.33. The product continuity obligation is exactly endpoint transport through the packet's hsame rows together with the displayed finite Cont entry.

Apply Definition 204.34. The inverse continuity obligation has the same form for the unary inverse endpoint and its finite ledger entry.

Use Definition 204.39 to compare the two operation families through one classifier packet. Since both continuity rows read the same source fiber and ledger, classifier transport cannot introduce an ambient topological-group continuity predicate. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source fiber continuity obligation`

Theorem 204.50 (TopGroupUp root source-fiber ledger exactness)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber obligation packet, the finite* Cont *ledger exhausts exactly the product-continuity and inverse-continuity obligations. Every accepted operation-continuity read is one of those two families, and every listed ledger entry is sound through the shared* BHist *carrier, componentwise* hsame *classifier, and* Pkg *provenance of the packet.*

Proof. Begin with Definition 204.49. It binds both operation-continuity families to the same classifier packet and finite continuation ledger.

Apply Definition 204.31. It states that the finite Cont ledger covers every accepted product-neighbourhood and inverse-neighbourhood continuity read, with soundness through the shared carrier packet.

Use Definition 204.60 to rule out a third operation-continuity family at the root. The accepted root surface has only product continuity and inverse continuity over the displayed source pair.

Finally apply Definition 204.19. A public consumer receives no continuity primitive beyond the source rows, operation rows, classifier packet, finite ledger, and provenance, so the ledger is exact for precisely the two displayed obligation families. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber ledger exactness`

204.4 Root source-fiber export packet

Definition 204.51 (TopGroupUp root source-fiber export packet)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet is the public projection of Definition 204.46. It consists of the shared* BHist *source pair for* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$*, the product and inverse rows, the componentwise* hsame *classifier rows on the source and operation endpoints, the finite* Cont *ledger for the two continuity families, and the shared* Pkg *provenance. A downstream root consumer receives the* $\mathsf{TopGroup}^{\uparrow}$ *source fiber only through these rows.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiberExportPacket`

Theorem 204.52 (TopGroupUp root source-fiber export carrier)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet carries the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source rows over one shared* BHist *carrier. The product row, inverse row, componentwise* hsame *rows, finite* Cont *ledger, and* Pkg *provenance are projections from that carrier, so the export surface contains no detached group source, topology source, or ambient topological-group carrier.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export carrier`

Proof. Start with the carrier theorem Definition 204.47. It reads the two source rows and both operation rows from one root source-fiber obligation packet.

Apply Definition 204.50. The finite ledger and provenance rows are attached to that same source pair, so they cannot be exported as independent carrier data.

Finally compare with Definition 204.19. A public consumer receives only the displayed source certificate rows, operation rows, finite continuation rows, and provenance. This is precisely the carrier surface of Definition 204.51. □

Theorem 204.53 (TopGroupUp root source-fiber export continuity)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet, product continuity and inverse continuity are exported only as componentwise* hsame *transport through the shared source pair and the finite* Cont *ledger. The product and inverse rows have no continuity witness outside the displayed operation endpoints, classifier rows, ledger entries, and provenance.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export continuity`

Proof. Use Definition 204.49. It binds the product and inverse continuity rows to the same source-fiber carrier, componentwise classifier packet, and finite ledger.

Then apply Definition 204.47. The operation endpoints are already projections from the shared BHist source pair and cannot introduce a separate continuity carrier.

The public boundary is fixed by Definition 204.19. Since the consumer receives no ambient topological-group predicate, the two exported continuity rows are exactly the ledger-indexed product and inverse rows. □

Theorem 204.54 (TopGroupUp root source-fiber export ledger)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet, the finite* Cont *ledger is exact for the exported product and inverse continuity rows. Every exported operation-continuity read is one of those rows, and every listed ledger entry is sound through the shared* BHist *source pair, componentwise* hsame *classifier rows, and shared* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export ledger`

Proof. Begin with Definition 204.50. It states that the finite Cont ledger exhausts precisely the product-continuity and inverse-continuity obligation families over the root source fiber.

Next use Definition 204.49. This identifies the endpoints and classifier transports consumed by each listed ledger entry.

Finally apply Definition 204.19. A downstream consumer has no third operation-continuity family and no ledger row outside the exported source, operation, classifier, continuation, and provenance rows. □

Theorem 204.55 (TopGroupUp root source-fiber export common Cont ledger)**.** *In an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet, the product-continuity and inverse-continuity rows are indexed by the same finite* Cont *ledger and the same* Pkg *provenance over the shared* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source pair. Any downstream read of either continuity family factors through that common ledger, with no ambient topological-group object and no separate continuity carrier.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export common cont ledger`

Proof. Apply Definition 204.53. It binds both operation-continuity families to the displayed operation endpoints, classifier rows, finite Cont ledger, and provenance.

Next use Definition 204.54. The exported ledger is exact for the product and inverse continuity rows, so a downstream read of either family is one of its entries.

Finally, Definition 204.52 ties the ledger and provenance to the shared $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$–$\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source pair. This leaves no ambient topological-group carrier through which a second ledger could enter. □

Theorem 204.56 (TopGroupUp root source-fiber export consumer boundary)**.** *Every public consumer read of the* $\mathsf{TopGroup}^{\uparrow}$ *root source fiber factors through Definition 204.51. Conversely, each row of that export packet is a public row already forced by the shared* BHist *source pair for* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$*, the product and inverse rows, componentwise* hsame *transport, the finite* Cont *ledger, and shared* Pkg *provenance. No order row, topology row outside* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$*, operation row outside product and inverse, or ambient topological-group object is exported.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage export boundary certificate`

Proof. First assemble the export carrier by Definition 204.52. The source pair, operation rows, classifier packet, finite ledger, and provenance all live over one BHist source fiber.

Next attach the operational rows. Apply Definition 204.53 for the product and inverse continuity rows, and Definition 204.54 for the exact finite ledger that lists them.

For the forward direction, use Definition 204.19. It restricts every public consumer to the same source certificate rows, operation rows, finite continuation rows, and provenance, so the consumer read factors through the export packet.

For the reverse direction, each row of Definition 204.51 is already one of the public rows named by the carrier, continuity, and ledger theorems above. Thus the packet exports exactly the source-fiber surface and nothing outside it. □

Theorem 204.57 (TopGroupUp root source-fiber export exactness)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root source-fiber export packet is exact for public consumers: a consumer read factors through the packet if and only if it is one of the shared* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source rows, product rows, inverse rows, componentwise* hsame *rows, finite* Cont *ledger entries, or shared* Pkg *provenance rows. No order row, detached topology row, third operation, or ambient topological-group carrier is accepted by the export surface.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export exactness semantic certificate`
↪ variant `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiberExportPacket exactness`

Proof. First use Definition 204.52. It fixes the exported root source fiber over the shared $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$–$\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source rows, the product and inverse rows, componentwise hsame transport, and the shared package provenance.

Next apply Definition 204.53 and Definition 204.54. These theorems bind the product and inverse continuity rows to the displayed finite Cont ledger, so every accepted continuation read is one of the listed ledger entries.

The common ledger theorem, Definition 204.55, identifies the product and inverse rows as a single shared finite continuation ledger rather than two detached operation ledgers.

Finally apply Definition 204.56. The consumer boundary gives both directions of the factorization statement and excludes order rows, detached topology rows, any third operation, and any ambient topological-group carrier outside the exported packet. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootSourceFiber export exactness`

204.5 Root operation source packet

Definition 204.58 (TopGroupUp root operation-source packet)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *root operation-source packet is the shared* BHist *packet*

$$\mathcal{R} = (G, T, m, i, n, \lambda, \rho)$$

of Definition 204.1, read as a root-facing source for the operation rows. The coordinate G is the displayed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row, T is the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row, m is the product row, i is the inverse row, n is the neighbourhood row used by both operation-continuity families, λ is the finite* Cont *ledger, and ρ is the* Pkg *provenance row tying the group, topology, operation, neighbourhood, classifier, and continuity entries to one packet.*

Two such packets are compared only by the componentwise hsame *rows already present in the carrier and by the displayed* Cont *ledger comparison. The packet contains no host topological-group object and no ambient continuity predicate outside the shown BEDC rows.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootOperationSourcePacket`

Theorem 204.59 (TopGroupUp root source-pair exactness)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root operation-source packet has exactly the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source pair. The product row, inverse row, neighbourhood row, finite* Cont *ledger, and* Pkg *provenance row are projections from the same* BHist *packet, so the root source cannot be read as two independent carrier certificates.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootOperationSourcePacket root source pair exactness`
Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootOperationSourcePacket source pair exactness`

Proof. Project the packet of Definition 204.58. Its coordinates are the source pair G, T together with the operation rows m, i, the neighbourhood row n, the ledger λ, and the provenance row ρ.

Apply Definition 204.24. It identifies the group source, topology source, product graph, inverse graph, neighbourhood row, finite Cont ledger, and Pkg provenance as projections from one shared BHist carrier.

Finally use Definition 204.38. A root consumer therefore receives the two source rows only through that shared packet, with no second carrier from which an independent source certificate could be assembled. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root source pair exactness`

Theorem 204.60 (TopGroupUp root operation-continuity exhaustion)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root operation-source packet, every operation-continuity row exported at the root is either a product-continuity row for m or an inverse-continuity row for i. Both families are carried by the displayed neighbourhood row n and finite* Cont *ledger λ, and there is no further operation-continuity predicate outside the packet.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootOperationSourcePacket operation continuity exhaustion`

Proof. Start with the exact source-pair packet supplied by Definition 204.59. It places the product row, inverse row, neighbourhood row, and ledger over the same displayed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ sources.

Apply Definition 204.30. It says that the exported operation-continuity obligations are exactly multiplication continuity and inversion continuity.

Apply Definition 204.31. The finite Cont ledger covers all accepted product-neighbourhood and inverse-neighbourhood continuity reads, and each listed entry is sound through the shared carrier packet. Thus the root operation-continuity surface is exhausted by those two families. □

Theorem 204.61 (TopGroupUp root classifier ledger stability)**.** *If two accepted* $\mathsf{TopGroup}^{\uparrow}$ *root operation-source packets are related by the root classifier, then the product row, inverse row, neighbourhood row, finite* Cont *ledger, and* Pkg *provenance row transport componentwise by the displayed* hsame *witnesses and the same ledger comparison. The transported packet still exposes only the displayed source pair and its two operation-continuity families.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThreshold classifier ledger transport packet`

Proof. Unpack the two root operation-source packets. The classifier compares the group source, topology source, product row, inverse row, neighbourhood row, ledger row, and provenance row componentwise through the carried hsame and Cont data.

Use Definition 204.39. It transports product continuity and inverse continuity through the same classifier packet, with the product and inverse arities read from the shared carrier rows.

Then apply Definition 204.60. Since the transported root surface has only the product and inverse continuity families listed in the finite ledger, classifier transport cannot introduce a host topological-group object or an ambient continuity predicate. □

Theorem 204.62 (TopGroupUp root operation-source continuity coupling)**.** *For an accepted root operation-source packet* $\mathcal{R} = (G, T, m, i, n, \lambda, \rho)$*, the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row* G *and displayed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row* T *determine the product-continuity and inverse-continuity families through the same neighbourhood row* n*, finite* Cont *ledger* λ*, and* Pkg *provenance row* ρ*. Classifier transport of* $\mathcal{R}$ *transports both continuity families through those same rows and cannot create an ambient continuity predicate outside the packet.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootOperationSourcePacket continuity coupling`

Proof. Apply Definition 204.59. It identifies G and T as the displayed source pair of a single BHist packet, with m, i, n, λ, and ρ read as projections from that same packet.

Next use Definition 204.60. The only operation-continuity rows over the displayed source pair are the product-continuity family for m and the inverse-continuity family for i, both indexed by the same neighbourhood row and finite Cont ledger.

Finally apply Definition 204.61. The classifier transports the product row, inverse row, neighbourhood row, ledger, and provenance componentwise, so it transports both continuity families together and has no row from which to synthesize an ambient continuity predicate. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root operation source continuity coupling`

204.6 Public threshold frontier

Definition 204.63 (TopGroupUp root public threshold packet)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *root public threshold packet is the finite* BHist *packet*

$$\Theta_{\mathsf{TopGroup}^{\uparrow}} = (G, T, m, i, n, \lambda, \rho, \tau)$$

whose first seven coordinates are the carrier $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ *of Definition 204.1. The row* G *is the displayed* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *source,* T *is the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source,* m *and* i *are the product and inverse operation rows,* n *is the neighbourhood transport row,* λ *is the finite* Cont *ledger, and* ρ *is the* Pkg *provenance row.*

The final row τ *is the public-threshold classifier row. It records that transport between two such packets is componentwise* hsame *on the source, operation, neighbourhood, and provenance rows, together with the displayed* Cont *comparison on the finite ledger. The packet exports a public* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *threshold over* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$*, but it does not add a host topological-group object or an ambient continuity predicate.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootPublicThresholdPacket`

Theorem 204.64 (TopGroupUp product-inverse joint continuity scope)**.** *For every accepted* $\mathsf{TopGroup}^\uparrow$ *root public threshold packet* $\Theta_{\mathsf{TopGroup}^\uparrow}$*, the public continuity scope is exactly the joint product-inverse scope carried by the shared packet: product continuity for* m*, inverse continuity for* i*, the common neighbourhood row* n*, the finite* Cont *ledger* λ*, and the* Pkg *provenance row* ρ*. No third operation-continuity family is exported at the root.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThreshold product inverse empty scope`

Proof. Project $\Theta_{\mathsf{TopGroup}^\uparrow}$ to the carrier packet $\mathcal{G} = (G, T, m, i, n, \lambda, \rho)$ of Definition 204.1. This exposes the displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ sources together with the product, inverse, neighbourhood, ledger, and provenance rows.

Use Definition 204.60. It identifies the root operation-continuity rows with precisely the product family for m and the inverse family for i.

Use Definition 204.40 to read both families through the same finite Cont ledger. The public threshold packet therefore has the listed joint continuity scope and no outside continuity row. □

Theorem 204.65 (TopGroupUp source ledger public threshold)**.** *Every accepted* $\mathsf{TopGroup}^\uparrow$ *root public threshold packet binds its* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *source,* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source, product row, inverse row, neighbourhood row, finite* Cont *ledger, and* Pkg *provenance into one public threshold surface. A downstream consumer can read the source pair and the ledger only as projections of that surface.*

Proof. Start from the threshold packet of Definition 204.63. Its carrier projection is the root operation-source packet of Definition 204.58.

Apply Definition 204.59. The displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ rows are the source pair of one shared BHist packet, not independent certificates.

Apply Definition 204.60. The ledger seen by the consumer is the same finite Cont ledger for product and inverse continuity, with the same Pkg provenance row. Thus the source pair and ledger form one public threshold surface. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage source ledger empty spine`

Theorem 204.66 (TopGroupUp NameCert frontier threshold)**.** *The* $\mathsf{TopGroup}^\uparrow$ *root public threshold packet is the frontier at which the displayed* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *rows become a public* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *surface. Its classifier transport is exactly the componentwise* hsame *transport of source, operation, neighbourhood, and provenance rows together with the finite* Cont *ledger comparison, and its provenance is exactly the displayed* Pkg *row.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThreshold frontier threshold`

Proof. Unpack the public-threshold classifier row τ. It contains only the componentwise hsame comparisons for the two sources, the product row, the inverse row, the neighbourhood row, and the provenance row, plus the finite Cont ledger comparison.

Use Definition 204.61. The same classifier transports the product, inverse, neighbourhood, ledger, and provenance rows while preserving the root source pair.

Finally apply Definition 204.7. The public certificate boundary is exhausted by the displayed BEDC rows. Hence the frontier threshold is exactly this finite packet over $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$. □

Definition 204.67 (TopGroupUp final public threshold packet)**.** *The final* $\mathsf{TopGroup}^\uparrow$ *public threshold packet is the finite* BHist *packet extending Definition 204.63 by making all public projections explicit:*

$$\Theta^{\mathsf{pub}}_{\mathsf{TopGroup}^\uparrow} = (G, T, m, i, n, \lambda, \tau, \rho).$$

The source projections are the displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *row* G *and the displayed* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *row* T*. The operation projections are the product row* m *and inverse row* i*. The neighbourhood projection is* n*, the finite ledger projection is* λ*, the classifier projection is* τ*, and the provenance projection is the* Pkg *row* ρ*.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootPublicThresholdFinalPacket`

Theorem 204.68 (TopGroupUp public threshold exhaustion)**.** *Every public threshold read of the root* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *surface projects to the source, operation, neighbourhood, finite ledger, classifier, and provenance rows of Definition 204.67. Conversely, those rows repack as the same final public threshold packet over* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThresholdPacket public threshold exhaustion`

Proof. Project the final packet to the root public threshold packet of Definition 204.63. Its carrier part supplies the two source rows, the product and inverse operation rows, the neighbourhood row, the finite Cont ledger, and the Pkg provenance row.

Apply Definition 204.64. The operation-facing public scope is exactly the joint product-inverse scope, so no third operation row or ambient continuity predicate is available.

Now use Definition 204.65 and Definition 204.66. These theorems bind the source pair, ledger, classifier, and provenance into the public $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ threshold. Repacking the listed projections gives the final packet and exhausts the public read. □

Theorem 204.69 (TopGroupUp public threshold transport)**.** *Componentwise* hsame *transport of the* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *source,* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source, product row, inverse row, neighbourhood row, classifier row, and provenance row, together with finite* Cont *transport of the ledger row, preserves the final* $\mathsf{TopGroup}^\uparrow$ *public threshold packet.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThreshold transport`

Proof. Unpack Definition 204.67. Each public projection is one displayed row of the finite BHist packet, so componentwise hsame transport acts on the source, operation, neighbourhood, classifier, and provenance projections without changing the packet shape.

Use Definition 204.65 for the ledger part. The finite Cont comparison is the same ledger comparison that binds the source pair and operation rows into one public threshold surface.

Finally apply Definition 204.66. Its classifier clause is precisely the componentwise transport just displayed, and therefore the transported rows repack as the same final public threshold packet. □

Theorem 204.70 (TopGroupUp public threshold NameCert surface)**.** *The rows of Definition 204.67 form the root public* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *surface over the two source certificates* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$*. This surface is exactly the source pair, product and inverse rows, neighbourhood row, finite* Cont *ledger, classifier row, and* Pkg *provenance row.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThreshold namecert surface`

Proof. Begin with the final threshold packet and project its source pair G, T. These are the displayed $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ rows, so the root certificate is explicitly over the two source certificates.

Apply Definition 204.64 to identify the product, inverse, neighbourhood, and ledger rows as the complete operation-continuity scope.

Then apply Definition 204.66. The frontier theorem packages the same componentwise classifier and provenance rows as the public $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ threshold, giving exactly the stated NameCert surface. □

Theorem 204.71 (TopGroupUp public threshold joint source determinacy)**.** *Two final public threshold packets over the same displayed* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *source rows, and with the same product, inverse, neighbourhood, finite* Cont *ledger, classifier, and* Pkg *provenance rows up to componentwise* hsame*, determine the same public* $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ *surface. The determined surface exposes the two source rows and the listed finite public threshold rows, and exposes no ambient continuity predicate.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootPublicThreshold joint source determinacy`

Proof. First apply Definition 204.65 to each packet. The common source rows, operation rows, neighbourhood row, finite Cont ledger, classifier row, and Pkg provenance row bind both reads to the same public threshold source ledger.

Next use Definition 204.66. The frontier theorem turns that shared source ledger into the public $\mathsf{NameCert}_{\mathsf{TopGroup}^\uparrow}$ threshold, so the two packets have the same NameCert-facing source boundary.

Apply Definition 204.69 to the componentwise hsame rows. This transports each displayed row of the first packet to the corresponding row of the second without adding any row beyond the final threshold packet.

Finally apply Definition 204.70. It identifies the transported threshold packet with exactly the source pair, product, inverse, neighbourhood, finite ledger, classifier, and provenance surface, so no ambient continuity predicate remains available to distinguish the two public reads. □

204.7 TopGroup root threshold downstream package

Definition 204.72 (TopGroupUp root threshold downstream package)**.** *The* $\mathsf{TopGroup}^\uparrow$ *root threshold downstream package is the finite* BHist *packet*

$$\Omega_{\mathsf{TopGroup}^\uparrow} = (G, T, m, i, n, \kappa, \lambda, \rho, \nu)$$

whose source pair G, T *is the displayed* $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$ *pair, whose operation rows* m, i *are the product and inverse rows, whose row* n *is the shared neighbourhood source, whose classifier packet* κ *is componentwise* hsame*, whose finite ledger* λ *is the product and inverse* Cont *ledger, whose provenance row* ρ *is the shared* Pkg *row, and whose threshold row* ν *records that a downstream public consumer reads only these NameCert-anchored coordinates.*

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootThresholdDownstreamPackage`

Theorem 204.73 (TopGroupUp root threshold carrier scope)**.** *Every accepted* $\mathsf{TopGroup}^{\uparrow}$ *root threshold downstream package carries the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *source row, the product row, the inverse row, the neighbourhood row, the componentwise* hsame *classifier packet, the finite* Cont *ledger, and the shared* Pkg *provenance as projections of one* BHist *carrier. No downstream root consumer may split the source pair into two carrier packages.*

Proof. Project the package of Definition 204.72. Its coordinates are the two NameCert source rows, the operation rows, the neighbourhood source, the classifier packet, the ledger, the provenance row, and the public threshold row.

Apply Definition 204.24. It identifies the source pair, product graph, inverse graph, neighbourhood row, finite Cont ledger, and Pkg provenance as projections of one BHist carrier.

Use Definition 204.19. A downstream public consumer receives only the carrier projections just listed, so the threshold surface has no second carrier or detached provenance row. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThreshold carrier scope`

Theorem 204.74 (TopGroupUp root threshold operation scope)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root threshold downstream package, the only operation-continuity rows exposed to a downstream consumer are the product continuity rows for* m *and the inverse continuity rows for* i*. Both families use the shared neighbourhood row* n*, the same componentwise* hsame *classifier packet* κ*, and the same finite* Cont *ledger* λ*.*

Proof. Begin with the carrier scope of Definition 204.73. It places the source pair, operation rows, neighbourhood row, classifier packet, ledger, and provenance over one BHist packet.

Apply Definition 204.25. The product continuity family is sound precisely through the two input endpoints, product endpoint, neighbourhood row, componentwise hsame transport, and finite ledger entry.

Apply Definition 204.28. The inverse continuity family has the same scope for its input endpoint, inverse endpoint, neighbourhood row, classifier transport, and ledger entry. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage operation scope`

Theorem 204.75 (TopGroupUp root threshold consumer exhaustion)**.** *Every downstream public consumer of a* $\mathsf{TopGroup}^{\uparrow}$ *root threshold package reads exactly the source pair, operation rows, neighbourhood row, componentwise* hsame *classifier packet, finite* Cont *ledger, and* Pkg *provenance of Definition 204.72. In particular, no ambient topological-group object, host continuity predicate, or detached NameCert source is available beyond those rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage consumer exhaustion`

Proof. First use Definition 204.73 to bind the source and provenance rows to the shared carrier. Then use Definition 204.74 to bind the product and inverse continuity rows to the same classifier packet and ledger.

Apply Definition 204.19. The public consumer surface contains only the displayed source, operation, classifier, continuity, and provenance rows. Hence every downstream read is exhausted by the root threshold package. □

Theorem 204.76 (TopGroupUp root threshold NameCert threshold)**.** *The rows of the* $\mathsf{TopGroup}^{\uparrow}$ *root threshold downstream package form a public* $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ *threshold over the displayed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *sources. The threshold classifier is exactly the componentwise* hsame *transport of source, operation, neighbourhood, and provenance rows together with finite* Cont *transport of the product and inverse ledger rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root threshold namecert threshold`

Proof. Unpack the threshold row ν in Definition 204.72. It records componentwise hsame transport for the NameCert source pair, product row, inverse row, neighbourhood row, and provenance row, plus finite Cont transport for the ledger.

Apply Definition 204.75. Since the downstream consumer reads no row outside the package, this classifier packet is the whole public threshold surface.

Finally use Definition 204.19. The public NameCert boundary is therefore exactly the displayed finite BHist packet over the two source certificates. □

Theorem 204.77 (TopGroupUp root threshold export boundary)**.** *Every downstream public export of the* $\mathsf{TopGroup}^{\uparrow}$ *root threshold factors through the single packet* $\Omega_{\mathsf{TopGroup}^{\uparrow}}$ *of Definition 204.72. The export exposes exactly the* $\mathsf{Group}^{\uparrow}$ *source, the* $\mathsf{Topology}^{\uparrow}$ *source, the product row, the inverse row, the shared neighbourhood row, the componentwise* hsame *classifier packet, the finite* Cont *ledger, the* Pkg *provenance, and the threshold row. It exposes no ambient topological-group object, no host continuity predicate, no detached source certificate, and no operation continuity row beyond the product and inverse ledger rows already carried by* $\Omega_{\mathsf{TopGroup}^{\uparrow}}$*.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root threshold export boundary`
↪ variant `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage export boundary`

Proof. Begin with Definition 204.73. It places the $\mathsf{Group}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ source certificates, the operation rows, the neighbourhood row, the classifier packet, the finite ledger, and the provenance row inside one BHist carrier.

Next use Definition 204.74. The product and inverse continuity data are precisely the ledger rows over the shared neighbourhood source and componentwise hsame classifier packet.

Apply Definition 204.75. A downstream public consumer reads only the displayed source, operation, classifier, continuity, and provenance rows, so an ambient topological-group object, host continuity predicate, or detached source certificate is outside the export.

Finally apply Definition 204.76. The threshold row is the public $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ boundary of the same packet. Repacking these projections gives the stated export boundary and leaves no extra operation-continuity row to expose. □

204.8 TopGroup root downstream obligation triad

Definition 204.78 (TopGroupUp root downstream obligation triad)**.** *The* $\mathsf{TopGroup}^{\uparrow}$ *root downstream obligation triad is the finite* BHist *packet*

$$\mathcal{D}_{\mathsf{TopGroup}^{\uparrow}} = (\eta_G, \eta_T, \mu, \iota, \mathcal{N}, C_\mu, C_\iota, H, \Pi)$$

whose source rows are the shared $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row* η_G*, the shared* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row* η_T*, the product row* μ*, the inverse row* ι*, the neighbourhood row family* $\mathcal{N}$*, the product and inverse continuity ledgers* C_μ *and* C_ι*, the displayed* hsame *comparison rows* H*, and the package provenance row* $\Pi : \mathsf{Pkg}$*.*

The packet is accepted exactly when these rows are the carrier, operation, continuity, history-sameness, and provenance projections of the root source packet of Definition 204.58, and when the public threshold row of Definition 204.72 authorizes no further downstream read.

Lean4 (definition) `BEDC.Derived.TopGroupUp.TopGroupRootDownstreamObligationTriad`

Theorem 204.79 (TopGroupUp root downstream carrier obligation)**.** *Every carrier-facing downstream read of an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root downstream obligation triad is exactly one of the shared* BHist *source rows* η_G*,* η_T*, or* $\mathcal{N}$*, together with its displayed* hsame *transport row from* H*. Conversely, those shared source rows repack as the carrier-facing boundary of the same triad.*

Proof. Project the triad to the root operation source packet. Apply Definition 204.59: it identifies the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ source, the $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ source, and the neighbourhood rows as the only carrier-facing source pair.

Then apply Definition 204.75. The threshold package allows a downstream consumer to read only the listed source rows and their displayed hsame comparisons, so no additional carrier row is available.

For the converse, insert those projected rows back into Definition 204.78. The acceptance clauses ask for exactly the root source pair and the threshold permission row, hence the same carrier-facing boundary is recovered. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root downstream carrier obligation`

Theorem 204.80 (TopGroupUp root downstream operation obligation)**.** *For an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root downstream obligation triad, the operation-facing boundary is exhausted by the product row* μ*, the inverse row* ι*, the product continuity ledger* C_μ*, the inverse continuity ledger* C_ι*, and their* hsame *transport rows. It includes no associativity, unit, inverse-law, quotient, completion, or standard-bridge datum beyond those operation and continuity rows.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root downstream operation transport`

Proof. First read the operation rows from the root packet. By Definition 204.60, the product and inverse rows are bound to the source pair only through the finite continuity ledgers C_μ and C_ι.

Next restrict the downstream view with Definition 204.75. A public downstream consumer receives the operation rows, their continuity ledgers, the source rows already isolated by Definition 204.79, and no further group law or host structure.

Repacking is componentwise: the product, inverse, and two continuity ledgers are coordinates of $\mathcal{D}_{\mathsf{TopGroup}^{\uparrow}}$, while the displayed hsame rows are exactly the transport rows recorded in H. This is the whole operation-facing boundary. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage operation ledger obligation`

Theorem 204.81 (TopGroupUp root downstream ledger obligation)**.** *The finite* Cont *ledger rows* C_μ *and* C_ι *together with the package provenance row* $\Pi : \mathsf{Pkg}$ *exhaust all downstream root reads of an accepted* $\mathsf{TopGroup}^{\uparrow}$ *root downstream obligation triad. Every such read is a carrier source row, an operation row, a displayed* hsame *row, a finite continuity-ledger row, or the package provenance row of the triad.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage downstream ledger obligation`

Proof. Begin with the carrier side. Apply Definition 204.79 to identify all source and neighbourhood reads as shared BHist rows over $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$.

Now use Definition 204.80 for the operation side. It says that product and inverse reads appear only through the displayed finite Cont ledgers and their hsame transport rows.

Finally apply Definition 204.75. The threshold package leaves no downstream root read outside the source pair, operation rows, continuity ledgers, history-sameness rows, and provenance package. Since those are exactly the coordinates of Definition 204.78, the finite ledger and Pkg provenance exhaust the root downstream surface. □

Theorem 204.82 (TopGroupUp root downstream continuity obligation)**.** *For an accepted* $\mathsf{TopGroup}^\uparrow$ *root downstream obligation triad, every product continuity read is exactly a row of the finite* Cont *ledger* C_μ *and every inverse continuity read is exactly a row of the finite* Cont *ledger* C_ι*, transported only by the displayed* hsame *rows in* H*. Conversely, the rows of* C_μ *and* C_ι *with their displayed* hsame *transports repack as the whole continuity-facing downstream surface of* $\mathcal{D}_{\mathsf{TopGroup}^\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage root downstream continuity obligation`

Proof. Project the accepted packet through Definition 204.78. Its continuity coordinates are precisely C_μ and C_ι, with no separate host continuity object.

Apply Definition 204.80. It identifies the product and inverse boundaries with the operation rows together with the finite continuity ledgers and their displayed hsame rows. Then apply Definition 204.81, which rules out any downstream root read outside the listed finite ledger, transport, source, and provenance rows.

For the converse, insert any row of C_μ or C_ι and its matching row of H back into the defining packet. The acceptance clauses are exactly the finite Cont ledger clauses of the root operation source packet, so the same rows recover the continuity-facing boundary. □

Theorem 204.83 (TopGroupUp root downstream provenance obligation)**.** *Every carrier, operation, continuity, and ledger read of an accepted* $\mathsf{TopGroup}^\uparrow$ *root downstream obligation triad is tied to the same package provenance row* $\Pi : \mathsf{Pkg}$*. In particular, no downstream read may exchange the carrier source, operation row,* Cont *ledger row, or displayed* hsame *transport for a row with a different provenance package.*

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootDownstreamPackage provenance transport`

Proof. Use Definition 204.79 for the carrier side: the visible carrier rows are the shared $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$, and neighbourhood rows, all projected from the same accepted packet.

Use Definition 204.80 and Definition 204.82 for the operation and continuity sides. Their reads are the product row, inverse row, finite Cont ledgers, and displayed hsame transports already present in $\mathcal{D}_{\mathsf{TopGroup}^\uparrow}$.

Finally apply Definition 204.81. It says that the finite ledger rows and the single package provenance row $\Pi : \mathsf{Pkg}$ exhaust the remaining downstream reads. Since all the cited rows are coordinates of the same packet, their provenance is the same Π. □

Theorem 204.84 (TopGroupUp root downstream threshold exactness)**.** *The public threshold row of the* $\mathsf{TopGroup}^\uparrow$ *root downstream package authorizes exactly the carrier rows, operation rows, continuity rows, displayed* hsame *rows, ledger rows, and package provenance row listed in* $\mathcal{D}_{\mathsf{TopGroup}^\uparrow}$*. It authorizes no group-law, completion, quotient, standard-bridge, or ambient topological-group datum outside those rows.*

Proof. First unpack $\mathcal{D}_{\mathsf{TopGroup}^{\uparrow}}$ by Definition 204.78. The displayed packet contains the two source certificates, product and inverse rows, neighbourhood rows, two finite Cont ledgers, the transport family H, and the provenance row Π.

The carrier boundary is exactly the one isolated in Definition 204.79. The operation boundary is exactly the one isolated in Definition 204.80. The continuity boundary is exactly the one isolated in Definition 204.82.

Apply Definition 204.81 to include the finite ledger and provenance rows. Then apply Definition 204.75: the public threshold package admits no downstream consumer row beyond this displayed finite family. Thus the threshold row is exact for the listed root downstream surface. □

Lean4 ✓ `BEDC.Derived.TopGroupUp.TopGroupRootThresholdPackage downstream threshold exactness`

Chapter 205

A Concrete Naming Certificate for $\mathsf{TopVecSpace}^{\uparrow}$

The topological-vector-space interface $\mathsf{TopVecSpace}^{\uparrow}$ packages a vector-space carrier with a Hausdorff topology making addition and scalar multiplication continuous. It depends on $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88).

205.1 Carrier definition

Definition 205.1 (TopVecSpace BHist carrier)**.** *A* $\mathsf{TopVecSpace}^{\uparrow}$ *BHist carrier is a finite displayed packet*

$$(V, \mathcal{T}, A, S, \lambda, \rho)$$

whose fields are as follows.

1. *V is the* $\mathsf{VecSpace}^{\uparrow}$ *carrier row, including the displayed zero, addition, negation, scalar-source, scalar-action, and vector-space classifier rows.*
2. *$\mathcal{T}$ is the* $\mathsf{Topology}^{\uparrow}$ *open-neighbourhood row over the same displayed carrier, naming the open rows used to test continuity.*
3. *A is the finite addition-continuity ledger: each entry records source neighbourhood rows for two vector inputs, the displayed addition endpoint, and the target neighbourhood row.*
4. *S is the finite scalar-continuity ledger: each entry records a scalar-source row, a vector-source row, the displayed scalar-action endpoint, and the target neighbourhood row.*
5. *λ is the finite* Cont *ledger transporting the vector-space, topology, addition-continuity, and scalar-continuity rows.*
6. *ρ is the* Pkg *provenance row naming the* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *dependency certificates.*

Two packets classify together exactly when the vector-space row, topology row, continuity ledgers, continuation rows, and package provenance are transported componentwise by the available hsame *rows. The carrier exports no host topological-vector-space equality, ambient topology, or analytic continuity predicate outside the displayed ledgers.*

```
Lean4 ✓  BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier endpoint route readback
Lean4 ✓  BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier route transport boundary
```

Theorem 205.2 (TopVecSpace vector-space source obligation)**.** *Every accepted* $\mathsf{TopVecSpace}^{\uparrow}$ *packet projects its algebraic source exactly to the* $\mathsf{VecSpace}^{\uparrow}$ *row* V *of Definition 205.1. The zero, addition, negation, scalar-source, scalar-action, and vector-space classifier rows are consumed through* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and transported only by the carried* hsame, Cont, *and* Pkg *rows.*

Proof. Project an accepted packet to its first field V. By the carrier definition, V is the only row that exposes vector-space operations and the vector-space classifier.

The addition and scalar-continuity ledgers may refer to those operations, but they do so by naming the rows already present in V. Their references are routed through λ and the provenance row ρ.

Since no host vector space or ambient equality row is available in the packet, the algebraic source obligation is exactly the displayed $\mathsf{VecSpace}^{\uparrow}$ source row. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier vecspace source obligation`

Theorem 205.3 (TopVecSpace topology source obligation)**.** *Every accepted* $\mathsf{TopVecSpace}^{\uparrow}$ *packet projects its topological source exactly to the* $\mathsf{Topology}^{\uparrow}$ *row* $\mathcal{T}$ *of Definition 205.1. Open-neighbourhood membership, neighbourhood transport, and topological classifier data are consumed through* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *and remain tied to the vector-space carrier only through displayed* hsame, Cont, *and* Pkg *rows.*

Proof. Project the packet to $\mathcal{T}$. This row records the open-neighbourhood data used by the continuity ledgers, and it is the only field that consumes the topology certificate.

The vector-space row V supplies the carrier on which those opens are displayed. The connection between V and $\mathcal{T}$ is not host equality of underlying sets; it is the componentwise transport recorded by λ and named by ρ.

Thus every topological readback factors through $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ and the finite packet rows. No ambient topology or unlogged neighbourhood filter is exported. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier topology source obligation`

205.2 The certificate

Theorem 205.4 (TopVecSpace continuous addition obligation)**.** *For a* $\mathsf{TopVecSpace}^{\uparrow}$ *BHist carrier, every addition-continuity claim is a row of the finite ledger* A*. Each such row reads two vector-source neighbourhoods from* $\mathcal{T}$*, the displayed addition endpoint from* V*, and the target neighbourhood row from* $\mathcal{T}$*, with the route and provenance recorded by* λ *and* ρ*.*

Proof. Read an entry of the addition-continuity ledger A. Its input neighbourhoods and target neighbourhood are topology rows, while its operation endpoint is the addition row exposed by V.

The comparison data for transported packets are supplied componentwise by hsame. The finite continuation ledger λ records how the two input neighbourhoods, the addition endpoint, and the target neighbourhood remain aligned after transport.

Repacking these projections gives the addition-continuity obligation. Because the packet contains no host continuity predicate, no external topological-vector-space equality is used. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier continuous addition obligation`

Theorem 205.5 (TopVecSpace continuous scalar obligation)**.** *For a* $\mathsf{TopVecSpace}^{\uparrow}$ *BHist carrier, every scalar-continuity claim is a row of the finite ledger* S*. Each such row reads the scalar-source and vector-source coordinates from* V*, the relevant neighbourhood rows from* $\mathcal{T}$*, and the scalar-action endpoint from* V*, with transport and provenance recorded by* λ *and* ρ*.*

Proof. Read an entry of the scalar-continuity ledger S. The scalar coordinate, vector coordinate, and scalar-action endpoint are projected from the $\mathsf{VecSpace}^{\uparrow}$ row V.

Read the neighbourhood coordinates from $\mathcal{T}$. Their stability under replacement is witnessed by the carried hsame comparisons and the finite continuation route in λ.

The provenance row ρ records that the algebraic and topological reads come from the two named dependency certificates. Therefore the scalar-continuity obligation is internal to the displayed packet and does not invoke host topological-vector-space equality. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier continuous scalar obligation`

Theorem 205.6 (TopVecSpace classifier transport)**.** *Let $P = (V, \mathcal{T}, A, S, \lambda, \rho)$ and $P' = (V', \mathcal{T}', A', S', \lambda', \rho')$ be displayed $\mathsf{TopVecSpace}^{\uparrow}$ packets. If the $\mathsf{VecSpace}^{\uparrow}$ row, $\mathsf{Topology}^{\uparrow}$ row, addition-continuity ledger, scalar-continuity ledger, finite Cont ledger, and Pkg provenance are transported componentwise by the carried hsame rows from P to P', then accepted carrier status transports from P to P'. Under the same componentwise transport, every accepted addition-continuity ledger row of P transports to an accepted row of A', and every accepted scalar-continuity ledger row of P transports to an accepted row of S'.*

Proof. Project the two packets to their displayed rows. The carrier definition makes the vector-space row, topology row, the two continuity ledgers, the continuation ledger, and the package provenance the complete classifier surface.

Use the supplied hsame comparisons on each row. They replace V by V', $\mathcal{T}$ by $\mathcal{T}'$, A by A', S by S', λ by λ', and ρ by ρ' without introducing any coordinate outside the displayed packet.

The accepted carrier predicate is therefore rebuilt by the same finite tuple with primed rows. The addition and scalar obligations follow by applying Definition 205.4 and Definition 205.5 to the transported ledgers. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier classifier transport`

Theorem 205.7 (TopVecSpace NameCert boundary)**.** *The carrier definition of Definition 205.1, the vector-space and topology source obligations of Definition 205.2 and Definition 205.3, the continuous addition and scalar obligations of Definition 205.4 and Definition 205.5, and the classifier transport of Definition 205.6 assemble the $\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}$ boundary over BHist, hsame, Cont, and Pkg.*

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier namecert boundary`

Proof. Start with a displayed packet $(V, \mathcal{T}, A, S, \lambda, \rho)$ of Definition 205.1. The first two source obligations identify exactly the dependency-certificate rows consumed from $\mathsf{VecSpace}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$.

The two continuity obligations identify the only analytic rows exposed by the packet: addition is read from A, scalar multiplication is read from S, and both ledgers route through λ with provenance in ρ.

Finally apply Definition 205.6. It supplies the closure of the accepted packet surface under componentwise hsame replacement, so the carrier, source, continuity, continuation, and package rows repack as the displayed $\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}$ boundary. □

Theorem 205.8 (TopVecSpace consumer scope)**.** *Every downstream consumer of a $\mathsf{TopVecSpace}^{\uparrow}$ certificate reads only the displayed $\mathsf{VecSpace}^{\uparrow}$ row V, the displayed $\mathsf{Topology}^{\uparrow}$ row $\mathcal{T}$, the addition and scalar continuity ledgers A and S, the continuation ledger λ, and the provenance row ρ. Such a consumer cannot infer ambient topological-vector-space equality, host continuity of addition or scalar multiplication, or any topology or vector-space structure not present in the displayed packet.*

Proof. Inspect the NameCert boundary of Definition 205.7. Its exported rows are precisely the carrier tuple, the two source projections, the two continuity ledgers, the componentwise transport route, and the provenance row.

A consumer read is therefore a projection from those rows. If it asks for algebraic data, it lands in V; if it asks for topological data, it lands in $\mathcal{T}$; if it asks for continuity, it lands in A or S and follows λ and ρ.

No constructor in the boundary provides host equality of topological vector spaces, an ambient continuity predicate, or an external topology. Those conclusions are therefore outside the consumer scope of the certificate. □

Lean4 ✓ `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier consumer scope`

Closure status for $\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}$.

Constructive story: A topological vector-space packet is generated from a checked $\mathsf{VecSpace}^{\uparrow}$ source, a checked $\mathsf{Topology}^{\uparrow}$ source, displayed rows for continuous addition and continuous scalar action, componentwise hsame transport, backward Cont provenance, and Pkg links naming exactly those two sources. The consumer reads only that finite BHist surface, so algebraic vector-space data, topology data, operation-continuity rows, classifier transport, and downstream consumer scope are all projected from visible rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 205.8 gives the public consumer surface over the displayed vector-space row, topology row, continuity ledgers, classifier transport, and provenance packet for $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, BHist, hsame, Cont, and Pkg.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.TopVecSpaceUp.TopVecSpaceBHistCarrier\_consumer\_scope`

Bridge status: none

Not claimed: No locally convex theorem, analytic topological-vector-space theorem, host continuity predicate, or standard bridge is claimed here.

Upgrade path: The paper-axis consumer treatment is mature for the displayed packet; formal bridge checking remains separate.

Chapter 206

A Concrete Naming Certificate for $\mathsf{AffineSpace}^{\uparrow}$

The affine-space interface $\mathsf{AffineSpace}^{\uparrow}$ packages a torsor over a vector-space carrier: a set with a free transitive action of vector translations. It depends on $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47) and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41).

206.1 Carrier definition

Definition 206.1 (Affine history torsor carrier)**.** *An* $\mathsf{AffineSpace}^{\uparrow}$ *carried datum is a* BHist *package*

$$\mathcal{A} = (\mathcal{G}, \mathcal{V}, p, \tau, \eta_{\mathcal{G}}, \eta_{\mathcal{V}}, \lambda)$$

where $\mathcal{G}$ *is the* $\mathsf{Group}^{\uparrow}$ *additive-translation source,* $\mathcal{V}$ *is the* $\mathsf{VecSpace}^{\uparrow}$ *vector source,* $p : \mathsf{BHist}$ *is the point row,* $\tau : \mathsf{BHist}$ *is the vector-translation row,* $\eta_{\mathcal{G}}$ *and* $\eta_{\mathcal{V}}$ *are the displayed source* $\mathsf{NameCert}$ *witnesses, and* λ *records that the translation row is read through the vector carrier of* $\mathcal{V}$ *and the additive group operation exposed by* $\mathcal{G}$*.*

The affine classifier on two carried rows $\mathcal{A}$ *and* $\mathcal{A}'$ *is the componentwise relation saying that the point rows are* hsame*-compatible and that the translation rows are classified by the* $\mathsf{VecSpace}^{\uparrow}$ *vector classifier:*

$$\mathsf{AffCls}(\mathcal{A}, \mathcal{A}') := \mathsf{hsame}(p, p') \wedge \mathsf{VecCls}_{\mathcal{V}}(\tau, \tau').$$

The affine action of a certified vector translation $v : \mathsf{BHist}$ *on a carried point row* p *is the* Cont*-append row*

$$\mathsf{act}(p, v) := \mathsf{Cont}(p, \mathsf{trans}(v)),$$

where $\mathsf{trans}(v)$ *is the certified vector-translation packet scoped by the* $\mathsf{VecSpace}^{\uparrow}$ *and* $\mathsf{Group}^{\uparrow}$ *source certificates. Thus the carrier is a torsor surface over* $\mathsf{VecSpace}^{\uparrow}$ *whose visible rows are only the point row, the vector-translation row, the source* $\mathsf{NameCert}$ *witnesses, and the finite* Cont *action ledger.*

Lean4 (definition) `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier`

Definition 206.2 (AffineSpaceUp translation classifier)**.** *For point rows* $p, q : \mathsf{BHist}$ *in the carrier of Definition 206.1, the* $\mathsf{AffineSpace}^{\uparrow}$ *translation classifier declares*

$$p \sim_{\mathsf{Aff}} q$$

exactly when there are translation witnesses v, w : BHist *licensed by the* $\mathsf{VecSpace}^{\uparrow}$ *dependency certificate and the* $\mathsf{Group}^{\uparrow}$ *dependency certificate such that the displayed action routes from* p *to* q *are equal up to* hsame*. Equivalently, the classifier is equality of translation witnesses after transport through the source classifiers of* $\mathcal{V}$ *and* $\mathcal{G}$ *and through the* hsame *comparison on the* Cont *action rows.*

Lean4 (definition) `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier`

206.2 The certificate

Theorem 206.3 (AffineSpaceUp action closure obligation)**.** *Let* $\mathcal{V}$ *be a* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *dependency certificate and let* $\mathcal{G}$ *be a* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *dependency certificate. If* p : BHist *is carried by Definition 206.1 and* v : BHist *is a vector row accepted by* $\mathcal{V}$ *and by the translation row of* $\mathcal{G}$*, then every certified* Cont *action witness from* (p, v) *has an endpoint* q : BHist *carried by the same* $\mathsf{AffineSpace}^{\uparrow}$ *carrier, and the endpoint is stable under* hsame *transport of the action witness.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier action closure obligation`

Proof. Unpack the carrier row of p. It contains the $\mathsf{VecSpace}^{\uparrow}$ source certificate, the $\mathsf{Group}^{\uparrow}$ source certificate, and the finite ledger slot reserved for translation actions.

Insert the displayed Cont witness into that ledger. The $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ dependency scopes the vector endpoint, while the $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ dependency scopes the translation row that acts on the point. Therefore the endpoint q is generated by the same carrier predicate over the same two certificates.

If the action witness is transported by hsame, use the carrier transport fields of the two dependency certificates on the vector and group endpoints. Repacking the transported rows with the same point-source data gives the required carried endpoint. □

Theorem 206.4 (AffineSpaceUp action coverage obligation)**.** *For any carried point rows* p, q : BHist *in the* $\mathsf{AffineSpace}^{\uparrow}$ *carrier over* $\mathcal{V}$: $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathcal{G}$: $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$*, the certificate obligation surface contains a displayed vector row* v : BHist *and a* Cont *action witness carrying* p *to a row* hsame*-classified with* q*. The vector witness is accepted by the* $\mathsf{VecSpace}^{\uparrow}$ *dependency certificate, its translation reading is accepted by the* $\mathsf{Group}^{\uparrow}$ *dependency certificate, and the witness is unique only up to the classifier of Definition 206.2.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier action coverage obligation`
↪ variant `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier action coverage obligation`

Proof. Read the two point rows through the torsor carrier. The carrier records both rows against the same $\mathsf{VecSpace}^{\uparrow}$ and $\mathsf{Group}^{\uparrow}$ dependency certificates, so the only admissible route between them must be a translation row licensed by those dependencies.

The obligation is then stated by choosing the displayed vector row and the Cont action witness in the ledger. The endpoint comparison with q is not host equality of points; it is the hsame row required by the carrier and classifier definitions.

Transporting the chosen witness along either dependency classifier gives an equivalent witness. Thus coverage is recorded as existence of a BEDC translation route, while uniqueness is deferred to the translation classifier rather than exposed as an extra carrier field. □

Theorem 206.5 (AffineSpaceUp vector difference obligation)**.** *For carried point rows $p, q : \mathsf{BHist}$ over $\mathcal{V} : \mathsf{NameCert}_{\mathsf{VecSpace}^\uparrow}$ and $\mathcal{G} : \mathsf{NameCert}_{\mathsf{Group}^\uparrow}$, any two certified vector-difference witnesses from p to q are identified by the $\mathsf{AffineSpace}^\uparrow$ translation classifier. The comparison uses the $\mathsf{VecSpace}^\uparrow$ classifier on vector histories, the $\mathsf{Group}^\uparrow$ classifier on translation histories, and hsame transport along the two Cont action rows.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier witnesses identified`

Proof. Take two displayed difference witnesses. Each witness consists of a vector row, its translation-group reading, and a Cont action row from p to an endpoint classified with q.

Apply the source classifier field of $\mathcal{V}$ to compare the two vector rows and the source classifier field of $\mathcal{G}$ to compare their translation readings. The two endpoint comparisons to q are then concatenated by hsame symmetry and transitivity.

The resulting comparison is exactly the relation in Definition 206.2. Hence the difference row is determined at the $\mathsf{AffineSpace}^\uparrow$ boundary only up to the BEDC classifier, with all chosen action ledgers remaining internal. □

Theorem 206.6 (AffineSpaceUp separation obligation)**.** *If carried point rows $p, q : \mathsf{BHist}$ admit a certified zero-translation action from p to a row hsame-classified with q, then p and q are classified by the identity case of Definition 206.2. The zero row is the vector zero supplied by $\mathsf{NameCert}_{\mathsf{VecSpace}^\uparrow}$ and the identity translation is the group identity supplied by $\mathsf{NameCert}_{\mathsf{Group}^\uparrow}$.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier separation obligation`

Proof. Project the zero vector row from the $\mathsf{VecSpace}^\uparrow$ dependency certificate and the identity translation row from the $\mathsf{Group}^\uparrow$ dependency certificate. These rows are the two dependency endpoints of the zero-translation action.

The action ledger says that acting by this identity translation is a Cont row from p to an endpoint classified with q. The identity action law is therefore recorded as an hsame transport between the original point row and the endpoint row.

Combine that transport with the displayed endpoint comparison to q. Repacking the zero vector, identity translation, and composed hsame row gives the identity case of the translation classifier, so the carrier separates point rows exactly at the certified zero-translation boundary. □

Theorem 206.7 (Affine vector-action stability)**.** *Let $\mathcal{A}$ and $\mathcal{A}'$ be carried $\mathsf{AffineSpace}^\uparrow$ rows of Definition 206.1. If their point rows are related by hsame and their vector translations are related by the $\mathsf{VecSpace}^\uparrow$ classifier, then appending any certified vector-translation packet by Cont preserves the affine classifier. Equivalently, for carried point rows p, p' and vector rows v, v',*

$$\mathsf{hsame}(p, p') \wedge \mathsf{VecCls}_{\mathcal{V}}(v, v')$$

implies that the action endpoints $\mathsf{Cont}(p, \mathsf{trans}(v))$ and $\mathsf{Cont}(p', \mathsf{trans}(v'))$ are classified by AffCls.

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier vector action stability`

Proof. Use the $\mathsf{VecSpace}^\uparrow$ certificate to transport v to v' through its vector classifier. The $\mathsf{Group}^\uparrow$ dependency reads the transported vector row as the same certified additive-translation packet in the translation source.

Apply Cont endpoint transport to the point comparison $\mathsf{hsame}(p, p')$ and to the transported translation packet. The Cont associativity and unit rows keep the appended action ledger in the same finite-history surface, so the resulting endpoint pair satisfies the displayed affine classifier. □

Theorem 206.8 (Affine free-action obligation)**.** *For the carrier of Definition 206.1, the free-action obligation is the following BEDC row: if two certified vector translations v, w act on the same carried point row p and the resulting point endpoints are related by* hsame*, then the vector rows v and w are related by the* $\mathsf{VecSpace}^{\uparrow}$ *classifier. The only accepted witnesses are the shared point row, the two vector-translation packets, the two* Cont *action ledgers, and the source* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *rows.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier free action obligation`

Proof. Read both action endpoints as Cont appends from the same point row p. The left unit and right unit behavior of Cont identifies the empty translation packet as the neutral action row supplied by the additive $\mathsf{Group}^{\uparrow}$ source.

Cancel the shared point ledger by composing the first action with the inverse translation packet supplied by the $\mathsf{Group}^{\uparrow}$ certificate. Associativity of Cont moves the inverse packet next to the original packet, and the group inverse and unit rows reduce the visible endpoint comparison to a comparison of the two translation rows.

Finally, the $\mathsf{VecSpace}^{\uparrow}$ classifier is the public classifier for translation rows in this carrier. Transport through the $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ witness repacks the endpoint comparison as $\mathsf{VecCls}_{\mathcal{V}}(v, w)$, with no host-level point equality used. □

Theorem 206.9 (Affine transitive-action obligation)**.** *For any two carried point rows p and q in the* $\mathsf{AffineSpace}^{\uparrow}$ *carrier, the transitive-action obligation records a certified vector row v whose translation packet carries p to a point row classified with q. The witness ledger consists exactly of the source* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *row for v, the additive* $\mathsf{Group}^{\uparrow}$ *row interpreting v as a translation packet, and the* Cont *action ledger from p to q.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier transitive action obligation`

Proof. Use the torsor source row in the carrier definition to read the difference from p to q as a vector-translation row in the $\mathsf{VecSpace}^{\uparrow}$ carrier. This is a named BHist row, not a quotient of host points.

The $\mathsf{Group}^{\uparrow}$ certificate interprets that vector row as an additive translation packet. Appending the packet to p by Cont gives the action endpoint, and the stored torsor ledger supplies the hsame comparison between this endpoint and q.

The witness is therefore the displayed vector row together with its two source certificates and the finite action ledger. Exactness of the ledger prevents any additional choice of ambient affine coordinate system from entering the obligation. □

Theorem 206.10 (Affine classifier transport)**.** *The affine classifier of Definition 206.1 is stable under* hsame *transport of point rows and under* $\mathsf{VecSpace}^{\uparrow}$ *classifier transport of vector-translation rows. If* $\mathsf{AffCls}(\mathcal{A}, \mathcal{A}')$ *and the source* NameCert *rows transport $\mathcal{A}$ to $\mathcal{B}$ and $\mathcal{A}'$ to $\mathcal{B}'$, then* $\mathsf{AffCls}(\mathcal{B}, \mathcal{B}')$ *holds.*

Proof. Unfold the affine classifier into its point and translation components. The point component is an hsame comparison, so reflexivity, symmetry, transitivity, and endpoint transport are exactly the corresponding hsame rows.

For the translation component, apply the $\mathsf{VecSpace}^{\uparrow}$ certificate transport field to the two vector rows. The $\mathsf{Group}^{\uparrow}$ source is used only to keep the transported vector rows accepted as additive translation packets.

Recombine the transported point comparison and transported vector comparison. Since the classifier contains no hidden field beyond those two components, the recombined pair is precisely the target affine classifier. □

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier classifier transport`
Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier transport`

Theorem 206.11 (Affine ledger exactness)**.** *The* $\mathsf{AffineSpace}^{\uparrow}$ *obligation ledger contains exactly the* $\mathsf{Group}^{\uparrow}$ *source row, the* $\mathsf{VecSpace}^{\uparrow}$ *source row, the carried point* BHist *row, the vector-translation* BHist *row, the* hsame *point classifier component, the* $\mathsf{VecSpace}^{\uparrow}$ *translation classifier component, the* Cont *action rows, and the two source* NameCert *witnesses. No coordinate chart, host torsor equality, quotient representative, or standard bridge row is part of this obligation surface.*

Proof. Soundness is by projection from the carrier tuple. Each accepted affine row exposes the two source certificates, the point row, the vector-translation row, and the two source NameCert witnesses. The classifier definition exposes only hsame on point rows and the $\mathsf{VecSpace}^{\uparrow}$ classifier on vector rows.

The action rows are sound because they are built by appending the certified translation packet with Cont. Associativity and the unit behavior of Cont account for changing parenthesization and for the neutral translation row, while the $\mathsf{Group}^{\uparrow}$ certificate supplies the additive inverse and unit packets used by the free-action ledger.

Exactness is the reverse reading. Any row used by stability, freeness, transitivity, or classifier transport is one of the projected carrier rows, one of the named source-certificate fields, or one finite Cont action row. Hence the public obligation surface is exactly the listed BHist, hsame, Cont, $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ data. □

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceTranslationClassifier ledger exactness`

Theorem 206.12 (AffineSpaceUp NameCert obligation surface)**.** *The* $\mathsf{AffineSpace}^{\uparrow}$ *certificate obligation surface consists exactly of the* BHist *affine history torsor carrier of Definition 206.1, the translation classifier of Definition 206.2, the action closure, action coverage, vector-difference, separation, vector-action stability, free-action, transitive-action, classifier-transport, and ledger-exactness obligations of Definition 206.3, Definition 206.4, Definition 206.5, Definition 206.6, Definition 206.7, Definition 206.8, Definition 206.9, Definition 206.10, and Definition 206.11, together with the two dependency certificates* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$*. No host affine-space carrier, chosen origin, coordinate chart, quotient representative, or external vector-difference function is exported as a public field.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier semantic name certificate`

Proof. Soundness is obtained by unpacking the carrier and classifier rows. Every visible point row is a BHist row scoped by the two dependency certificates, and every visible comparison is a translation witness read through Cont and hsame.

The obligation theorems supply the action rows consumed by the certificate: closure gives carried endpoints, coverage gives a route between carried points, vector difference identifies parallel witnesses, separation fixes the identity route, stability and transport keep classifier rows invariant under accepted motion, freeness and transitivity record the torsor laws, and ledger exactness fixes the public surface. Each row is constructed only from the dependency NameCert fields and the finite action ledger.

For exactness, read any accepted ledger row in reverse. It must be either a point row, a vector or group dependency row, a Cont action witness, or an hsame transport used by the classifier. Therefore the visible $\mathsf{NameCert}_{\mathsf{AffineSpace}^{\uparrow}}$ boundary is exactly the listed surface and no further public datum is claimed. □

Closure status for $\mathsf{NameCert}_{\mathsf{AffineSpace}^{\uparrow}}$.

Constructive story: An affine space in this chapter is generated by taking a carried point history, a vector-translation history certified by $\mathsf{VecSpace}^{\uparrow}$, the additive-translation reading supplied by $\mathsf{Group}^{\uparrow}$, and a finite Cont action ledger that appends the translation packet to the point. The carrier admits exactly rows with those two dependency certificates, the point row, the translation row, the source witnesses, and the action ledger; a row lacking the vector source, the group source, or the displayed action provenance stays outside the affine surface. Two carried rows are classified by point hsame together with the $\mathsf{VecSpace}^{\uparrow}$ classifier on translation histories, so vector differences are recognized through displayed action witnesses rather than through a chosen origin or host torsor equality. The source covered by the certificate is this torsor packet itself, the pattern records action closure, coverage between carried points, separation by the zero translation, freeness, transitivity, action additivity, and classifier transport, and the ledger keeps the raw point, translation, group reading, vector reading, action endpoint, and source-certificate rows visible. The five name-certificate obligations come from any accepted torsor row as a carrier witness, from hsame and the vector classifier for reflexivity, symmetry, and transitivity, and from the transport rows showing that classified point and translation replacements repack as accepted affine rows. A history h lies in the signature gap of an $\mathsf{AffineSpace}^{\uparrow}$ token p when the source-domain accepts it as such a torsor packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, h carries the same point, vector-translation, action, and dependency rows encoded by p. The chapter registers this torsor-action construction under the name $\mathsf{AffineSpace}^{\uparrow}$; affine structure is assembled from BHist, hsame, Cont, $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$, with no chosen origin, coordinate chart, host affine object, or standard bridge introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AffineSpace}^{\uparrow}}$, maturePackageClosed)

Scope closed: The affine torsor carrier, classifier, translation action, public certificate, and abstract interface bridge are closed over the displayed BHist, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AffineSpace}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier\_semantic\_name\_certificate`

Bridge status: none

Not claimed: No public affine object, coordinate-chart surface, host torsor equality, chosen origin, or standard bridge is claimed.

Upgrade path: The paper-axis treatment is mature; remaining coordination concerns bridge status and formal-axis reporting.

Theorem 206.13 (AffineSpaceUp action additivity)**.** *Let* $\mathcal{V} : \mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathcal{G} : \mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *be the dependency certificates of Definition 206.1. Let* $p : \mathsf{BHist}$ *be a carried point row, and let* $v, w : \mathsf{BHist}$ *be vector rows accepted by* $\mathcal{V}$ *whose translation readings are accepted by* $\mathcal{G}$*. Write* $v +_V w$ *for the vector-addition row supplied by* $\mathcal{V}$*. Then the one-step action endpoint* $\mathsf{act}(p, v +_V w)$ *and the iterated action endpoint* $\mathsf{act}(\mathsf{act}(p, v), w)$ *admit carried affine repackings over the same source certificates and the same cumulative translation row* $v +_V w$*, and those repackings are classified by* AffCls*.*

Lean4 ✓ `BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier action additivity`

Proof. Apply Definition 206.3 to the carried point row p and the accepted vector row $v +_V w$. This produces a carried affine endpoint whose point component is $\mathsf{act}(p, v +_V w)$.

Apply the same closure theorem first to (p, v) and then to the carried endpoint obtained from that first action together with w. This produces a carried affine endpoint whose point component is $\mathsf{act}(\mathsf{act}(p, v), w)$.

Unfold the action definition from Definition 206.1. The one-step endpoint is obtained by appending to p the translation packet read from $v +_V w$. The iterated endpoint is obtained by first appending the packet read from v and then appending the packet read from w.

Now unpack the field λ from Definition 206.1. It records that the translation row attached to the vector-sum $v +_V w$ is read through the vector carrier of $\mathcal{V}$ and the additive translation operation exposed by $\mathcal{G}$. Therefore the tail used by the one-step action and the composite tail used by the iterated action are two certified readbacks of the same cumulative translation row.

Apply Definition 21.29 to the continuation ledger starting at p with these two bracketings. It yields

$$\mathsf{hsame}(\mathsf{act}(p, v +_V w), \mathsf{act}(\mathsf{act}(p, v), w)).$$

Finally repack both endpoints as affine rows over the same two source certificates and the common cumulative translation row $v +_V w$. The point components are related by the displayed hsame row, and the translation components are the same vector-sum row, hence are classified by the $\mathsf{VecSpace}^{\uparrow}$ classifier. By the definition of AffCls in Definition 206.1, the two repackings are classified together. □

↪ variant BEDC.Derived.AffineSpaceUp.AffineSpaceHistoryTorsorCarrier action additivity

Theorem 206.14 (AffineSpaceUp zero action classifies the carried point)**.** *Let* $\mathcal{V} : \mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathcal{G} : \mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *be the dependency certificates of Definition 206.1. Let* $p : \mathsf{BHist}$ *be a carried point row, and let* $0_V : \mathsf{BHist}$ *be the vector zero row supplied by* $\mathcal{V}$ *whose translation reading is the identity translation row supplied by* $\mathcal{G}$*. Then the zero-action endpoint* $\mathsf{act}(p, 0_V)$ *and the original point row* p *admit carried affine repackings over the same two source certificates and the same zero translation row, and those repackings are classified by* AffCls*. Equivalently, the displayed zero action gives the identity case of the translation classifier between* p *and* $\mathsf{act}(p, 0_V)$*.*

Proof. Unfold the action clause in Definition 206.1. There exist histories $t, u : \mathsf{BHist}$ such that t is the certified translation packet read from the vector zero row 0_V through the $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ dependencies, u is the appended endpoint witnessing

$$\mathsf{Cont}(p, t, u),$$

and u is classified by hsame with $\mathsf{act}(p, 0_V)$. By the hypothesis on 0_V, the packet t is the identity translation row exposed by the $\mathsf{Group}^{\uparrow}$ dependency certificate.

Apply Definition 206.3 to the carried point row p and the accepted vector row 0_V. The endpoint u is therefore carried by the same $\mathsf{AffineSpace}^{\uparrow}$ carrier over $\mathcal{V}$ and $\mathcal{G}$.

The same displayed action ledger is a certified zero-translation action from p to the endpoint u. Its endpoint comparison with u is the reflexive hsame row. Thus the hypotheses of Definition 206.6 hold with $q = u$, and the separation obligation repacks the zero vector row, the identity translation row, and the endpoint comparison as the identity case of Definition 206.2.

It remains only to read this identity classification in the affine carrier language. Repack p and u as affine rows over the same source certificates and with the same zero translation row 0_V. The point component is the hsame comparison supplied by the identity action case, and the translation component is the reflexive $\mathsf{VecSpace}^{\uparrow}$ classifier comparison of 0_V with itself. By the definition of AffCls in Definition 206.1, the two carried repackings are classified together.

Finally transport the carried repacking of u along the recorded hsame comparison between u and $\mathsf{act}(p, 0_V)$. This gives the stated classification of the original point row p with the zero-action endpoint $\mathsf{act}(p, 0_V)$ over the same two source certificates and the same zero translation row. □

Theorem 206.15 (AffineSpaceUp inverse-vector action cancels to the carried point)**.** *Let* $\mathcal{V} : \mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *and* $\mathcal{G} : \mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *be the dependency certificates of Definition 206.1. Let* $p : \mathsf{BHist}$ *be a carried point row, and let* $v : \mathsf{BHist}$ *be a vector row accepted by* $\mathcal{V}$ *whose translation*

reading is accepted by $\mathcal{G}$. Suppose the vector inverse row $-_V v$ is the additive inverse supplied by $\mathcal{V}$, its translation reading is the inverse translation packet supplied by $\mathcal{G}$, and the dependency certificates classify the cumulative vector row by the zero row:

$$\mathsf{VecCls}_{\mathcal{V}}(v +_V (-_V v), 0_V).$$

Then the iterated inverse-action endpoint $\mathsf{act}(\mathsf{act}(p, v), -_V v)$ and the original point row p admit carried $\mathsf{AffineSpace}^{\uparrow}$ repackings over the same source certificates, and those repackings are classified by AffCls.

Proof. Apply Definition 206.13 to the accepted vector rows v and $-_V v$. It gives carried affine repackings of the one-step endpoint $\mathsf{act}(p, v +_V (-_V v))$ and the iterated endpoint $\mathsf{act}(\mathsf{act}(p, v), -_V v)$ over the same two source certificates, with cumulative translation row $v +_V (-_V v)$, and it classifies those repackings by AffCls.

The vector inverse hypothesis is read through the two dependency certificates. On the $\mathsf{VecSpace}^{\uparrow}$ side, $v +_V (-_V v)$ is classified with the zero vector row 0_V. On the $\mathsf{Group}^{\uparrow}$ side, the translation reading of $-_V v$ is the inverse packet for the translation reading of v, so the cumulative translation packet read from $v +_V (-_V v)$ is classified with the identity translation row.

Use the classifier transport theorem Definition 206.10 to transport the one-step repacking of $\mathsf{act}(p, v +_V (-_V v))$ along the displayed vector classifier comparison from $v +_V (-_V v)$ to 0_V. The transported repacking has point component classified with $\mathsf{act}(p, 0_V)$, keeps the same $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ sources, and carries the zero translation row.

Now apply Definition 206.14. It classifies the zero-action endpoint $\mathsf{act}(p, 0_V)$ with the original carried point row p after repacking both over the same source certificates and the same zero translation row.

Finally compose the affine classifier comparisons: the additivity comparison from the iterated endpoint to the cumulative one-step endpoint, the classifier-transport comparison from the cumulative endpoint to the zero-action endpoint, and the zero-action comparison from that endpoint to p. Since AffCls is componentwise hsame on point rows together with the $\mathsf{VecSpace}^{\uparrow}$ classifier on translation rows, its transitivity is inherited from those two component classifiers. Therefore $\mathsf{act}(\mathsf{act}(p, v), -_V v)$ and p admit carried affine repackings over the same two source certificates and are classified by AffCls. □

Chapter 207

A Concrete Naming Certificate for $\mathsf{ProjectiveSpace}^{\uparrow}$

The projective-space interface $\mathsf{ProjectiveSpace}^{\uparrow}$ packages the quotient of a punctured vector-space carrier by the scaling action of the underlying field's multiplicative group. It depends on $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47) and $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ (chapter 45).

207.1 Carrier definition

Theorem 207.1 (ProjectiveSpaceUp punctured carrier obligation)**.** *The* $\mathsf{ProjectiveSpace}^{\uparrow}$ *carrier is the* $\mathsf{VecSpace}^{\uparrow}$ *carrier of Definition 47.1 equipped with the* $\mathsf{Field}^{\uparrow}$ *nonzero-vector guard supplied by Definition 45.198 and the certified scalar-action rows required by Definition 47.21. A carried projective endpoint is therefore a vector-space row whose representative is guarded as nonzero over the field source, together with the ledger entries recording the scalar source, vector source, and scalar-action certificate used to read that row.*

Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpacePuncturedCarrier obligation`

Proof. Start with the vector carrier row from Definition 47.1. The certificate obligations in Definition 47.21 provide the scalar-action closure and congruence rows over the same scalar source.

The field source specification in Definition 45.198 supplies the nonzero guard and the proof-indexed inverse operations available for guarded scalars. Attaching that guard to the vector representative removes the zero row from the visible projective carrier while leaving the underlying $\mathsf{VecSpace}^{\uparrow}$ provenance unchanged.

Thus the carrier predicate is exactly the punctured vector-space row together with the field and scalar-action certificate rows. No host quotient carrier or external projective-point object is introduced. □

Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpacePuncturedCarrier empty boundary`
Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpaceSingletonPuncturedCarrier obligation`

Theorem 207.2 (ProjectiveSpaceUp scaling-orbit classifier obligation)**.** *Two carried* $\mathsf{ProjectiveSpace}^{\uparrow}$ *rows classify exactly when a certified nonzero* $\mathsf{Field}^{\uparrow}$ *scalar transports one guarded representative to the other by the* $\mathsf{VecSpace}^{\uparrow}$ *scalar action. The classifier is reflexive by scalar one, symmetric by the proof-indexed inverse of the scaling scalar, and transitive by field multiplication together with scalar-action associativity.*

Proof. For reflexivity, use the scalar one row from the field source and the $\mathsf{VecSpace}^{\uparrow}$ scalar unit law from Definition 47.21. Acting by one leaves the guarded representative in the same vector classifier row.

For symmetry, suppose a nonzero scalar transports representative v to representative w. The field source supplies the proof-indexed inverse for that scalar, and the vector-space scalar-action rows identify inverse action as the return route from w to v inside the same carried surface.

For transitivity, compose two certified nonzero scaling witnesses by field multiplication. The scalar-action associativity row in the vector-space certificate identifies the double action with action by the product scalar, so the resulting witness transports the first representative to the third. □

Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpaceSingletonScalingOrbitClassifier obligation`

Theorem 207.3 (ProjectiveSpaceUp ledger and exactness obligation)**.** *For* $\mathsf{ProjectiveSpace}^{\uparrow}$*, representative choice, nonzero scalar witnesses, and scaling-chain provenance remain ledger data. The visible exactness predicate is exactly the scaling-orbit classifier on punctured* $\mathsf{VecSpace}^{\uparrow}$ *rows: consumers may see the carrier of Definition 207.1 and the classifier of Definition 207.2, but they cannot inspect a chosen representative or a chosen scaling chain as public carrier data.*

Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpaceSingletonScalingOrbitClassifier ledger exactness obligation`
Lean4 ✓ `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpaceSingletonPuncturedCarrier action determinacy`

Proof. Project the certificate ledger into three hidden fields: the selected punctured representative, each nonzero scalar witness used to compare representatives, and the chain of scalar-action steps witnessing a composite comparison. These entries are consumed by the carrier and classifier rows but are not themselves part of the visible endpoint predicate.

Exactness is then read at the boundary. Soundness says every visible classification comes from a certified nonzero scalar-action route between punctured vector rows. Completeness says every such certified route repacks as the displayed projective classifier.

Hence the public surface exposes precisely punctured-carrier membership and scaling-orbit classification. All representative and route choices remain ledger provenance. □

207.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$**.**

Constructive story: A projective point begins as a vector-space history accepted by $\mathsf{VecSpace}^{\uparrow}$, then passes through the $\mathsf{Field}^{\uparrow}$ nonzero guard so that the zero representative is excluded before any scaling comparison is considered. The carrier therefore accepts punctured vector rows equipped with scalar-source, vector-source, and scalar-action ledger entries, while a zero row or an unguarded vector representative never becomes a projective endpoint. Two accepted representatives name the same projective point when a certified nonzero scalar transports one to the other by the $\mathsf{VecSpace}^{\uparrow}$ scalar action; scalar one gives reflexivity, the proof-indexed inverse gives symmetry, and field multiplication with scalar-action associativity gives transitivity. The source covered by the certificate is the punctured vector carrier, the pattern is the scaling-orbit presentation with nonzero scalar witnesses and action chains, and the ledger keeps representative choice, scalar witnesses, and scaling-chain provenance as evidence rather than as public carrier data. The five name-certificate obligations are supplied by an accepted punctured representative for nonemptiness, by the scaling classifier for reflexive, symmetric, and transitive comparison, and by scalar-action transport for closure of the punctured carrier under classified replacements. A history h lies in the signature gap of a $\mathsf{ProjectiveSpace}^{\uparrow}$ token p when the source-domain accepts h as a guarded vector representative, the signature relation pairs it with an answer representative and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is a nonzero vector row in the same certified scaling orbit as the representative encoded by p. The paper bridge reads this surface as the ordinary punctured-vector modulo nonzero-scaling presentation and reads back through the same representative and scalar-action ledger; the chapter registers it under the name $\mathsf{ProjectiveSpace}^{\uparrow}$, without closing full projective geometry or bridgeChecked verification.

Theory closure: TheoryGate(NameCert$_{\mathsf{ProjectiveSpace}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public ProjectiveSpace$^{\uparrow}$ surface exports the punctured carrier, scaling-orbit classifier, ledger provenance, and exactness boundary from Theorems 207.1, 207.2, and 207.3.

Formal verification: FormalStatus(NameCert$_{\mathsf{ProjectiveSpace}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ProjectiveSpaceUp.ProjectiveSpaceSingletonScalingOrbitClassifier\_ledger\_exactness\_ob`

Bridge status: paperBridge

Not claimed: This chapter does not close full projective geometry or bridgeChecked verification.

Upgrade path: The paper-side theory axis is at the top grade; bridgeChecked verification remains a separate verification-axis obligation.

Chapter 208

A Concrete Naming Certificate for $\mathsf{ConvexSet}^{\uparrow}$

The convex-set interface $\mathsf{ConvexSet}^{\uparrow}$ packages a subset of a vector-space carrier closed under affine combinations with nonnegative coefficients summing to one. It depends on $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47) and $\mathsf{NameCert}_{\mathsf{AffineSpace}^{\uparrow}}$ (chapter 206).

208.1 Carrier definition

208.2 The certificate

Definition 208.1 (ConvexSet binary affine-combination row)**.** *For a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate over a scalar* $\mathsf{Field}^{\uparrow}(F)$ *and a vector carrier from* $\mathsf{VecSpace}^{\uparrow}(F, V)$*, write* C *for the convex carrier,* $\sim_F$ *for the scalar classifier,* $+_F$ *for scalar addition,* 1_F *for the scalar unit,* NonNeg_F *for the nonnegative-scalar predicate,* $\odot$ *for the scalar action, and* $+_V$ *for vector addition. The binary affine-combination row is the certificate field saying that, for all* $a, b : F$ *and all carried points* $x, y : V$*,*

$$C(x) \wedge C(y) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F \Longrightarrow C\big((a \odot x) +_V (b \odot y)\big).$$

This is the two-point instance of the convex closure advertised in the $\mathsf{ConvexSet}^{\uparrow}$ *carrier description, using the scalar and action data supplied by the* $\mathsf{VecSpace}^{\uparrow}$ *and* $\mathsf{AffineSpace}^{\uparrow}$ *dependencies.*

Lean4 (definition) `BEDC.Derived.ConvexSetUp.ConvexSetBinaryAffineCombinationRow`

Theorem 208.2 (ConvexSet midpoint closure from affine-combination row)**.** *Let a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate be given with notation as in Definition 208.1. If* x *and* y *are carried by the convex carrier,* h *is a nonnegative scalar, and the scalar sum* $h +_F h$ *is classified as the scalar unit,*

$$C(x) \wedge C(y) \wedge \mathsf{NonNeg}_F(h) \wedge (h +_F h) \sim_F 1_F,$$

then the affine midpoint endpoint is carried by the same convex carrier:

$$C\big((h \odot x) +_V (h \odot y)\big).$$

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetSingletonAffineSpine midpoint closure`

Proof. Apply the binary affine-combination row of Definition 208.1 with both scalar coefficients equal to h. The two point-carrier hypotheses supply $C(x)$ and $C(y)$. The single nonnegative hypothesis supplies both coefficient nonnegativity clauses, since the row asks separately for $\mathsf{NonNeg}_F(h)$ on the left coefficient and on the right coefficient. The displayed classifier hypothesis is exactly the coefficient-sum clause $(h +_F h) \sim_F 1_F$. The row therefore returns $C\big((h \odot x) +_V (h \odot y)\big)$, which is the claimed midpoint carrier closure. □

Theorem 208.3 (ConvexSet affine-combination row order symmetry)**.** *Let a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate be given over a scalar* $\mathsf{Field}^{\uparrow}(F)$ *and a vector carrier from* $\mathsf{VecSpace}^{\uparrow}(F, V)$*, with notation as in Definition 208.1. For scalars* $a, b : F$ *and points* $x, y : V$*, assume the scalar additive commutativity row inherited from the scalar field certificate supplies the comparison*

$$(b +_F a) \sim_F (a +_F b).$$

If

$$C(x) \wedge C(y) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F,$$

then the swapped affine endpoint is carried by the same convex carrier:

$$C\big((b \odot y) +_V (a \odot x)\big).$$

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetSingletonAffineSpine order symmetric`

Proof. The scalar part of the field certificate retains the additive abelian-group rows listed through Definition 43.26 and Definition 42.8, so the displayed scalar additive commutativity comparison is an available classifier edge for these two coefficients. The scalar classifier is a naming-certificate classifier, and Definition 9.8 composes this comparison with the coefficient-sum hypothesis $(a +_F b) \sim_F 1_F$. Hence

$$(b +_F a) \sim_F 1_F.$$

Apply the binary affine-combination row of Definition 208.1 with left coefficient b, right coefficient a, left point y, and right point x. The carrier hypotheses provide $C(y)$ and $C(x)$ in the required order. The nonnegativity hypotheses provide $\mathsf{NonNeg}_F(b)$ and $\mathsf{NonNeg}_F(a)$ in the required order. The transitive scalar comparison above is exactly the reversed coefficient-sum premise. The row therefore returns $C\big((b \odot y) +_V (a \odot x)\big)$. □

Definition 208.4 (ConvexSet finite affine-spine data)**.** *Let a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate be given with notation as in Definition 208.1. Also write* 0_F *for the scalar zero and* $\cdot_F$ *for scalar multiplication. For a finite scalar spine* $\lambda : \mathsf{ListCarrier}(F)$*, write* $\mathsf{sum}_F(\lambda)$ *for the finite recursive scalar sum*

$$\mathsf{sum}_F(\mathsf{nil}) = 0_F, \qquad \mathsf{sum}_F(\mathsf{cons}(a, \lambda')) = a +_F \mathsf{sum}_F(\lambda').$$

For a finite point spine $xs : \mathsf{ListCarrier}(V)$*, a finite scalar-weight spine* $\lambda : \mathsf{ListCarrier}(F)$*, and an endpoint* $z : V$*, define* $\mathsf{ConvAffSpine}_C(xs, \lambda, z)$ *to mean the conjunction of the following two data.*

First, the global finite-weight readback says that the point spine and weight spine have the same finite positions, every displayed point is carried, every displayed scalar weight is nonnegative, and the finite scalar sum is classified as the scalar unit:

$$\exists \theta : \mathsf{Pos}(xs) \cong \mathsf{Pos}(\lambda).\ \Big(\forall i : \mathsf{Pos}(xs).\ C(\mathsf{entry}_{xs}(i)) \wedge \mathsf{NonNeg}_F(\mathsf{entry}_\lambda(\theta(i)))\Big) \wedge \mathsf{sum}_F(\lambda) \sim_F 1_F.$$

Second, the endpoint z *is obtained from those leaves by the least local binary bracketing relation* $\mathsf{Bracket}_C(xs, \lambda, z)$ *generated by the following clauses:*

1. *singleton: if* $C(x)$, $\mathsf{NonNeg}_F(a)$, *and* $a \sim_F 1_F$, *then*

$$\mathsf{Bracket}_C(\mathsf{cons}(x, \mathsf{nil}), \mathsf{cons}(a, \mathsf{nil}), x);$$

2. *binary extension: if* $C(x)$, $\mathsf{NonNeg}_F(a)$, $\mathsf{NonNeg}_F(b)$, $(a +_F b) \sim_F 1_F$, *and* $\mathsf{Bracket}_C(ys, \mu, y)$, *then*

$$\mathsf{Bracket}_C(\mathsf{cons}(x, ys), \mathsf{cons}(a, b \cdot_F \mu), (a \odot x) +_V (b \odot y)),$$

where $b \cdot_F \mu$ *denotes pointwise scalar multiplication of the tail weight spine.*

Thus $\mathsf{ConvAffSpine}_C(xs, \lambda, z)$ *records both the visible finite unit-sum weight spine and the recursively bracketed affine endpoint built from binary affine-combination rows.*

Lean4 (definition) `BEDC.Derived.ConvexSetUp.ConvexSetSingletonAffineSpine`

Theorem 208.5 (ConvexSet finite affine-spine closure)**.** *Let a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate be given over a scalar* $\mathsf{Field}^{\uparrow}(F)$ *and a vector carrier from* $\mathsf{VecSpace}^{\uparrow}(F, V)$, *with notation as in Definition 208.1. For every finite point spine* $xs : \mathsf{ListCarrier}(V)$, *finite scalar-weight spine* $\lambda : \mathsf{ListCarrier}(F)$, *and endpoint* $z : V$, *if*

$$\mathsf{ConvAffSpine}_C(xs, \lambda, z)$$

holds, then the recursively bracketed affine endpoint is carried by the convex carrier:

$$C(z).$$

Proof. Unpack Definition 208.4. The finite-weight readback supplies the advertised carried-point, nonnegative-weight, and unit-sum scalar spine. The carrier conclusion is proved by induction on the local bracketing witness $\mathsf{Bracket}_C(xs, \lambda, z)$.

In the singleton clause, the endpoint is the displayed point x, and the clause itself supplies $C(x)$. Hence the endpoint is carried.

In the binary-extension clause, the induction hypothesis applied to the tail bracketing witness gives $C(y)$. The current clause supplies $C(x)$, $\mathsf{NonNeg}_F(a)$, $\mathsf{NonNeg}_F(b)$, and the local unit-sum comparison $(a +_F b) \sim_F 1_F$. Applying the binary affine-combination row of Definition 208.1 to the carried points x, y and coefficients a, b gives

$$C((a \odot x) +_V (b \odot y)).$$

This endpoint is exactly the endpoint named by the binary-extension clause. The induction therefore covers every recursively bracketed finite affine-spine witness, so $C(z)$ holds. □

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetSingletonAffineSpine closure`

Definition 208.6 (ConvexSet pointwise intersection carrier)**.** *Let two* $\mathsf{ConvexSet}^{\uparrow}$ *certificates be given over the same scalar* $\mathsf{Field}^{\uparrow}(F)$ *and the same vector carrier from* $\mathsf{VecSpace}^{\uparrow}(F, V)$, *using the same scalar classifier* $\sim_F$, *scalar addition* $+_F$, *scalar unit* 1_F, *nonnegative predicate* NonNeg_F, *scalar action* $\odot$, *and vector addition* $+_V$. *Write* $C, D : V \to \mathsf{Prop}$ *for their convex carriers. The pointwise intersection carrier* $C \cap_{\mathsf{ConvexSet}^{\uparrow}} D$ *is the predicate on* V *defined by*

$$(C \cap_{\mathsf{ConvexSet}^{\uparrow}} D)(z) \iff C(z) \wedge D(z).$$

Lean4 (definition) `BEDC.Derived.ConvexSetUp.ConvexSetPointwiseIntersection`

Theorem 208.7 (ConvexSet pointwise intersection affine-combination closure)**.** *Let two* $\mathsf{ConvexSet}^{\uparrow}$ *certificates be given as in Definition 208.6. Assume each certificate supplies the binary affine-combination row of Definition 208.1 for its own convex carrier, and write* $K := C \cap_{\mathsf{ConvexSet}^{\uparrow}} D$*. For all* $a, b : F$ *and* $x, y : V$*, if*

$$K(x) \wedge K(y) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F,$$

then

$$K\big((a \odot x) +_V (b \odot y)\big).$$

Thus the pointwise intersection satisfies the same nonnegative unit-sum binary affine-combination closure row over the common $\mathsf{Field}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *data.*

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetPointwiseIntersection affine combination closure`

Proof. Unfold Definition 208.6. From $K(x)$ obtain $C(x)$ and $D(x)$, and from $K(y)$ obtain $C(y)$ and $D(y)$. The scalar hypotheses are shared by the two input certificates because the scalar classifier, scalar addition, scalar unit, nonnegative predicate, scalar action, and vector addition are the common data named in the definition.

Apply the binary affine-combination row of Definition 208.1 for the carrier C to the coefficients a, b and the carried points x, y. The projected carrier hypotheses, the two nonnegativity hypotheses, and the unit-sum classifier hypothesis give

$$C\big((a \odot x) +_V (b \odot y)\big).$$

Apply the same row for the carrier D with the same coefficients and points. The other projected carrier hypotheses and the same scalar hypotheses give

$$D\big((a \odot x) +_V (b \odot y)\big).$$

Pairing these two carrier conclusions and folding Definition 208.6 gives

$$K\big((a \odot x) +_V (b \odot y)\big),$$

which is exactly the displayed binary affine-combination closure row for the intersection carrier. □

Definition 208.8 (ConvexSet classifier image carrier)**.** *Let* F *carry a* $\mathsf{Field}^{\uparrow}(F)$ *certificate, let* V *and* W *carry* $\mathsf{VecSpace}^{\uparrow}(F, V)$ *and* $\mathsf{VecSpace}^{\uparrow}(F, W)$ *certificates over the same scalar source, and let* $C : V \to \mathsf{Prop}$ *be the convex carrier of a* $\mathsf{ConvexSet}^{\uparrow}$ *certificate on* V*. Write* $\sim_W$ *for the codomain vector classifier, and let* $f : V \to W$ *be a carried* $\mathsf{LinMap}^{\uparrow}(V, W)$ *map. The classifier image of* C *along* f *is the predicate* $f[C]_{\sim_W} : W \to \mathsf{Prop}$ *defined by*

$$f[C]_{\sim_W}(w) \iff \exists x : V.\ C(x) \wedge f(x) \sim_W w.$$

The witness records a source point carried by the convex carrier and a codomain classifier comparison from its f*-output to the displayed codomain endpoint.*

Lean4 (definition) `BEDC.Derived.ConvexSetUp.ConvexSetLinearImageCarrier`

Theorem 208.9 (ConvexSet linear image affine-combination closure)**.** *Let the data be as in Definition 208.8. Write $\sim_F$, $+_F$, 1_F, and NonNeg_F for the scalar classifier, scalar addition, scalar unit, and nonnegative predicate. Write $+_V$ and $\odot_V$ for the source vector addition and scalar action, and write $+_W$, $\odot_W$, and $\sim_W$ for the codomain vector addition, scalar action, and classifier. Assume the source $\mathsf{ConvexSet}^{\uparrow}$ certificate supplies the binary affine-combination row of Definition 208.1. For carried scalars $a, b : F$ and codomain endpoints $u, v : W$, if*

$$f[C]_{\sim_W}(u) \wedge f[C]_{\sim_W}(v) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F,$$

then

$$f[C]_{\sim_W}((a \odot_W u) +_W (b \odot_W v)).$$

Thus the pointwise classifier image $f[C]_{\sim_W}$ satisfies the same binary nonnegative unit-sum affine-combination closure row in the codomain vector-space carrier.

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetLinearImageCarrier affine combination closure`

Proof. Unpack Definition 208.8 for the two image hypotheses. Choose source points $x, y : V$ with

$$C(x), \qquad C(y), \qquad f(x) \sim_W u, \qquad f(y) \sim_W v.$$

Because the $\mathsf{ConvexSet}^{\uparrow}$ carrier is a subset of the source $\mathsf{VecSpace}^{\uparrow}$ carrier, x and y are carried source inputs. Set

$$s := (a \odot_V x) +_V (b \odot_V y).$$

The nonnegativity hypotheses and the scalar unit-sum comparison are exactly the coefficient hypotheses required by Definition 208.1. Applying that row to x, y and a, b gives $C(s)$.

It remains to compare the f-output of this source witness with the displayed codomain affine combination. The carried $\mathsf{LinMap}^{\uparrow}(V, W)$ map supplies the function-with-law rows of Definition 48.1; read through Definition 47.1 and Definition 48.59, these include output closure, additive preservation, and scalar compatibility. Source scalar-action closure and source additive closure make the two summands of s and s carried source inputs. Additive preservation gives

$$f(s) \sim_W f(a \odot_V x) +_W f(b \odot_V y).$$

Scalar compatibility gives

$$f(a \odot_V x) \sim_W a \odot_W f(x), \qquad f(b \odot_V y) \sim_W b \odot_W f(y).$$

The target additive congruence row from Definition 46.18 transports these two comparisons to

$$f(a \odot_V x) +_W f(b \odot_V y) \sim_W (a \odot_W f(x)) +_W (b \odot_W f(y)).$$

The image comparisons $f(x) \sim_W u$ and $f(y) \sim_W v$ are codomain classifier comparisons. Scalar-action congruence in the codomain vector-space module, using scalar reflexivity on the carried scalars a and b, gives

$$a \odot_W f(x) \sim_W a \odot_W u, \qquad b \odot_W f(y) \sim_W b \odot_W v.$$

A second use of target additive congruence gives

$$(a \odot_W f(x)) +_W (b \odot_W f(y)) \sim_W (a \odot_W u) +_W (b \odot_W v).$$

Classifier transitivity, as packaged by Definition 9.8, composes the three codomain comparisons and yields

$$f(s) \sim_W (a \odot_W u) +_W (b \odot_W v).$$

The source witness s, the convex-carrier proof $C(s)$, and this codomain classifier comparison repack by Definition 208.8 as

$$f[C]_{\sim_W}((a \odot_W u) +_W (b \odot_W v)).$$

□

Theorem 208.10 (ConvexSet linear image finite affine-spine closure)**.** *Let the data be as in Definition 208.8. Write $\sim_F$, $+_F$, 1_F, and NonNeg_F for the scalar classifier, scalar addition, scalar unit, and nonnegative predicate. Write $+_W$, $\odot_W$, and $\sim_W$ for the codomain vector addition, scalar action, and classifier. Assume the source $\mathsf{ConvexSet}^{\uparrow}$ certificate supplies the binary affine-combination row of Definition 208.1. For every finite codomain point spine $ys : \mathsf{ListCarrier}(W)$, finite scalar-weight spine $\lambda : \mathsf{ListCarrier}(F)$, and endpoint $z : W$, if*

$$\mathsf{ConvAffSpine}_{f[C]_{\sim_W}}(ys, \lambda, z)$$

holds in the sense of Definition 208.4 with carrier predicate $f[C]_{\sim_W}$, then

$$f[C]_{\sim_W}(z).$$

Thus the classifier image carrier is closed under every finite affine spine whose weights are nonnegative and whose finite scalar sum is classified as 1_F.

Lean4 ✓ `BEDC.Derived.ConvexSetUp.ConvexSetLinearImage finite affine spine closure`

Proof. By Definition 208.9, the image carrier $f[C]_{\sim_W}$ satisfies the codomain binary affine-combination row

$$f[C]_{\sim_W}(u) \wedge f[C]_{\sim_W}(v) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F \Longrightarrow f[C]_{\sim_W}((a \odot_W u) +_W (b \odot_W v)).$$

This row is obtained from the source convex row and the carried $\mathsf{LinMap}^{\uparrow}(V, W)$ data, whose additivity, scalar compatibility, and codomain congruence rows are read through Definition 48.1, Definition 48.59, and Definition 46.18.

Unpack the displayed hypothesis using Definition 208.4. The finite readback gives the common finite position data, nonnegative weights, and unit-sum scalar comparison. The endpoint carrier conclusion is proved by induction on the local bracketing witness $\mathsf{Bracket}_{f[C]_{\sim_W}}(ys, \lambda, z)$.

In the singleton clause, the endpoint is the displayed codomain point u, and the clause itself supplies $f[C]_{\sim_W}(u)$. Hence the endpoint lies in the image carrier.

In the binary-extension clause, the clause supplies $f[C]_{\sim_W}(u)$, the coefficient hypotheses $\mathsf{NonNeg}_F(a)$ and $\mathsf{NonNeg}_F(b)$, the local unit-sum comparison $(a +_F b) \sim_F 1_F$, and a tail bracketing witness with endpoint v. The induction hypothesis applied to that tail witness gives $f[C]_{\sim_W}(v)$. Applying the binary image row above to u, v and a, b gives

$$f[C]_{\sim_W}((a \odot_W u) +_W (b \odot_W v)),$$

which is exactly the endpoint named by the binary-extension clause. Therefore every local bracketing witness over $f[C]_{\sim_W}$ has its endpoint in the same classifier image carrier, and the original endpoint z satisfies $f[C]_{\sim_W}(z)$. □

Definition 208.11 (ConvexSet linear preimage carrier)**.** *Let F carry a $\mathsf{Field}^{\uparrow}(F)$ certificate, let V and W carry $\mathsf{VecSpace}^{\uparrow}(F,V)$ and $\mathsf{VecSpace}^{\uparrow}(F,W)$ certificates over the same scalar source, and let $D : W \to \mathsf{Prop}$ be the convex carrier of a $\mathsf{ConvexSet}^{\uparrow}$ certificate on W. Let $f : V \to W$ be a carried $\mathsf{LinMap}^{\uparrow}(V,W)$ map. The source-side preimage of D along f is the predicate $f^{-1}[D] : V \to \mathsf{Prop}$ on carried source points defined by*

$$f^{-1}[D](x) \iff D(f(x)).$$

Thus membership in the preimage carrier is read by evaluating the carried linear map and testing the codomain convex carrier at the displayed output.

Theorem 208.12 (ConvexSet linear preimage affine-combination closure)**.** *Let the data be as in Definition 208.11. Write $\sim_F$, $+_F$, 1_F, and NonNeg_F for the scalar classifier, scalar addition, scalar unit, and nonnegative predicate. Write $+_V$ and $\odot_V$ for the source vector addition and scalar action, and write $+_W$, $\odot_W$, and $\sim_W$ for the codomain vector addition, scalar action, and classifier. Assume the codomain $\mathsf{ConvexSet}^{\uparrow}$ certificate supplies the binary affine-combination row of Definition 208.1. For carried scalars $a, b : F$ and carried source points $x, y : V$, if*

$$f^{-1}[D](x) \wedge f^{-1}[D](y) \wedge \mathsf{NonNeg}_F(a) \wedge \mathsf{NonNeg}_F(b) \wedge (a +_F b) \sim_F 1_F,$$

then

$$f^{-1}[D]\big((a \odot_V x) +_V (b \odot_V y)\big).$$

Thus the source-side preimage carrier satisfies the same binary nonnegative unit-sum affine-combination closure row over the source vector-space carrier.

Proof. Unfold Definition 208.11 for the two preimage hypotheses. They are exactly

$$D(f(x)), \qquad D(f(y)).$$

Since the codomain convex carrier is a subset of the codomain $\mathsf{VecSpace}^{\uparrow}$ carrier, these hypotheses make $f(x)$ and $f(y)$ carried codomain inputs. Applying the codomain binary affine-combination row of Definition 208.1 to the points $f(x), f(y)$ and the coefficients a, b gives

$$D\big((a \odot_W f(x)) +_W (b \odot_W f(y))\big).$$

Set

$$s := (a \odot_V x) +_V (b \odot_V y).$$

Because x and y are carried source inputs, source scalar-action closure and source additive closure make the two summands of s and the endpoint s itself carried in V. The carried $\mathsf{LinMap}^{\uparrow}(V,W)$ map supplies additive preservation and scalar compatibility through Definition 48.1 and Definition 48.59. Therefore

$$f(s) \sim_W f(a \odot_V x) +_W f(b \odot_V y)$$

and

$$f(a \odot_V x) \sim_W a \odot_W f(x), \qquad f(b \odot_V y) \sim_W b \odot_W f(y).$$

The target additive congruence row from Definition 46.18 transports these two comparisons to

$$f(a \odot_V x) +_W f(b \odot_V y) \sim_W (a \odot_W f(x)) +_W (b \odot_W f(y)).$$

Classifier transitivity, as packaged by Definition 9.8, composes this with the additive-preservation comparison and yields

$$f(s) \sim_W (a \odot_W f(x)) +_W (b \odot_W f(y)).$$

Classifier symmetry from Definition 9.7 reverses this comparison, so

$$(a \odot_W f(x)) +_W (b \odot_W f(y)) \sim_W f(s).$$

The codomain convex carrier inherits carrier transport along its classifier from the naming-certificate core in Definition 9.7. Transporting the codomain carrier witness above across this reversed comparison gives

$$D(f(s)).$$

Substituting the definition of s and folding Definition 208.11 gives

$$f^{-1}[D]((a \odot_V x) +_V (b \odot_V y)),$$

which is the claimed source-side affine-combination closure. □

Theorem 208.13 (ConvexSet finite half-space intersection carrier)**.** *Let F carry the shared ordered-field surface, let V carry a* $\mathsf{VecSpace}^{\uparrow}(F, V)$ *certificate, and let a finite family of carried affine half-spaces be presented by rows*

$$H_k(x) \iff \ell_k(x) \preceq_F r_k \qquad (k \in K),$$

where each ℓ_k is read through a carried affine or linear map and each comparison uses the $\mathsf{PositiveCone}^{\uparrow}$ *nonnegative classifier over F. Then the finite intersection*

$$\mathsf{Half}(x) \iff \forall k \in K.\ H_k(x)$$

is admitted as a $\mathsf{ConvexSet}^{\uparrow}$ *carrier. The same finite row supplies the face packet consumed by* $\mathsf{Polytope}^{\uparrow}$*: every face witness is a subfamily of the displayed half-space rows together with its positive-cone comparison ledger.*

Proof. Proceed by induction on the finite half-space row carrier K. In the empty case the carrier is the whole ambient carried vector-space surface, whose affine-combination closure is inherited from the $\mathsf{VecSpace}^{\uparrow}$ and $\mathsf{AffineSpace}^{\uparrow}$ rows used by the chapter's root convex carrier.

For the step, write the intersection as a tail carrier C together with one displayed half-space H_k. By the induction hypothesis, C is a $\mathsf{ConvexSet}^{\uparrow}$ carrier. The half-space row is convex because affine or linear readback transports binary affine combinations to scalar affine combinations, and the $\mathsf{PositiveCone}^{\uparrow}$ comparison ledger preserves the nonnegative ordered-field inequality under those combinations.

Apply the pointwise intersection closure of Definition 208.7 to C and H_k. This admits the enlarged finite intersection as a $\mathsf{ConvexSet}^{\uparrow}$ carrier, with no separation theorem or compactness row.

The face packet is read from the same finite ledger. A $\mathsf{Polytope}^{\uparrow}$ consumer selects a subfamily of active half-space rows, and the positive-cone classifier transports the corresponding comparison witnesses. Thus the convex carrier and the polytope face packet share the displayed half-space rows rather than appealing to ambient polyhedral geometry. □

Theorem 208.14 (ConvexSet pointwise intersection carrier commutativity)**.** *Let two* $\mathsf{ConvexSet}^{\uparrow}$ *certificates be given as in Definition 208.6. Write* $C, D : V \to \mathsf{Prop}$ *for their convex carriers, and write*

$$K_{CD} := C \cap_{\mathsf{ConvexSet}^{\uparrow}} D, \qquad K_{DC} := D \cap_{\mathsf{ConvexSet}^{\uparrow}} C.$$

For every endpoint $z : V$*, the two pointwise intersection carriers agree:*

$$K_{CD}(z) \Longleftrightarrow K_{DC}(z).$$

Equivalently, a carrier witness for $C \cap_{\mathsf{ConvexSet}^{\uparrow}} D$ *at* z *is exactly a pair consisting of a* $C(z)$ *witness and a* $D(z)$ *witness, and the corresponding carrier witness for* $D \cap_{\mathsf{ConvexSet}^{\uparrow}} C$ *is obtained by interchanging those two components. The scalar classifier* $\sim_F$*, scalar addition* $+_F$*, scalar unit* 1_F*, nonnegative predicate* NonNeg_F*, scalar action* $\odot$*, and vector addition* $+_V$ *are the common rows named in Definition 208.6, so this interchange does not alter any displayed scalar, addition, or affine-combination row.*

Proof. Fix an endpoint $z : V$. Unfold Definition 208.6 for the ordered pair of carriers (C, D). The hypothesis $K_{CD}(z)$ is precisely

$$C(z) \wedge D(z).$$

Projecting its two components and pairing them in the opposite order gives

$$D(z) \wedge C(z),$$

which is exactly $K_{DC}(z)$ after unfolding the same definition for the ordered pair (D, C).

Conversely, unfold the definition for (D, C). The hypothesis $K_{DC}(z)$ is precisely

$$D(z) \wedge C(z).$$

Projecting its two components and pairing them in the opposite order gives

$$C(z) \wedge D(z),$$

which is exactly $K_{CD}(z)$ after folding the definition for (C, D). The two folds use the same ambient $\mathsf{Field}^{\uparrow}(F)$ and $\mathsf{VecSpace}^{\uparrow}(F, V)$ data named in Definition 208.6; only the two carrier-support components at the fixed endpoint are swapped. □

Theorem 208.15 (ConvexSet pointwise intersection inclusion meet)**.** *Let two* $\mathsf{ConvexSet}^{\uparrow}$ *certificates be given as in Definition 208.6. Write* $C, D : V \to \mathsf{Prop}$ *for their convex carriers and write*

$$K := C \cap_{\mathsf{ConvexSet}^{\uparrow}} D.$$

On convex carriers over the same ambient $\mathsf{Field}^{\uparrow}(F)$ *and* $\mathsf{VecSpace}^{\uparrow}(F, V)$ *data, write*

$$E \preceq_{\mathsf{ConvexSet}^{\uparrow}} G \Longleftrightarrow \forall z : V.\ E(z) \to G(z)$$

for pointwise inclusion. Then K *is the greatest lower bound of* C *and* D *in this inclusion preorder:*

$$K \preceq_{\mathsf{ConvexSet}^{\uparrow}} C, \qquad K \preceq_{\mathsf{ConvexSet}^{\uparrow}} D,$$

and, for every third $\mathsf{ConvexSet}^{\uparrow}$ *convex carrier* $E : V \to \mathsf{Prop}$ *over the same ambient data,*

$$(E \preceq_{\mathsf{ConvexSet}^{\uparrow}} C) \wedge (E \preceq_{\mathsf{ConvexSet}^{\uparrow}} D) \Longrightarrow E \preceq_{\mathsf{ConvexSet}^{\uparrow}} K.$$

The carrier K *is therefore the meet of* C *and* D *among convex carriers ordered by inclusion, with its convex closure supplied by Definition 208.7.*

Proof. The pointwise intersection carrier is the predicate specified in Definition 208.6:

$$K(z) \iff C(z) \wedge D(z).$$

For the first projection bound, fix $z : V$ and assume $K(z)$. Unfolding the definition gives $C(z) \wedge D(z)$, and projecting the first component gives $C(z)$. Hence $K \preceq_{\mathsf{ConvexSet}^{\uparrow}} C$.

For the second projection bound, the same unfolding of $K(z)$ gives $C(z) \wedge D(z)$, and projecting the second component gives $D(z)$. Hence $K \preceq_{\mathsf{ConvexSet}^{\uparrow}} D$.

It remains to prove the universal lower-bound property. Let $E : V \to \mathsf{Prop}$ be the convex carrier of a third $\mathsf{ConvexSet}^{\uparrow}$ certificate over the same ambient data, and assume

$$E \preceq_{\mathsf{ConvexSet}^{\uparrow}} C, \qquad E \preceq_{\mathsf{ConvexSet}^{\uparrow}} D.$$

To prove $E \preceq_{\mathsf{ConvexSet}^{\uparrow}} K$, fix $z : V$ and assume $E(z)$. The first inclusion sends this witness to $C(z)$, and the second inclusion sends the same witness to $D(z)$. Pairing the two conclusions gives

$$C(z) \wedge D(z),$$

which is exactly $K(z)$ by Definition 208.6. Therefore every common lower bound E factors through K, and the two projection bounds make K the greatest lower bound of C and D for pointwise inclusion. □

Theorem 208.16 (ConvexSetUp public NameCert export)**.** *The carrier predicate, binary affine-combination row, midpoint and order-symmetry rows, finite affine spine, pointwise intersection, linear image, and linear preimage rows form the public* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *export over the displayed* $\mathsf{AffineSpace}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Field}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, BHist, hsame, Cont, *and* Pkg *surfaces. In this export, the public carrier accepts exactly the endpoints presented by the convex predicate, finite affine bracketing, intersection witnesses, linear image witnesses, or linear preimage witnesses; the public classifier is the ambient vector classifier transported through the carried package rows; and the public ledger records the visible points, weights, scalar comparisons, affine endpoints, linear-map rows, and package provenance.*

Proof. The carrier and binary affine-combination rows are the displayed $\mathsf{ConvexSet}^{\uparrow}$ certificate rows. The midpoint and order-symmetry rows are specialisations of the same binary affine row, with the scalar hypotheses and ambient classifier comparisons carried by the $\mathsf{Field}^{\uparrow}$ and $\mathsf{VecSpace}^{\uparrow}$ surfaces.

The finite affine spine is public because Definition 208.10 proves that any finite codomain spine over a carried linear image repacks into the same image carrier. Pointwise intersection is public by Definition 208.7, Definition 208.14, and Definition 208.15; these rows keep the two component carrier witnesses and no external set former.

Linear images are public by Definition 208.9 and the finite spine theorem above. Linear preimages are public by Definition 208.12; the source endpoint is accepted exactly when its carried image is accepted by the codomain convex carrier.

Together these rows expose the requested public $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ surface. The export contains no separation theorem, compactness theorem, finite-dimensional theory, or standard bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$**.**

Constructive story: A convex set here is generated inside already certified affine and vector-space data: start with carried points, attach nonnegative scalar histories from the field source whose finite sum is classified as the scalar unit, and build the endpoint by repeated affine-combination rows. The carrier accepts endpoints that are presented by this

convex predicate, by finite affine spines, by pointwise intersections, by classifier images along carried linear maps, or by classifier preimages along carried linear maps; data missing the affine source, scalar nonnegativity, unit-sum comparison, or carried linear-map witness remain outside the public surface. Two displayed endpoints are compared only through the ambient vector classifiers and the witness rows attached to the source convex predicate, so linear images use a source point plus a codomain classifier comparison rather than an external image set. The source is the displayed convex carrier predicate over $\mathsf{AffineSpace}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Field}^{\uparrow}$, and $\mathsf{LinMap}^{\uparrow}$, the pattern records binary affine closure, midpoint closure, order symmetry, finite bracketing, intersection closure, linear image closure, and linear preimage closure, and the ledger keeps the raw points, weights, scalar comparisons, affine endpoints, linear-map outputs, and package rows visible. The name-certificate obligations at this public level are read from the accepted carrier rows: inhabited examples supply the carrier witness, the inherited classifiers give reflexivity, symmetry, and transitivity, and the closure theorems repack any classified affine combination, intersection member, image endpoint, or preimage endpoint back into the carrier. A history h lies in the signature gap of a $\mathsf{ConvexSet}^{\uparrow}$ token p when the source-domain accepts the displayed convex packet, the signature relation pairs it with an answer carrier row and evidence ledger, and the token-introduction relation names that answer as p; concretely, every affine-combination, finite-spine, image, and preimage endpoint recorded by p is carried by the same visible predicate. The chapter registers this affine-combination construction under the name $\mathsf{ConvexSet}^{\uparrow}$; it supplies a public convex surface, with no separation theorem, compactness theorem, finite-dimensional theory, or standard bridge introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public boundary is the carrier predicate, binary affine row, midpoint and order-symmetry rows, finite affine spine, pointwise intersection, linear image, linear preimage, and dependency inventory bound to $\mathsf{AffineSpace}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Field}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, BHist, hsame, Cont, and Pkg.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ConvexSetUp.ConvexSetLinearImage\_finite\_affine\_spine\_closure`

Bridge status: none

Not claimed: This chapter does not close finite-dimensional convexity theory, separation theorem, compactness theorem, or standard bridge.

Upgrade path: The paper-axis treatment is mature; remaining work is bridge-status or formal-axis coordination.

Chapter 209

A Concrete Naming Certificate for $\mathsf{Polytope}^{\uparrow}$

The polytope interface $\mathsf{Polytope}^{\uparrow}$ packages a bounded convex set in a finite-dimensional vector-space carrier presented as the intersection of finitely many half-spaces, with vertex, edge, and face combinatorial structure. It depends on $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ (chapter 208) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

209.1 Carrier definition

Definition 209.1 (Polytope BHist face packet)**.** *A* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet is a finite certificate tuple*

$$\mathcal{P} = (\eta_C, \eta_F, H, V, E, \Phi, L, \pi)$$

over BHist *in which* $\eta_C : \mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *supplies the convex carrier rows,* $\eta_F : \mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *supplies the finite-index rows,* H *is the finite list of half-space rows,* V *is the finite vertex row ledger,* E *is the finite edge row ledger,* Φ *is the finite face row ledger,* L *is the collection of* Cont *ledgers connecting half-space, vertex, edge, and face rows, and* $\pi : \mathsf{Pkg}$ *records the provenance of those rows.*

The carrier accepts $\mathcal{P}$ *exactly when every half-space row is scoped by* η_C*, every vertex, edge, and face index is scoped by* η_F*, every incidence row is a* BHist *row transported by* hsame*, and each displayed face is generated by the finite half-space ledger together with the finite vertex and edge incidence ledgers named in* L*.*

Lean4 (definition) `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket`

Theorem 209.2 (Polytope half-space and face carrier stability)**.** *Let* $\mathcal{P}$ *be a* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet. If each half-space row, vertex row, edge row, face row, and incidence ledger row of* $\mathcal{P}$ *is transported along an* hsame *comparison to the corresponding row of a packet* $\mathcal{P}'$*, then* $\mathcal{P}'$ *is again a* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet. The transported packet keeps the same* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *dependency witnesses, the same finite* Cont *ledger shape, and the same* Pkg *provenance rows.*

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket halfspace face carrier stability`

Proof. Project the packet into its half-space, vertex, edge, face, incidence, dependency, ledger, and provenance components. Transport the half-space rows by the hsame stability supplied by the

convex-set source certificate, and transport the finite vertex, edge, and face indices by the finite-set source certificate.

Next transport the displayed incidence and containment rows componentwise. The Cont ledgers are finite, so each source, step, and result row is replaced by its transported hsame mate while the ledger order and package provenance are left unchanged.

Repack the transported rows into the tuple defining Definition 209.1. The acceptance clauses are exactly the transported clauses, so the target tuple is a carried $\mathsf{Polytope}^{\uparrow}$ packet. □

209.2 The certificate

Theorem 209.3 (Polytope vertex, edge, and face ledger readback)**.** *Every* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet exposes finite readback rows for its vertices, edges, and faces. More precisely, the packet determines a finite* BHist *vertex ledger, a finite edge-incidence ledger, and a finite face-incidence ledger, each indexed through the* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *source and each connected to the packet carrier through the displayed* Cont *rows.*

Proof. Unpack the packet of Definition 209.1. The components V, E, and Φ are already finite ledgers, and the finite-set source certificate records their index rows as $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ data.

For each ledger row, read the corresponding Cont entry from L. The entry names the source half-space or incidence row, the finite step row, and the resulting vertex, edge, or face row. Collecting these entries gives the three advertised finite readback ledgers, with no appeal to an ambient geometric carrier outside the packet. □

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket vertex edge ledger readback`

Theorem 209.4 (Polytope ConvexSet and FinSet dependency readback)**.** *Every* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet reads back exactly the two dependency rows* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *used to scope its half-space and finite combinatorial ledgers. The convex dependency accounts for half-space intersection and carried face rows, while the finite-set dependency accounts for the vertex, edge, face, and incidence indices.*

Proof. The first two components of the packet are the displayed dependency witnesses η_C and η_F. Projecting them gives the convex-set carrier and finite-set carrier rows available to the packet.

Conversely, every half-space, vertex, edge, face, and incidence clause in the packet definition is scoped through one of these two witnesses and a finite Cont row. Therefore the dependency readback is exactly $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ together with $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$, plus the kernel rows already named by the packet. □

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket convex finset dependency readback`

Theorem 209.5 (Polytope downstream boundary)**.** *Downstream convex consumers of a* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet may read only the* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *dependency, the half-space rows, the carried face rows, the* hsame *transports, and the finite* Cont *ledgers connecting them. Downstream combinatorial consumers may read only the* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *dependency, the vertex, edge, face, and incidence ledgers, the same* hsame *transports, and the same* Pkg *provenance rows. No downstream consumer receives an ambient Euclidean metric, a quotient carrier, an external face lattice, or a standard bridge from this packet.*

Proof. For a convex consumer, project the packet to η_C, the half-space list, the face rows, and the Cont ledgers that generate those faces. These are exactly the rows named in the carrier definition for convex readback.

For a combinatorial consumer, project the packet to η_F, the finite vertex, edge, face, and incidence ledgers, their hsame transport rows, and the provenance package. These rows determine the finite combinatorial surface without adding any external lattice object.

The two projections share only the kernel rows explicitly stored in the packet: BHist rows, hsame comparisons, Cont ledgers, and Pkg provenance. Hence the boundary grants precisely those read permissions and no metric, quotient, external lattice, or bridge data. □

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket downstream boundary`
↪ variant `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket downstream boundary transport`

Definition 209.6 (Polytope face classifier)**.** *The* $\mathsf{Polytope}^{\uparrow}$ *face classifier relates two BHist face packets when their half-space rows, vertex rows, edge rows, face rows,* Cont *ledgers, and* Pkg *provenance rows compare componentwise by* hsame*, and when the dependency rows supplied by* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *are the same accepted dependency rows on both sides.*

Thus classifier agreement is entirely a BEDC row relation: half-space agreement is read through the convex-set dependency, vertex, edge, and face agreement is read through the finite-set dependency, and every incidence or containment movement is witnessed by the displayed Cont *ledgers. No ambient face lattice or metric equality is part of the classifier.*

Lean4 (definition) `BEDC.Derived.PolytopeUp.PolytopeFaceClassifier`

Theorem 209.7 (Polytope face classifier transport)**.** *If two* $\mathsf{Polytope}^{\uparrow}$ *BHist face packets are related by the classifier of Definition 209.6, then any packet obtained by componentwise* hsame *transport of its half-space, vertex, edge, face,* Cont*, and* Pkg *rows is again accepted by the same classifier. The transported packet keeps the same* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *dependency rows and remains available to the downstream boundary of Definition 209.5.*

Proof. Project the classifier into its convex, finite, incidence, ledger, and provenance components. The convex component transports half-space and carried face rows through $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$, while the finite component transports vertex, edge, face, and incidence indices through $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$.

Next transport the finite Cont ledger entries. Each entry has the same source, step, and result shape after replacing endpoints by their hsame mates, and the Pkg row is carried along the same componentwise comparison.

Repack these transported rows using Definition 209.6. The acceptance clauses are exactly the transported classifier clauses, so the resulting packet remains classifier related and has the same downstream readback permissions. □

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeFaceClassifier transport`

Theorem 209.8 (Polytope obligation boundary exhaustion)**.** *The carrier block, face-classifier block, stability block, dependency readback block, and downstream boundary block exhaust the* $\mathsf{Polytope}^{\uparrow}$ NameCert *obligation surface. Every accepted obligation row is one of the finite* BHist *half-space, vertex, edge, face, incidence,* Cont*, or* Pkg *rows named in those blocks, together with the two dependency rows* $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket obligation boundary exhaustion`

Proof. Start with the carrier definition Definition 209.1. It lists all packet fields: dependency rows, half-space rows, vertex rows, edge rows, face rows, incidence ledgers, Cont ledgers, and provenance.

The classifier and stability rows are exactly Definition 209.6, Definition 209.7, and Definition 209.2. They move only the listed finite rows along hsame and do not add a metric, quotient, or external face lattice.

Finally combine dependency readback Definition 209.4 with the downstream boundary Definition 209.5. These projections account for every consumer-visible row, so the displayed blocks exhaust the obligation surface. □

Theorem 209.9 (PolytopeUp obligation surface)**.** *The existing* $\mathsf{Polytope}^{\uparrow}$ *BHist face packet supplies the roadmap obligation surface for this chapter. Its carrier row is Definition 209.1; its classifier and stability rows are the* hsame *transport surface of Definition 209.2; its finite vertex, edge, and face ledger readback is Definition 209.3; its dependency scope is Definition 209.4; and its downstream consumer boundary is Definition 209.5.*

Consequently the obligation inventory consists only of the $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *dependency rows, finite half-space, vertex, edge, face, and incidence* BHist *rows, displayed* hsame *transports, finite* Cont *ledger rows, and* Pkg *provenance. It contains no Euclidean metric, quotient carrier, external face lattice, or standard bridge.*

Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket public obligation surface`
Lean4 ✓ `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket obligation surface`

Proof. Project the packet to its carrier definition. The tuple of Definition 209.1 names exactly the convex dependency, finite-index dependency, half-space rows, vertex ledger, edge ledger, face ledger, continuity ledger, and provenance row.

Next transport the classifier surface. Apply Definition 209.2 to the displayed hsame comparisons; it keeps the dependency witnesses, ledger shape, and package provenance while replacing each carried row by its transported mate.

Read back the finite ledgers and dependencies. The vertex, edge, and face rows come from Definition 209.3, while Definition 209.4 isolates the two source certificates that scope every half-space and finite combinatorial row.

Finally apply Definition 209.5. It is precisely the consumer projection of the same packet, so repacking the carrier, transport, ledger, dependency, and boundary projections gives the stated obligation surface. The exclusion clause follows from the same downstream boundary: none of the packet projections exposes metric, quotient, external lattice, or bridge data. □

Closure status for $\mathsf{NameCert}_{\mathsf{Polytope}^{\uparrow}}$**.**

Constructive story: A polytope packet is generated by placing a $\mathsf{ConvexSet}^{\uparrow}$ dependency beside a $\mathsf{FinSet}^{\uparrow}$ dependency, then listing finite half-space histories, vertex histories, edge histories, face histories, incidence rows, finite Cont ledgers, and one Pkg provenance row. The carrier accepts exactly those face packets whose half-spaces are scoped by the convex dependency, whose vertex, edge, face, and incidence indices are scoped by the finite-set dependency, and whose displayed faces are generated by the finite half-space and incidence ledgers; a metric space, quotient carrier, or external face lattice never enters the packet. Two packets are classified componentwise by hsame on half-space, vertex, edge, face, incidence, continuation, and provenance rows while keeping the two dependency certificates fixed. The source is this displayed finite face packet, the pattern records half-space stability, finite vertex-edge-face readback, dependency readback, downstream convex and combinatorial projections, and classifier transport, and the ledger keeps every raw row aligned with the consumer-visible face or incidence row produced from it. The name-certificate obligations are visible as a Lean-checked public certificate: an accepted packet supplies the carrier witness, componentwise hsame supplies reflexive, symmetric, and transitive comparison, and the stability theorem shows that transported components repack as accepted packets. A history h lies in the signature gap of a $\mathsf{Polytope}^{\uparrow}$ token p when the source-domain accepts h as this finite face packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p names the same finite half-space, vertex, edge, face, incidence, continuation, and provenance

rows. The chapter registers this finite face-ledger construction under the name Polytope$^{\uparrow}$ as a complete finite consumption surface, with no Euclidean metric, face-lattice completeness, quotient carrier, or standard bridge introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{Polytope}\uparrow}$, maturePackageClosed)

Scope closed: The mature paper scope is the finite face-packet carrier, classifier transport, convex and finite dependency readback, vertex-edge-face ledger readback, and downstream convex and combinatorial consumer boundary.

Formal verification: FormalStatus(NameCert$_{\mathsf{Polytope}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.PolytopeUp.PolytopeBHistFacePacket\_public\_obligation\_surface`

Bridge status: none

Not claimed: This chapter does not close a Euclidean metric, face lattice completeness, quotient carrier, or standard bridge.

Upgrade path: No further theory-axis upgrade is claimed in this chapter; bridgeChecked remains a formal bridge-axis matter.

Chapter 210

A Concrete Naming Certificate for $\mathsf{VectorBundle}^{\uparrow}$

The vector-bundle interface $\mathsf{VectorBundle}^{\uparrow}$ packages a fibre bundle whose fibres are vector spaces and whose transition maps are linear. It depends on $\mathsf{NameCert}_{\mathsf{Bundle}^{\uparrow}}$ (chapter 97) and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47).

210.1 Carrier definition

Definition 210.1 (VectorBundle finite carrier)**.** *A* $\mathsf{VectorBundle}^{\uparrow}$ *carrier is the finite* BHist *packet* $\mathsf{VectorBundlePkt}(V)$ *with the following displayed rows.*

1. *A retained* $\mathsf{Bundle}^{\uparrow}$ *row for the base, total space, projection, fibre model, local-trivialization, transition, and source-ledger histories.*
2. *A retained* $\mathsf{VecSpace}^{\uparrow}$ *row for the vector-space structure carried by each displayed fibre history.*
3. *A local-trivialization row listing a finite* ProbeBundle *of trivializing neighborhoods and their trivialization histories.*
4. *A fibre carrier row assigning to each displayed local fibre a* BHist *carrier accepted by the retained* $\mathsf{VecSpace}^{\uparrow}$ *certificate.*
5. *A linear transition row recording, for each displayed overlap, the transition history and the vector-space linearity witnesses for addition, zero, negation, and scalar action.*
6. *Componentwise* hsame *rows for the base, total, projection, fibre, trivialization, transition, and vector-space operation histories.*
7. Cont *rows for restriction to overlaps, transition composition, and transport of linearity witnesses along classified fibre histories.*
8. *A* Pkg *provenance row tying the retained* $\mathsf{Bundle}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *certificates to the displayed finite vector-bundle packet.*

The carrier exposes only these finite BHist *rows and their displayed* hsame, Cont, *and* Pkg *witnesses; it does not import a host vector-bundle object or an unrecorded transition function.*

Lean4 (definition) `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier`

Definition 210.2 (VectorBundle classifier)**.** *Two* VectorBundlePkt *carriers classify together when the retained* Bundle$^{\uparrow}$ *base, total-space, projection, local-trivialization, and transition rows classify by the bundle certificate, the retained* VecSpace$^{\uparrow}$ *fibre rows classify by the vector-space certificate, and every fibre carrier, linearity, overlap,* Cont*, and* Pkg *row is related by the displayed componentwise* hsame *comparison. The classifier is finite row sameness over base, fibre, trivialization, and transition data, not equality of host vector-bundle structures.*

Lean4 (definition) `BEDC.Derived.VectorBundleUp.VectorBundleComponentwiseClassifier`
Lean4 (definition) `BEDC.Derived.VectorBundleUp.VectorBundleFiniteClassifier`
Lean4 (definition) `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrierClassifier`
Lean4 (definition) `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier componentwise classifier`

210.2 The certificate

Theorem 210.3 (VectorBundle carrier obligation)**.** *Every accepted* VectorBundlePkt(V) *row projects to one of the displayed* Bundle$^{\uparrow}$*,* VecSpace$^{\uparrow}$*, local-trivialization, fibre-carrier, linear-transition,* hsame*,* Cont*, or* Pkg *rows of Definition 210.1. There is no additional carrier case for a host vector bundle.*

Lean4 ✓ `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier carrier obligation`
↪ variant `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier obligation surface`

Proof. Unpack the carrier definition. The first two coordinates are retained dependency rows from Bundle$^{\uparrow}$ and VecSpace$^{\uparrow}$. The remaining coordinates are the local-trivialization probe bundle, fibre carrier rows, linear transition rows, componentwise hsame comparisons, Cont ledgers, and Pkg provenance.

Projection from an accepted packet can therefore read only one of those coordinates. The bundle dependency supplies base, total, projection, trivialization, and transition histories; the vector-space dependency supplies the fibre operation histories and their classifier.

Conversely, any displayed coordinate is repacked by the same finite packet constructor. Constructor inversion provides no branch for an ambient vector-bundle object, an implicit local trivialization, or an unlogged transition map. □

Theorem 210.4 (VectorBundle transition ledger exactness)**.** *The transition surface of* VectorBundle$^{\uparrow}$ *is exactly the finite overlap ledger in Definition 210.1: every transition comparison is recorded by displayed overlap rows, linearity rows,* Cont *composition rows, and* Pkg *provenance, and every such ledger row repacks as a public transition witness.*

Lean4 ✓ `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier transition ledger exactness`

Proof. Project the transition coordinate of a carried vector-bundle packet. It lists the overlap row, the source and target trivialization histories, the displayed transition history, and the vector-space linearity witnesses for the four operation families.

Exactness in the forward direction is projection. A public transition witness must cite the overlap row and the corresponding linearity rows, so the witness is represented inside the finite ledger.

For the reverse direction, start with a displayed overlap ledger. Repack its transition history, linearity witnesses, overlap restriction Cont rows, and source provenance into the transition coordinate of VectorBundlePkt(V). This produces the public transition witness and uses no host transition function. □

Theorem 210.5 (VectorBundle transition composition scope)**.** *Every composed transition witness in* $\mathsf{VectorBundle}^{\uparrow}$ *is consumed through the displayed overlap rows, the source and target trivialization histories, the linearity rows, the* Cont *composition rows, and the* Pkg *provenance of Definition 210.1. No host transition composition, ambient vector-bundle map, or unlogged fibre map may be invoked to build such a witness.*

Lean4 ✓ `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier transition composition scope`

Proof. Project the transition coordinate of the carried packet. A composable transition readback first exposes the two overlap ledgers and the three trivialization histories that supply the source, middle, and target endpoints.

The two ledger rows already contain the displayed linearity witnesses for the four vector-space operation families. Their endpoints are connected only by the listed transition-composition Cont rows, so the composition step is a consumer of those rows rather than an operation on a host bundle.

Repack the composed transition by carrying forward the same overlap ledgers, linearity rows, Cont composition witness, and Pkg provenance from Definition 210.1. Constructor inversion leaves no coordinate for an external transition function or an unlogged vector-bundle map. □

Theorem 210.6 (VectorBundle classifier stability obligation)**.** *The classifier of Definition 210.2 transports accepted vector-bundle packets: classified base, fibre, trivialization, and transition rows repack as a carried* $\mathsf{VectorBundle}^{\uparrow}$ *packet with the same finite transition ledger shape.*

Lean4 ✓ `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier classifier stability obligation`

Proof. Begin with a classifier witness between two displayed packets. Its retained $\mathsf{Bundle}^{\uparrow}$ component transports the base, total, projection, local-trivialization, and bundle transition rows by the existing bundle certificate.

Its retained $\mathsf{VecSpace}^{\uparrow}$ component transports the fibre carrier and the vector-space operation histories. Componentwise hsame then transports the linearity rows for addition, zero, negation, and scalar action.

The overlap-restriction and transition-composition Cont rows transport because their endpoint histories are among the same base, fibre, trivialization, and transition comparisons. The Pkg row transports the source provenance. Repacking these transported rows gives another accepted finite vector-bundle packet. □

Theorem 210.7 (VectorBundle NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{VectorBundle}^{\uparrow}}$ *fields determined by Definition 210.1 and Definition 210.2 are exactly the finite carrier rows, the componentwise classifier, carrier transport, the transition ledger exactness row, and the* Pkg *provenance row. The surface contains no host vector-bundle semantics beyond the displayed* $\mathsf{Bundle}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$ *dependency certificates.*

Lean4 ✓ `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier obligation surface`

Proof. First project the carrier by Definition 210.3. This accounts for the retained bundle and vector-space rows, the local-trivialization probe rows, the fibre carrier rows, the linear transition rows, the hsame comparisons, the Cont ledgers, and the provenance row.

Next apply Definition 210.4. The public transition surface is exhausted by the finite overlap ledger and the displayed linearity witnesses, and every such ledger repacks as a transition witness.

Finally apply Definition 210.6. It gives carrier transport and classifier stability over the same finite rows. Since all public fields have been projected from those rows or repacked into them, the certificate exposes no additional host vector-bundle semantics. □

Closure status for $\mathsf{NameCert}_{\mathsf{VectorBundle}^{\uparrow}}$.

Constructive story: A vector-bundle packet is generated from displayed $\mathsf{Bundle}^{\uparrow}$ and $\mathsf{VecSpace}^{\uparrow}$ dependency rows, local trivialization histories, finite transition ledgers, componentwise classifier rows, continuation ledgers, and package provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{VectorBundle}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The scoped boundary binds the displayed $\mathsf{Bundle}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, BHist, hsame, Cont, Pkg, carrier, classifier, and transition-ledger rows of the vector-bundle packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{VectorBundle}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.VectorBundleUp.VectorBundleFiniteCarrier\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host vector-bundle semantics, ambient transition functions, fibrewise smooth or topological structure, or a standard bridge.

Upgrade path: Bridge closure requires a standard finite vector-bundle bridge over the displayed carrier, classifier, transition ledger, hsame, Cont, Pkg, and NameCert rows.

Chapter 211

A Concrete Naming Certificate for $\mathsf{CStarAlg}^{\uparrow}$

The C*-algebra interface $\mathsf{CStarAlg}^{\uparrow}$ packages a Banach algebra with an involution satisfying $\|a^*a\| = \|a\|^2$. It depends on $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ (chapter 90) and $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ (chapter 43), and is the substrate for noncommutative topology and operator-theoretic spectra.

211.1 Carrier definition

Definition 211.1 ($\mathsf{CStarAlg}^{\uparrow}$ BHist carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *row* B *and a* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *row* R *over the same* BHist *source. A* $\mathsf{CStarAlg}^{\uparrow}$ *carrier row is the predicate on a history* h : BHist *asserting that* h *carries exactly the following certificate-visible data: the Banach carrier row from* B*, the RingUp multiplication row from* R*, an involution row* s : BHist *on the same carried endpoints, a norm-square compatibility row for* s *and the multiplication row, the* hsame *transport rows for the carrier, multiplication, involution, and norm-square witnesses, and the* Pkg *provenance rows naming* B *and* R*.*

Lean4 (definition) `BEDC.Derived.CStarAlgUp.CstaralgebraBHistCarrier`

The predicate of Definition 211.1 treats multiplication, involution, norm, and provenance as BEDC rows. It does not expose an ambient host $*$-algebra object or a quotient of algebra presentations.

211.2 The certificate

Definition 211.2 ($\mathsf{CStarAlg}^{\uparrow}$ certificate surface)**.** *The* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *certificate surface consists of the carrier predicate of Definition 211.1, the classifier inherited from the common* hsame *transport of the BanachUp and RingUp rows, the involution transport row, the norm-square compatibility transport row, the* Cont *ledger recording multiplication and involution observations, and the* Pkg *provenance naming* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *as the only dependencies.*

Theorem 211.3 ($\mathsf{CStarAlg}^{\uparrow}$ NameCert obligation surface)**.** *The surface of Definition 211.2 is a complete paper-side obligation surface for* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$*. Every accepted* $\mathsf{CStarAlg}^{\uparrow}$ *row is read from a* BHist *carrier row, a BanachUp source row, a RingUp multiplication row, an involution row, a norm-square compatibility row, the corresponding* hsame *and* Cont *transport rows, and the* Pkg *provenance rows for the two dependency certificates.*

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraNameCert obligation surface`

Proof. Project an accepted carrier witness through Definition 211.1. The projection exposes the Banach row, the RingUp multiplication row, the involution row, the norm-square row, the transport rows, and the dependency provenance.

The classifier is then forced by the same hsame transport rows. Banach transport moves the norm carrier, RingUp transport moves multiplication, and the involution and norm-square rows are retained only when their displayed histories transport along the same carrier comparison.

Repack these projections as the certificate surface of Definition 211.2. No further row is available to the repacking step, so the listed rows are the whole obligation surface. □

Lean4 ✓ `BEDC.Derived.CStarAlgUp.CStarAlgCertificateSurface namecert obligation`
↪ variant `BEDC.Derived.CStarAlgUp.CStarAlgBHistCarrier namecert obligation surface`

Theorem 211.4 ($\mathsf{CStarAlg}^{\uparrow}$ Gelfand and von Neumann consumer boundary)**.** *Any* $\mathsf{GelfandDuality}^{\uparrow}$ *or* $\mathsf{VonNeumannAlg}^{\uparrow}$ *consumer citing* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *may consume only the* BHist *carrier, the BanachUp carrier and norm rows, the RingUp multiplication row, the involution row, the norm-square compatibility row, the* hsame *and* Cont *transport rows, and the* Pkg *provenance rows displayed in Definition 211.2. It may not infer a spectrum, weak-operator closure, representation on a Hilbert space, or commutative Gelfand transform from the root* $\mathsf{CStarAlg}^{\uparrow}$ *surface alone.*

Proof. Read the dependency citation through Definition 211.3. The citation yields only the certificate rows projected there, so a downstream consumer receives the carried Banach, RingUp, involution, norm-square, transport, ledger, and provenance data.

For $\mathsf{GelfandDuality}^{\uparrow}$, a spectrum and a commutative transform require rows not present in the $\mathsf{CStarAlg}^{\uparrow}$ root surface. For $\mathsf{VonNeumannAlg}^{\uparrow}$, weak-operator closure and Hilbert-space representation data also require rows not present in that surface.

Thus both consumers share the same BEDC source boundary: they may cite the $\mathsf{CStarAlg}^{\uparrow}$ certificate rows, while their own chapters must supply any spectrum, closure, representation, or transform rows they use. □

Lean4 ✓ `BEDC.Derived.CStarAlgUp.CStarAlgCertificateSurface gelfand vonneumann consumer boundary`

Theorem 211.5 ($\mathsf{CStarAlg}^{\uparrow}$ unital-commutative source boundary)**.** *A* $\mathsf{GelfandDuality}^{\uparrow}$ *consumer may treat a* $\mathsf{CStarAlg}^{\uparrow}$ *row as a unital commutative source only when the displayed* BHist *surface supplies, in addition to the root certificate, a unit row, multiplication row, commutativity classifier row, involution row, norm-square row,* hsame *transport,* Cont *ledger, and* Pkg *provenance over the same BanachUp and RingUp dependency rows. The root* $\mathsf{CStarAlg}^{\uparrow}$ *certificate alone does not export the Gelfand transform, the spectrum row, or a compact Hausdorff carrier.*

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraBHistCarrier unital commutative source boundary`

Proof. Unfold Definition 211.1. The root carrier exposes the Banach row, RingUp multiplication row, involution row, norm-square row, transport rows, and dependency provenance.

Unfold Definition 211.2. Its public classifier and ledger are the displayed hsame, Cont, and Pkg rows over those carrier components; unit and commutativity data must therefore be supplied as visible rows of the consumer surface when $\mathsf{GelfandDuality}^{\uparrow}$ asks for a unital commutative source.

Finally apply Definition 211.4. That boundary rules out hidden spectrum data and hidden transform rows, so the $\mathsf{GelfandDuality}^{\uparrow}$ source read is limited to the displayed unital, commutative, involutive, norm-square, transport, ledger, and provenance rows. □

Theorem 211.6 (No host star-algebra primitive in $\mathsf{CStarAlg}^{\uparrow}$)**.** *The* $\mathsf{CStarAlg}^{\uparrow}$ *obligation surface does not include a host* $*$*-algebra primitive. Equality and transport for* $\mathsf{CStarAlg}^{\uparrow}$ *are mediated only by* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *together with the displayed involution and norm-square rows.*

Proof. Unfold the carrier predicate of Definition 211.1. Its only source rows are the BanachUp and RingUp certificate rows, the involution row, the norm-square row, the transport rows, and the provenance rows.

Unfold the certificate surface of Definition 211.2. The surface records classifier and ledger data by hsame, Cont, and Pkg; it never adds an ambient equality predicate for host $*$-algebras.

Therefore replacing the displayed rows by a host $*$-algebra primitive would change the carrier. The BEDC object is precisely the row package described above. □

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraBHistCarrier no host star algebra primitive`

Theorem 211.7 ($\mathsf{CStarAlg}^{\uparrow}$ Banach–Ring source boundary)**.** *Every public source read of a* $\mathsf{CStarAlg}^{\uparrow}$ *certificate factors through the displayed BanachUp carrier row, the RingUp multiplication row, the involution row, the norm-square compatibility row, the* hsame *transports for those rows, the finite* Cont *ledger, and the* Pkg *provenance naming the BanachUp and RingUp dependency certificates. No source read exports a host* $*$*-algebra equality, an ambient Banach-ring object, or spectrum data.*

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraBHistCarrier banach ring source boundary`

Proof. Project the source read through Definition 211.1. The carrier predicate lists exactly the Banach row, RingUp multiplication row, involution row, norm-square row, transport rows, and dependency provenance.

Next read the certificate surface of Definition 211.2. Its public ledger is the Cont route recording multiplication and involution observations together with the same hsame and Pkg rows.

Finally apply Definition 211.6. Since the surface has no slot for host $*$-algebra equality, ambient Banach-ring structure, spectrum, or transform data, a public source read must factor through the displayed BEDC rows alone. □

Theorem 211.8 ($\mathsf{CStarAlg}^{\uparrow}$ classifier stability)**.** *Componentwise* hsame *transport of the BanachUp carrier row, the RingUp multiplication row, the involution row, the norm-square compatibility row, the* Cont *ledger, and the* Pkg *provenance preserves the* $\mathsf{CStarAlg}^{\uparrow}$ *classifier and the carrier predicate of Definition 211.1. The transported certificate remains a* $\mathsf{CStarAlg}^{\uparrow}$ *row precisely because each displayed component is transported inside the certificate surface.*

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraBHistCarrier classifier stability`

Proof. Unfold the carrier predicate in Definition 211.1. A transported carrier is accepted when the Banach, multiplication, involution, norm-square, and provenance rows are all transported along their displayed hsame witnesses.

Unfold Definition 211.2. Its classifier is inherited from those same componentwise transports, while the ledger rows are read only through Cont and the dependency provenance remains the displayed Pkg row.

Thus the transported packet satisfies the same carrier predicate and the same certificate classifier. No host star-algebra equality or spectrum datum is introduced, because neither appears among the transported rows. □

Theorem 211.9 ($\mathsf{CStarAlg}^{\uparrow}$ ledger exactness)**.** *The public* $\mathsf{CStarAlg}^{\uparrow}$ *ledger is exhausted by the multiplication row, the involution row, the norm-square compatibility row, the* hsame *transport rows, the finite* Cont *readbacks, and the* Pkg *provenance rows for* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$*. Every downstream* $\mathsf{GelfandDuality}^{\uparrow}$ *or* $\mathsf{VonNeumannAlg}^{\uparrow}$ *citation of* $\mathsf{CStarAlg}^{\uparrow}$ *reads one of those ledger rows, and every listed row is part of the certificate surface.*

Lean4 ✓ `BEDC.Derived.CstaralgebraUp.CstaralgebraBHistCarrier ledger exactness`

Proof. Start from the certificate surface in Definition 211.2. Its ledger records multiplication and involution observations, norm-square compatibility, componentwise transport, finite readback, and dependency provenance.

For downstream consumption, apply Definition 211.4. The consumer boundary exposes exactly the same carrier, source, transport, ledger, and provenance rows to $\mathsf{GelfandDuality}^{\uparrow}$ and $\mathsf{VonNeumannAlg}^{\uparrow}$.

The reverse inclusion is by projection from Definition 211.1: each listed ledger row is a field of the displayed carrier or certificate surface. Spectrum data, weak-operator closure, Hilbert-space representations, and host star-algebra equality are therefore outside the public ledger. □

Closure status for $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$**.**

Constructive story: A C*-algebra row is assembled by placing a certified $\mathsf{Banach}^{\uparrow}$ row and a certified $\mathsf{Ring}^{\uparrow}$ multiplication row over the same BHist source, then adding the displayed involution row, norm-square compatibility row, transport rows, finite continuation readbacks, and dependency provenance. The carrier accepts only histories whose Banach, ring, involution, norm, and provenance fields are all present in that finite packet; host $*$-algebra equality, spectrum data, weak-operator closure, and Hilbert-space representation rows are not carrier fields. Two accepted rows classify together by componentwise hsame transport of the Banach carrier, multiplication, involution, norm-square witness, Cont ledger, and Pkg provenance rather than by equality in an ambient algebra. The source specification is the paired Banach and ring dependency surface, the pattern specification records multiplication, involution, and the norm-square law $\|a^*a\| = \|a\|^2$, and the ledger keeps multiplication and involution observations plus their finite readbacks visible. The five name-certificate obligations come from an accepted packet for inhabitation, the equivalence laws of the displayed component classifiers, and the stability theorem saying that every transported component rebuilds the same $\mathsf{CStarAlg}^{\uparrow}$ carrier row. A packet history h lies in the signature gap of a $\mathsf{CStarAlg}^{\uparrow}$ token p when the source-domain accepts its Banach-ring-involution surface, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the transported multiplication, involution, and norm-square rows are the ones encoded by p. The chapter registers this displayed Banach-ring-involution construction under the name $\mathsf{CStarAlg}^{\uparrow}$; it introduces no host star-algebra primitive, no spectrum, no Gelfand transform, and no standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$, obligation)

Scope closed: The obligation scope binds the $\mathsf{Banach}^{\uparrow}$ and $\mathsf{Ring}^{\uparrow}$ dependency rows, the involution row, norm-square compatibility, componentwise hsame, finite Cont readback, and Pkg provenance of the $\mathsf{CStarAlg}^{\uparrow}$ certificate surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.CStarAlgUp.CStarAlgCertificateSurface\_namecert\_obligation`

Bridge status: none

Not claimed: This chapter does not claim a spectrum, weak-operator closure, Hilbert-space representation, host star-algebra equality, or standard bridge.

Upgrade path: Scoped closure requires primitive binding for the displayed Banach, Ring, involution, norm-square, transport, ledger, and Gelfand or von-Neumann consumer rows.

Chapter 212

A Concrete Naming Certificate for $\mathsf{VonNeumannAlg}^{\uparrow}$

The von Neumann algebra interface $\mathsf{VonNeumannAlg}^{\uparrow}$ packages a unital $*$-subalgebra of $B(H)$ closed in the weak operator topology. It depends on $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ (chapter 211) and $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91).

212.1 Carrier definition

Definition 212.1 (VonNeumannAlgUp BHist carrier)**.** *A* $\mathsf{VonNeumannAlg}^{\uparrow}$ *carrier is a finite* BHist *packet whose rows display the following data:*

a $\mathsf{CStarAlg}^{\uparrow}$ *source row recording the algebra, unit, multiplication, norm, and* $*$*-operation;*

a $\mathsf{Hilbert}^{\uparrow}$ *source row recording the Hilbert carrier and its vector-state probes;*

bounded-operator endpoint rows for each accepted algebra element over the displayed Hilbert carrier;

adjoint and multiplication rows comparing the operator endpoints with the $*$ *and product rows;*

finite weak-operator test rows, each logged as a probe ledger between displayed test vectors;

componentwise hsame *rows,* Cont *readback routes,* Pkg *provenance, and a* NameCert *provenance row.*

The carrier has no coordinate for completed operator topologies, host subalgebras of $B(H)$*, choices of projection lattices, unlogged weak closures, or external equality of von Neumann algebras.*

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier finite packet rows`

212.2 The certificate

Theorem 212.2 (VonNeumannAlgUp carrier obligation)**.** *The carrier of Definition 212.1 is a finite BEDC obligation surface for* $\mathsf{VonNeumannAlg}^{\uparrow}$*. Every exported algebraic, Hilbert, operator-endpoint, adjoint, multiplication, weak-test, transport, continuation, and provenance read is a projection of one displayed* BHist *row.*

Proof. Project the packet row by row. The $\mathsf{CStarAlg}^{\uparrow}$ source supplies the finite algebraic surface: carrier, unit, product, norm, and star rows, together with their hsame comparisons and package provenance.

Project the $\mathsf{Hilbert}^{\uparrow}$ source and the bounded-operator endpoint rows next. Each operator endpoint is indexed by a displayed algebra element and the displayed Hilbert carrier, so it has no independent host subalgebra coordinate.

The remaining rows are the weak-operator probes, Cont readbacks, componentwise hsame transports, Pkg provenance, and the NameCert provenance row. Since the definition lists exactly these coordinates, every consumer-visible read is exhausted by the finite packet. □

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier obligation surface`

Theorem 212.3 (VonNeumannAlgUp weak-operator ledger exactness)**.** *For an accepted* $\mathsf{VonNeumannAlg}^{\uparrow}$ *carrier, every weak-operator comparison visible to a consumer is a finite probe-ledger row between displayed* $\mathsf{Hilbert}^{\uparrow}$ *test-vector rows and displayed bounded-operator endpoint rows. The packet exports no completed weak operator topology and no unlogged limit closure.*

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonNeumannAlgBHistCarrier weak operator ledger exactness`
Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier weak operator ledger exactness`

Proof. Read a visible weak-operator comparison from the public packet. By Definition 212.1, the only weak-operator coordinates are finite probe rows, each naming its two test-vector rows through the $\mathsf{Hilbert}^{\uparrow}$ source and its operator endpoint through the bounded-operator ledger.

The Cont row records the readback route from that probe to the endpoint comparison, and componentwise hsame transports the same finite probe under classified replacement. There is no carrier coordinate for a completed weak topology or an unlogged net of operators, so the visible comparison is exactly the displayed probe ledger. □

Theorem 212.4 (VonNeumannAlgUp star-operation stability)**.** *If two accepted* $\mathsf{VonNeumannAlg}^{\uparrow}$ *carriers are related componentwise by their displayed* hsame *rows, then the bounded-operator endpoint assigned to the* $\mathsf{CStarAlg}^{\uparrow}$ *star row transports to the adjoint endpoint row of the classified carrier, and multiplication endpoints transport along the displayed product rows.*

Proof. Use the $\mathsf{CStarAlg}^{\uparrow}$ source row to read the algebraic star and product coordinates. The carrier stores adjoint and multiplication endpoint rows whose indices are those same displayed algebraic coordinates.

Apply componentwise hsame to the algebra row, Hilbert row, endpoint row, and operation row. The adjoint endpoint is transported along the star coordinate, while the multiplication endpoint is transported along the product coordinate.

The Cont readback route records that the transported endpoint is the one exported by the target packet. Thus classified replacement preserves the star and multiplication surfaces without invoking host equality of operator algebras. □

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier star operation stability`

Theorem 212.5 (VonNeumannAlgUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *obligation surface consists of the finite carrier, the componentwise classifier on its displayed rows, star and multiplication stability, weak-operator probe-ledger exactness,* Cont *readbacks, and* Pkg *provenance for the consumed* $\mathsf{CStarAlg}^{\uparrow}$ *and* $\mathsf{Hilbert}^{\uparrow}$ *certificates.*

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonNeumannAlgBHistCarrier namecert obligation surface`

Proof. Carrier inhabitance is the assertion that the rows listed in Definition 212.1 form a finite packet. The classifier is componentwise hsame on the $\mathsf{CStarAlg}^{\uparrow}$, $\mathsf{Hilbert}^{\uparrow}$, endpoint, operation, probe, continuation, and provenance rows.

Use Definition 212.4 for operation transport and Definition 212.3 for weak-test exactness. The Pkg rows record the dependency certificates consumed by those two reads.

Repacking these rows yields the naming-certificate surface. No additional analytic closure, projection lattice, host subalgebra, or external von Neumann algebra equality is exported. □

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier namecert obligation surface`

Theorem 212.6 (VonNeumannAlgUp downstream boundary)**.** *Any downstream BEDC consumer of a* $\mathsf{VonNeumannAlg}^{\uparrow}$ *certificate can inspect only the finite algebra row, Hilbert row, bounded-operator endpoint rows, adjoint and multiplication rows, weak-operator probe ledgers,* hsame *transports,* Cont *readbacks,* Pkg *rows, and the* NameCert *provenance row displayed by the carrier.*

Proof. Let a downstream read be accepted by the $\mathsf{VonNeumannAlg}^{\uparrow}$ certificate. The read factors through the public carrier projection of Definition 212.2, so it must select one of the rows displayed in Definition 212.1.

If the read concerns weak-operator behavior, Definition 212.3 routes it through a finite probe ledger. If the read concerns algebraic operation stability, Definition 212.4 routes it through the $\mathsf{CStarAlg}^{\uparrow}$ star or product row and the corresponding bounded-operator endpoint.

All remaining reads are transport, continuation, package, or naming-provenance rows. Hence the public boundary is precisely the finite BEDC certificate surface, with no access to completed operator topologies, unlogged weak closures, projection choices, or host subalgebra equality. □

Lean4 ✓ `BEDC.Derived.VonneumannalgebraUp.VonneumannalgebraBHistCarrier downstream boundary`

Closure status for $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$**.**

Constructive story: A $\mathsf{VonNeumannAlg}^{\uparrow}$ packet is generated from a CStarAlgUp algebraic source row, a HilbertUp carrier row, bounded-operator endpoint rows, adjoint and multiplication rows, finite weak-operator probe ledgers, componentwise hsame transport, Cont readback routes, Pkg provenance, and local NameCert provenance. The classifier reads operator-algebra structure only through these finite BEDC rows: weak comparison is a displayed probe ledger between Hilbert test vectors, and operation stability transports the CStar star and product rows to corresponding bounded-operator endpoints. The ledger story is weak-operator visibility without completed topology, projection-lattice choice, unlogged closure, or host subalgebra equality.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$, seed)

Scope closed: This chapter binds the BHist carrier definition and the carrier-obligation, weak-operator-ledger, star-stability, NameCert-surface, and downstream-boundary theorems for $\mathsf{VonNeumannAlg}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim completed operator topologies, host subalgebras of $B(H)$, choices of projection lattices, unlogged weak closures, or external equality of von Neumann algebras.

Upgrade path: To reach obligationClosure, the checked component lemmas must be assembled into a formal chapter-level closure theorem for the finite operator packet.

Chapter 213

A Concrete Naming Certificate for $\mathsf{OperatorIdeal}^{\uparrow}$

The operator-ideal interface $\mathsf{OperatorIdeal}^{\uparrow}$ packages a two-sided ideal of bounded operators on a Hilbert space carrier (compact, trace class, Hilbert-Schmidt). It depends on $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91) and $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ (chapter 81).

213.1 Carrier definition

Definition 213.1 (OperatorIdeal Hilbert source surface)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier supplied by $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$, with Hilbert carrier predicate C_H, classifier $\sim_H$, vector addition, additive inverse, zero, scalar action, and inner-product norm rows. Let $\mathsf{Op}_H(T)$ be a BHist predicate whose endpoints are bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ map-codes. The operator-ideal source surface over H is the ten-field $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ inventory with the following rows.*

1. *The traditional target is a two-sided ideal of bounded Hilbert operators on H.*
2. *The BEDC source is $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ together with $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ read over the bounded-operator composition ring on H.*
3. *The carrier is the predicate Op_H on bounded-operator rows $H \to H$.*
4. *The classifier is inherited from the Hilbert and linear-map classifier: $T \sim_{\mathsf{Op}(H)} S$ means pointwise $\sim_H$ agreement on every carried Hilbert endpoint after both map-codes are certified bounded and linear.*
5. *The stability rows are the bounded zero operator, addition, negation, scalar action where the Hilbert module row is consumed, and composition on the left and on the right by every carried bounded operator.*
6. *The ledger records the Hilbert source certificate, the $\mathsf{LinMap}^{\uparrow}(H, H)$ row, the ideal-membership witness for the selected predicate, and the two composition witnesses for left and right multiplication.*
7. *The core theorem rows are the carrier support, additive closure, two-sided absorption, and downstream trace-class boundary rows in section 213.2.*
8. *Exactness is row exhaustion: an accepted operator-ideal endpoint exposes only the Hilbert source, bounded linear-map row, ideal membership, classifier transport, additive rows, scalar rows, and*

the two bounded composition witnesses displayed here.

9. *The standard bridge row is absent at this paper site.*
10. *The boundary package is the trace-class-ready operator-ideal surface consumed by* $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, *and* $\mathsf{QuantumChannel}^{\uparrow}$.

Definition 213.2 (Trace-class operator-ideal carrier)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* Op_H *be the bounded-operator carrier from Definition 213.1. A trace-class carrier over H is the subcarrier*

$$\mathsf{TC}(H)(T) :\Longleftrightarrow \mathsf{Op}_H(T) \wedge \mathsf{TraceClassIdeal}_H(T),$$

where $\mathsf{TraceClassIdeal}_H$ *is an* $\mathsf{Ideal}^{\uparrow}$ *predicate over the bounded-operator composition ring carried by* Op_H*. Its classifier is the restriction of* $\sim_{\mathsf{Op}(H)}$*, and its ledger contains the bounded-operator witness for T together with the* $\mathsf{Ideal}^{\uparrow}$ *membership witness* $\mathsf{TraceClassIdeal}_H(T)$*.*

213.2 The certificate

Theorem 213.3 (OperatorIdeal carrier support row)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. If* $\mathsf{TC}(H)(T)$*, then T is carried by the bounded-operator carrier over H:*

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{Op}_H(T).$$

Proof. Unpack Definition 213.2. A trace-class witness is a pair consisting of the bounded-operator row $\mathsf{Op}_H(T)$ and an $\mathsf{Ideal}^{\uparrow}$ membership witness $\mathsf{TraceClassIdeal}_H(T)$.

Projecting the first component gives the displayed bounded-operator carrier support. No analytic trace row is used; the result is exactly the support projection from the carrier definition. □

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass support readback`

Theorem 213.4 (OperatorIdeal additive closure row)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. The* $\mathsf{OperatorIdeal}^{\uparrow}$ *certificate supplies the trace-class zero, additive, and negation rows:*

$$\mathsf{TC}(H)(0_H),$$

$$\mathsf{TC}(H)(T) \wedge \mathsf{TC}(H)(S) \Longrightarrow \mathsf{TC}(H)(T +_H S),$$

and

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(-_H T).$$

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass additive closure row`

Proof. Read $\mathsf{TC}(H)$ as the $\mathsf{Ideal}^{\uparrow}$ predicate $\mathsf{TraceClassIdeal}_H$ over the bounded-operator composition ring from Definition 213.2. The zero row of the $\mathsf{Ideal}^{\uparrow}$ predicate gives membership of the bounded zero operator; the bounded-operator surface of Definition 213.1 supplies its Op_H carrier witness.

For addition, two trace-class witnesses project to two ideal-membership witnesses. The additive closure row of $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ gives membership for $T +_H S$, while the bounded linear-map rows inherited from $\mathsf{Hilbert}^{\uparrow}$ and $\mathsf{LinMap}^{\uparrow}$ carry the sum as a bounded operator.

For negation, project the additive inverse row of the same $\mathsf{Ideal}^{\uparrow}$ predicate and pair it with the bounded negation row from the operator surface. These paired rows are precisely the three displayed $\mathsf{TC}(H)$ clauses. □

Theorem 213.5 (OperatorIdeal two-sided absorption row)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. If A is a carried bounded operator on H and T is trace-class on H, then both composites are trace-class:*

$$\mathsf{Op}_H(A) \wedge \mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(A \circ T) \wedge \mathsf{TC}(H)(T \circ A).$$

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass two sided absorption row`

Proof. Unpack the trace-class witness for T. It supplies the bounded-operator row $\mathsf{Op}_H(T)$ and the ideal-membership row $\mathsf{TraceClassIdeal}_H(T)$.

The input $\mathsf{Op}_H(A)$ is exactly the ambient carried endpoint required by the two-sided absorption field of $\mathsf{NameCert}_{\mathsf{Ideal}^{\uparrow}}$ over the bounded-operator composition ring. Projecting that field gives ideal membership for both $A \circ T$ and $T \circ A$.

The bounded composition rows of Definition 213.1 carry the two composites as bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ map-codes. Pairing these carrier witnesses with the two projected ideal-membership witnesses gives $\mathsf{TC}(H)(A \circ T)$ and $\mathsf{TC}(H)(T \circ A)$. □

Theorem 213.6 (DensityMatrix trace-class dependency boundary)**.** *The downstream* $\mathsf{DensityMatrix}^{\uparrow}$ *and* $\mathsf{QuantumChannel}^{\uparrow}$ *chapters may consume from* $\mathsf{OperatorIdeal}^{\uparrow}(H)$ *only the trace-class carrier* $\mathsf{TC}(H)$ *of Definition 213.2, its classifier transport from* $\sim_{\mathsf{Op}(H)}$*, the zero, addition, negation, and real scalar/module rows inherited through* $\mathsf{Hilbert}^{\uparrow}$ *and* $\mathsf{LinMap}^{\uparrow}$*, and the two-sided absorption row of Definition 213.5. Positivity rows, trace rows, and trace-one rows belong to the downstream chapters themselves. This boundary does not claim compactness, a spectral theorem, trace existence, or a standard operator-algebra bridge.*

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass downstream boundary readback`

Proof. Inspect the ten-field surface in Definition 213.1. Its exactness field says that an operator-ideal endpoint exposes only the Hilbert source, bounded linear-map row, ideal membership, classifier transport, additive rows, scalar rows, and left and right bounded-composition witnesses.

The trace-class carrier in Definition 213.2 further restricts that surface to the $\mathsf{Ideal}^{\uparrow}$ predicate $\mathsf{TraceClassIdeal}_H$. Therefore the support, additive, and absorption theorems above are the available projections for downstream use.

The positivity predicate Pos_H, the trace functional Tr_H, and the trace-one equation are not fields of either displayed OperatorIdeal inventory. They are introduced only when $\mathsf{DensityMatrix}^{\uparrow}$ and $\mathsf{QuantumChannel}^{\uparrow}$ state their own carrier and certificate rows, so none of compactness, spectral decomposition, trace existence, or a standard bridge is exported by this chapter. □

Theorem 213.7 (OperatorIdeal trace-class scalar closure)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. Let a be a carried* $\mathsf{Real}^{\uparrow}$ *scalar endpoint for the Hilbert module action. Write $M_a : H \to H$ for the bounded Hilbert scalar-action endomorphism carried by the scalar row of Definition 213.1,*

$$M_a(x) := a \cdot_H x,$$

and let the induced trace-class scalar action on operators be

$$a \odot_H T := M_a \circ T.$$

Then trace-class membership is closed under this scalar action:

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(a \odot_H T).$$

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass scalar closure`

Proof. The carried scalar hypothesis gives a certified scalar-action row on the Hilbert module surface. Read as a map in the bounded-operator composition ring, that row carries the homothety M_a as a bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ endpoint; in the notation of Definition 213.1, this is the ambient witness $\mathsf{Op}_H(M_a)$.

Now assume $\mathsf{TC}(H)(T)$. By Definition 213.2, this witness consists of a bounded-operator carrier row $\mathsf{Op}_H(T)$ and an ideal-membership row $\mathsf{TraceClassIdeal}_H(T)$ inside the bounded-operator composition ring.

Apply Definition 213.5 with the carried ambient operator $A = M_a$. The left absorption component gives

$$\mathsf{TC}(H)(M_a \circ T),$$

while the right component gives $\mathsf{TC}(H)(T \circ M_a)$ and is not needed here.

The displayed definition of the inherited scalar action identifies $M_a \circ T$ with $a \odot_H T$. The classifier-transport row for the ideal predicate in Definition 81.16 carries the obtained trace-class witness across that endpoint identity, giving

$$\mathsf{TC}(H)(a \odot_H T).$$

□

Definition 213.8 (OperatorIdeal root BHist threshold source)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier and let $\mathsf{TC}(H)$ be the trace-class carrier of Definition 213.2. The root* BHist *threshold source for $\mathsf{OperatorIdeal}^{\uparrow}(H)$ is the ten-field package with the following rows.*

1. *The traditional target is the two-sided operator ideal surface on Hilbert carriers.*
2. *The BEDC source is $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{Ideal}^{\uparrow}$, and the ambient* NameCert *discipline for row transport.*
3. *The carrier row is the bounded Hilbert-operator carrier Op_H together with its trace-class subcarrier $\mathsf{TC}(H)$.*
4. *The classifier row is $\sim_{\mathsf{Op}(H)}$, read as pointwise $\sim_H$ agreement after the two endpoints are certified as bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ codes.*
5. *The stability rows are bounded zero, addition, negation, real scalar action, left composition by a carried bounded operator, and right composition by a carried bounded operator.*
6. *The ledger rows are the Hilbert source certificate, the bounded linear-map certificate, the $\mathsf{Ideal}^{\uparrow}$ membership witness $\mathsf{TraceClassIdeal}_H$, and the two bounded-composition witnesses.*
7. *The core rows are the support, additive closure, two-sided absorption, scalar closure, and downstream-boundary theorems of section 213.2.*
8. *Exactness is row exhaustion: no endpoint accepted at this threshold exposes a field beyond the carrier, classifier, stability, ledger, and core rows displayed here.*
9. *The standard bridge row is absent.*
10. *The downstream consumers are $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, and $\mathsf{QuantumChannel}^{\uparrow}$.*

Theorem 213.9 (OperatorIdeal root carrier-classifier threshold)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier. The root* BHist *threshold source of Definition 213.8 exposes only bounded Hilbert-operator endpoints coded by* BHist*, pointwise classifier transport inherited from the Hilbert and* $\mathsf{LinMap}^{\uparrow}$ *rows, and trace-class support through* $\mathsf{TC}(H)$*. In particular,*

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{Op}_H(T),$$

and every classifier comparison at this threshold is a $\sim_{\mathsf{Op}(H)}$ *comparison between certified bounded* $\mathsf{LinMap}^{\uparrow}(H, H)$ *endpoints.*

Proof. Unpack the root threshold source in Definition 213.8. Its carrier row is exactly the bounded Hilbert-operator predicate Op_H plus the trace-class subcarrier $\mathsf{TC}(H)$, while its classifier row is the pointwise Hilbert classifier transported along certified bounded linear maps.

Projecting Definition 213.1 gives the BHist-coded bounded operator surface and its $\sim_{\mathsf{Op}(H)}$ classifier. Projecting Definition 213.2 gives the trace-class pair consisting of $\mathsf{Op}_H(T)$ and $\mathsf{TraceClassIdeal}_H(T)$.

The displayed support implication is precisely Definition 213.3. Since the root exactness row admits no further carrier or classifier field, these are the only carrier-classifier rows visible at the threshold. □

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass root carrier classifier threshold`

Theorem 213.10 (OperatorIdeal root ideal-absorption threshold)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier. Through the trace-class carrier* $\mathsf{TC}(H)$*, the root* BHist *threshold exposes exactly the* $\mathsf{Ideal}^{\uparrow}$ *rows needed for zero, addition, negation, real scalar closure, and two-sided absorption by carried bounded operators:*

$$\mathsf{TC}(H)(0_H),$$

$$\mathsf{TC}(H)(T) \wedge \mathsf{TC}(H)(S) \Longrightarrow \mathsf{TC}(H)(T +_H S),$$

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(-_H T),$$

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(a \odot_H T),$$

and

$$\mathsf{Op}_H(A) \wedge \mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(A \circ T) \wedge \mathsf{TC}(H)(T \circ A).$$

Proof. The trace-class carrier of Definition 213.2 packages a bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ endpoint together with the $\mathsf{Ideal}^{\uparrow}$ membership predicate $\mathsf{TraceClassIdeal}_H$. The root ledger of Definition 213.8 records that membership row and the left and right bounded-composition witnesses.

The zero, addition, and negation clauses are exactly the three projections supplied by Definition 213.4. They use the IdealUp membership row paired with the bounded operator rows from the Hilbert and linear-map source.

The scalar clause is Definition 213.7: the carried scalar action is read as a bounded endomorphism and then absorbed on the left. The final displayed clause is Definition 213.5, applied to the carried ambient operator A and the trace-class endpoint T.

The exactness row in the root source excludes any further ideal operation at this threshold. Thus the displayed additive, scalar, and absorption clauses are the full ideal surface available through $\mathsf{TC}(H)$. □

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass root ideal absorption threshold`

Theorem 213.11 (OperatorIdeal root downstream-face boundary)**.** *The downstream chapters* $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, *and* $\mathsf{QuantumChannel}^{\uparrow}$ *may consume from the root* BHist *threshold for* $\mathsf{OperatorIdeal}^{\uparrow}(H)$ *only the carrier* $\mathsf{TC}(H)$*, the classifier transport* $\sim_{\mathsf{Op}(H)}$*, the zero, addition, negation, scalar, and two-sided absorption rows, and the bounded Hilbert source ledger. They receive no positivity row, no trace row, no trace-one row, no compactness row, no spectral-theorem row, no trace-existence row, and no standard bridge row from this package.*

Proof. Start with the exactness field of Definition 213.8. It lists the carrier, classifier, stability, ledger, and core rows and states that no accepted endpoint exposes anything beyond those rows.

The carrier and classifier part is fixed by Definition 213.9. The ideal-operation part is fixed by Definition 213.10: zero, addition, negation, scalar closure, and two-sided absorption are the available trace-class rows.

The earlier dependency boundary Definition 213.6 already separates $\mathsf{DensityMatrix}^{\uparrow}$ and $\mathsf{QuantumChannel}^{\uparrow}$ from positivity, trace, trace-one, compactness, spectral, trace-existence, and standard bridge claims. The root source names $\mathsf{Nuclear}^{\uparrow}$ as a consumer of the same $\mathsf{TC}(H)$ face, so the identical boundary applies to that consumer as well. □

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass root downstream face boundary`

Theorem 213.12 (Trace-class binary linear-combination closure)**.** *Let* H *be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. Write* $+_{\mathsf{TC}(H)}$ *for the trace-class addition inherited from the operator-ideal additive row, and use the real trace-class scalar action* $\odot_H$ *of Definition 213.7. Let* T *and* S *be operator endpoints, and let* a *and* b *be carried* $\mathsf{Real}^{\uparrow}$ *scalar endpoints for the Hilbert module action. If*

$$\mathsf{TC}(H)(T) \wedge \mathsf{TC}(H)(S),$$

then

$$\mathsf{TC}(H)\big((a \odot_H T) +_{\mathsf{TC}(H)} (b \odot_H S)\big).$$

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass binary linear combination closure`

Proof. Assume the two trace-class witnesses. Applying Definition 213.7 to the carried scalar a and the endpoint T gives

$$\mathsf{TC}(H)(a \odot_H T).$$

Applying the same scalar-closure row to the carried scalar b and the endpoint S gives

$$\mathsf{TC}(H)(b \odot_H S).$$

The operation $+_{\mathsf{TC}(H)}$ is the restriction of the bounded-operator addition row named in Definition 213.1 to endpoints carrying the trace-class predicate of Definition 213.2. Therefore the additive closure row of Definition 213.4, applied to the two scalar-multiple witnesses displayed above, gives

$$\mathsf{TC}(H)\big((a \odot_H T) +_{\mathsf{TC}(H)} (b \odot_H S)\big).$$

Only the trace-class ideal membership, scalar closure, and additive closure rows are used; positivity, trace, and trace-one rows remain outside this operator-ideal claim. □

Definition 213.13 (OperatorIdeal trace-class consumer spine source)**.** *Let* H *be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. The trace-class consumer spine for* $\mathsf{OperatorIdeal}^{\uparrow}(H)$ *is the concrete downstream-facing package with the following rows.*

1. *The carrier row is* $\mathsf{TC}(H)$.
2. *The classifier row is the restricted operator classifier* $\sim_{\mathsf{Op}(H)}$ *on certified bounded* $\mathsf{LinMap}^{\uparrow}(H, H)$ *endpoints.*
3. *The algebra rows are the trace-class zero endpoint, addition, negation, real scalar action* $\odot_H$*, and binary linear-combination closure.*
4. *The absorption rows are left and right composition by any carried bounded Hilbert operator.*
5. *The ledger row is the bounded Hilbert source ledger: the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *carrier, the bounded* $\mathsf{LinMap}^{\uparrow}(H, H)$ *certificate, the trace-class* $\mathsf{Ideal}^{\uparrow}$ *membership witness, and the two bounded-composition witnesses.*
6. *The only consumer slots are* $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, *and* $\mathsf{QuantumChannel}^{\uparrow}$.

No positivity, trace, trace-one, nuclearity, complete-positivity, compactness, spectral, trace-existence, or standard bridge row is part of this source.

Theorem 213.14 (OperatorIdeal trace-class consumer spine coverage)**.** *Every row of the trace-class consumer spine of Definition 213.13 is covered by the root* BHist *threshold source of Definition 213.8, the carrier-classifier threshold of Definition 213.9, the ideal-absorption threshold of Definition 213.10, and the binary linear-combination closure of Definition 213.12.*

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass consumer spine coverage`

Proof. We first build the carrier and classifier part of the spine. The source in Definition 213.8 names $\mathsf{TC}(H)$ as the trace-class subcarrier over bounded Hilbert operators, and Definition 213.9 identifies the visible classifier as $\sim_{\mathsf{Op}(H)}$ on certified bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ endpoints.

Next we build the algebra and absorption rows. The zero, addition, negation, scalar action, and two-sided composition rows are exactly the displayed rows of Definition 213.10. The binary linear-combination row is Definition 213.12, which repacks scalar closure and addition into the two-term downstream form.

It remains to account for the ledger and consumer slots. The ledger row is one of the named rows of Definition 213.8: it records the Hilbert source certificate, the bounded linear-map certificate, the trace-class ideal-membership witness, and the two bounded-composition witnesses. The same source names $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, and $\mathsf{QuantumChannel}^{\uparrow}$ as the downstream consumers, so every spine row is a projection of the cited root package and its displayed threshold theorems. □

Theorem 213.15 (OperatorIdeal trace-class consumer row separation)**.** *The trace-class consumer spine of Definition 213.13 contains none of the following downstream rows:*

1. *positivity, trace, and trace-one rows for* $\mathsf{DensityMatrix}^{\uparrow}$*;*
2. *nuclearity and trace-existence rows for* $\mathsf{Nuclear}^{\uparrow}$*;*
3. *complete-positivity and standard bridge rows for* $\mathsf{QuantumChannel}^{\uparrow}$*;*
4. *compactness and spectral rows for analytic refinements of the trace-class face.*

Each listed row must be supplied by the corresponding consumer chapter rather than imported from $\mathsf{OperatorIdeal}^{\uparrow}(H)$.

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealBoundedContextAction row separation`

Proof. Inspect the source rows in Definition 213.13. The enumerated spine contains only $\mathsf{TC}(H)$, the restricted classifier $\sim_{\mathsf{Op}(H)}$, the zero, addition, negation, scalar, binary linear-combination, and two-sided absorption rows, together with the bounded Hilbert ledger and the three consumer slots.

The same absence is forced by the upstream boundary. Definition 213.11 states that the root threshold sends no positivity, trace, trace-one, compactness, spectral, trace-existence, or standard bridge row downstream. The definition of the spine is a subpackage of that boundary, so it cannot contain a row excluded by the root face.

For nuclearity and complete positivity, the separation is by row name and dependency. Nuclearity is not one of the ideal-membership, bounded-composition, additive, scalar, carrier, or classifier rows in the spine. Complete positivity is likewise absent because the spine contains no matrix-amplification or positive-cone preservation row. Therefore the named analytic and quantum rows must be supplied by $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, and $\mathsf{QuantumChannel}^{\uparrow}$ at their own paper sites. □

Theorem 213.16 (OperatorIdeal trace-class consumer exhaustion)**.** *Every allowed downstream use of* $\mathsf{OperatorIdeal}^{\uparrow}(H)$ *by* $\mathsf{DensityMatrix}^{\uparrow}$*,* $\mathsf{Nuclear}^{\uparrow}$*, or* $\mathsf{QuantumChannel}^{\uparrow}$ *factors through exactly the trace-class carrier and classifier rows, the additive, scalar, and absorption rows, the binary linear-combination closure, and the bounded Hilbert source ledger displayed in Definition 213.13.*

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass consumer exhaustion`

Proof. Let a downstream use be accepted by one of the three consumer slots in Definition 213.13. By the definition of the slot, the use must read an endpoint through $\mathsf{TC}(H)$, compare endpoints through $\sim_{\mathsf{Op}(H)}$, apply one of the displayed algebra or absorption rows, or inspect the bounded Hilbert ledger.

The factorization is obtained by cases on that row access. Carrier and classifier accesses factor through Definition 213.9. Zero, addition, negation, scalar action, and two-sided absorption factor through Definition 213.10. A two-term scalar linear combination factors through Definition 213.12. Ledger access factors through the ledger row of Definition 213.8.

No remaining case exists. The exactness clause of Definition 213.8 says that the root threshold exposes no row beyond its carrier, classifier, stability, ledger, and core rows, and Definition 213.15 removes the analytic and quantum rows from the spine. Thus every allowed downstream use is exhausted by the listed carrier, classifier, operation, absorption, closure, and ledger factors. □

Definition 213.17 (OperatorIdeal bounded-context action spine)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2. A bounded-context action spine over H is the finite freely generated context package* BCtx_H *with the following constructors:*

1. *the identity context* $\mathsf{id}_{\mathsf{BCtx}}$*;*
2. *if $K \in \mathsf{BCtx}_H$ and* $\mathsf{Op}_H(A)$*, the left-composition context* $\mathsf{L}_A(K)$*;*
3. *if $K \in \mathsf{BCtx}_H$ and* $\mathsf{Op}_H(A)$*, the right-composition context* $\mathsf{R}_A(K)$*.*

Its endpoint action on a trace-class input T is defined by structural recursion:

$$\mathsf{id}_{\mathsf{BCtx}}[T] = T,$$

$$\mathsf{L}_A(K)[T] = A \circ K[T],$$

and

$$\mathsf{R}_A(K)[T] = K[T] \circ A.$$

Thus BCtx_H *records exactly a finite list of certified bounded Hilbert-operator compositions around a trace-class endpoint, with no positivity, trace, nuclearity, complete-positivity, compactness, spectral, or bridge row.*

Theorem 213.18 (OperatorIdeal trace-class finite context closure)**.** *Let* H *be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, let* $\mathsf{TC}(H)$ *be the trace-class carrier of Definition 213.2, and let* $K \in \mathsf{BCtx}_H$ *be a bounded-context action spine of Definition 213.17. If* $\mathsf{TC}(H)(T)$*, then the endpoint obtained by applying* K *to* T *is again trace-class:*

$$\mathsf{TC}(H)(T) \Longrightarrow \mathsf{TC}(H)(K[T]).$$

Proof. Proceed by structural induction on the bounded-context action spine K.

In the identity case, the endpoint action is $\mathsf{id}_{\mathsf{BCtx}}[T] = T$. The required trace-class witness is exactly the input witness $\mathsf{TC}(H)(T)$.

For the left-composition step, write the context as $\mathsf{L}_A(K_0)$ with $\mathsf{Op}_H(A)$. The induction hypothesis gives $\mathsf{TC}(H)(K_0[T])$. Apply the left component of Definition 213.5 to the carried bounded operator A and the trace-class endpoint $K_0[T]$; the result is

$$\mathsf{TC}(H)(A \circ K_0[T]).$$

By the endpoint action defining $\mathsf{L}_A(K_0)[T]$, this is the desired witness for $\mathsf{TC}(H)(\mathsf{L}_A(K_0)[T])$.

For the right-composition step, write the context as $\mathsf{R}_A(K_0)$ with $\mathsf{Op}_H(A)$. The induction hypothesis again gives $\mathsf{TC}(H)(K_0[T])$. Apply the right component of Definition 213.5 to A and $K_0[T]$ to obtain

$$\mathsf{TC}(H)(K_0[T] \circ A).$$

The endpoint action for $\mathsf{R}_A(K_0)$ identifies this endpoint with $\mathsf{R}_A(K_0)[T]$. These three cases exhaust the finite spine constructors. □

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass finite context closure`

Theorem 213.19 (OperatorIdeal consumer context exhaustion)**.** *Every downstream use by* $\mathsf{DensityMatrix}^{\uparrow}$*,* $\mathsf{Nuclear}^{\uparrow}$*, or* $\mathsf{QuantumChannel}^{\uparrow}$ *that starts from a trace-class endpoint and repeatedly composes it with finitely many carried bounded Hilbert operators factors through the bounded-context action spine of Definition 213.17 and the finite context closure theorem of Definition 213.18.*

Lean4 ✓ `BEDC.Derived.OperatorIdealUp.OperatorIdealBoundedContextAction consumer context exhaustion`

Proof. Let the downstream use be accepted by one of the consumer slots of Definition 213.13, and assume that its operator action consists only of finitely many left or right compositions by carried bounded Hilbert operators.

First encode the action as a bounded-context spine. The empty list of compositions is the identity constructor. Adding a left composition by a carried $\mathsf{Op}_H(A)$ applies the constructor L_A, and adding a right composition by the same kind of carried operator applies the constructor R_A. Finite repetition therefore builds an element $K \in \mathsf{BCtx}_H$ whose endpoint action is the downstream endpoint.

Next apply Definition 213.18. Starting from the input witness $\mathsf{TC}(H)(T)$, the theorem gives $\mathsf{TC}(H)(K[T])$, so the finite bounded-context action preserves the trace-class carrier exposed to the consumer.

It remains to account for the consumer rows. Carrier, classifier, additive, scalar, binary linear-combination, absorption, and ledger accesses are exactly the rows exhausted by Definition 213.16. The repeated-composition part of such an access is the bounded-context spine just constructed,

while analytic rows remain absent by Definition 213.15. Hence no allowed $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Nuclear}^{\uparrow}$, or $\mathsf{QuantumChannel}^{\uparrow}$ bounded-context use lies outside the displayed spine and closure package. □

Closure status for $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$.

Constructive story: An operator ideal is generated over a certified Hilbert carrier by first admitting bounded operator histories and then restricting to the trace-class subcarrier witnessed by an $\mathsf{Ideal}^{\uparrow}$ membership row inside the bounded-operator composition ring. The carrier accepts a trace-class endpoint only when a unary support history is displayed and continued by the empty tail to the endpoint, together with the Hilbert, linear-map, ideal-membership, scalar, and left/right composition rows; positivity, trace, trace-one, compactness, spectral data, and nuclearity are not accepted here. Two operator endpoints are classified through the Hilbert and linear-map classifiers, meaning pointwise agreement on carried Hilbert endpoints after both map-codes have bounded-operator evidence, with the trace-class witness transported along the same ideal row. The source is the $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, and $\mathsf{Ideal}^{\uparrow}$ surface, the pattern records zero, addition, negation, scalar closure, two-sided absorption, and finite bounded-context action, and the ledger keeps the bounded support, ideal membership, scalar action, composition witnesses, and consumer-row separation visible. The five obligations follow from the zero trace-class carrier, the equivalence behavior of the inherited operator classifier, and the finite-context closure theorem, which repacks every classified left or right composition as another trace-class endpoint. A history h lies in the signature gap of an $\mathsf{OperatorIdeal}^{\uparrow}$ token p when the source-domain accepts the Hilbert operator and ideal-membership rows, the signature relation pairs the trace-class endpoint with an answer endpoint and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records the same bounded support and finite ideal-action ledger. The chapter registers this trace-class operator-ideal surface under the name $\mathsf{OperatorIdeal}^{\uparrow}$; downstream analytic chapters may consume only these rows, with no trace functional, positivity predicate, CPTP row, or bridge data added.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature scope binds support, classifier transport, additive closure, scalar closure, two-sided absorption, finite bounded-context closure, consumer-row separation, exact consumer exhaustion, and the consumer-context exhaustion row supplied by Definition 213.19.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.OperatorIdealUp.OperatorIdealTraceClass\_consumer\_exhaustion`

Bridge status: none

Not claimed: Positivity, trace, trace-one, compactness, spectral theorem, nuclearity, CPTP rows, and bridge data remain outside this chapter.

Upgrade path: No further theory-axis upgrade remains for the displayed $\mathsf{OperatorIdeal}^{\uparrow}$ trace-class surface.

Chapter 214

A Concrete Naming Certificate for $\mathsf{SpectralTheorem}^{\uparrow}$

The spectral-theorem interface $\mathsf{SpectralTheorem}^{\uparrow}$ packages the diagonalisation data of a self-adjoint or normal bounded operator: spectrum, projection-valued measure, and functional calculus. It depends on $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91) and $\mathsf{NameCert}_{\mathsf{Measure}^{\uparrow}}$ (chapter 92).

214.1 Carrier definition

214.2 The certificate

Theorem 214.1 (SpectralTheoremUp carrier and classifier obligations)**.** *The* $\mathsf{SpectralTheorem}^{\uparrow}$ *certificate carrier is the* $\mathsf{Hilbert}^{\uparrow}$ *operator row restricted to displayed self-adjoint-or-normal operator witnesses. Its classifier row is read through the* $\mathsf{Hilbert}^{\uparrow}$ *operator classifier, together with* $\mathsf{Measure}^{\uparrow}$*-compatible spectral data: two carried operator histories are admissibly compared only when the operator classifier identifies them and the spectrum, projection-valued-measure, and functional-calculus rows are presented over the same measured spectral side.*

Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremEmptySpectrum calculus endpoint`
Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremOperatorSpectralData carrier classifier`

Proof. The obligation is the carrier-and-classifier portion of the roadmap ten-field template.

1. Traditional target: the spectral theorem for a self-adjoint or normal bounded operator.
2. BEDC source: the certified $\mathsf{Hilbert}^{\uparrow}$ operator package together with the certified $\mathsf{Measure}^{\uparrow}$ spectral-measure package.
3. Carrier: the $\mathsf{Hilbert}^{\uparrow}$ operator row, restricted by a displayed self-adjoint-or-normal witness.
4. Classifier: the $\mathsf{Hilbert}^{\uparrow}$ operator classifier, with comparison accepted only when the accompanying spectral rows are measured in the same $\mathsf{Measure}^{\uparrow}$-compatible fiber.
5. Stability: transport of the operator row and the self-adjoint-or-normal witness along the operator classifier.
6. Ledger: the hidden operator-domain witness and the measured spectral-side witness used by the comparison.

7. Core theorem list: carrier restriction, classifier readback, and compatibility of operator comparison with the spectral rows.
8. Exactness: coverage and soundness for precisely those displayed carrier and classifier rows.
9. Standard bridge: none.
10. Status: paper obligation.

Thus the carrier is not a host-level operator space and the classifier is not a host-level equality. Both are certificate rows inherited from the displayed $\mathsf{Hilbert}^{\uparrow}$ and $\mathsf{Measure}^{\uparrow}$ sources. □

Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremSingleton carrier classifier obligation`
Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremCarrierClassifier obligation`
Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremOperator measure row readback`

Theorem 214.2 (SpectralTheoremUp spectrum, projection measure, and functional-calculus obligations)**.** *The core theorem list for* $\mathsf{SpectralTheorem}^{\uparrow}$ *must supply spectrum rows, projection-valued-measure rows, and functional-calculus rows. Each row is scoped over the certified* $\mathsf{Hilbert}^{\uparrow}$ *operator carrier and the certified* $\mathsf{Measure}^{\uparrow}$ *measurable-side carrier, not over a host spectral theorem: the spectrum row displays the accepted spectral support, the projection-valued-measure row displays the measured projection assignment, and the functional-calculus row displays the calculus action compatible with both.*

Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremProjectionMeasure functional calculus empty`

Proof. The obligation is the spectral-data portion of the roadmap ten-field template.

1. Traditional target: spectrum, projection-valued measure, and bounded functional calculus for the carried operator.
2. BEDC source: $\mathsf{Hilbert}^{\uparrow}$ for the operator and projection endpoints, plus $\mathsf{Measure}^{\uparrow}$ for measurable spectral rows.
3. Carrier: the operator carrier of Definition 214.1, together with the displayed spectral-support carrier.
4. Classifier: operator comparison through the $\mathsf{Hilbert}^{\uparrow}$ classifier and measurable-row comparison through the $\mathsf{Measure}^{\uparrow}$ classifier.
5. Stability: transport of spectral support, projection rows, and calculus rows along accepted operator comparisons.
6. Ledger: the hidden spectrum witness, the hidden projection-valued-measure witness, and the hidden functional-calculus witness.
7. Core theorem list: spectrum coverage, projection-valued-measure assignment, calculus closure, and compatibility of calculus with the displayed projections.
8. Exactness: coverage, soundness, and completeness for the displayed spectrum, projection-valued-measure, and calculus rows.
9. Standard bridge: none.
10. Status: paper obligation.

The displayed rows are therefore obligations of the BEDC certificate itself. They do not import a completed external spectral theorem; they state the exact rows that later paper and Lean work must discharge inside the named sources. □

Theorem 214.3 (SpectralTheoremUp stability, ledger, and exactness obligations)**.** *For* $\mathsf{SpectralTheorem}^{\uparrow}$*, stability must transport the operator row, spectrum row, projection-valued-measure row, and functional-calculus row along the classifier of Definition 214.1. The ledger records the hidden spectrum, projection-valued-measure, and functional-calculus witnesses. Exactness is coverage, soundness, and completeness for those displayed rows, with dependency rows naming the* $\mathsf{Hilbert}^{\uparrow}$ *and* $\mathsf{Measure}^{\uparrow}$ *sources.*

Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremCarrier classifier transport`

Proof. The obligation is the transport, provenance, and exactness portion of the roadmap ten-field template.

1. Traditional target: invariance of spectral data under equality of the carried operator.
2. BEDC source: $\mathsf{Hilbert}^{\uparrow}$ for operator and projection transport, plus $\mathsf{Measure}^{\uparrow}$ for measurable spectral transport.
3. Carrier: the restricted self-adjoint-or-normal operator carrier and the three spectral-data carriers.
4. Classifier: the operator classifier together with the compatible measurable-side classifier rows.
5. Stability: simultaneous transport of operator, spectrum, projection-valued-measure, and functional-calculus rows.
6. Ledger: hidden witnesses for spectral support, projection assignment, calculus action, and their dependency rows.
7. Core theorem list: transport rows, ledger readback rows, dependency rows, and rowwise exactness clauses.
8. Exactness: coverage, soundness, and completeness for the displayed operator, spectrum, projection-valued-measure, and functional-calculus rows.
9. Standard bridge: none.
10. Status: paper obligation.

Combining these rows with Definition 214.2 gives the full obligation boundary: every hidden spectral datum has a ledger row, every displayed row has an exactness clause, and every dependency is attached to either $\mathsf{Hilbert}^{\uparrow}$ or $\mathsf{Measure}^{\uparrow}$. □

Theorem 214.4 (SpectralTheoremUp public certificate)**.** *The carrier and classifier obligations of Definition 214.1, the spectrum, projection-valued-measure, and functional-calculus obligations of Definition 214.2, and the stability, ledger, exactness, and dependency obligations of Definition 214.3 assemble the public* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *export surface over the* $\mathsf{Hilbert}^{\uparrow}$ *operator source and the* $\mathsf{Measure}^{\uparrow}$ *spectral side. The exported surface is public as a BEDC naming certificate and does not claim a standard spectral theorem bridge.*

Lean4 ✓ `BEDC.Derived.SpectralTheoremUp.SpectralTheoremCarrier public certificate`

Proof. Apply Definition 214.1 to fix the carried operator row, the self-adjoint-or-normal witness, and the classifier row through the certified $\mathsf{Hilbert}^{\uparrow}$ operator source. This determines the operator side of the public export surface.

Apply Definition 214.2 to attach the spectrum, projection-valued-measure, and functional-calculus rows over the certified $\mathsf{Measure}^{\uparrow}$ spectral side. These rows provide the visible spectral data exported by $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$.

Finally apply Definition 214.3 to pack the transport, ledger, exactness, and dependency rows around the same carrier and classifier. The result is the public certificate surface for $\mathsf{SpectralTheorem}^{\uparrow}$; since no StandardBridge row is part of the package, the construction remains a public BEDC certificate and not a standard spectral theorem bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$.

Constructive story: A spectral-theorem package starts from a certified $\mathsf{Hilbert}^{\uparrow}$ operator row restricted by a displayed self-adjoint-or-normal witness, then appends measured spectral-side rows for spectrum, projection-valued measure, and functional calculus through the cited $\mathsf{Measure}^{\uparrow}$ source. The carrier accepts only histories whose operator, spectral support, projection, calculus, and provenance rows are displayed in this Hilbert-measure package, while a completed host spectral theorem or bridge-checked standard model is not part of the carrier. Two carried packages are classified when the Hilbert operator classifier identifies the operator rows and the spectral data live over the same measured side, so the comparison transports spectrum, projection-valued-measure, and calculus ledgers rather than equating ambient operators externally. The source is the paired $\mathsf{Hilbert}^{\uparrow}$ and $\mathsf{Measure}^{\uparrow}$ certificate surface, the pattern records the self-adjoint-or-normal restriction plus spectrum, projection, and calculus obligations, and the ledger keeps hidden spectrum, projection-valued-measure, calculus, dependency, and provenance witnesses visible. Since the restricted operator carrier is inhabited in the displayed singleton boundary, the inherited Hilbert and measure classifiers are equivalence rows, and the transport theorem repacks the spectral data over a classified endpoint, the five name-certificate obligations reduce to those componentwise rows. A package h lies in the signature gap of a $\mathsf{SpectralTheorem}^{\uparrow}$ token p when the source-domain accepts its Hilbert operator and measured spectral rows, the signature relation pairs them with an answer spectral package and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records the same operator together with its displayed spectrum, projection measure, and calculus rows. The chapter registers this Hilbert-measure spectral-data package under the name $\mathsf{SpectralTheorem}^{\uparrow}$; it closes the BEDC certificate surface without importing the full external spectral theorem.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature package is exactly the $\mathsf{Hilbert}^{\uparrow}$ source, the $\mathsf{Measure}^{\uparrow}$ source, the carrier and classifier rows of Definition 214.1, the spectral-data rows of Definition 214.2, the stability, ledger, exactness, and dependency rows of Definition 214.3, the public certificate theorem of Definition 214.4, and the standard-boundary rows for the exported spectral data.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SpectralTheoremUp.SpectralTheoremCarrier\_classifier\_transport`

Bridge status: none

Not claimed: This chapter does not claim the full external spectral theorem or bridge-checked verification.

Upgrade path: Only bridge-checked verification remains outside the paper-side mature treatment.

Chapter 215

A Concrete Naming Certificate for $\mathsf{Nuclear}^{\uparrow}$

The nuclear-operator interface $\mathsf{Nuclear}^{\uparrow}$ packages compact operators between Banach spaces representable as absolutely convergent rank-one sums. It depends on $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ (chapter 90) and $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ (chapter 213).

215.1 Carrier definition

Theorem 215.1 (NuclearUp carrier obligation)**.** *The carrier for* $\mathsf{Nuclear}^{\uparrow}$ *is a* BHist *predicate packaging a* $\mathsf{Banach}^{\uparrow}$ *source endpoint, an* $\mathsf{OperatorIdeal}^{\uparrow}$ *compact-operator surface, and a unary rank-index ledger. The carried endpoint records the visible* BHist *rows, their* Pkg *provenance, and the rank-index observations used by the nuclear expansion; hidden representatives of the Banach spaces, compact operators, and rank-one terms are not carrier equality.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearCarrier obligation`

Proof. Unfold the carrier field of the ten-field certificate template. The named source object is $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, the operator surface is $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$, and the rank index is represented as a unary BHist ledger row.

Packing these three rows through BHist and Pkg gives the visible carrier predicate. Since all remaining data are placed behind the ledger row, the carrier equality is exactly the displayed BEDC package equality and not equality of host representatives. □

Theorem 215.2 (NuclearUp compact-operator obligation)**.** *The compactness row for* $\mathsf{Nuclear}^{\uparrow}$ *is read through certified* $\mathsf{OperatorIdeal}^{\uparrow}$ *approximation data and* $\mathsf{Banach}^{\uparrow}$ *classifier transport. It is not an appeal to external norm compactness: compactness is visible only when the* $\mathsf{OperatorIdeal}^{\uparrow}$ *surface supplies the approximation row and the* $\mathsf{Banach}^{\uparrow}$ *endpoints transport it along the displayed* hsame *classifier.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearCompactOperator prefix transport obligation`
Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearCompactOperator banach classifier transport`
↪ variant `BEDC.Derived.NuclearUp.NuclearCompactOperator banach transport surface`

Proof. Unfold the compact-operator field of the certificate template after Definition 215.1. The available objects are the $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ approximation row and the $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ classifier on source and target histories.

The construction transports approximation observations along the $\mathsf{Banach}^{\uparrow}$ classifier and then repacks them as the compact row of the carried BHist endpoint. No norm-compactness principle is introduced, because the only compactness witness consumed by the template is the certified operator-ideal approximation row. □

215.2 The certificate

Theorem 215.3 (NuclearUp rank-one-sum obligation)**.** *Rank-one expansion data for* $\mathsf{Nuclear}^{\uparrow}$ *supplies unary* BHist *indices, coefficient and vector observations, a tail modulus, and* Cont*-compatible partial sums. The partial-sum rows are stable under* hsame*, so changing the displayed Banach histories by the certified classifier preserves the carried nuclear expansion package.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearRankOnePrefixLedger semantic name certificate`

Proof. Unfold the expansion field of the ten-field template. Each unary index names one rank-one row, with its scalar coefficient, source vector observation, target vector observation, and tail-modulus entry recorded as BHist data.

The Cont row is then applied to the finite partial sums generated by those indices. Stability follows by transporting the coefficient and vector observations along hsame before repacking the same tail-modulus ledger, so the expansion remains a carried nuclear package. □

Theorem 215.4 (NuclearUp ledger exactness obligation)**.** *The* $\mathsf{Nuclear}^{\uparrow}$ *ledger hides exactly rank indices, rank-one projections, and tail-modulus evidence. Its exactness row must supply coverage for every visible nuclear package, soundness for every ledger entry projected to the visible carrier, and completeness saying that no visible compact rank-one-sum package is lost by the hidden ledger representation.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearLedgerExactness obligation`

Proof. Unfold the ledger and exactness fields of the certificate template. The hidden rows are precisely the unary rank index, the rank-one projection data named by that index, and the tail-modulus witness used by the expansion row.

Coverage reads a visible nuclear package back into such ledger rows. Soundness projects any ledger row to the BHist carrier of Definition 215.1, and completeness states that the projection captures all visible compact rank-one-sum packages admitted by Definition 215.2 and Definition 215.3. □

Theorem 215.5 (NuclearUp dependency boundary)**.** *Downstream consumers of* $\mathsf{Nuclear}^{\uparrow}$ *may use only the* $\mathsf{Banach}^{\uparrow}$ *interface, the* $\mathsf{OperatorIdeal}^{\uparrow}$ *interface, and the rank-one ledger specified in this chapter. They may not use a trace-class principle, a spectral principle, choice, or host compactness as part of the* $\mathsf{Nuclear}^{\uparrow}$ *certificate.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearDependencyBoundary obligation`

Proof. Unfold the dependency field of the ten-field template. The declared dependencies are exactly $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$, and the unary rank-one ledger rows fixed by Definition 215.3.

Every public observation is obtained by projecting those named dependencies through BHist, Pkg, hsame, and Cont. Since trace-class, spectral, choice, and host compactness principles are not dependency rows, they cannot be consumed by the certified $\mathsf{Nuclear}^{\uparrow}$ surface. □

Theorem 215.6 (NuclearUp carrier compact-operator obligation)**.** *A* $\mathsf{Nuclear}^{\uparrow}$ *carrier must expose a* $\mathsf{Banach}^{\uparrow}$ *source pair, an* $\mathsf{OperatorIdeal}^{\uparrow}$ *compact-operator row, and a carrier predicate over* BHist *for operators represented by certificate-visible finite prefixes of compact maps. The source pair names the domain and codomain Banach carriers, the compact-operator row records that each visible prefix endpoint is compact in the cited operator-ideal surface, and the carrier predicate admits only histories whose operator evidence factors through those finite prefixes.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearCompactPrefixCarrier banach operator rows`

Proof. Project the $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ row named in the introduction to obtain the source and target Banach carriers and their classifier transport fields.

Next project the $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ dependency row. Its compact-operator entry is the only operator-ideal evidence exposed to the nuclear carrier at this level, so every admitted operator history must be witnessed by a finite prefix of compact maps visible in that row.

The carrier predicate is then the BEDC history predicate that stores exactly these three projections: Banach source, Banach target, and compact-prefix evidence. No host operator or infinite expansion is admitted without an accompanying finite prefix row. □

Theorem 215.7 (NuclearUp rank-one-sum ledger obligation)**.** *The* $\mathsf{Nuclear}^{\uparrow}$ *pattern row records each rank-one summand, coefficient-bound witness, finite-prefix certificate, and convergence ledger entry. Consequently no unrecorded infinite sum or host sequence is used by the certificate surface.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearRankOnePrefixLedger tail readback`

Proof. Read the pattern row as a finite BEDC ledger. The empty prefix carries no summand and no endpoint beyond the zero prefix certified by the dependency rows.

For a nonempty prefix, project its head row. It contains the rank-one summand, its coefficient-bound witness, the finite-prefix endpoint, and the ledger entry that relates the endpoint to the previous prefix.

Apply induction over the finite prefix spine. The induction hypothesis accounts for every earlier summand and bound, while the head projection accounts for the current row. Since every accepted prefix is built by these constructors, an infinite host sequence can be referenced only through the displayed convergence ledger and never as unrecorded data. □

Theorem 215.8 (NuclearUp OperatorIdeal and Banach dependency obligation)**.** *Stability and exactness for* $\mathsf{Nuclear}^{\uparrow}$ *are scoped only to the cited* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ *rows: carrier transport uses Banach classifier transport, ideal closure uses the* $\mathsf{OperatorIdeal}^{\uparrow}$ *compactness and ideal-law rows, and exactness is the visible rank-one ledger iff the nuclear classifier.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearOperatorIdealBanachDependency rank rows`

Proof. For carrier transport, use only the two Banach classifiers named by the source pair. Transport of a carried nuclear operator changes the visible source or target history only along those $\mathsf{Banach}^{\uparrow}$ classifier witnesses.

For ideal closure, project the compactness and ideal-law rows from $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$. Composition or finite linear recombination is accepted exactly when the cited operator-ideal laws produce the next compact-prefix witness.

For exactness, unfold the nuclear classifier as equality of the visible rank-one ledger modulo the Banach and operator-ideal transports just named. The forward direction projects the ledger equivalence from the classifier witness. The reverse direction repacks the same ledger equivalence, together with the Banach transport and compact-prefix witnesses, as the nuclear classifier. □

Theorem 215.9 (NuclearUp scoped BEDC boundary)**.** *The carrier, compact-prefix, rank-one-ledger, and dependency rows of Definition 215.6, Definition 215.7, and Definition 215.8 are scoped exactly to* BHist, Pkg, hsame, Cont, $\mathsf{NameCert}_{\mathsf{Banach}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^\uparrow}$, *unary rank-index rows, rank-one projection rows, compact-prefix witnesses, coefficient-bound witnesses, and tail-modulus ledger rows. No trace-class row, spectral row, choice principle, host compactness datum, or host infinite-sequence datum is part of this boundary.*

Lean4 ✓ `BEDC.Derived.NuclearUp.NuclearScopedBHistBoundary rows`

Proof. Project the carrier and compact-prefix rows of Definition 215.6. The accepted data are the BHist carrier predicate, its Pkg provenance, Banach classifier transport through hsame, the $\mathsf{OperatorIdeal}^\uparrow$ compact row, and the compact-prefix witnesses exposed by that operator-ideal surface.

Project the pattern row of Definition 215.7. Each admitted prefix contributes only a unary rank-index row, a rank-one projection row, a coefficient-bound witness, a compact-prefix endpoint, and a tail-modulus ledger row, with Cont used only for the finite partial-sum observation named by those rows.

Finally project the dependency rows of Definition 215.8. They name exactly $\mathsf{NameCert}_{\mathsf{Banach}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^\uparrow}$ as external certificate inputs, so every accepted dependency is already one of the displayed BEDC rows. Since trace-class, spectral, choice, host compactness, and host infinite-sequence data are never produced by these projections, they are outside the scoped boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{Nuclear}^\uparrow}$.

Constructive story: A nuclear operator is generated from a pair of certified $\mathsf{Banach}^\uparrow$ source and target histories, a compact-operator row supplied by $\mathsf{OperatorIdeal}^\uparrow$, and a unary rank-index ledger that records finite rank-one prefixes. The carrier accepts only BHist endpoints whose operator evidence factors through those visible compact prefixes and whose expansion ledger displays coefficients, vector observations, rank-one projections, partial sums, and tail-modulus rows; trace-class principles, spectral principles, choice, host compactness, and unrecorded infinite sequences are excluded. Two nuclear packages are classified by Banach source and target transport together with the visible rank-one ledger and compact-prefix witnesses, so changing representatives means repacking the same finite expansion rows under hsame rather than comparing host operators. The source is the $\mathsf{Banach}^\uparrow$ and $\mathsf{OperatorIdeal}^\uparrow$ certificate pair, the pattern records compact-prefix support and rank-one-sum ledger exactness, and the ledger keeps unary rank indices, coefficient bounds, vector rows, compact-prefix endpoints, partial-sum continuations, and tail moduli visible. The five obligations hold because an admitted compact-prefix package supplies habitation, the Banach and operator-ideal classifiers give reflexive, symmetric, and transitive transport, and rank-ledger exactness proves that classified finite prefixes remain admitted. A package h lies in the signature gap of a $\mathsf{Nuclear}^\uparrow$ token p when the source-domain accepts the Banach endpoints, compact-operator row, and rank-one ledger, the signature relation pairs the visible nuclear package with an answer package and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records the same compact prefix and coefficient-tail modulus data. The chapter registers this compact-prefix rank-one construction under the name $\mathsf{Nuclear}^\uparrow$ as a paper-side bridge boundary for the exported public surface, while trace-class principles, spectral principles, and machine-checked standard-reference comparison remain outside the chapter.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Nuclear}^\uparrow}$, maturePackageClosed)

Scope closed: The public surface exports the $\mathsf{Banach}^\uparrow$ source pair, $\mathsf{OperatorIdeal}^\uparrow$ compact-operator row, rank-index ledger, BHist carrier, hsame transport, Cont-compatible prefix rows, and NameCert boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Nuclear}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.NuclearUp.NuclearCompactPrefixCarrier\_banach\_operator\_rows`

Bridge status: paperBridge

Not claimed: Machine-checked standard bridge, trace-class theorem, spectral principle, choice principle, and host compactness theorem are not closed here.

Upgrade path: Only a machine-checked standard bridge can raise the formal bridge axis; trace-class and spectral principles remain outside the chapter.

Chapter 216

A Concrete Naming Certificate for $\mathsf{Factor}^{\uparrow}$

The factor interface $\mathsf{Factor}^{\uparrow}$ packages a von Neumann algebra with trivial centre, classified into types I, II_1, II_∞, III. It depends on $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ (chapter 212).

216.1 Carrier definition

Definition 216.1 (Factor BHist source packet)**.** *A* $\mathsf{Factor}^{\uparrow}$ *source packet is a* BHist *row carrying a* $\mathsf{VonNeumannAlg}^{\uparrow}$ *dependency row, a displayed centre row, a trivial-centre witness, and a factor-type classifier row with value in* I, II_1, II_∞, *or* III. *The carrier accepts exactly those packets whose algebra component is accepted by* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$, *whose centre witness is transported by the same* hsame *evidence, and whose type row is recorded in the visible ledger.*

Theorem 216.2 (Factor carrier trivial-centre obligation)**.** *Every accepted* $\mathsf{Factor}^{\uparrow}$ *carrier row projects to a* $\mathsf{VonNeumannAlg}^{\uparrow}$ *carrier row together with a centre witness whose only visible carrier is the scalar endpoint of the source algebra. Conversely, a* $\mathsf{VonNeumannAlg}^{\uparrow}$ *carrier row, a displayed centre row, and a trivial-centre witness transported through the same* hsame *comparison repack as a* $\mathsf{Factor}^{\uparrow}$ *carrier row. No host equality of algebras or ambient Hilbert-space realization is read by this obligation.*

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket trivial centre obligation`
Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket carrier trivial centre obligation`

Proof. Project the dependency row from the source packet of Definition 216.1. The $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ row supplies the algebra carrier and the classifier used to compare its visible history.

The trivial-centre field is then read as a displayed witness over that same history. Transport along hsame preserves the centre row because the packet stores the centre witness beside the algebra dependency rather than as a host property.

For the converse direction, place the algebra dependency, centre row, and trivial-centre witness into the packet constructor and apply Cont to the shared history comparison. The result is exactly the factor carrier surface. □

Theorem 216.3 (Factor type classifier stability obligation)**.** *The factor-type classifier row of a* $\mathsf{Factor}^{\uparrow}$ *packet is stable under accepted* hsame *replacement of the underlying* $\mathsf{VonNeumannAlg}^{\uparrow}$ *history. If two source packets compare through the algebra classifier, the transported trivial-centre witnesses determine the same displayed type row among* I, II_1, II_∞, *and* III.

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket type classifier stability obligation`

Proof. Start with the algebra comparison supplied by $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$. It transports the carrier, operation, and classifier rows of the source von Neumann algebra through the accepted hsame evidence.

The factor packet keeps the type classifier in the same ledger as the trivial-centre witness. Therefore the transported centre witness is read before the type row is compared, so the classification cannot change without leaving the displayed packet.

Repacking the transported algebra row, centre witness, and type row gives the same $\mathsf{Factor}^{\uparrow}$ classifier surface for the target packet. □

Theorem 216.4 (Factor ledger exactness obligation)**.** *The* $\mathsf{Factor}^{\uparrow}$ *ledger consists exactly of the* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency row, the* BHist *algebra carrier row, the centre row, the trivial-centre witness row, the factor-type classifier row, and their* hsame *and* Cont *transport evidence. Coverage, soundness, and completeness hold for precisely those rows; spectral decomposition theorems, representation theorems, measure-class data, and standard bridge rows are excluded.*

Proof. Coverage projects an accepted packet into its visible ledger entries: the von Neumann algebra dependency, the algebra carrier, the centre row, the trivial-centre witness, the factor-type row, and the transport witnesses.

Soundness reads those entries back through the packet constructor. The dependency certificate justifies the algebra component, while hsame and Cont carry the centre and type rows across the accepted history comparison.

Completeness follows because the packet has no ledger coordinate for spectral decomposition, representation, measure class, or bridge data. Any accepted row therefore exposes exactly the listed entries and no larger analytic surface. □

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket ledger exactness obligation`

Theorem 216.5 (Factor root threshold unblock surface)**.** *The rows of Definition 216.1, Definition 216.2, Definition 216.3, and Definition 216.4 form the dependency-ready surface for* $\mathsf{Factor}^{\uparrow}$*. A downstream certificate may consume the* BHist *carrier,* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency, trivial-centre witness, factor-type classifier, and exact ledger exclusions, but it must supply any standard bridge or analytic classification theorem separately.*

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket root threshold unblock surface`

Proof. The definition fixes the source packet and names every row that can enter the factor certificate. The carrier obligation recovers the algebra dependency and the trivial-centre witness from any accepted packet.

The stability obligation gives the classifier transport needed by downstream NameCert rows. The ledger exactness obligation then closes the readback by excluding every row outside the displayed packet.

Combining these three obligations gives a concrete finite-history interface over BHist rather than an empty chapter shell. Later bridges may attach to this surface, but they are not part of the factor packet itself. □

216.2 The certificate

Theorem 216.6 (Factor type row no-confusion)**.** *An accepted* $\mathsf{Factor}^{\uparrow}$ *packet cannot expose two distinct visible factor-type rows under the same transported trivial-centre witness. If the packet carries a* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency, a* BHist *algebra carrier, a centre row, a trivial-centre witness transported by the displayed* hsame *evidence, and visible type rows* T *and* T'*, then the certificate ledger identifies* T *and* T' *as the same row among* I, II_1, II_∞, *and* III.

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket type row no confusion`

Proof. Project the accepted packet through Definition 216.2. The projection gives one von Neumann algebra dependency and one transported trivial-centre witness over the displayed centre row.

Now read the type coordinates through Definition 216.3. The classifier row is stored in the same ledger as the transported centre witness, so two visible type rows under that witness must be compared by the same hsame evidence.

Finally apply Definition 216.4. Since the ledger has exactly one factor-type coordinate and no hidden representation or spectral coordinate, the two displayed type rows are the same certificate row. □

Theorem 216.7 (Factor centre ledger transport determinacy)**.** *For a* $\mathsf{Factor}^{\uparrow}$ *packet,* hsame *transport of the* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency, the* BHist *algebra carrier, the centre row, the trivial-centre witness, and the* Cont *provenance determines the transported* $\mathsf{Factor}^{\uparrow}$ *centre ledger. No additional representation row, spectral row, or ambient Hilbert-space equality can change the transported ledger.*

Proof. Start from the dependency row named by Definition 216.1. Its $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ component transports the algebra carrier through the displayed hsame evidence.

Transport the centre row and the trivial-centre witness along the same history comparison. The Cont provenance records that these rows move together as one factor packet rather than as independent host data.

The ledger exactness theorem Definition 216.4 then leaves no further centre coordinate to choose. The transported dependency, carrier, centre, trivial-centre witness, and Cont provenance therefore determine the transported centre ledger. □

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket centre ledger transport determinacy`

Theorem 216.8 (Factor VonNeumann dependency consumer boundary)**.** *Every downstream consumer of the* $\mathsf{Factor}^{\uparrow}$ *certificate may read only the* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency, the* BHist *algebra carrier, the centre row, the trivial-centre witness, the factor-type classifier, and the* $\mathsf{hsame}/\mathsf{Cont}$ *ledger. It may not read representation data, spectral decomposition data, measure-class data, ambient Hilbert-space equality, or any row not displayed by the factor source packet.*

Proof. The source packet of Definition 216.1 lists the complete visible input surface: dependency, carrier, centre, trivial-centre witness, type classifier, and transport provenance.

Apply Definition 216.4 to the consumer read. The coverage direction supplies exactly those visible rows, while soundness and completeness repack only rows of the same listed kinds.

The excluded analytic data have no coordinate in the packet and no entry in the ledger. Hence a consumer that remains inside the $\mathsf{Factor}^{\uparrow}$ certificate can read the displayed dependency and centre surface, but cannot inspect representation or spectral information. □

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket vonneumann dependency consumer boundary`

Theorem 216.9 (FactorUp public NameCert export)**.** *The source packet of Definition 216.1, the trivial-centre carrier obligation of Definition 216.2, the classifier stability obligation of Definition 216.3, the ledger exactness obligation of Definition 216.4, and the root threshold surface of Definition 216.5 together export the public* $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$ *surface.*

Consumers of this certificate may read only the $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency row, the centre row, the trivial-centre witness, the factor-type classifier, the* hsame/Cont *transport rows, and the ledger exclusions listed by the packet. Representation theory, spectral decomposition, measure-class data, and standard bridge rows remain outside the certificate.*

Proof. The source packet fixes the only rows available to $\mathsf{Factor}^{\uparrow}$: a $\mathsf{VonNeumannAlg}^{\uparrow}$ dependency, a displayed centre row, a trivial-centre witness, a factor-type classifier, and the shared transport ledger.

Apply the trivial-centre carrier obligation to project an accepted packet to the von Neumann algebra carrier and its scalar-centre witness. Apply the classifier stability obligation to transport the displayed factor type along the same hsame comparison.

The ledger exactness obligation then says that the visible rows are exactly the dependency, centre, trivial-centre, classifier, hsame, and Cont entries. The root threshold surface packages these rows for downstream consumers, so the public $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$ surface contains precisely those entries and no representation-theoretic, spectral, measure-class, or bridge datum. □

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket public namecert export`

Theorem 216.10 (FactorUp public bridge boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$ *surface is exactly the BEDC-side boundary available to any later standard bridge packet. It exposes the* $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ *dependency, the centre row, the trivial-centre witness, the factor-type classifier, the* hsame/Cont *transport rows, and the ledger exclusions.*

It exposes no representation data, spectral decomposition, measure-class data, ambient Hilbert-space equality, or bridge row unless those data are supplied by a separate bridge packet.

Proof. Apply Definition 216.9. The exported public surface already packages the von Neumann algebra dependency, centre row, trivial-centre witness, classifier, transport provenance, and ledger exclusions.

Next apply Definition 216.8 to any consumer that reads the certificate as the input face of a standard bridge. The consumer boundary permits exactly the displayed dependency and centre surface and blocks representation, spectral, measure-class, and Hilbert-space equality data.

Finally apply Definition 216.4. Ledger exactness says that no additional public row is available inside the $\mathsf{Factor}^{\uparrow}$ source packet. Hence bridge data can enter only through a separate bridge packet, not through the public $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$ surface itself. □

Lean4 ✓ `BEDC.Derived.FactorUp.FactorBHistSourcePacket public bridge boundary`

Theorem 216.11 (Factor bridge consumer completeness)**.** *Any finite consumer of the displayed* $\mathsf{Factor}^{\uparrow}$ *bridge surface reads exactly the dependency* $\mathsf{VonNeumannAlg}^{\uparrow}$ *row, algebra carrier, centre row, transported trivial-centre witness, factor-type classifier, and shared* hsame/Cont/Pkg *ledger already exported by Definition 216.9 and Definition 216.10.*

It cannot read a host von Neumann algebra, central decomposition, trace theorem, or ambient factor classification.

Proof. Apply Definition 216.8. It fixes the consumer boundary at the displayed $\mathsf{VonNeumannAlg}^{\uparrow}$ dependency, algebra carrier, centre row, and trivial-centre witness.

Next apply Definition 216.9. The public certificate adds the factor-type classifier and the shared hsame/Cont/Pkg ledger, and ledger exactness prevents any hidden classifier or representation row from being read.

Finally apply Definition 216.10. The bridge-facing surface is precisely the same public packet, so a finite consumer receives no host von Neumann algebra, central decomposition, trace theorem, or ambient factor classification. □

Closure status for $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$**.**

Constructive story: A $\mathsf{Factor}^{\uparrow}$ row is built as a finite BHist packet whose visible coordinates are the $\mathsf{NameCert}_{\mathsf{VonNeumannAlg}^{\uparrow}}$ dependency, the algebra carrier, the centre row, the transported trivial-centre witness, the factor-type classifier, and the shared hsame/Cont ledger. The carrier theorem reads the dependency and trivial-centre witness directly from that packet, while the surrounding certificate theorems record classifier stability, ledger exactness, consumer boundaries, and the public bridge-facing surface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface is the listed BHist source packet, trivial-centre carrier, classifier, $\mathsf{VonNeumannAlg}^{\uparrow}$ consumer rows, exported public $\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$ certificate, and the cited Lean target.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Factor}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FactorUp.FactorBHistSourcePacket\_public\_bridge\_boundary`

Bridge status: paperBridge

Not claimed: This chapter does not close spectral decomposition, representation theorems, measure-class data, or standard bridge rows.

Upgrade path: No stronger paper theory grade remains; bridgeChecked is a separate verification-axis target.

The $\mathsf{QuantumState}^{\uparrow}$ hub consumes the Hilbert source boundary of chapter 91 and the ProjectiveSpace phase classifier of chapter 207, then exposes readback boundaries to chapter 218, chapter 220, and chapter 221.

Chapter 217

A Concrete Naming Certificate for $\mathsf{QuantumState}^{\uparrow}$

The quantum-state interface $\mathsf{QuantumState}^{\uparrow}$ packages a unit vector in a Hilbert space carrier together with the equivalence under global phase. It depends on $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91) and $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$ (chapter 207).

217.1 Carrier definition

Definition 217.1 (QuantumStateUp BHist carrier)**.** *A* $\mathsf{QuantumState}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho).$$

The row $\mathcal{H}$ *is a consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *row. The row* $\mathcal{P}$ *is a consumed* $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$ *row over the displayed projective line determined by* $\mathcal{H}$*. The endpoint* v *is the unit-vector row projected from* $\mathcal{H}$*,* n *is the norm-one ledger row,* ϕ *is the global-phase row, and* p *is the projective-line endpoint row projected from* $\mathcal{P}$*.*

The rows λ_H *and* λ_P *are the inherited Hilbert and projective classifier rows, respectively. The row* ρ *is the* Pkg *provenance record witnessing that the two consumed certificates and all displayed endpoint rows belong to the same finite packet. No carrier datum outside* $\mathcal{H}$*,* $\mathcal{P}$*,* v*,* n*,* ϕ*,* p*,* λ_H*,* λ_P*, and* ρ *is part of the public* $\mathsf{QuantumState}^{\uparrow}$ *row.*

217.2 The certificate

Theorem 217.2 (QuantumStateUp Hilbert source boundary)**.** *For every carrier packet* $\mathcal{Q}$ *of Definition 217.1, all vector, norm, and inner-product rows used by the* $\mathsf{QuantumState}^{\uparrow}$ *interface are projected from the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *row* $\mathcal{H}$*. In particular, the visible vector endpoint* v*, the norm-one ledger* n*, and every inner-product row used to test unit length are read through* $\mathcal{H}$ *and the inherited classifier* λ_H*, not through an ambient Hilbert-space carrier.*

Proof. The traditional target is a Hilbert-space unit vector carrying the usual norm and inner-product data. The BEDC source is the consumed $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ row $\mathcal{H}$, and the carrier choice is the finite packet $\mathcal{Q}$ of Definition 217.1.

Unpack the definition of $\mathcal{Q}$. The only fields naming Hilbert-side data are $\mathcal{H}$, v, n, and λ_H, together with the provenance row ρ. Thus the classifier choice is the inherited Hilbert classifier λ_H, stability is hsame transport through that classifier, and the ledger is the norm-one row n.

The core theorem list for this boundary consists of the visible endpoint projection, the norm-one ledger projection, and the inner-product projection. Exactness says that every Hilbert-side row visible to $\mathsf{QuantumState}^{\uparrow}$ is one of those projected rows. There is no standard bridge supplied here, and the status is a paper obligation for the $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ Hilbert source boundary. □

Theorem 217.3 (QuantumStateUp projective phase classifier)**.** *The classified* $\mathsf{QuantumState}^{\uparrow}$ *rows are exactly the Hilbert unit-vector rows* v *whose projective endpoints* p *are related by the global-phase row* ϕ *and the* $\mathsf{ProjectiveSpace}^{\uparrow}$ *classifier* λ_P*. Equivalently, two carrier packets*

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho)$$

and

$$\mathcal{Q}' = (\mathcal{H}', \mathcal{P}', v', n', \phi', p', \lambda'_H, \lambda'_P, \rho')$$

classify the same quantum state precisely when the Hilbert endpoint rows are unit-vector rows and the projective endpoints are identified by the displayed global-phase/projective-space classifier rows. The classifier records no host vector equality, no independent Hilbert-space quotient, and no primitive quotient object beyond the projective scaling classifier supplied by $\mathcal{P}$*.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier projective phase classifier`

Proof. The traditional target is equality of pure quantum states modulo global phase. The BEDC source is the pair of consumed certificates $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$. The carrier choice is the packet $\mathcal{Q}$, while the classifier choice is the pair formed by the global-phase row ϕ and the projective classifier λ_P.

For the forward reading, a classified $\mathsf{QuantumState}^{\uparrow}$ row first exposes a Hilbert endpoint v and its norm-one ledger n through Definition 217.2. It then exposes the projective endpoint p through $\mathcal{P}$. The row ϕ records the allowed phase change, and λ_P records the projective classifier that accepts the resulting endpoint comparison.

For the reverse reading, a Hilbert unit-vector endpoint with a norm-one ledger and a projective endpoint accepted by ϕ and λ_P supplies all fields of Definition 217.1. Stability is componentwise hsame transport through λ_H and λ_P, the ledger is n together with the phase row ϕ, and exactness says that no host quotient is read. The core theorem list is this classifier row together with the Hilbert source boundary. The standard bridge is absent, and the status is a paper obligation for the $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ classifier. □

Theorem 217.4 (QuantumStateUp global phase stability)**.** *Let* $\mathcal{Q}$ *and* $\mathcal{Q}'$ *be two carrier packets of Definition 217.1. If the Hilbert rows* $\mathcal{H}, v, n, \lambda_H$ *and the projective rows* $\mathcal{P}, p, \lambda_P$ *are transported componentwise by* hsame*, then the global-phase classifier row is preserved and the norm-one ledger remains a valid* $\mathsf{QuantumState}^{\uparrow}$ *ledger row. Thus* hsame *transport of the consumed Hilbert and projective certificates preserves the phase classifier and the norm-one condition.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier global phase stability`

Proof. The traditional target is invariance of a pure state under change of certified presentation. The BEDC source is the pair of source certificates $\mathcal{H}$ and $\mathcal{P}$, the carrier choice is the packet $\mathcal{Q}$, and the classifier choice is λ_H, λ_P, and the phase row ϕ.

Transport the Hilbert side first. The hsame witnesses for $\mathcal{H}$, v, n, and λ_H move the unit-vector endpoint and the norm-one ledger through the Hilbert classifier without opening any host vector equality.

Transport the projective side next. The hsame witnesses for $\mathcal{P}$, p, and λ_P move the projective endpoint and its classifier row. The phase row ϕ is preserved because its source and target endpoints are exactly the transported Hilbert and projective endpoints.

The ledger consists of the norm-one row, the phase row, and the provenance row. The core theorem list is the Hilbert source boundary, the projective phase classifier, and this transport row. Exactness says that every preserved row is one of the displayed packet fields. No standard bridge is supplied, and the status is a paper obligation for $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ stability. □

Theorem 217.5 (QuantumStateUp public obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *surface consists exactly of the carrier packet of Definition 217.1, the projective phase classifier of Definition 217.3, the stability row of Definition 217.4, the norm-one ledger, the projective exactness predicate, and the hidden global-phase rows needed to witness the endpoint comparison. These rows form the carrier, classifier, stability, ledger, exactness, and hidden global-phase obligations exported by* $\mathsf{QuantumState}^\uparrow$*. The surface contains no density-matrix row, measurement row, channel row, or spectral row.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier namecert obligation surface`

Proof. The traditional target is the pure-state naming certificate. The BEDC source is the pair $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^\uparrow}$, and the carrier choice is the displayed packet $\mathcal{Q}$. The classifier choice is the global-phase/projective classifier, while stability is Definition 217.4.

The ledger is finite: it contains the norm-one row n, the phase row ϕ, the two inherited classifier rows λ_H and λ_P, and the provenance row ρ. The core theorem list is the Hilbert source boundary, the projective phase classifier, and the global-phase stability row.

Exactness says that every public $\mathsf{QuantumState}^\uparrow$ row is assembled from those fields and that every hidden phase row is used only to classify projective endpoints. The named dependency certificates expose no density-matrix, measurement, channel, or spectral row at this site. The standard bridge field is empty. The status is a paper obligation for the $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ public surface. □

Theorem 217.6 (QuantumStateUp observable measurement input boundary)**.** *An* $\mathsf{Observable}^\uparrow$ *expectation row may consume a* $\mathsf{QuantumState}^\uparrow$ *input only through the Hilbert row* $\mathcal{H}$*, the projective endpoint* p*, the phase classifier* ϕ*, the norm-one ledger* n*, the package provenance* ρ*, and the displayed* hsame/Cont *transport rows exported by Definition 217.5. The expectation row cannot inspect host vector equality, an ambient quotient object, or a phase witness except through the* $\mathsf{QuantumState}^\uparrow$ *classifier used to compare the projective endpoint.*

Proof. The observable expectation source is the row E in Definition 218.1. By Definition 218.5, that row is read through $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ and is transported only by the displayed classifier ledger of the observable packet.

Now read the public surface of Definition 217.5. Its exported state input rows are exactly the Hilbert source $\mathcal{H}$, the projective endpoint p, the phase classifier ϕ, the norm-one ledger n, the provenance row ρ, and the hsame/Cont transport rows attached to those fields.

The exclusion clauses follow from exactness of the same surface. Host vector equality is not a field of Definition 217.1, quotient equality is replaced by the projective classifier, and hidden phase data are visible only through the classifier row. Thus an observable measurement input has precisely the displayed BHist boundary. □

Theorem 217.7 (QuantumStateUp density-matrix pure-state boundary)**.** *Any* $\mathsf{DensityMatrix}^\uparrow$ *pure-state row sourced from a* $\mathsf{QuantumState}^\uparrow$ *carrier packet must factor through the projective*

endpoint p and the norm-one ledger n of that packet. The hidden phase data of the source state are visible only through the $\mathsf{QuantumState}^{\uparrow}$ *phase classifier ϕ and projective classifier λ_P, and no mixed-state ledger, affine-mixture spine, trace-class classifier, spectral row, or channel row is imported back into the* $\mathsf{QuantumState}^{\uparrow}$ *carrier.*

Proof. Use Definition 217.3 to identify the source pure state by its unit Hilbert endpoint and projective endpoint rather than by host vector equality. The norm side is fixed by Definition 217.4: hsame transport of the Hilbert and projective rows preserves the phase classifier and the norm-one ledger.

A density-matrix row then reads only the target density obligations. The carrier and ledger clauses of Definition 220.1 and Definition 220.3 describe trace-class membership, positivity, trace one, and the restricted trace-class comparison on the density side.

Those density rows are consumer rows, not source-state fields. The public $\mathsf{QuantumState}^{\uparrow}$ surface of Definition 217.5 contains no density-matrix row or affine-mixture ledger, so the only source information available to a pure-state density row is the projective endpoint together with the norm-one and phase-classifier data already carried by $\mathsf{QuantumState}^{\uparrow}$. □

Theorem 217.8 (QuantumStateUp quantum-channel pure input boundary)**.** $\mathsf{QuantumChannel}^{\uparrow}$ *may act on a* $\mathsf{QuantumState}^{\uparrow}$ *pure input only after the associated density or projective input row has been read through the same public* $\mathsf{QuantumState}^{\uparrow}$ *surface described in Definition 217.5. The channel output is a density-matrix endpoint produced by the channel carrier and density-image rows; it does not identify source states by host Hilbert-vector equality or by any equality outside the* $\mathsf{QuantumState}^{\uparrow}$ *projective classifier and the density-matrix classifier it consumes.*

Proof. First pass the pure input through the two preceding boundaries. The observable boundary fixes the permitted $\mathsf{QuantumState}^{\uparrow}$ input rows, while the density-matrix pure-state boundary says that a density input sourced from a pure state factors through the projective endpoint and norm-one ledger.

Now apply the channel surface. By Definition 221.2, a channel acts on trace-class density endpoints, and Definition 221.3 sends carried density inputs to carried density outputs. For finite density mixtures, Definition 221.8 preserves the density affine-spine rows without opening the source state carrier.

Therefore a channel may read the pure input only after it has been presented as the permitted density or projective input row. The output comparison lives in the density-matrix and channel ledgers, while source-state comparison remains the $\mathsf{QuantumState}^{\uparrow}$ projective classifier transported through $\mathsf{hsame}/\mathsf{Cont}$ rows. □

Theorem 217.9 (Observable expectation readback)**.** *Every expectation row in an* $\mathsf{Observable}^{\uparrow}$ *packet that consumes a* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *state input is read from a displayed* BHist *and* $\mathsf{NameCert}$ *packet consisting only of the Hilbert source row $\mathcal{H}$, the projective endpoint row p, the global-phase classifier ϕ, the norm ledger n, and the provenance row ρ of Definition 217.1. The observable expectation site may pair those rows with the observable endpoint rows of chapter 218, but it receives no host Hilbert-vector equality, no quotient object, and no density-matrix or channel row from* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$.

Proof. The downstream observable input is the expectation-source row named in chapter 218. Read its state component through the public $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ surface of Definition 217.5. That surface exposes exactly the carrier packet of Definition 217.1, the projective classifier, the norm ledger, and the provenance row.

Now apply Definition 217.5. It gives the complete consumer frontier for $\mathsf{Observable}^{\uparrow}$: expectation evaluation may use the Hilbert source row, projective endpoint, phase classifier, norm ledger, and provenance. The observable endpoint itself is supplied by the observable chapter, so no extra state equality, quotient representative, density row, or channel row is imported from the state certificate. □

Theorem 217.10 (DensityMatrix pure-state readback)**.** *Every pure-state density row assembled by* $\mathsf{DensityMatrix}^{\uparrow}$ *from a* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *input is assembled only from the same displayed unit-vector, projective-phase, norm, and provenance packet of Definition 217.1, together with the density-matrix carrier boundary of chapter 220. The readback does not expose a host vector equality, a quotient representative, or a spectral decomposition as an additional state-side input.*

Proof. The source packet is the $\mathsf{QuantumState}^{\uparrow}$ carrier of Definition 217.1. Its public certificate surface is fixed by Definition 217.5: the available state rows are the Hilbert source, projective endpoint, phase classifier, norm ledger, and provenance rows, with hidden phase data readable only through the classifier.

The density-matrix side supplies its own trace-class, positivity, and trace-one carrier rows in chapter 220. Combining that carrier boundary with Definition 217.5 leaves only the unit-vector/projective-phase packet as the state-side readback. Thus the pure-state density row is assembled from the certified state packet plus the density carrier boundary, not from host vector equality, quotient representatives, or spectral data. □

Theorem 217.11 (QuantumChannel input readback)**.** *A* $\mathsf{QuantumChannel}^{\uparrow}$ *input may consume a* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *packet only through the certified density and expectation boundary determined by Definition 217.1, Definition 217.5, and Definition 217.5. Its channel-side rows in chapter 221 may refer to the state only through those certified readbacks; they may not appeal to host Hilbert-vector equality, quotient equality, or an unrecorded representative.*

Proof. The channel input is downstream of the density-matrix and observable interfaces named in chapter 220 and chapter 218. Those interfaces can read the state only through the public rows of Definition 217.5, namely the carrier packet of Definition 217.1 and its classifier, ledger, and provenance rows.

Apply Definition 217.5 at the $\mathsf{QuantumChannel}^{\uparrow}$ site of chapter 221. The certified density and expectation readbacks exhaust the permitted state access. Since host vector equality, quotient equality, and unrecorded representatives are not rows of the public state packet, they cannot be consumed by the channel input. □

Theorem 217.12 (QuantumStateUp density-matrix readback boundary)**.** *A* $\mathsf{DensityMatrix}^{\uparrow}$ *consumer that reads back a rank-one density row from a public* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *packet may read only the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the norm ledger* n*, the phase classifier* ϕ*, and the package provenance* ρ *exported by Definition 217.1. Any rank-one density row sourced from the state must factor through the projective classifier of Definition 217.3; it may not use host Hilbert-vector equality as a public input.*

Proof. Project the state packet $\mathcal{Q}$ through Definition 217.1. The readable rows are exactly the Hilbert source, projective endpoint, norm ledger, phase classifier, and provenance fields already exposed by Definition 217.5.

The rank-one readback step is then forced through the projective classifier. Apply Definition 217.3 to convert the hidden phase witness into the public endpoint comparison, and use Definition 217.4 to keep that comparison stable under the same classified packet.

Finally, package the allowed rows through BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ provenance. No density row adds a host vector equality: the only equality available to the consumer is the projective classifier row exported by the public surface. □

Theorem 217.13 (QuantumStateUp observable expectation source)**.** *An* $\mathsf{Observable}^{\uparrow}$ *expectation row sourced from a public* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *packet uses the observable packet together with exactly the* $\mathsf{QuantumState}^{\uparrow}$ *Hilbert source row* $\mathcal{H}$ *and projective endpoint row* p*. The phase witness remains hidden behind the classifier* ϕ*, and the expectation source may read no host vector equality, density-matrix row, measurement outcome row, or ambient function-space equality from* $\mathsf{QuantumState}^{\uparrow}$*.*

Proof. Begin with the observable packet and the public state packet $\mathcal{Q}$. The state side contributes only the Hilbert and projective rows displayed in Definition 217.1, together with the norm ledger and provenance fields named by Definition 217.5.

The phase data is not passed as a separate witness. Use Definition 217.3 to expose only the classified endpoint row, and use Definition 217.4 to show that the observable source is insensitive to changing representatives inside the same classified state packet.

The expectation source is therefore repackaged through BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ provenance using only those rows. Since no other $\mathsf{QuantumState}^{\uparrow}$ field is projected, no density, measurement, or ambient function-space equality is introduced. □

Theorem 217.14 (QuantumStateUp channel input exactness)**.** $\mathsf{QuantumChannel}^{\uparrow}$ *input transport is exact for the public* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *packet. A classified input packet exposes the same Hilbert source row* $\mathcal{H}$*, projective endpoint row* p*, norm ledger* n*, phase row* ϕ*, and package provenance* ρ *as the source packet, and it adds no density-matrix row, measurement row, or ambient function-space equality.*

Proof. Project the source packet through Definition 217.1. The transported input is classified by the same public rows: Hilbert source, projective endpoint, norm ledger, phase classifier, and provenance.

Exactness follows by using Definition 217.5 as the complete list of exported state rows. Apply Definition 217.3 to keep the projective endpoint as the channel-visible state classifier, and apply Definition 217.4 to preserve the phase row under classified transport.

The channel input is then repacked through BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ provenance. Because the repacking uses only the displayed packet fields, the input surface is exact and no density-matrix, measurement, or ambient function-space equality is added. □

Theorem 217.15 (QuantumStateUp density-matrix consumer exclusion)**.** *A* $\mathsf{DensityMatrix}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *may read only the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the global-phase classifier* ϕ*, the norm ledger* n*, and the package provenance* ρ *from the pure-state certificate. The trace-class row, positivity row, and trace-one row required for a density matrix must be supplied by* $\mathsf{DensityMatrix}^{\uparrow}$ *itself. They are not fields of the finite* BHist *packet* $\mathcal{Q}$ *and are not consequences of the pure-state package provenance alone.*

Proof. Unpack the carrier packet of Definition 217.1. Its public rows are $\mathcal{H}$, $\mathcal{P}$, v, n, ϕ, p, λ_H, λ_P, and ρ, with the consumer-readable boundary restricted by Definition 217.5.

Compare this finite list with the public obligation surface of Definition 217.5. The only rows exported to a downstream construction are the Hilbert source, projective endpoint, phase classifier, norm ledger, and provenance rows. None of the displayed fields is a trace-class carrier, a positivity witness, or a trace-one ledger.

Thus a $\mathsf{DensityMatrix}^{\uparrow}$ construction may use the pure-state certificate as its input boundary, but its density rows must enter through its own BHist packet and Pkg provenance. Reading those rows from $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ would require a field absent from the carrier and from the obligation surface. □

Theorem 217.16 (QuantumStateUp observable measurement readback boundary)**.** *An* $\mathsf{Observable}^{\uparrow}$ *measurement readback over a* $\mathsf{QuantumState}^{\uparrow}$ *input factors through the Hilbert classifier row* λ_H *and the projective phase classifier formed by* ϕ *and* λ_P*. The outcome row, spectral row, and observable package provenance are supplied by* $\mathsf{Observable}^{\uparrow}$ *rather than by the state certificate, and cannot be read as hidden rows of* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$*.*

Proof. Project the consumer-readable rows described in Definition 217.5. The state input gives a Hilbert source row, a projective endpoint row, a phase classifier, a norm ledger, and the package provenance for the pure-state packet.

Measurement readback uses these rows only to classify the input state. The Hilbert part is read through λ_H, while the projective part is read through ϕ and λ_P as in Definition 217.3.

The observable rows have different provenance. Outcome and spectral data are introduced by the observable packet and its own Pkg row, so they are separate from the BHist fields listed in Definition 217.1. Therefore the readback boundary factors through the state classifiers and leaves observable output rows to $\mathsf{Observable}^{\uparrow}$. □

Theorem 217.17 (QuantumStateUp channel phase-classifier preservation)**.** *A* $\mathsf{QuantumChannel}^{\uparrow}$ *consumer transporting a pure-state input by* hsame *and* Cont *ledgers must preserve the displayed projective phase classifier of* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$*. It may repack the Hilbert source, projective endpoint, phase classifier, norm ledger, and provenance rows as its channel input boundary, but it may not replace the phase classifier by host vector equality or by equality in an ambient quotient object.*

Proof. Start with the hsame transport row of Definition 217.4. It preserves the Hilbert source rows, the projective endpoint rows, the norm-one ledger, and the global-phase classifier through the displayed carrier fields.

The classifier being preserved is the one characterized by Definition 217.3. That theorem identifies the public comparison with the projective endpoint row and the phase classifier, not with host Hilbert-vector equality and not with an ambient quotient equality.

Finally, repack the allowed rows using Definition 217.5. The channel side may attach its own Cont ledger to transport the input boundary, but the incoming phase row remains the displayed $\mathsf{QuantumState}^{\uparrow}$ classifier. Any replacement by host equality would add a row absent from the carrier packet and from the public obligation surface. □

Theorem 217.18 (QuantumStateUp observable expectation input exactness)**.** *An* $\mathsf{Observable}^{\uparrow}$ *expectation consumer that receives* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *may read exactly the state rows* $\mathcal{H}$*,* v*,* n*,* p*,* ϕ*,* λ_H*,* λ_P*, and* ρ *from the carrier packet of Definition 217.1. The expectation input is the* BHist *endpoint* v *scoped by the Hilbert row* $\mathcal{H}$*, the norm-one ledger* n*, the projective endpoint* p*, the global-phase row* ϕ*, the inherited classifier rows* λ_H *and* λ_P*, and the* Pkg *provenance row* ρ*. It may not read an observable spectrum row, measurement-result row, host-level vector equality, or state data outside the displayed* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *classifier.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier observable expectation input exactness`

Proof. Unpack the carrier packet of Definition 217.1. The rows available to any consumer are the two source certificates, the Hilbert endpoint, the norm-one ledger, the phase and projective endpoint data, the two inherited classifiers, and the finite provenance package. The observable expectation site uses the state side of this packet, so its state input is the listed eight rows

$$\mathcal{H}, v, n, p, \phi, \lambda_H, \lambda_P, \rho.$$

The classifier is fixed by Definition 217.3. Thus v is not read as a raw host vector: it is read as a Hilbert BHist endpoint whose admissible comparisons pass through λ_H, ϕ, and λ_P. The stability available to the expectation consumer is exactly Definition 217.4, so changing certified presentations transports the same input rows by hsame rather than by a host quotient.

Exactness follows from Definition 217.5 together with Definition 217.5. The public surface contains no spectral, measurement, density-matrix, or channel row, and the consumer boundary forbids equality outside the Hilbert and projective classifiers. Therefore the observable expectation input is precisely the displayed BHist and Pkg row family. □

Theorem 217.19 (QuantumStateUp density-matrix pure ray readback)**.** *A* $\mathsf{DensityMatrix}^{\uparrow}$ *pure-state consumer reading* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *may recover only the projective ray endpoint* p *together with the Hilbert source row* $\mathcal{H}$*, the endpoint row* v*, the norm-one ledger* n*, the global-phase row* ϕ*, the inherited classifiers* λ_H, λ_P*, and the provenance row* ρ*. Its readback is a certified pure ray in* $\mathsf{BHist}/\mathsf{hsame}$ *terms, not a host vector quotient and not an already supplied density-matrix row.*

Proof. Start with the carrier packet

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho).$$

The pure-density consumer needs a ray source and a unit ledger. These are already the projective endpoint p and the norm-one Hilbert ledger n, with v serving only as the certified Hilbert endpoint from which the ray row is projected.

Apply Definition 217.3 to identify the ray comparison used by the consumer. The global-phase row ϕ and the projective classifier λ_P determine sameness of pure rays, while λ_H scopes the Hilbert endpoint and norm ledger. Apply Definition 217.4 to transport this readback along hsame without changing the rows that the consumer may inspect.

The exclusion is the constructive content. By Definition 217.5, no density-matrix row is exported by $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$. By Definition 217.5, no host vector quotient or equality outside the displayed classifiers is available. Thus a pure-state density-matrix consumer can build its downstream row only from the certified ray endpoint, the norm-one Hilbert ledger, and the same Pkg provenance record. □

Theorem 217.20 (QuantumStateUp projective ray non-escape)**.** *Every pure-state downstream consumer reading* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *factors through the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the norm-one ledger* n*, the global-phase row* ϕ*, the inherited classifiers* λ_H, λ_P*, and the provenance row* ρ*. The state packet exports no host vector quotient, ambient projective equality, density-matrix row, observable spectrum row, or channel row.*

Proof. Start with the projective phase classifier of Definition 217.3. It identifies pure-state sameness through the displayed projective endpoint and global-phase classifier, not through a host quotient of vectors or an ambient projective equality.

Next use global phase stability from Definition 217.4. Transport along hsame preserves the Hilbert source, projective endpoint, norm-one ledger, phase row, inherited classifiers, and provenance row as the same finite packet data.

Apply the public obligation surface of Definition 217.5. Its exactness clause lists the exported $\mathsf{QuantumState}^{\uparrow}$ rows and does not include density-matrix data, observable spectra, or channel rows.

Finally use the density-matrix pure ray readback of Definition 217.19. Even a density-matrix consumer of a pure ray receives only the projective ray endpoint, norm-one Hilbert ledger, classifiers, and provenance supplied by the state packet. Thus every pure-state consumer remains inside the displayed ray route, and all excluded rows must be supplied by separate downstream certificates. □

Theorem 217.21 (QuantumStateUp channel consumer input boundary)**.** *A* $\mathsf{QuantumChannel}^{\uparrow}$ *state-input consumer of* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *is stable under the same global-phase/projective classifier as* $\mathsf{QuantumState}^{\uparrow}$*. Its input rows are limited to* $\mathcal{H}$*,* v*,* n*,* p*,* ϕ*,* λ_H*,* λ_P*, and* ρ *from the carrier packet; it carries no independent channel row, no density-matrix row, and no classifier other than the inherited* BHist*,* hsame*,* Pkg*, and* NameCert *data already exported by the state certificate.*

Proof. Unpack Definition 217.1 and read the state input as a finite BHist package. The endpoint supplied to a channel is v together with its norm-one ledger n, its projective endpoint p, the phase row ϕ, the inherited classifiers λ_H, λ_P, and the provenance row ρ tying these rows to the consumed source certificates.

The classifier for this input is not chosen by the channel consumer. It is the classifier of Definition 217.3: Hilbert endpoint transport is scoped by λ_H, and ray transport is scoped by ϕ and λ_P. The stability required by the channel input is exactly Definition 217.4, which keeps the same finite row family under componentwise hsame transport.

Finally apply Definition 217.5 and Definition 217.5. The public surface exports no channel datum and no density-matrix datum, while the consumer boundary forbids a separate quotient or host equality. Repacking the displayed rows therefore gives the whole channel state-input boundary in BHist/hsame/Pkg/NameCert terms. □

Theorem 217.22 (QuantumStateUp observable state boundary)**.** *An* $\mathsf{Observable}^{\uparrow}$ *expectation row may read a* $\mathsf{QuantumState}^{\uparrow}$ BHist *packet only through the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the global-phase classifier* ϕ*, the norm ledger* n*, and the package provenance* ρ *exposed by Definition 217.5, together with the observable endpoint, self-adjoint witness, spectral-data row, and expectation row displayed by* $\mathsf{Observable}^{\uparrow}$*. It may not replace the certified state input by host vector equality, a raw quotient representative, or an expectation row whose Hilbert source is not the shared* $\mathcal{H}$ *endpoint.*

Proof. Project the accepted quantum-state packet through Definition 217.5. The only state-side rows visible to a downstream consumer are $\mathcal{H}$, p, ϕ, n, and ρ.

Now apply the expectation boundary of Definition 218.5. The observable packet contributes its operator endpoint, self-adjoint witness, spectral-data row, and expectation row, and that theorem requires the expectation input to be compatible with the same Hilbert source.

Combining the two projections gives the displayed boundary. Any host vector equality, quotient representative, or Hilbert-mismatched expectation row would have to enter through a field not present in one of the two cited packet surfaces, so it is not readable by the consumer. □

Theorem 217.23 (QuantumStateUp density-matrix boundary)**.** *A* $\mathsf{QuantumState}^{\uparrow}$ BHist *packet does not itself supply a* $\mathsf{DensityMatrix}^{\uparrow}$ *row. A density-matrix consumer of a pure projective state*

must add, as separate displayed rows, trace-class membership, positivity, trace-one evidence, and any rank-one projection bridge that turns the projective endpoint into a positive trace-class trace-one operator. These rows are not part of the Hilbert source, projective endpoint, phase classifier, norm ledger, or provenance exposed by Definition 217.5.

Proof. Read the quantum-state packet fields from Definition 217.5. They certify the Hilbert source, projective endpoint, phase classifier, norm ledger, and package provenance, but no field has the form of a trace-class operator on the Hilbert carrier.

Compare this with the density carrier obligation of Definition 220.1. A $\mathsf{DensityMatrix}^{\uparrow}$ endpoint is accepted only when trace-class membership, positivity, and trace-one evidence are all displayed over the Hilbert carrier.

Therefore a pure-state-to-density-matrix use must introduce the trace-class, positivity, trace-one, and rank-one projection bridge rows at the consumer site. The quantum-state packet can supply the named source and projective endpoint for such a bridge, but it does not supply the density row itself. □

Theorem 217.24 (QuantumStateUp quantum-channel input boundary)**.** *A* $\mathsf{QuantumChannel}^{\uparrow}$ *consumer may use a* $\mathsf{QuantumState}^{\uparrow}$ *packet as an input only after a displayed* $\mathsf{DensityMatrix}^{\uparrow}$*-compatible input row has been supplied for the same Hilbert source. Channel image closure can then read the* $\mathsf{DensityMatrix}^{\uparrow}$ *row and the CPTP carrier of the channel, but it cannot read host vector equality, a raw pure-state quotient, or a direct channel action on the projective endpoint.*

Proof. First apply Definition 217.23. The quantum-state packet alone has no density-matrix row, so a channel input must pass through a separately displayed trace-class, positivity, trace-one, and rank-one projection bridge package.

Next use the CPTP carrier of Definition 221.2. Its source type is the trace-class carrier over the input Hilbert space, and its density-state action is stated over $\mathsf{DensityMatrix}^{\uparrow}$ inputs rather than over projective representatives.

Finally apply the density-matrix image lemma Definition 221.3. Once the compatible density row is present, the channel image closure reads exactly that row and the CPTP channel rows. The excluded host equality, quotient representative, and direct projective action are outside the displayed density and channel carrier surfaces. □

Theorem 217.25 (ObservableUp expectation-row boundary)**.** *When* $\mathsf{Observable}^{\uparrow}$ *forms expectation or eigenvalue rows from a* $\mathsf{QuantumState}^{\uparrow}$ *source, it may read only the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the global-phase classifier* ϕ*, the norm ledger* n*, and the provenance row* ρ *of Definition 217.1. The observable consumer may combine those rows with its own observable certificate, but it receives no density-matrix row, measurement row, channel row, spectral row, quotient object, or host Hilbert-vector equality from* $\mathsf{QuantumState}^{\uparrow}$ *itself.*

Proof. Unpack the carrier packet $\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho)$ of Definition 217.1. The rows available to an observable construction are the Hilbert source row, the projected endpoint, the phase classifier, the norm ledger, and the provenance row.

Apply the Hilbert source boundary of Definition 217.2 to locate all vector, norm, and inner-product inputs inside $\mathcal{H}$ and λ_H. Apply Definition 217.3 and Definition 217.4 to replace any phase choice by the projective endpoint classifier.

The public surface theorem, Definition 217.5, identifies the complete exported row list. Expectation and eigenvalue rows therefore require a separate $\mathsf{Observable}^{\uparrow}$ certificate for observable, measurement, or spectral data. Since none of those rows occurs in $\mathcal{Q}$, and since quotient and

host-vector equalities are excluded by the classifier boundary, the displayed rows are the whole $\mathsf{QuantumState}^{\uparrow}$ input boundary for this consumer. □

Theorem 217.26 (DensityMatrixUp rank-one row boundary)**.** *When* $\mathsf{DensityMatrix}^{\uparrow}$ *forms a rank-one projector row from a* $\mathsf{QuantumState}^{\uparrow}$ *source, it may read only the projective endpoint row* p *and the norm-one ledger* n*, together with the provenance row* ρ *that records their common packet. The density-matrix consumer may not read a host quotient, an ambient vector equality, a measurement row, a channel row, a spectral row, or any density-matrix row unless that row is supplied by its own downstream certificate.*

Proof. Unpack Definition 217.1. The rank-one projector input is not a new field of $\mathcal{Q}$; the packet exposes only the projective endpoint p, the norm-one ledger n, the inherited classifiers, and the provenance row ρ.

Use Definition 217.2 to read n through the Hilbert source row rather than through an ambient vector equality. Use Definition 217.3 to read p through the projective endpoint classifier, and use Definition 217.4 to ensure that replacing a unit-vector representative by a certified phase-equivalent representative does not change the exposed projector input.

Finally apply Definition 217.5. Its exactness clause contains no density-matrix, measurement, channel, or spectral row, and it contains no quotient object or host-vector equality. Thus any matrix row, operator row, or spectral decomposition must come from the $\mathsf{DensityMatrix}^{\uparrow}$ certificate itself, while $\mathsf{QuantumState}^{\uparrow}$ contributes only the projective endpoint, norm ledger, and provenance needed to form the rank-one boundary. □

Theorem 217.27 (QuantumChannelUp pure-state input boundary)**.** *When* $\mathsf{QuantumChannel}^{\uparrow}$ *consumes pure-state input or output rows from a* $\mathsf{QuantumState}^{\uparrow}$ *source, it may use the exported* $\mathsf{QuantumState}^{\uparrow}$ *classifier and provenance only: the Hilbert source row* $\mathcal{H}$*, the projective endpoint row* p*, the global-phase classifier* ϕ*, the norm ledger* n*, and the provenance row* ρ*. Channel action, density-matrix data, measurement data, spectral data, quotient objects, and host Hilbert-vector equalities must be supplied by the channel-side certificate rather than by* $\mathsf{QuantumState}^{\uparrow}$*.*

Proof. Unpack the packet of Definition 217.1. A pure-state input or output row can name the state only through the Hilbert source row, the projective endpoint, the phase classifier, the norm ledger, and the provenance row.

Apply Definition 217.2 to keep vector and norm data inside the consumed Hilbert certificate. Apply Definition 217.3 to expose equality of pure states only through the projective/global-phase classifier, and apply Definition 217.4 to transport that classifier across certified presentations.

The public obligation surface of Definition 217.5 is exact. It exports no channel map, no density-matrix row, no measurement row, no spectral row, and no quotient or host-vector equality. Therefore $\mathsf{QuantumChannel}^{\uparrow}$ may attach its channel certificate to the exported classifier and provenance, but all channel action and output certification remains a downstream obligation. □

Closure status for $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$**.**

Constructive story: A quantum-state row is built by consuming a $\mathsf{Hilbert}^{\uparrow}$ packet and a $\mathsf{ProjectiveSpace}^{\uparrow}$ packet, then displaying the Hilbert unit-vector endpoint, norm-one ledger, global-phase row, projective endpoint, inherited classifier rows, and shared provenance in one finite BHist carrier. The carrier accepts only packets whose vector and norm data are projected from the Hilbert source and whose projective endpoint and phase comparison are projected from the projective-space source; density matrices, observables, channel actions, spectral data, host vector equality, and quotient objects are outside this public row. Two accepted packets name the same quantum state when the unit-vector endpoints are related through the displayed global-phase/projective classifier while Hilbert and projective rows transport componentwise by hsame, not by equality of vectors in an ambient Hilbert space. The source specification is the Hilbert-plus-projective dependency surface, the pattern specification records norm-one projection, projective phase classification, global-phase

stability, provenance exactness, observable and density readback boundaries, and channel input boundaries, and the ledger keeps the Hilbert row, projective endpoint, phase row, norm row, and provenance visible. The five name-certificate obligations are read from the consumed classifiers: an admitted packet inhabits the carrier, the projective phase classifier is reflexive, symmetric, and transitive through its dependency rows, and classified Hilbert/projective transports repack as another admitted quantum-state packet. A packet h lies in the signature gap of a $\mathsf{QuantumState}^{\uparrow}$ token p when the source-domain accepts its Hilbert and projective rows, the signature relation pairs it with an answer state packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, the unit vector, norm-one row, phase comparison, projective endpoint, and provenance must be the entries encoded by p. The chapter registers this projective-unit-vector construction under the name $\mathsf{QuantumState}^{\uparrow}$; downstream observable, density, and channel consumers may read only the exported classifier and provenance, with no density-matrix carrier, measurement spectrum, channel row, host vector equality, or primitive quotient introduced here.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$, maturePackageClosed)

Scope closed: The carrier, classifier, stability, ledger, exactness, observable, density, and channel consumer-readback obligations are enumerated by Definition 217.5, Definition 217.16, Definition 217.19, and Definition 217.27.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier\_projective\_phase\_classifier`

Bridge status: none

Not claimed: The chapter does not close density-matrix rows, observable spectra, channel rows, host vector equality, or quotient primitives.

Upgrade path: Broader density-matrix, observable-spectrum, and channel packages require separate certificates beyond the exported $\mathsf{QuantumState}^{\uparrow}$ surface.

Theorem 217.28 (QuantumStateUp provenance row exactness)**.** *For every carrier packet*

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho)$$

of Definition 217.1, the provenance row ρ partitions the public rows of $\mathcal{Q}$ exactly into the consumed $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *packet $\mathcal{H}$, the consumed* $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$ *packet $\mathcal{P}$, the displayed norm row n, phase row ϕ, projective endpoint row p, Hilbert endpoint row v, and inherited classifier rows λ_H, λ_P. No observable row, density-matrix row, channel row, spectral row, host-vector-equality row, or quotient row belongs to the public* BHist *packet witnessed by ρ.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier provenance row exactness`

Proof. Use the carrier display in Definition 217.1 as the row inventory. The packet has the two consumed NameCert rows $\mathcal{H}$ and $\mathcal{P}$, the endpoint and ledger rows v, n, ϕ, p, the inherited classifiers λ_H, λ_P, and the provenance row ρ. The row ρ is therefore the Pkg record tying exactly those rows into one finite BHist packet.

The Hilbert portion is supplied by Definition 217.5: it exposes the carrier, classifier, stability, ledger, exactness, and hidden phase rows but no downstream observable object. The projective portion is supplied by Definition 217.3: it reads phase classification through ϕ and λ_P, not through a host quotient.

Finally apply the consumer boundary in Definition 217.5. A downstream row may inspect only the named Hilbert, projective, phase, norm, and provenance fields. Together with the global-phase stability theorem Definition 217.4, this proves that ρ is exact for the displayed NameCert package and excludes every observable, density-matrix, channel, spectral, host-vector-equality, and quotient row from the public surface. □

Theorem 217.29 (QuantumStateUp phase ledger exhaustion)**.** *Every hidden row used to classify two* $\mathsf{QuantumState}^{\uparrow}$ *carrier packets is one of the displayed phase row ϕ, inherited Hilbert classifier λ_H, inherited projective classifier λ_P, norm-one ledger n, endpoint* hsame *transport row, or provenance row ρ from the carrier of Definition 217.1. Conversely, those rows reconstruct exactly the projective phase classifier of Definition 217.3 inside the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{ProjectiveSpace}^{\uparrow}}$ *packets.*

Lean4 ✓ `BEDC.Derived.QuantumStateUp.QuantumStateBHistCarrier phase ledger exhaustion`

Proof. Start from two displayed packets

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho)$$

and

$$\mathcal{Q}' = (\mathcal{H}', \mathcal{P}', v', n', \phi', p', \lambda'_H, \lambda'_P, \rho').$$

The carrier definition lists the only rows available to the classifier. Thus a hidden classifier row must be read from the phase row, one of the inherited classifiers, the norm ledger, the endpoint hsame transport data, or the Pkg provenance record.

For exhaustion, use Definition 217.5 to identify the public $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ obligations and Definition 217.5 to rule out consumer access to a stronger equality. The stability row in Definition 217.4 accounts for every endpoint transport through hsame, while the provenance exactness of Definition 217.28 keeps those transports inside the same finite BHist package.

For reconstruction, read the Hilbert endpoint through λ_H, read the norm ledger through n, and read the projective endpoint comparison through ϕ and λ_P. These are precisely the inputs named by Definition 217.3; repacking them with ρ recovers the same projective phase classifier and adds no hidden row beyond the displayed ledger. □

Theorem 217.30 (QuantumStateUp consumer readback completeness)**.** *Every downstream* $\mathsf{Observable}^\uparrow$, $\mathsf{DensityMatrix}^\uparrow$, *and* $\mathsf{QuantumChannel}^\uparrow$ *consumer row reading* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *factors through the five public fields named in Definition 217.5: the Hilbert source row* $\mathcal{H}$*, projective endpoint row* p*, global-phase classifier* ϕ*, norm ledger* n*, and package provenance* ρ*. Conversely, any consumer depending only on those five fields is stable under Definition 217.4.*

Proof. The forward direction is a readback claim. By Definition 217.1, a consumer begins with a finite BHist packet carried by Pkg provenance. By Definition 217.5, the public $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ surface supplies the carrier, classifier, stability, ledger, exactness, and hidden phase obligations, but it supplies no observable, density-matrix, channel, or spectral row.

Apply Definition 217.5. The rows that remain readable by $\mathsf{Observable}^\uparrow$, $\mathsf{DensityMatrix}^\uparrow$, and $\mathsf{QuantumChannel}^\uparrow$ consumers are exactly $\mathcal{H}$, p, ϕ, n, and ρ. The projective classifier theorem Definition 217.3 explains how the endpoint and phase comparison behind those five fields is classified without exposing host vector equality or a quotient primitive.

For the converse direction, suppose a consumer depends only on $\mathcal{H}$, p, ϕ, n, and ρ. Transport the Hilbert and projective source data by the hsame rows governed by λ_H and λ_P. The global-phase stability theorem Definition 217.4 preserves the phase row and norm ledger, and Definition 217.28 preserves the finite package boundary. Therefore the consumer readback is unchanged under certified global-phase transport. □

Theorem 217.31 (QuantumStateUp phase-provenance scoped readback)**.** *Every* $\mathsf{Observable}^\uparrow$, $\mathsf{DensityMatrix}^\uparrow$, *or* $\mathsf{QuantumChannel}^\uparrow$ *consumer row reading* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *has a unique scoped* BHist *read surface. This surface consists exactly of the Hilbert source row* $\mathcal{H}$*, projective endpoint row* p*, global-phase classifier* ϕ*, norm ledger* n*, package provenance* ρ*, and the inherited Hilbert and projective classifier witnesses* λ_H, λ_P *from the carrier*

$$\mathcal{Q} = (\mathcal{H}, \mathcal{P}, v, n, \phi, p, \lambda_H, \lambda_P, \rho)$$

of Definition 217.1. Conversely, these rows reconstruct the same consumer-visible projective phase classifier and exclude observable, density-matrix, channel, spectral, host-vector-equality, and quotient rows from the scoped readback surface.

Proof. Begin with the provenance boundary. By Definition 217.28, the BEDC source BHist packet carried by ρ is exactly the finite package surface of $\mathcal{Q}$: the carrier is $\mathsf{QuantumStateBHistCarrier}$, the classifier and projective phase row are ϕ together with λ_P, stability is read through hsame, and the ledger is packaged by Pkg.

Next apply Definition 217.29. It identifies all phase and hidden-classifier rows available to a consumer with the displayed rows $\phi, n, \lambda_H, \lambda_P$ and the endpoint transport governed by hsame. Thus the Hilbert and projective classifier witnesses are not extra public objects; they are the inherited witnesses needed to read the projective phase classifier.

Finally use Definition 217.30. For each downstream consumer, the per-object template is the same: the source is the BHist packet above, the carrier is $\mathsf{QuantumStateBHistCarrier}$, the classifier is the projective phase row, stability is by hsame, the ledger is by Pkg provenance, and the downstream readers are $\mathsf{Observable}^{\uparrow}$, $\mathsf{DensityMatrix}^{\uparrow}$, and $\mathsf{QuantumChannel}^{\uparrow}$. These three consumers therefore see exactly the same projective phase classifier and no observable, density-matrix, channel, spectral, host-vector-equality, or quotient row outside the scoped surface. □

Chapter 218

A Concrete Naming Certificate for $\mathsf{Observable}^{\uparrow}$

The observable interface $\mathsf{Observable}^{\uparrow}$ packages a self-adjoint operator on a Hilbert space carrier together with its spectrum and expectation pairing with quantum states. It depends on $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91), $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ (chapter 214), and $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ (chapter 217).

218.1 Carrier definition

Definition 218.1 (ObservableUp BHist operator carrier)**.** *An* $\mathsf{Observable}^{\uparrow}$ *packet is a finite displayed* BHist *row package*

$$\mathcal{O} = (H, A, S, E, W, \rho, \lambda).$$

The row H is the consumed $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *carrier row. The endpoint $A : \mathsf{BHist}$ is the visible operator endpoint over H. The row W records the self-adjointness witness for that endpoint. The row S is the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *spectrum row attached to (H, A, W). The row E records the expectation-source endpoints read through* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *and paired with the observable endpoint A. The row ρ is the shared finite* Pkg *provenance tying H, A, S, E, and W into one certificate packet, and λ is the finite* $\mathsf{Cont/hsame}$ *ledger used by every transported row.*

The packet is admitted as an $\mathsf{Observable}^{\uparrow}$ *carrier exactly when all Hilbert space structure is projected from H, all spectral data is projected from S, all expectation sources are projected from E, and the only observable endpoint outside the dependency rows is the displayed* BHist *row A with its witness row W. No host operator equality, ambient Hilbert-space equality, or external spectral primitive is part of the carrier.*

Lean4 (definition) `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier`

Definition 218.2 (ObservableUp spectral expectation classifier)**.** *Let*

$$\mathcal{O} = (H, A, S, E, W, \rho, \lambda) \quad \textit{and} \quad \mathcal{O}' = (H', A', S', E', W', \rho', \lambda')$$

be admitted $\mathsf{Observable}^{\uparrow}$ *packets. The* $\mathsf{Observable}^{\uparrow}$ *classifier holds exactly when* hsame *transports the Hilbert carrier row, the operator endpoint row, the self-adjointness witness row, the spectral row, the expectation-source endpoints, and the shared package ledger:*

$$H\mathsf{hsame}H' \wedge A\mathsf{hsame}A' \wedge W\mathsf{hsame}W' \wedge S\mathsf{hsame}S' \wedge E\mathsf{hsame}E' \wedge \rho\mathsf{hsame}\rho' \wedge \lambda\mathsf{hsame}\lambda'.$$

The H comparison is read through $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$*, the S comparison is read through* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$*, and the expectation endpoint comparison is read through* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$*. The classifier therefore identifies only displayed rows and their common* Pkg *provenance. It does not compare host operators by equality.*

Lean4 (definition) `BEDC.Derived.ObservableUp.ObservableSpectralExpectationClassifier`

218.2 The certificate

Theorem 218.3 (ObservableUp Hilbert source boundary)**.** *For every admitted* $\mathsf{Observable}^\uparrow$ *packet of Definition 218.1, every operator row, spectral row, and expectation row reads its Hilbert source only through the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ *row H and* hsame *transport. In particular, the operator endpoint A, the spectral-data row S, and the expectation-source row E cannot inspect an ambient Hilbert carrier apart from the certified source row and its displayed classifier transport.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier hilbert source readback`
Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier hilbert source boundary`

Proof. Unpack the packet $\mathcal{O} = (H, A, S, E, W, \rho, \lambda)$. The only field that names a Hilbert source is H, and the only transport field available to move Hilbert-side data is the Cont ledger λ recording hsame-compatible rows.

Project the operator endpoint A and its self-adjointness witness row W from the packet. Their source is required to be the same H because the endpoint is displayed over the Hilbert source field rather than over a separate carrier. Project the spectral row S next; by construction it is the spectral-data row for that same displayed endpoint and witness.

Finally project the expectation row E. Its state input is constrained by $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$, while its vector-space and inner-product source is still the consumed Hilbert row H. Repacking these projections with ρ gives the stated source boundary: all Hilbert reads factor through H and the displayed hsame transport rows. □

Theorem 218.4 (ObservableUp spectral data ledger)**.** *The spectral rows consumed by* $\mathsf{Observable}^\uparrow$ *are exactly the* $\mathsf{SpectralTheorem}^\uparrow$ *spectrum, projection-measure, and functional-calculus rows for the displayed self-adjoint operator endpoint (A, W), all with the same package provenance row ρ. No spectral support, projection assignment, or calculus action is accepted by the observable packet unless it is one of the rows carried by the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$ *entry S.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier spectral data ledger`

Proof. Read the spectral-data field S of Definition 218.1. It is not an independent host spectral theorem; it is the consumed $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$ row for the operator endpoint field A and witness field W.

The forward projection exposes precisely the spectral entries supplied by that certificate: the spectrum row, the projection-measure row, and the functional-calculus row. The provenance row ρ attaches these entries to the same finite packet as H, A, and W.

For the reverse reading, any displayed spectrum, projection-measure, and functional-calculus rows with the shared ρ provenance repack as the spectral field S only when they are accepted by $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$. Thus the ledger is exact for those spectral rows and contains no further spectral datum. □

Theorem 218.5 (ObservableUp quantum-state expectation boundary)**.** *Expectation evaluation in an* $\mathsf{Observable}^{\uparrow}$ *packet may consume only* $\mathsf{QuantumState}^{\uparrow}$*-compatible input rows over the same Hilbert source* H*. If the Hilbert source, operator endpoint, witness row, spectral row, and quantum-state expectation row are transported by the displayed classifiers in* λ*, then the expectation readback transports to the corresponding expectation row over the transported packet.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier expectation transport readback`

Proof. Project the expectation-source row E from the packet. By definition E is read through $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$, so every state input used by the expectation pairing is a certified quantum-state row rather than an arbitrary vector row.

Use Definition 218.3 to identify the Hilbert source of the operator endpoint, witness row, spectral row, and expectation row with the same consumed row H. The quantum-state boundary then supplies only state inputs whose Hilbert field is compatible with that source.

Transport a classified packet through λ. The hsame rows move H, A, W, S, and the expectation-source componentwise. Since the expectation readback is displayed as the pairing of the transported operator endpoint with the transported state input, it repacks as the transported expectation row and remains inside the $\mathsf{Observable}^{\uparrow}$ carrier. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier quantumstate expectation boundary`

Theorem 218.6 (ObservableUp Hilbert and spectral boundary)**.** *For every admitted* $\mathsf{Observable}^{\uparrow}$ *packet of Definition 218.1, carrier acceptance exposes exactly the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *row* H*, the operator endpoint* A*, the self-adjointness witness row* W*, the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *row* S*, the expectation-source row* E*, the shared* Pkg *provenance row* ρ*, and the finite* Cont *ledger* λ*. The exposed boundary is stable only by the displayed* hsame *transport rows in* λ*.*

Proof. Unpack the carrier packet of Definition 218.1. The definition lists exactly the consumed Hilbert certificate, the operator endpoint, its witness row, the consumed spectral certificate, the expectation-source row, the provenance row, and the continuation ledger.

Acceptance is therefore a row-readback property. A consumer may inspect H, A, W, S, E, ρ, and λ, and every stability witness must be one of the hsame rows named by λ.

There is no additional carrier whose fields could expose an ambient Hilbert space, an ambient spectral theorem, a host operator equality, or an external state primitive. The boundary is precisely the displayed finite packet. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier hilbert spectral boundary`

Theorem 218.7 (ObservableUp expectation ledger exactness)**.** *For every admitted* $\mathsf{Observable}^{\uparrow}$ *packet of Definition 218.1, each public expectation row of* $\mathsf{Observable}^{\uparrow}$ *is read from the expectation-source endpoint row* E*, the operator endpoint* A*, the self-adjointness witness row* W*, the spectral row* S*, the shared* Pkg *provenance row* ρ*, and the finite* Cont *ledger* λ*. The readback uses the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *packet* H*, the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *packet* S*, and the consumed* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *rows inside* E *only through their displayed rows and their* hsame *transport entries in* λ*, not through host operator equality.*

Proof. The expectation interface is the row E. Its observable source is the endpoint A with witness row W, its spectral support is the consumed row S, and its package membership is recorded by ρ.

Exactness follows by restricting public expectation readback to those fields. The ledger λ supplies the only permitted hsame transport data for moving the Hilbert source, the operator row, the witness row, the spectral row, and the expectation row across admitted presentations.

Thus equality of expectation rows is not recovered from an external operator identity. It is the certificate-local relation determined by E, A, W, S, ρ, λ, and the displayed rows of the consumed dependency certificates. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier expectation ledger exactness`

Theorem 218.8 (ObservableUp spectral transport stability)**.** *Let $\mathcal{O} = (H, A, S, E, W, \rho, \lambda)$ and $\mathcal{O}' = (H', A', S', E', W', \rho', \lambda')$ be admitted* $\mathsf{Observable}^{\uparrow}$ *packets of Definition 218.1. If the two packets are related by the classifier of Definition 218.2, then the transported packet is an admitted* $\mathsf{Observable}^{\uparrow}$ *packet. The displayed expectation boundary of Definition 218.7 is preserved with the transported* Pkg *provenance and finite* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier spectral transport stability`

Proof. Transport the Hilbert dependency first. The classifier moves the Hilbert carrier row from H to H', and the relevant hsame witness is recorded in the continuation ledger.

Transport the observable endpoint and witness next. The rows A and W move to A' and W', so the spectral row S transports to S' over the transported endpoint and witness, again using only the hsame entries named by the ledger.

The expectation-source row is then transported as a dependent endpoint over the already transported Hilbert, operator, witness, and spectral rows. The provenance row is carried from ρ to ρ', and the ledger changes from λ to λ'.

All fields of the target tuple are now present, so the target tuple is admitted by Definition 218.1. The expectation boundary is unchanged in form because the public rows are still exactly E', A', W', S', ρ', and λ' over H'. □

Theorem 218.9 (Observable Hilbert-spectral ledger exactness)**.** *For every admitted* $\mathsf{Observable}^{\uparrow}$ *packet of Definition 218.1, the public* $\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$ *ledger exposes exactly the Hilbert carrier row H, the operator endpoint A, the self-adjointness witness row W, the* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *spectrum row S, the* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *expectation-source row E, the shared* Cont/hsame *transport ledger λ, and the shared* Pkg *provenance ρ. No other row is exported by the certificate.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier hilbert spectral ledger exactness`

Proof. Unpack the carried tuple $(H, A, S, E, W, \rho, \lambda)$. The first projection is the consumed $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ row, so all inner-product, vector, and scalar structure available to the observable is read through H.

Project the spectral and state rows. The spectrum row S is consumed through $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ for the displayed endpoint and witness (A, W), while the expectation row E supplies the quantum-state endpoints through $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$.

The remaining projections are the visible operator endpoint A, the self-adjointness witness row W, the package provenance ρ, and the finite transport ledger λ. Repacking these projections gives exactly the displayed public ledger. Since the carrier contains no host operator equality and no external spectral primitive, no additional ledger row can be read from the certificate. □

Theorem 218.10 (Observable classifier stability)**.** *If two admitted* $\mathsf{Observable}^{\uparrow}$ *packets are related by the classifier of Definition 218.2, then* hsame *transport preserves the carried Hilbert row, operator*

endpoint row, self-adjointness row, spectral row, expectation endpoint row, shared Pkg *provenance, and finite* Cont *ledger.*

Proof. Start from the classifier relation. It supplies the displayed comparisons $H\mathsf{hsame}H'$, $A\mathsf{hsame}A'$, $W\mathsf{hsame}W'$, $S\mathsf{hsame}S'$, $E\mathsf{hsame}E'$, $\rho\mathsf{hsame}\rho'$, and $\lambda\mathsf{hsame}\lambda'$.

Transport the dependency rows first. The Hilbert comparison moves all carrier reads through $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$, and the spectral comparison moves the spectrum read through $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ with the transported endpoint and witness.

Transport the expectation row through $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ and keep the package boundary fixed by $\rho\mathsf{hsame}\rho'$. The ledger comparison $\lambda\mathsf{hsame}\lambda'$ then identifies every finite Cont row used by the source packet with the corresponding row in the target packet. Thus the target packet has the same visible carrier and spectral-expectation rows, up to the displayed classifier. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier classifier stability`

Theorem 218.11 (Observable expectation pairing boundary)**.** *Every expectation value exported by an admitted* $\mathsf{Observable}^{\uparrow}$ *packet is read through the carried* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *expectation-source row E and the observable endpoint ledger (A, W, ρ, λ). It is not justified by host-level inner-product equality, host operator equality, or an external spectral primitive.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier expectation pairing boundary`

Proof. Take an exported expectation value. By ledger exactness it must appear in the expectation-source row E of the carried packet, because no other row in the packet is allowed to export expectation endpoints.

The observable side of the pairing is the displayed endpoint A together with its self-adjointness witness row W. The spectrum row S may be used only as the consumed $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ dependency row attached to those displayed observable data.

Finally attach the provenance and transport boundary. The Pkg row ρ places the state endpoint and observable endpoint in the same finite packet, and the Cont/hsame ledger λ supplies the only admissible transport of the readback. Therefore the expectation pairing is a packet-level readback, not a claim about equality of host inner products or host operators. □

Theorem 218.12 (ObservableUp public row family)**.** *The public* $\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$ *family consists exactly of the finite* BHist *carrier packet of Definition 218.1, the classifier of Definition 218.2, the Hilbert source boundary, the spectral data ledger, the quantum-state expectation boundary, the Hilbert-spectral boundary, the expectation ledger exactness rows, the spectral transport rows, the classifier stability rows, and the expectation pairing boundary. Its public fields are the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *packet, the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *packet, the consumed* $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ *expectation-source row, the observable endpoint, the self-adjointness witness row, the* Pkg *provenance row, the finite* Cont *ledger, and the displayed* hsame *transport family.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier public row family`

Proof. Start with the carrier packet. It supplies the Hilbert dependency, observable endpoint, spectral dependency, expectation-source dependency, self-adjointness witness, package provenance, and continuation ledger.

The classifier identifies the admitted packet coordinates by hsame. The boundary theorems identify the rows that carrier acceptance exposes. The exactness theorems then state that public spectral and expectation readback is confined to the displayed dependency, observable, provenance, and ledger rows.

The transport and classifier stability theorems supply stability under the displayed classifiers of the dependency packets. Combining these rows gives the carrier, classifier, transport, ledger, and exactness pieces of the public $\mathsf{NameCert}_{\mathsf{Observable}^\uparrow}$ obligation family. No host-level observable, operator-equality primitive, independent state primitive, or extra spectral primitive is part of this surface. □

Theorem 218.13 (Observable NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Observable}^\uparrow}$ *obligation surface consists exactly of the carrier of Definition 218.1, the classifier of Definition 218.2, Hilbert source boundary, spectral data ledger, quantum-state expectation boundary, Hilbert-spectral ledger exactness, classifier stability, expectation-pairing boundary, and the shared* Cont/Pkg *ledger clauses for the displayed rows* $H, A, S, E, W, \rho, \lambda$*. It consumes the existing* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$*,* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *dependency surfaces and consumes no host operator equality or independent spectral primitive.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableNameCert obligation surface`
Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier semanticNameCert`
Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier namecert obligation surface`

Proof. Collect the carrier rows first. The finite tuple $(H, A, S, E, W, \rho, \lambda)$ displays the Hilbert dependency, observable endpoint, spectral dependency, expectation-source dependency, self-adjointness witness, package provenance, and transport ledger.

Collect the classifier rows next. The spectral expectation classifier compares exactly those displayed coordinates by hsame, with dependency reads delegated to the Hilbert, spectral-theorem, and quantum-state certificates named by the chapter dependencies.

Use Definition 218.3 for the Hilbert source boundary, Definition 218.4 for spectral ledger exactness, Definition 218.5 for the state-input boundary, Definition 218.9 for public ledger coverage, Definition 218.10 for transported stability, and Definition 218.11 for the expectation readback boundary. These clauses cover every public request admitted by the carrier and classifier. Since none of the collected rows contains host operator equality or an external spectral primitive, the stated clauses form the full paper-side $\mathsf{Observable}^\uparrow$ obligation surface. □

Definition 218.14 (ObservableUp expectation interface packet)**.** *The downstream expectation interface exported by* $\mathsf{Observable}^\uparrow$ *is the finite* BHist *packet*

$$\mathcal{I}_{\mathsf{Observable}^\uparrow} = (H, A, W, S, E, \rho, \lambda).$$

Here H *is the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ *carrier row,* A *is the displayed observable endpoint,* W *is its self-adjointness witness row,* S *is the consumed* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$ *spectral row for* (H, A, W)*, and* E *is the consumed* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *expectation-source row over the same Hilbert source. The row* ρ *is the shared finite* Pkg *provenance for these entries, and* λ *is the shared finite* Cont/hsame *transport ledger.*

The packet is exact as a consumer boundary: a downstream quantum-facing chapter may read Hilbert structure, spectral structure, state endpoints, expectation readback, provenance, and transport only through the seven rows displayed above. It contains no host operator equality and no ambient spectral or state primitive.

Lean4 (definition) `BEDC.Derived.ObservableUp.ObservableExpectationInterfacePacket`

Theorem 218.15 (ObservableUp spectral-state source coherence)**.** *For every admitted expectation interface packet* $\mathcal{I}_{\mathsf{Observable}^\uparrow} = (H, A, W, S, E, \rho, \lambda)$ *of Definition 218.14, the spectral row* S *and the*

expectation row E share the same Hilbert source H, the same operator endpoint A, the same self-adjointness witness W, the same package provenance ρ, and the same transport ledger λ. Their coherence is a displayed BHist *coherence: it is witnessed by projection from the carrier packet and by* hsame *rows in λ, not by host equality of Hilbert spaces, operators, spectra, or states.*

Proof. Project the expectation interface packet to the carrier tuple of Definition 218.1. The rows are the same rows, only ordered for consumer readback as $(H, A, W, S, E, \rho, \lambda)$.

Use Definition 218.3 to identify H as the sole Hilbert source available to the operator endpoint, witness row, spectral row, and expectation row. Use Definition 218.4 to read S as the consumed spectral certificate for the displayed endpoint and witness (A, W).

Use Definition 218.5 to read E through certified quantum-state endpoints over the same source H. The rows ρ and λ are then the shared package and transport rows supplied by the packet itself, so repacking these projections gives the stated spectral-state coherence without adding any host equality. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier spectral state source coherence`

Theorem 218.16 (ObservableUp expectation transport exactness)**.** *Let $\mathcal{I}_{\mathsf{Observable}^\uparrow} = (H, A, W, S, E, \rho, \lambda)$ and $\mathcal{I}'_{\mathsf{Observable}^\uparrow} = (H', A', W', S', E', \rho', \lambda')$ be admitted expectation interface packets. If the two packets are related by the* $\mathsf{Observable}^\uparrow$ *classifier, then classifier transport preserves the whole expectation interface packet:*

$$H\mathsf{hsame}H', \quad A\mathsf{hsame}A', \quad W\mathsf{hsame}W', \quad S\mathsf{hsame}S', \quad E\mathsf{hsame}E', \quad \rho\mathsf{hsame}\rho', \quad \lambda\mathsf{hsame}\lambda'.$$

The transported packet is again an admitted downstream interface, and this transport produces no host operator equality, ambient Hilbert equality, or external equality of spectral or state primitives.

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier expectation transport exactness`

Proof. Start from the classifier of Definition 218.2. It supplies exactly the displayed hsame comparisons for H, A, W, S, E, ρ, and λ.

Apply Definition 218.10 to transport the carried Hilbert row, endpoint row, witness row, spectral row, expectation endpoint row, provenance row, and continuation ledger. Apply Definition 218.8 to repack the target rows as an admitted $\mathsf{Observable}^\uparrow$ carrier.

Finally read the target carrier through Definition 218.14. The packet components are exactly $(H', A', W', S', E', \rho', \lambda')$, so the consumer interface is preserved componentwise. Since the classifier relation contains only displayed hsame rows, no host operator equality or ambient equality is created by the transport. □

Theorem 218.17 (ObservableUp public consumer exhaustion)**.** *Every downstream consumer of the public* $\mathsf{Observable}^\uparrow$ *interface reads only the finite expectation interface packet of Definition 218.14 together with the public* $\mathsf{NameCert}_{\mathsf{Observable}^\uparrow}$ *obligation surface of Definition 218.13. Thus every permitted consumer request factors through the rows $H, A, W, S, E, \rho, \lambda$, the displayed* Cont/hsame *transport ledger, and the consumed* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{QuantumState}^\uparrow}$ *surfaces. No downstream request can require a row outside that finite* BHist *packet or a host operator equality.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier public consumer exhaustion`

Proof. Begin with an arbitrary public consumer request. The obligation surface of Definition 218.13 says that public requests are exhausted by the carrier, classifier, Hilbert source boundary, spectral data ledger, quantum-state expectation boundary, Hilbert-spectral ledger exactness, classifier stability, expectation-pairing boundary, and the shared Cont/Pkg ledger clauses.

The carrier and classifier rows are exactly the rows repacked by Definition 218.14. The Hilbert source boundary, spectral data ledger, and expectation boundary reduce the dependency reads to H, S, and E with endpoint and witness rows A and W.

The remaining public clauses are ledger clauses. Use Definition 218.9 for finite public row coverage, Definition 218.10 for transported stability, and Definition 218.11 for expectation readback. These rows are all contained in $(H, A, W, S, E, \rho, \lambda)$ and the named dependency certificates, so the consumer has no additional public source to inspect. □

Theorem 218.18 (ObservableUp dependency NameCert exactness)**.** *For every admitted* $\mathsf{Observable}^{\uparrow}$ *packet* $\mathcal{O} = (H, A, S, E, W, \rho, \lambda)$ *of Definition 218.1, every* $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{SpectralTheorem}^{\uparrow}$, *and* $\mathsf{QuantumState}^{\uparrow}$ *dependency read performed by the packet factors through the displayed rows* H, S, *and* E *together with the finite* hsame/Cont *ledger* λ. *No dependency read is justified by an ambient Hilbert carrier, a host operator equality, an external spectral theorem, or an independent state endpoint outside those rows.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier dependency namecert exactness`

Proof. Project the admitted packet as $(H, A, S, E, W, \rho, \lambda)$. The carrier definition names H as the only Hilbert source, S as the only spectral dependency row, and E as the only quantum-state expectation source.

Apply Definition 218.3 to the Hilbert reads, Definition 218.4 to the spectral reads, and Definition 218.5 to the state-input and expectation reads.

The remaining admissible movement is the finite ledger λ. Its hsame rows are the only transport witnesses exposed by Definition 218.9, so every dependency read factors through H, S, E, and λ. □

Theorem 218.19 (ObservableUp operator-row classifier determinacy)**.** *Let* $\mathcal{O} = (H, A, S, E, W, \rho, \lambda)$ *and* $\mathcal{O}' = (H', A', S', E', W', \rho', \lambda')$ *be admitted* $\mathsf{Observable}^{\uparrow}$ *packets related by the classifier of Definition 218.2. Then the two packets determine the same public operator endpoint row, self-adjointness witness row, spectral row, expectation row, package provenance, and transport ledger up to the displayed* hsame *comparisons. The determinacy is a row-level certificate claim and does not assert equality of host operators.*

Proof. Unpack the classifier. It supplies exactly the comparisons $H\mathsf{hsame}H'$, $A\mathsf{hsame}A'$, $W\mathsf{hsame}W'$, $S\mathsf{hsame}S'$, $E\mathsf{hsame}E'$, $\rho\mathsf{hsame}\rho'$, and $\lambda\mathsf{hsame}\lambda'$.

Repack the public rows through these comparisons. The endpoint and witness are determined by $A\mathsf{hsame}A'$ and $W\mathsf{hsame}W'$, the spectral row by $S\mathsf{hsame}S'$, the expectation row by $E\mathsf{hsame}E'$, and the provenance and ledger by $\rho\mathsf{hsame}\rho'$ and $\lambda\mathsf{hsame}\lambda'$.

Use Definition 218.10 to identify the transported public surface. Since the classifier contains no host operator equality field, the resulting determinacy is precisely the displayed row determinacy. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier operator row classifier determinacy`

Theorem 218.20 (ObservableUp spectral row consumer coverage)**.** *Every downstream consumer of the public* $\mathsf{Observable}^{\uparrow}$ *surface can read only the consumed Hilbert row* H, *the operator endpoint*

A, the self-adjointness witness row W, the consumed $\mathsf{SpectralTheorem}^{\uparrow}$ *row S, the* $\mathsf{QuantumState}^{\uparrow}$ *expectation row E, the* Pkg *provenance row ρ, and the finite* Cont/hsame *ledger λ. In particular, spectral consumers receive the displayed spectral row and its certified dependencies, not an extra host-level spectral object.*

Proof. Start from Definition 218.9. It lists exactly the Hilbert, operator, witness, spectral, expectation, provenance, and ledger rows exported by an admitted packet.

Then apply Definition 218.12. The public family is assembled from the carrier, classifier, boundary, transport, and ledger clauses already named in the chapter, so a downstream consumer has no additional row source to inspect.

Thus a spectral consumer reads S together with H, A, W, E, ρ, and λ only through the public certificate family. The coverage claim is therefore exact for the displayed $\mathsf{Observable}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier spectral row consumer coverage`

Theorem 218.21 (ObservableUp expectation row transport composition)**.** *For admitted packets $\mathcal{O} = (H, A, S, E, W, \rho, \lambda)$ and $\mathcal{O}' = (H', A', S', E', W', \rho', \lambda')$ related by the classifier of Definition 218.2, classifier transport followed by expectation readback agrees with expectation readback over the transported packet. The composite uses only the rows E, A, W, S, ρ, and λ together with their displayed transported counterparts.*

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier expectation row transport composition`

Proof. Apply Definition 218.5 to identify the expectation readback as a certified state-input row paired with the observable endpoint and witness over the common Hilbert source.

Apply Definition 218.8 to transport the packet. The classifier moves A, W, S, E, ρ, and λ to their displayed target rows, and the transported tuple is again admitted as an $\mathsf{Observable}^{\uparrow}$ packet.

Finally use Definition 218.11. It confines the readback to E, A, W, S, ρ, and λ, so reading before transport and then transporting gives the same displayed row as reading from the transported packet. □

Theorem 218.22 (ObservableUp complete paper obligation surface)**.** *The complete paper-side* $\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$ *obligation inventory is formed by the carrier of Definition 218.1, the classifier of Definition 218.2, the ledger exactness rows, the public row family, the obligation surface of Definition 218.13, dependency* NameCert *exactness, operator-row classifier determinacy, spectral consumer coverage, and expectation transport composition. This inventory supplies the downstream read boundary for* $\mathsf{QuantumState}^{\uparrow}$ *and* $\mathsf{SpectralTheorem}^{\uparrow}$ *consumers of* $\mathsf{Observable}^{\uparrow}$.

Proof. Collect the existing carrier and classifier definitions. They give the finite packet $(H, A, S, E, W, \rho, \lambda)$ and the displayed hsame comparisons that control admitted presentations.

Collect the existing boundary rows through Definition 218.9, Definition 218.12, and Definition 218.13. These rows specify the public carrier, dependency, transport, provenance, and readback clauses.

The four preceding theorems make the dependency exactness, classifier determinacy, consumer coverage, and transport-composition obligations explicit. Together they cover every public dependency and readback used by downstream $\mathsf{QuantumState}^{\uparrow}$ and $\mathsf{SpectralTheorem}^{\uparrow}$ consumers, while excluding host operator equality and external spectral primitives from the paper surface. □

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier namecert obligation surface complete`

Theorem 218.23 (ObservableUp public surface bridge boundary)**.** *The complete paper-side* $\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$ *inventory of Definition 218.22 determines the bridge boundary to the standard observable schema by reading the Hilbert source row, operator endpoint, self-adjointness witness, spectral row, expectation input rows,* hsame *transports,* Cont *routes, and* Pkg *provenance from the concrete* BHist *packet* $(H, A, S, E, W, \rho, \lambda)$*.*

This boundary records exactly the standard-observable input faces exposed by the public surface. It does not claim a checked standard bridge, host operator equality, ambient Hilbert equality, or an external spectral primitive.

Lean4 ✓ `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier public surface bridge boundary`

Proof. Project the complete obligation surface of Definition 218.22. The projection exposes the carrier packet, classifier, public row family, dependency rows, transport rows, provenance row, and readback rows of the concrete BHist presentation.

Use Definition 218.3, Definition 218.4, Definition 218.5, and Definition 218.9. These rows make the Hilbert source, spectral dependency, expectation pairing, and dependency exactness ledger explicit.

Finally use Definition 218.11, Definition 218.20, and Definition 218.21. They exhaust the public consumer faces and show that transport and readback remain inside the displayed rows $H, A, S, E, W, \rho, \lambda$.

The resulting boundary is therefore the standard-observable input surface and nothing beyond it. Since each cited row is stated without host operator equality, ambient Hilbert equality, or an external spectral primitive, the boundary also preserves those exclusions and leaves the checked bridge as a separate obligation. □

Closure status for $\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$**.**

Constructive story: An observable is displayed as the finite packet $(H, A, S, E, W, \rho, \lambda)$: the Hilbert source H is consumed from Hilbert$^{\uparrow}$, the operator endpoint A and self-adjointness witness W are visible histories over that source, the spectral row S is consumed from SpectralTheorem$^{\uparrow}$, and the expectation inputs E are read through QuantumState$^{\uparrow}$. The carrier predicate encoded here admits only packets whose Hilbert, spectral, expectation, self-adjointness, provenance, and transport rows are all displayed, and the classifier identifies two packets by transporting exactly those rows through hsame and through the three dependency certificates rather than by comparing host operators. The source therefore covers this Hilbert-operator packet, the pattern is self-adjoint operator plus spectrum, projection-measure, functional-calculus, and state-expectation readback, and the ledger keeps $H, A, S, E, W, \rho, \lambda$ as the exact public inventory. Within this obligation surface, an admitted packet provides the carrier witness, componentwise history-sameness and dependency classifiers give reflexivity, symmetry, and transitivity, and the carrier remains stable when each visible row is replaced by a classified row with the same provenance. A packet h lies in the signature gap of an Observable$^{\uparrow}$ token p when the source-domain accepts the Hilbert row, operator endpoint, self-adjointness witness, spectral data, expectation rows, and finite ledger, the signature relation pairs that packet with an answer packet and evidence ledger, and token introduction names the answer as p; unfolded, p records the same displayed operator together with its certified spectral and expectation rows. No standard bridge or full observable certificate is exported by this chapter. The chapter registers this encoded operator packet under the name Observable$^{\uparrow}$; an observable is a HilbertUp-sourced BHist operator with spectral and state-expectation ledgers, with no host operator equality, ambient Hilbert equality, or external spectral primitive introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper-side treatment is the displayed spectral-data ledger, expectation transport ledger, public consumer exhaustion row, dependency exactness row, and their Pkg, Cont, and hsame readback boundaries.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Observable}^{\uparrow}}$, encodedDef)

Lean target: `BEDC.Derived.ObservableUp.ObservableBHistOperatorCarrier`

Bridge status: none

Not claimed: This chapter does not claim a Lean standard bridge or host-operator equality beyond the exported observable packet.

Upgrade path: The remaining upgrade path is Lean-side bridge verification for the already enumerated public surface.

Chapter 219

A Concrete Naming Certificate for $\mathsf{UnitaryGroup}^{\uparrow}$

The unitary-group interface $\mathsf{UnitaryGroup}^{\uparrow}$ packages the Lie group of inner-product-preserving automorphisms of a Hilbert space carrier. It depends on $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91) and $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140).

219.1 Carrier definition

Theorem 219.1 (UnitaryGroup source classifier obligation)**.** *The source carrier for* $\mathsf{UnitaryGroup}^{\uparrow}$ *is a* $\mathsf{Hilbert}^{\uparrow}$ *endpoint equipped with a* $\mathsf{LieGroup}^{\uparrow}$ *operation row and a displayed inner-product-preservation witness. Its classifier is the combined row obtained from the* $\mathsf{Hilbert}^{\uparrow}$ *endpoint classifier, the* $\mathsf{LieGroup}^{\uparrow}$ *operation classifier, and transport of the preservation row along the accepted histories.*

Proof. Unpack the two dependency certificates named in the introduction. The $\mathsf{Hilbert}^{\uparrow}$ source supplies the carried endpoint row and the Hilbert classifier, while the $\mathsf{LieGroup}^{\uparrow}$ source supplies the multiplication, inverse, and unit operation rows over the same visible history surface.

The unitary carrier is then the BHist package that stores those two source projections together with a preservation witness for the Hilbert inner product. A comparison is accepted only when the Hilbert endpoint classifier, the Lie-group operation classifier, and the preservation witness are all transported through the same hsame evidence.

Repacking these rows through Cont and $\mathsf{NameCert}$ gives the required classifier surface. No host equality of operators is consumed; the accepted comparison is exactly the displayed BEDC row transport. □

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupSourceClassifier obligation`

Theorem 219.2 (UnitaryGroup operation preservation obligation)**.** *The multiplication, inverse, and unit rows of* $\mathsf{UnitaryGroup}^{\uparrow}$ *are inherited from the* $\mathsf{LieGroup}^{\uparrow}$ *source certificate, and each inherited row preserves the* $\mathsf{Hilbert}^{\uparrow}$ *inner-product classifier on every carried endpoint. In particular, a product, inverse, or unit endpoint is admitted by the unitary carrier only when the corresponding* $\mathsf{LieGroup}^{\uparrow}$ *operation row repacks with the displayed Hilbert inner-product-preservation witness.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupOperation preservation obligation`

Proof. Project the operation rows from $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$. The product row supplies a carried composite endpoint, the inverse row supplies a carried inverse endpoint, and the unit row supplies the identity endpoint of the same source group package.

Next project the Hilbert classifier and inner-product rows from $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$. For each Lie-group operation, transport the input endpoint histories through hsame, apply the operation row through Cont, and carry the inner-product-preservation witness along the resulting endpoint comparison.

The resulting endpoint is repacked as a $\mathsf{UnitaryGroup}^\uparrow$ row precisely because it contains both pieces: the inherited Lie-group operation evidence and the Hilbert preservation witness. Thus operation closure does not extend the source group structure; it restricts it to the inner-product-preserving subcarrier. □

Theorem 219.3 (UnitaryGroup stability ledger exactness obligation)**.** *The* $\mathsf{UnitaryGroup}^\uparrow$ *certificate has coverage, soundness, and completeness for exactly the Hilbert carrier row, the* $\mathsf{LieGroup}^\uparrow$ *operation rows, the inner-product preservation rows, the classifier transport rows, and the dependency ledger naming* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$*. No additional operator, spectral, measure, or channel row is part of this ledger.*

Proof. Coverage reads any carried unitary endpoint back into its visible components: the $\mathsf{Hilbert}^\uparrow$ carrier row, the $\mathsf{LieGroup}^\uparrow$ operation rows, the preservation witness, the classifier transport evidence, and the two source NameCert dependencies.

Soundness is the forward projection. Given those ledger entries, the BHist carrier repacks the endpoint, hsame supplies the classifier transport, and Cont supplies the operation-composition rows needed by multiplication, inverse, and unit.

Completeness is the reverse reading. Any visible row accepted by the unitary carrier must be one of the listed Hilbert, Lie-group, preservation, transport, or dependency rows, because the certificate exposes no other ledger field. Hence the exactness boundary is precisely the displayed ledger and not a larger analytic operator surface. □

219.2 The certificate

Theorem 219.4 (UnitaryGroup carrier and classifier obligation)**.** *The carrier for* $\mathsf{UnitaryGroup}^\uparrow$ *is the* $\mathsf{Hilbert}^\uparrow$ *carrier together with the* $\mathsf{LieGroup}^\uparrow$ *automorphism rows whose source and target Hilbert carriers are classifier-compatible. Its classifier is inherited componentwise from the* $\mathsf{Hilbert}^\uparrow$ *carrier classifier and the* $\mathsf{LieGroup}^\uparrow$ *automorphism classifier, restricted to histories that preserve the displayed Hilbert source and target rows.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupCarrier classifier obligation`
↪ variant `BEDC.Derived.UnitaryGroupUp.UnitaryGroupCarrierClassifier obligation`

Proof. Unpack the carrier, classifier, source, and dependency fields of the ten-field roadmap template. The introduction supplies exactly the two certificate dependencies: $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ for Hilbert carriers and classifiers, and $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$ for automorphism rows and their group surface.

The carrier is obtained by pairing a Hilbert carrier row with a Lie-group automorphism row whose source and target projections land back in the Hilbert carrier and are related by the Hilbert classifier. Repacking these projections gives the displayed BHist carrier predicate for $\mathsf{UnitaryGroup}^\uparrow$.

The classifier field is then the restricted componentwise classifier. The Hilbert component is transported by $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$, the automorphism component by $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$, and the

restriction records that both transported endpoints remain classifier-compatible Hilbert carriers. □

Theorem 219.5 (UnitaryGroup operation stability obligation)**.** *The product, inverse, and identity rows of* $\mathsf{UnitaryGroup}^{\uparrow}$ *are the* $\mathsf{LieGroup}^{\uparrow}$ *operation rows restricted to the carrier of Definition 219.4. Product, inverse, and identity witnesses are stable under the displayed classifier because their source, target, and result rows remain Hilbert-carrier-preserving automorphisms.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupOperation stability obligation`

Proof. Project the operation fields of the ten-field roadmap template after the carrier has been fixed. The only available product, inverse, and identity operations are the rows exposed by $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$.

For product, compose two accepted automorphism rows through the $\mathsf{LieGroup}^{\uparrow}$ product row and then project the Hilbert source and target rows. Because each factor preserves the Hilbert carrier, the composite also lands in the same classifier-compatible Hilbert carrier rows.

For inverse and identity, use the corresponding $\mathsf{LieGroup}^{\uparrow}$ rows and apply the same restriction. The inverse row swaps source and target while preserving classifier compatibility, and the identity row is the Hilbert-carrier-preserving automorphism already exposed by the restricted carrier.

Stability follows by transporting every source, target, and result row along the classifier built in Definition 219.4. Repacking those transported rows gives the same product, inverse, and identity witnesses in the restricted $\mathsf{UnitaryGroup}^{\uparrow}$ package. □

Theorem 219.6 (UnitaryGroup inner-product preservation obligation)**.** *Every automorphism carried by* $\mathsf{UnitaryGroup}^{\uparrow}$ *transports the* $\mathsf{Hilbert}^{\uparrow}$ *inner-product classifier to itself. The preservation row is stable under classifier replacement: if the carried automorphism is replaced by an equivalent restricted* $\mathsf{LieGroup}^{\uparrow}$ *automorphism and the Hilbert carrier is replaced by an equivalent* $\mathsf{Hilbert}^{\uparrow}$ *carrier, the transported inner-product row is the same* $\mathsf{Hilbert}^{\uparrow}$ *classifier row.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupInnerProduct preservation obligation`

Proof. Read the inner-product field of the ten-field roadmap template through the $\mathsf{Hilbert}^{\uparrow}$ dependency. The Hilbert certificate supplies the inner-product classifier row, while the restricted automorphism carrier supplies the source and target histories on which that classifier is evaluated.

For a carried automorphism, apply its endpoint-preservation row to the Hilbert source and target projections. The result says that transporting an inner-product observation along the automorphism returns an observation classified by the same $\mathsf{Hilbert}^{\uparrow}$ inner-product row.

For classifier replacement, first transport the Hilbert carrier by the $\mathsf{Hilbert}^{\uparrow}$ classifier and the automorphism by the restricted $\mathsf{LieGroup}^{\uparrow}$ classifier. Then apply the preservation row to the transported endpoints. Repacking gives the identical inner-product-preservation witness for the classified $\mathsf{UnitaryGroup}^{\uparrow}$ row. □

Theorem 219.7 (UnitaryGroup ledger exactness obligation)**.** *The* $\mathsf{UnitaryGroup}^{\uparrow}$ *ledger consists exactly of the* $\mathsf{Hilbert}^{\uparrow}$ *carrier and classifier rows, the* $\mathsf{LieGroup}^{\uparrow}$ *operation rows, inverse, product, and identity witnesses, inner-product-preservation witnesses, classifier-transport rows, and dependency rows. Coverage, soundness, and completeness hold for precisely that package: every accepted unitary-group row exposes those entries, every such entry projects to a valid carried row, and every package with exactly those entries is accepted. No spectral theorem, operator-algebra theorem, or standard bridge claim is part of this ledger.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupLedger exactness obligation`

Proof. Unpack the ledger, exactness, and dependency fields of the ten-field roadmap template. The dependency rows are exactly $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$, and the visible ledger entries are the carrier, classifier, operation, preservation, and transport rows specified in Definition 219.4, Definition 219.5, and Definition 219.6.

Coverage projects an accepted $\mathsf{UnitaryGroup}^\uparrow$ row into those entries: the Hilbert carrier and classifier, the restricted Lie-group automorphism row, the product, inverse, and identity witnesses, the inner-product-preservation witness, and the classifier-transport rows.

Soundness reads any displayed ledger entry back through the corresponding BEDC primitive. Hilbert entries are justified by $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$, operation entries by $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$, and the preservation and transport entries by the restrictions already carried in the unitary-group package.

Completeness repacks a package with exactly these entries as the public obligation surface. Since spectral principles, operator-algebra theorems, and standard bridges are not among the dependency or ledger rows, they cannot be consumed by this certificate. □

Theorem 219.8 (UnitaryGroupUp public NameCert export)**.** *The carrier-classifier row of Definition 219.4, the product, inverse, and identity stability rows of Definition 219.5, the inner-product preservation row of Definition 219.6, and the ledger exactness row of Definition 219.7 assemble the public* $\mathsf{NameCert}_{\mathsf{UnitaryGroup}^\uparrow}$ *export over the source certificates* $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$*. The exported surface consists exactly of restricted Hilbert-carrier-preserving Lie-group automorphisms, their inherited group-operation rows, the displayed Hilbert inner-product-preservation witness, classifier transport for those rows, and the two dependency rows. It exports no spectral theorem, operator-algebra theorem, quantum-channel row, or standard bridge claim.*

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupPublicNameCert export`

Proof. Apply Definition 219.4. This fixes the public carrier as the $\mathsf{Hilbert}^\uparrow$ carrier together with the restricted $\mathsf{LieGroup}^\uparrow$ automorphism row whose source and target remain classifier-compatible Hilbert carriers. It also fixes the public classifier componentwise from the Hilbert carrier classifier and the Lie-group automorphism classifier, with the Hilbert source and target restrictions retained as visible rows.

Apply Definition 219.5. The only product, inverse, and identity rows available to the exported object are the inherited $\mathsf{LieGroup}^\uparrow$ operation rows after restriction to the carrier just fixed. Their stability witnesses say precisely that each operation result remains a Hilbert-carrier-preserving automorphism and that the operation witnesses transport through the public classifier.

Apply Definition 219.6. This supplies the additional unitary condition: every carried automorphism transports the $\mathsf{Hilbert}^\uparrow$ inner-product classifier to itself, and the preservation row is stable when the Hilbert carrier and the restricted Lie-group automorphism are replaced by classifier-equivalent representatives. Thus the public group operations do not merely preserve the carrier; they preserve the displayed Hilbert inner-product row that defines the unitary subcarrier.

Apply Definition 219.7. Coverage projects any accepted $\mathsf{UnitaryGroup}^\uparrow$ row to the Hilbert carrier and classifier rows, the restricted Lie-group operation rows, the product, inverse, identity, inner-product-preservation, classifier-transport, and dependency rows. Soundness repacks exactly those rows as an accepted unitary-group package. Completeness excludes every row not listed in that ledger. Therefore the four obligation rows assemble the public $\mathsf{NameCert}_{\mathsf{UnitaryGroup}^\uparrow}$ export surface over $\mathsf{NameCert}_{\mathsf{Hilbert}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$, with no additional analytic or bridge component. □

Theorem 219.9 (UnitaryGroupUp public standard bridge boundary)**.** *The restricted Hilbert-preserving* $\mathsf{LieGroup}^{\uparrow}$ *automorphism packet exported in Definition 219.8 is the public bridge surface for the standard unitary-group schema. Its bridge-facing rows are exactly the* $\mathsf{Hilbert}^{\uparrow}$ *carrier and classifier rows, the restricted* $\mathsf{LieGroup}^{\uparrow}$ *automorphism row, product, inverse, and identity rows, the displayed inner-product-preservation witness, classifier transport, and the two dependency rows. The boundary adds no spectral theorem, operator-algebra row, quantum-channel row, or host-level equality of unitary operators.*

Proof. Start from the public export theorem. It assembles the carrier, classifier, operation stability, inner-product preservation, and ledger exactness rows over $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$.

The standard unitary-group schema reads exactly the Hilbert carrier together with the group automorphism rows that preserve the displayed inner-product classifier. Those are the rows exported by the restricted packet, and their transport is already supplied by the classifier and ledger obligations.

The ledger exactness theorem excludes all rows outside this list. Therefore the exported packet is a bridge boundary for the standard schema while leaving spectral, operator-algebraic, channel, and host-equality claims outside the chapter. □

Lean4 ✓ `BEDC.Derived.UnitaryGroupUp.UnitaryGroupUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{UnitaryGroup}^{\uparrow}}$.

Constructive story: A unitary-group element is built by pairing a $\mathsf{Hilbert}^{\uparrow}$ carrier row with a $\mathsf{LieGroup}^{\uparrow}$ automorphism row and then requiring the displayed automorphism to preserve the Hilbert inner-product classifier. The carrier accepts only those restricted automorphism packets whose source and target Hilbert rows are classifier-compatible and whose product, inverse, and identity witnesses come from the same $\mathsf{LieGroup}^{\uparrow}$ operation surface; the classifier compares the Hilbert endpoint, automorphism endpoint, operation rows, and preservation witness through the two dependency certificates and hsame transport. The source therefore covers Hilbert-carrier-preserving automorphism rows, the pattern records multiplication, inverse, identity, inner-product preservation, and operation stability under the restricted classifier, and the ledger exposes exactly the Hilbert rows, Lie-group rows, preservation witnesses, classifier transports, and dependency rows. Because the underlying Hilbert and Lie-group classifiers are equivalence relations and the preservation row is transported with the accepted histories, an admitted restricted automorphism supplies the carrier witness, the classifier is reflexive, symmetric, and transitive, and products, inverses, identities, and classified replacements remain in the carrier. A packet h lies in the signature gap of a $\mathsf{UnitaryGroup}^{\uparrow}$ token p when the source-domain accepts its Hilbert row, restricted automorphism row, operation witnesses, preservation witness, and ledger, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names the answer as p; unfolded, the automorphism represented by h is exactly the inner-product-preserving group element encoded by p. The chapter registers this restricted-automorphism construction under the name $\mathsf{UnitaryGroup}^{\uparrow}$; the public bridge boundary is the standard unitary-group schema surface, with no spectral theorem, operator-algebra package, quantum-channel row, or host unitary group introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UnitaryGroup}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public scope binds exactly the carrier and classifier, operation stability, inner-product preservation, ledger exactness, public NameCert export, and standard bridge boundary rows in Definition 219.4, Definition 219.5, Definition 219.6, Definition 219.7, Definition 219.8, and Definition 219.9.

Chapter 220

A Concrete Naming Certificate for $\mathsf{DensityMatrix}^{\uparrow}$

The density-matrix interface $\mathsf{DensityMatrix}^{\uparrow}$ packages a positive trace-class operator of trace one on a Hilbert space carrier (a mixed quantum state). It depends on $\mathsf{NameCert}_{\mathsf{OperatorIdeal}^{\uparrow}}$ (chapter 213) and $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91).

220.1 Carrier definition

220.2 The certificate

Theorem 220.1 (DensityMatrix carrier obligation)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier supplied by $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$. The carrier row of $\mathsf{DensityMatrix}^{\uparrow}(H)$ is exactly the positive trace-class trace-one subcarrier*

$$\mathsf{Dens}_H(\rho) :\Longleftrightarrow \rho \in \mathsf{TC}(H) \wedge \mathsf{Pos}_H(\rho) \wedge \mathrm{Tr}_H(\rho) = 1.$$

The trace-class membership row $\rho \in \mathsf{TC}(H)$ is read from the $\mathsf{OperatorIdeal}^{\uparrow}$ trace-class surface of Definition 221.1, while the Hilbert carrier, positivity predicate, and trace functional are read over the $\mathsf{Hilbert}^{\uparrow}$ endpoint named in chapter 91. No object is carried by $\mathsf{DensityMatrix}^{\uparrow}(H)$ unless all three displayed rows are present, and any endpoint with all three rows is a carried density matrix.

Lean4 (definition) `BEDC.Derived.DensityMatrixUp.DensityMatrixCarrier`
Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixCarrier carrier obligation rows`
Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixTraceLedgerCarrier rows`

Proof. Unpack the density carrier named in Definition 221.1. Its carrier field is the intersection of the trace-class carrier with the positivity row and the trace-one equation, so the forward direction projects the three displayed witnesses.

For the reverse direction, repack the same three witnesses in the order required by the carrier field. The trace-class witness is supplied by the $\mathsf{OperatorIdeal}^{\uparrow}$ dependency surface, while positivity and trace are rows over the underlying $\mathsf{Hilbert}^{\uparrow}$ carrier. □

Theorem 220.2 (DensityMatrix restricted classifier obligation)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier, and write $\sim_{\mathsf{TC}(H)}$ for the trace-class classifier consumed from the $\mathsf{OperatorIdeal}^{\uparrow}$ boundary. The classifier row of $\mathsf{DensityMatrix}^{\uparrow}(H)$ is the restricted classifier of Definition 220.7:*

$$T \sim_{\mathsf{Dens}(H)} S :\Longleftrightarrow \mathsf{Dens}_H(T) \wedge \mathsf{Dens}_H(S) \wedge T \sim_{\mathsf{TC}(H)} S.$$

Thus every density classifier comparison carries both density endpoints and the inherited trace-class comparison. Its reflexivity, symmetry, transitivity, and transport rows are inherited from the trace-class classifier together with transport of the carrier rows of Definition 220.1.

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixTraceLedgerCarrier positivity trace ledger obligation`
Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixTraceLedgerCarrier restricted classifier transport`

Proof. Unpack Definition 220.7. The comparison is a restricted trace-class comparison, so projection gives the two density endpoints and the underlying trace-class classifier witness.

Reflexivity uses density-carrier reflexivity together with trace-class classifier reflexivity. Symmetry and transitivity keep the endpoint carrier witnesses and apply the corresponding inherited trace-class classifier rows.

For transport, use the carrier description of Definition 220.1. Trace-class membership is transported by the $\mathsf{OperatorIdeal}^{\uparrow}$ classifier row, while positivity and trace-one evidence are transported over the Hilbert endpoint; repacking gives the transported density-carrier endpoint required by the restricted classifier. □

Theorem 220.3 (DensityMatrix positivity and trace ledger obligation)**.** *For a* $\mathsf{Hilbert}^{\uparrow}$ *carrier* H*, the ledger hidden by the* $\mathsf{DensityMatrix}^{\uparrow}(H)$ *seal consists exactly of the trace-class membership witness* $\rho \in \mathsf{TC}(H)$*, positivity evidence* $\mathsf{Pos}_H(\rho)$*, trace-one evidence* $\mathrm{Tr}_H(\rho) = 1$*, the restricted trace-class classifier comparison of Definition 220.7, and the finite affine-mixture weight and bracketing data of Definition 220.4 when that operation is invoked. The seal contains no spectral decomposition, purification, channel action, dilation, or measurement-interface data.*

Proof. The carrier ledger is fixed by Definition 220.1: one trace-class witness, one positivity witness, and one trace-one witness. The classifier ledger is fixed by Definition 220.2: two carried density endpoints together with the inherited trace-class comparison.

When an affine mixture is used, Definition 220.4 adds only the finite list of density entries, the finite real-weight list, nonnegative unit-sum evidence, and the local bracketing endpoint. These data are read over the trace-class vector surface supplied by $\mathsf{OperatorIdeal}^{\uparrow}$ and the scalar rows supplied through the $\mathsf{Hilbert}^{\uparrow}$ dependency.

The named dependency surfaces do not expose spectral decompositions, purifications, channel actions, dilations, or measurement rows at this paper site. Therefore none of those structures can be part of the hidden ledger of the $\mathsf{DensityMatrix}^{\uparrow}(H)$ seal. □

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixTraceLedgerCarrier trace one unit readback`

Definition 220.4 (DensityMatrix affine mixture spine)**.** *Let* H *be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier, and let* $\mathsf{TC}(H)$*,* Pos_H*,* Tr_H*, and* Dens_H *be as in Definition 221.1. Use the real trace-class scalar action* $\odot_H$ *and trace-class addition* $+_{\mathsf{TC}(H)}$ *inherited from the* $\mathsf{OperatorIdeal}^{\uparrow}$ *and* $\mathsf{Hilbert}^{\uparrow}$ *dependency surfaces of chapter 220. For a finite trace-class spine* $xs : \mathsf{ListCarrier}(\mathsf{TC}(H))$*, a finite real-weight spine* $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$*, and an endpoint* $\rho_{\mathrm{mix}} \in \mathsf{TC}(H)$*, define*

$$\mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}}) :\Longleftrightarrow \mathsf{ConvAffSpine}_{\mathsf{Dens}_H}(xs, \lambda, \rho_{\mathrm{mix}})$$

where the right side is the finite affine-spine datum of Definition 208.4 read with carrier $C = \mathsf{Dens}_H$*, scalar action* $\odot_H$*, and vector addition* $+_{\mathsf{TC}(H)}$*. Thus the datum records a position match between density-matrix entries and real weights, nonnegative weights whose finite sum is classified as* $1_{\mathsf{Real}^{\uparrow}}$*, and a recursive bracketing endpoint for the displayed affine mixture.*

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine unary endpoint`

Lemma 220.5 (DensityMatrix binary convex closure)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier. Let $\rho, \sigma \in \mathsf{TC}(H)$ and let a, b be real scalar coefficients. If*

$$\mathsf{Dens}_H(\rho) \wedge \mathsf{Dens}_H(\sigma) \wedge \mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(a) \wedge \mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(b) \wedge a + b = 1,$$

then the binary affine mixture is a carried density matrix:

$$\mathsf{Dens}_H\big((a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \sigma)\big).$$

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine binary convex closure`

Proof. Unpack Dens_H by Definition 221.1. The two input hypotheses give

$$\rho, \sigma \in \mathsf{TC}(H), \qquad \mathsf{Pos}_H(\rho), \mathsf{Pos}_H(\sigma), \qquad \mathrm{Tr}_H(\rho) = \mathrm{Tr}_H(\sigma) = 1.$$

The trace-class carrier is closed under real scalar action and addition by the vector-space surface inherited from the $\mathsf{OperatorIdeal}^{\uparrow}$ and $\mathsf{Hilbert}^{\uparrow}$ dependencies, so

$$(a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \sigma) \in \mathsf{TC}(H).$$

The positivity cone on trace-class operators is closed under multiplication by nonnegative real scalars and under addition. The two nonnegativity hypotheses therefore give

$$\mathsf{Pos}_H\big((a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \sigma)\big).$$

Trace linearity over the same trace-class vector carrier gives

$$\mathrm{Tr}_H\big((a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \sigma)\big) = a\,\mathrm{Tr}_H(\rho) + b\,\mathrm{Tr}_H(\sigma) = a + b = 1.$$

These are exactly the trace-class, positivity, and trace-one clauses of Definition 221.1 for the displayed affine mixture. □

Theorem 220.6 (DensityMatrix finite affine mixture closure)**.** *Let H be a* $\mathsf{Hilbert}^{\uparrow}$ *carrier. For every finite trace-class spine $xs : \mathsf{ListCarrier}(\mathsf{TC}(H))$, finite real-weight spine $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$, and endpoint $\rho_{\mathrm{mix}} \in \mathsf{TC}(H)$, if*

$$\mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}}),$$

then

$$\mathsf{Dens}_H(\rho_{\mathrm{mix}}).$$

Equivalently, any finite affine mixture of carried $\mathsf{DensityMatrix}^{\uparrow}(H)$ *entries with nonnegative real weights whose finite sum is classified as one is again a carried* $\mathsf{DensityMatrix}^{\uparrow}(H)$ *entry.*

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine finite closure`

Proof. Unpack Definition 220.4. The hypothesis is the finite affine-spine datum of Definition 208.4 specialized to the concrete carrier $C = \mathsf{Dens}_H$ on the trace-class vector carrier $\mathsf{TC}(H)$. It contains both the finite readback of carried entries and nonnegative unit-sum weights, and a local bracketing witness for the endpoint ρ_{mix}.

Induct on that local bracketing witness. In the singleton clause, the endpoint is the displayed trace-class operator ρ, and the clause itself supplies $\mathsf{Dens}_H(\rho)$.

In the binary clause, the induction hypothesis gives that the tail endpoint τ is carried by Dens_H. The same clause supplies a carried head ρ, nonnegative real coefficients a, b, and the local unit-sum identity $a + b = 1$. Applying Definition 220.5 to ρ, τ, a, and b gives

$$\mathsf{Dens}_H\big((a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \tau)\big),$$

which is exactly the endpoint named by the binary bracketing clause.

The induction covers every recursive affine bracketing packaged by $\mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}})$. Hence the finite mixture endpoint ρ_{mix} satisfies $\mathsf{Dens}_H(\rho_{\mathrm{mix}})$. □

Definition 220.7 (DensityMatrix restricted classifier)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier. Write $\sim_{\mathsf{TC}(H)}$ for the trace-class classifier inherited from the $\mathsf{OperatorIdeal}^{\uparrow}$ boundary of Definition 213.6. The density-matrix classifier is the restricted trace-class classifier*

$$T \sim_{\mathsf{Dens}(H)} S :\Longleftrightarrow \mathsf{Dens}_H(T) \wedge \mathsf{Dens}_H(S) \wedge T \sim_{\mathsf{TC}(H)} S.$$

Thus a density classifier comparison records both density-carrier endpoints and the underlying trace-class classifier comparison.

Lean4 (definition) `BEDC.Derived.DensityMatrixUp.DensityMatrixRestrictedClassifier`

Lemma 220.8 (DensityMatrix binary constant affine exactness)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier, and use the notation of Definition 220.7. Let $\rho, \sigma, \rho_0 \in \mathsf{TC}(H)$ and let a, b be real scalar coefficients. Put*

$$E := (a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \sigma).$$

If

$$\mathsf{Dens}_H(E) \wedge \rho \sim_{\mathsf{Dens}(H)} \rho_0 \wedge \sigma \sim_{\mathsf{Dens}(H)} \rho_0 \wedge (a + b) \sim_{\mathsf{Real}^{\uparrow}} 1_{\mathsf{Real}^{\uparrow}},$$

then

$$E \sim_{\mathsf{Dens}(H)} \rho_0.$$

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine binary constant exactness`

Proof. Unpack Definition 220.7 for the two input density-classifier comparisons. They give the density carrier of ρ_0 and trace-class classifier comparisons

$$\rho \sim_{\mathsf{TC}(H)} \rho_0, \qquad \sigma \sim_{\mathsf{TC}(H)} \rho_0.$$

By Definition 213.6, the trace-class carrier inherits the real scalar action, vector addition, and trace-class classifier from the operator-ideal and Hilbert module surface. Reading that surface through Definition 47.19 and Definition 46.18, scalar-action congruence and additive congruence give

$$E \sim_{\mathsf{TC}(H)} (a \odot_H \rho_0) +_{\mathsf{TC}(H)} (b \odot_H \rho_0).$$

The scalar-distributivity row over scalar addition gives the reverse comparison from the displayed sum to the single scalar action:

$$(a \odot_H \rho_0) +_{\mathsf{TC}(H)} (b \odot_H \rho_0) \sim_{\mathsf{TC}(H)} ((a + b) \odot_H \rho_0).$$

Scalar-action congruence applied to $(a + b) \sim_{\mathsf{Real}^{\uparrow}} 1_{\mathsf{Real}^{\uparrow}}$ and classifier reflexivity of the carried endpoint ρ_0 gives

$$((a + b) \odot_H \rho_0) \sim_{\mathsf{TC}(H)} (1_{\mathsf{Real}^{\uparrow}} \odot_H \rho_0).$$

The scalar unit law in the same module surface gives

$$(1_{\mathsf{Real}^{\uparrow}} \odot_H \rho_0) \sim_{\mathsf{TC}(H)} \rho_0.$$

Transitivity of the trace-class classifier composes the four displayed comparisons into

$$E \sim_{\mathsf{TC}(H)} \rho_0.$$

Pair this comparison with the assumed carrier $\mathsf{Dens}_H(E)$ and the carrier of ρ_0 obtained from either input density-classifier comparison. Folding Definition 220.7 gives $E \sim_{\mathsf{Dens}(H)} \rho_0$. □

Theorem 220.9 (DensityMatrix constant affine-spine exactness)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier, and use the notation of Definition 220.7. Let $xs : \mathsf{ListCarrier}(\mathsf{TC}(H))$ be a finite trace-class spine, let $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$ be a finite real-weight spine, and let $\rho_{\mathrm{mix}}, \rho_0 \in \mathsf{TC}(H)$. If*

$$\mathsf{Dens}_H(\rho_0) \wedge \mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}}) \wedge \Big(\forall i : \mathsf{Pos}(xs).\ \mathsf{entry}_{xs}(i) \sim_{\mathsf{Dens}(H)} \rho_0\Big),$$

then

$$\rho_{\mathrm{mix}} \sim_{\mathsf{Dens}(H)} \rho_0.$$

Proof. Unpack $\mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}})$ by Definition 220.4. This is the finite affine-spine datum of Definition 208.4 specialized to the concrete density carrier Dens_H, the trace-class scalar action $\odot_H$, and trace-class addition $+_{\mathsf{TC}(H)}$. It contains a local bracketing witness $\mathsf{Bracket}_{\mathsf{Dens}_H}(xs, \lambda, \rho_{\mathrm{mix}})$.

Prove the stronger statement for every displayed sub-bracketing: if every leaf displayed in that sub-spine is density-classifier equal to ρ_0, then the sub-bracketing endpoint is density-classifier equal to ρ_0. Induct on the local bracketing witness.

In the singleton clause, the endpoint is the displayed leaf ρ. The finite-position hypothesis applied to the unique displayed position gives

$$\rho \sim_{\mathsf{Dens}(H)} \rho_0,$$

which is exactly the endpoint claim.

In the binary-extension clause, write the endpoint as

$$E = (a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \tau).$$

The head position of the displayed cons spine gives

$$\rho \sim_{\mathsf{Dens}(H)} \rho_0.$$

The tail positions inherit the same leafwise hypothesis, so the induction hypothesis gives

$$\tau \sim_{\mathsf{Dens}(H)} \rho_0.$$

The binary bracketing clause supplies $\mathsf{Dens}_H(\rho)$, the nonnegative coefficient rows, the local unit-sum comparison $(a + b) \sim_{\mathsf{Real}^{\uparrow}} 1_{\mathsf{Real}^{\uparrow}}$, and the tail bracketing witness. Since the induction hypothesis includes $\mathsf{Dens}_H(\tau)$ through Definition 220.7, the specialized binary affine-combination row of Definition 208.1, concretely proved for density matrices in Definition 220.5, gives

$$\mathsf{Dens}_H(E).$$

Now apply Definition 220.8 to ρ, τ, ρ_0, a, and b. The result is

$$E \sim_{\mathsf{Dens}(H)} \rho_0,$$

which is the endpoint claim for the binary node.

The induction applies to the full bracketing witness packaged by the original affine-spine datum. Therefore the endpoint ρ_{mix} is density-classifier equal to the fixed carried density matrix ρ_0. □

Lean4 ✓ `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine restricted constant exactness`

Closure status for $\mathsf{NameCert}_{\mathsf{DensityMatrix}^{\uparrow}}$.

Constructive story: A density matrix over a carried Hilbert source H is obtained by reading the trace-class carrier from OperatorIdeal$^{\uparrow}$, then keeping only those endpoints ρ that also display positivity and a trace classified with the real unit. The carrier accepts exactly positive trace-class trace-one endpoints, and the classifier is the inherited trace-class classifier restricted to pairs that both remain in that density carrier, so equality never comes from a host matrix identity outside the displayed rows. The source therefore covers Hilbert-indexed trace-class endpoints, the pattern records positivity, trace-one readback, binary and finite affine-mixture closure, and constant-mixture exactness, and the ledger keeps the trace-class witness, positivity witness, trace-one witness, restricted classifier comparison, real weights, list positions, and affine bracketing data visible when mixtures are formed. Since the trace-class classifier is reflexive, symmetric, and transitive and the carrier rows transport through the Hilbert$^{\uparrow}$, OperatorIdeal$^{\uparrow}$, and Real$^{\uparrow}$ surfaces, an admitted density endpoint supplies the carrier witness and classified replacements remain positive, trace-class, and trace one. A row h lies in the signature gap of a DensityMatrix$^{\uparrow}$ token p when the source-domain accepts its Hilbert source, trace-class endpoint, positivity row, trace-one row, and any finite affine ledger, the signature relation pairs that row with an answer endpoint and evidence ledger, and token introduction names the answer as p; unfolded, the endpoint is precisely the positive trace-one trace-class operator encoded by p, with finite mixtures evaluated by the displayed affine spine. The finite affine-mixture certificate is the paper bridge from the concrete density-matrix construction to the abstract density-matrix schema. The chapter registers this trace-class trace-one construction under the name DensityMatrix$^{\uparrow}$; mixed quantum states are certified by positivity and trace ledgers over OperatorIdealUp and HilbertUp, with no spectral decomposition, purification, channel action, or host density-matrix type introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DensityMatrix}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature finite affine-mixture and constant affine-spine boundary is closed for the carrier, restricted classifier, positivity and trace-one ledger, affine-mixture spine, finite closure, constant affine-spine exactness rows, and paper bridge through the finite affine-mixture certificate over the Hilbert$^{\uparrow}$, OperatorIdeal$^{\uparrow}$, Real$^{\uparrow}$, and ListCarrier surfaces used by the cited proofs.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DensityMatrix}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DensityMatrixUp.DensityMatrixAffineMixtureSpine\_finite\_closure`

Bridge status: paperBridge

Not claimed: This chapter does not close the full quantum-state interface, spectral decomposition, purification, channel interaction, or standard-model density-matrix claims.

Upgrade path: No higher paper-side theory grade remains; standard bridge checking is a separate formal-axis target beyond the finite affine-mixture paper bridge.

Chapter 221

A Concrete Naming Certificate for $\mathsf{QuantumChannel}^{\uparrow}$

The quantum-channel interface $\mathsf{QuantumChannel}^{\uparrow}$ packages a completely positive trace-preserving (CPTP) linear map between density-matrix spaces. It depends on $\mathsf{NameCert}_{\mathsf{DensityMatrix}^{\uparrow}}$ (chapter 220) and $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$ (chapter 48).

221.1 Carrier definition

221.2 The certificate

Definition 221.1 (DensityMatrix trace-class carrier)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier, and let $\mathsf{TC}(H)$ be the trace-class operator-ideal carrier supplied for H by the $\mathsf{OperatorIdeal}^{\uparrow}$ dependency of chapter 220. Write $\mathsf{Pos}_H(T)$ for positivity of a trace-class operator on H and $\mathrm{Tr}_H(T)$ for its trace. The concrete $\mathsf{DensityMatrix}^{\uparrow}(H)$ carrier is*

$$\mathsf{Dens}_H(\rho) :\Longleftrightarrow \rho \in \mathsf{TC}(H) \wedge \mathsf{Pos}_H(\rho) \wedge \mathrm{Tr}_H(\rho) = 1.$$

Thus a carried density matrix is exactly positive trace-class trace-one data on the Hilbert carrier named by section 220.1.

Definition 221.2 (QuantumChannel CPTP carrier)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers. A map $\Phi : \mathsf{TC}(H) \to \mathsf{TC}(K)$ is carried by $\mathsf{QuantumChannel}^{\uparrow}(H, K)$, written $\mathsf{QChan}_{H,K}(\Phi)$, when it carries the $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K))$ map-code of Definition 48.1 and satisfies the following two operator rows:*

1. *complete positivity: for every finite ancilla Hilbert carrier A and every positive trace-class operator X on $A \otimes H$, the amplified operator $(\mathrm{id}_A \otimes \Phi)(X)$ is positive trace-class on $A \otimes K$;*
2. *trace preservation: for every $T \in \mathsf{TC}(H)$,*

$$\mathrm{Tr}_K(\Phi(T)) = \mathrm{Tr}_H(T).$$

The carrier is the CPTP linear-map interface announced in chapter 221; its middle space for composition is the displayed trace-class carrier $\mathsf{TC}(K)$.

Lemma 221.3 (QuantumChannel density-matrix image)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers. If*

$$\mathsf{QChan}_{H,K}(\Phi) \qquad \textit{and} \qquad \mathsf{Dens}_H(\rho),$$

then

$$\mathsf{Dens}_K(\Phi(\rho)).$$

Proof. Unpack $\mathsf{Dens}_H(\rho)$ by Definition 221.1. It gives that ρ is trace-class on H, positive, and has trace one. Unpack $\mathsf{QChan}_{H,K}(\Phi)$ by Definition 221.2. The carried $\mathsf{LinMap}^{\uparrow}$ row supplies output closure, so $\Phi(\rho)$ is trace-class on K.

Apply complete positivity with the one-dimensional ancilla. The amplification by the one-dimensional identity is the original map on trace-class operators, hence positivity of ρ gives positivity of $\Phi(\rho)$ on K. Trace preservation gives

$$\mathrm{Tr}_K(\Phi(\rho)) = \mathrm{Tr}_H(\rho) = 1.$$

The three rows are exactly the Dens_K carrier clauses in Definition 221.1. □

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelSingleton densitymatrix image`

Theorem 221.4 (QuantumChannel composition closure)**.** *Let H, K, and L be* $\mathsf{Hilbert}^{\uparrow}$ *carriers with trace-class spaces* $\mathsf{TC}(H)$*,* $\mathsf{TC}(K)$*, and* $\mathsf{TC}(L)$*. If*

$$\mathsf{QChan}_{H,K}(\Phi) \qquad \textit{and} \qquad \mathsf{QChan}_{K,L}(\Psi),$$

then the composite map $\Psi \circ \Phi : \mathsf{TC}(H) \to \mathsf{TC}(L)$ *is carried by* $\mathsf{QuantumChannel}^{\uparrow}(H, L)$*:*

$$\mathsf{QChan}_{H,L}(\Psi \circ \Phi).$$

Moreover every $\mathsf{DensityMatrix}^{\uparrow}(H)$ *input is sent to a* $\mathsf{DensityMatrix}^{\uparrow}(L)$ *output:*

$$\mathsf{Dens}_H(\rho) \Longrightarrow \mathsf{Dens}_L((\Psi \circ \Phi)(\rho)).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine composition closure`

Proof. Unpack the two channel carriers by Definition 221.2. Their $\mathsf{LinMap}^{\uparrow}$ rows are maps

$$\Phi : \mathsf{TC}(H) \to \mathsf{TC}(K) \qquad \text{and} \qquad \Psi : \mathsf{TC}(K) \to \mathsf{TC}(L)$$

with the matching middle trace-class carrier $\mathsf{TC}(K)$. The trace-class carriers are module and vector-space carriers inherited from the operator-ideal and Hilbert surfaces cited in chapter 220. Therefore the composition row of Definition 48.50, concretely supplied by Definition 48.60, gives the carried $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(L))$ map-code for $\Psi \circ \Phi$.

For complete positivity, let A be a finite ancilla Hilbert carrier and let X be a positive trace-class operator on $A \otimes H$. Complete positivity of Φ gives that

$$Y := (\mathrm{id}_A \otimes \Phi)(X)$$

is positive trace-class on $A \otimes K$. Complete positivity of Ψ applied to Y gives that

$$(\mathrm{id}_A \otimes \Psi)(Y)$$

is positive trace-class on $A \otimes L$. The amplified-map ledger is functorial in the operator argument, so

$$(\mathrm{id}_A \otimes \Psi)((\mathrm{id}_A \otimes \Phi)(X)) = (\mathrm{id}_A \otimes (\Psi \circ \Phi))(X).$$

Thus $\Psi \circ \Phi$ is completely positive.

For trace preservation, let $T \in \mathsf{TC}(H)$. Output closure for Φ gives $\Phi(T) \in \mathsf{TC}(K)$. Trace preservation for Ψ, followed by trace preservation for Φ, gives

$$\mathrm{Tr}_L((\Psi \circ \Phi)(T)) = \mathrm{Tr}_L(\Psi(\Phi(T))) = \mathrm{Tr}_K(\Phi(T)) = \mathrm{Tr}_H(T).$$

The linear-map row, complete positivity row, and trace-preservation row are precisely the three clauses of Definition 221.2; hence $\mathsf{QChan}_{H,L}(\Psi \circ \Phi)$ holds.

Finally assume $\mathsf{Dens}_H(\rho)$. Applying Definition 221.3 to the composite channel just constructed gives

$$\mathsf{Dens}_L((\Psi \circ \Phi)(\rho)),$$

which is the asserted $\mathsf{DensityMatrix}^{\uparrow}$ output closure. □

Definition 221.5 (QuantumChannel affine mixture spine)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers, and write*

$$\mathsf{Map}_{H,K} := \mathsf{TC}(H) \to \mathsf{TC}(K).$$

Use the pointwise real scalar action and pointwise trace-class addition on maps,

$$(a \odot_{H,K} \Phi)(T) := a \odot_K \Phi(T), \qquad (\Phi \oplus_{H,K} \Psi)(T) := \Phi(T) +_{\mathsf{TC}(K)} \Psi(T).$$

For a finite map spine $\Phi_s : \mathsf{ListCarrier}(\mathsf{Map}_{H,K})$, a finite real-weight spine $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$, and an endpoint $\Phi_{\mathrm{mix}} : \mathsf{Map}_{H,K}$, define

$$\mathsf{QChanAffSpine}_{H,K}(\Phi_s, \lambda, \Phi_{\mathrm{mix}}) :\Longleftrightarrow \mathsf{ConvAffSpine}_{\mathsf{QChan}_{H,K}}(\Phi_s, \lambda, \Phi_{\mathrm{mix}}),$$

where the right side is the finite affine-spine datum of Definition 208.4 read with carrier $C = \mathsf{QChan}_{H,K}$, scalar action $\odot_{H,K}$, and addition $\oplus_{H,K}$. Thus the datum records carried channel entries, nonnegative real weights with total weight classified as one, and a recursive pointwise affine endpoint.

Lemma 221.6 (QuantumChannel binary convex mixture closure)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers. Let $\Phi, \Psi : \mathsf{TC}(H) \to \mathsf{TC}(K)$ and let a, b be real scalar coefficients. Define $\Phi_{\mathrm{mix}} : \mathsf{TC}(H) \to \mathsf{TC}(K)$ pointwise by*

$$\Phi_{\mathrm{mix}}(T) = (a \odot_K \Phi(T)) +_{\mathsf{TC}(K)} (b \odot_K \Psi(T)).$$

If

$$\mathsf{QChan}_{H,K}(\Phi) \wedge \mathsf{QChan}_{H,K}(\Psi) \wedge \mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(a) \wedge \mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(b) \wedge a + b = 1,$$

then

$$\mathsf{QChan}_{H,K}(\Phi_{\mathrm{mix}}).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelSingleton binary convex mixture closure`

Proof. Unpack the two channel hypotheses by Definition 221.2. Their first rows carry the two $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K))$ map-codes of Definition 48.1. The trace-class carriers are real vector-space and module carriers inherited from the $\mathsf{OperatorIdeal}^{\uparrow}$ and $\mathsf{Hilbert}^{\uparrow}$ dependency surfaces cited in chapter 220.

The pointwise formula for Φ_{mix} gives a carried linear-map code. Indeed, output closure follows from output closure for Φ and Ψ together with scalar-action and addition closure in $\mathsf{TC}(K)$. Source-classifier descent follows by applying the descent rows for Φ and Ψ, then scalar-action congruence and additive congruence in the target trace-class module. Additivity follows from the additivity rows for Φ and Ψ, scalar distributivity over target addition, and the middle-four additive

law in the target module. Scalar compatibility follows from the scalar rows for Φ and Ψ, scalar associativity and commutativity in the real field, and target scalar distributivity over addition. Zero preservation follows from the zero rows for Φ and Ψ, the target zero-action laws, and the target additive unit law. These are exactly the rows of Definition 48.59; equivalently, they are the pointwise-sum mechanism of Definition 48.66 applied after checking the two pointwise scalar multiples. Hence Φ_{mix} carries the required $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K))$ map-code.

For complete positivity, let A be a finite ancilla Hilbert carrier and let X be a positive trace-class operator on $A \otimes H$. Complete positivity of Φ and Ψ gives positive trace-class operators

$$Y_\Phi := (\mathrm{id}_A \otimes \Phi)(X), \qquad Y_\Psi := (\mathrm{id}_A \otimes \Psi)(X)$$

on $A \otimes K$. The amplified-map ledger is pointwise affine in the channel argument, so

$$(\mathrm{id}_A \otimes \Phi_{\mathrm{mix}})(X) = (a \odot_{A\otimes K} Y_\Phi) +_{\mathsf{TC}(A\otimes K)} (b \odot_{A\otimes K} Y_\Psi).$$

The positivity cone on trace-class operators is closed under nonnegative real scalar action and addition, and the hypotheses supply $\mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(a)$ and $\mathsf{NonNeg}_{\mathsf{Real}^{\uparrow}}(b)$. Therefore $(\mathrm{id}_A \otimes \Phi_{\mathrm{mix}})(X)$ is positive trace-class on $A \otimes K$. Since A and X were arbitrary, Φ_{mix} is completely positive.

For trace preservation, let $T \in \mathsf{TC}(H)$. Trace linearity over the trace-class vector carrier and trace preservation for Φ and Ψ give

$$\begin{aligned}
\mathrm{Tr}_K(\Phi_{\mathrm{mix}}(T)) &= a\,\mathrm{Tr}_K(\Phi(T)) + b\,\mathrm{Tr}_K(\Psi(T)) \\
&= a\,\mathrm{Tr}_H(T) + b\,\mathrm{Tr}_H(T) \\
&= (a+b)\,\mathrm{Tr}_H(T) \\
&= \mathrm{Tr}_H(T).
\end{aligned}$$

Thus the linear-map row, complete-positivity row, and trace-preservation row required by Definition 221.2 all hold for Φ_{mix}. □

Theorem 221.7 (QuantumChannel finite convex mixture closure)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers. For every finite map spine $\Phi_s : \mathsf{ListCarrier}(\mathsf{Map}_{H,K})$, finite real-weight spine $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$, and endpoint $\Phi_{\mathrm{mix}} : \mathsf{Map}_{H,K}$, if*

$$\mathsf{QChanAffSpine}_{H,K}(\Phi_s, \lambda, \Phi_{\mathrm{mix}}),$$

then the pointwise affine mixture is carried by $\mathsf{QuantumChannel}^{\uparrow}(H, K)$:

$$\mathsf{QChan}_{H,K}(\Phi_{\mathrm{mix}}).$$

Equivalently, any finite pointwise affine mixture of carried $\mathsf{QChan}_{H,K}$ entries with nonnegative real weights whose finite sum is classified as one is again a carried quantum channel from H to K.

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine finite closure`

Proof. Unpack Definition 221.5. The hypothesis is the finite affine-spine datum of Definition 208.4 specialized to the concrete carrier $C = \mathsf{QChan}_{H,K}$ on the pointwise map carrier $\mathsf{Map}_{H,K}$. It contains the visible finite readback of carried channel entries and nonnegative unit-sum weights, together with a local bracketing witness for the endpoint Φ_{mix}.

Induct on the local bracketing witness. In the singleton clause, the endpoint is the displayed map Φ, and the clause itself supplies $\mathsf{QChan}_{H,K}(\Phi)$.

In the binary-extension clause, the induction hypothesis gives that the tail endpoint Θ is carried by $\mathsf{QChan}_{H,K}$. The same clause supplies a carried head map Φ, nonnegative real coefficients a, b, and the local unit-sum identity $a + b = 1$. Its endpoint is the pointwise map

$$T \longmapsto (a \odot_K \Phi(T)) +_{\mathsf{TC}(K)} (b \odot_K \Theta(T)).$$

Applying Definition 221.6 to Φ, Θ, a, and b gives that this endpoint is carried by $\mathsf{QChan}_{H,K}$.

The induction covers every recursive affine bracketing packaged by $\mathsf{QChanAffSpine}_{H,K}(\Phi_s, \lambda, \Phi_{\mathrm{mix}})$. Hence $\mathsf{QChan}_{H,K}(\Phi_{\mathrm{mix}})$ holds. □

Theorem 221.8 (QuantumChannel finite density-mixture preservation)**.** *Let H and K be $\mathsf{Hilbert}^{\uparrow}$ carriers, let $\Phi : \mathsf{TC}(H) \to \mathsf{TC}(K)$, let $xs : \mathsf{ListCarrier}(\mathsf{TC}(H))$ be a finite trace-class spine, let $\lambda : \mathsf{ListCarrier}(\mathsf{Real}^{\uparrow})$ be a finite real-weight spine, and let $\rho_{\mathrm{mix}} \in \mathsf{TC}(H)$. Write $\Phi_* xs$ for the entrywise image spine defined by*

$$\Phi_*(\mathsf{nil}) := \mathsf{nil}, \qquad \Phi_*(\mathsf{cons}(\rho, xs')) := \mathsf{cons}(\Phi(\rho), \Phi_*(xs')).$$

If

$$\mathsf{QChan}_{H,K}(\Phi) \qquad \textit{and} \qquad \mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}}),$$

then

$$\mathsf{DensAffSpine}_K(\Phi_* xs, \lambda, \Phi(\rho_{\mathrm{mix}})) \qquad \textit{and} \qquad \mathsf{Dens}_K(\Phi(\rho_{\mathrm{mix}})).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine density mixture preservation`

Proof. Unpack $\mathsf{QChan}_{H,K}(\Phi)$ by Definition 221.2. Its carried $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K))$ row, read through Definition 48.1, supplies output closure, additivity, and scalar compatibility on the trace-class vector carriers. Hence for carried trace-class endpoints T, U and real scalars a, b,

$$\Phi\big((a \odot_H T) +_{\mathsf{TC}(H)} (b \odot_H U)\big) = (a \odot_K \Phi(T)) +_{\mathsf{TC}(K)} (b \odot_K \Phi(U)).$$

Unpack $\mathsf{DensAffSpine}_H(xs, \lambda, \rho_{\mathrm{mix}})$ by Definition 220.4. This is the affine-spine datum of Definition 208.4 for the concrete carrier Dens_H. The global readback gives a position match between xs and λ, carried source entries, nonnegative weights, and unit finite weight sum. The recursive definition of $\Phi_* xs$ has the same finite positions as xs, so the same position match applies to $\Phi_* xs$ and λ. For each displayed source entry ρ, the readback gives $\mathsf{Dens}_H(\rho)$; applying Definition 221.3 gives $\mathsf{Dens}_K(\Phi(\rho))$. The weight nonnegativity clauses and the finite unit-sum clause are unchanged, since the weight spine is still λ.

It remains to rebuild the local bracketing witness over K. Induct on the source bracketing witness packaged by Definition 208.4. In the singleton clause, the source clause supplies $\mathsf{Dens}_H(\rho)$, nonnegativity of the displayed weight, and classification of that weight as the scalar unit. The density-image lemma gives $\mathsf{Dens}_K(\Phi(\rho))$, and the singleton bracketing clause over K gives the target bracket for $\mathsf{cons}(\Phi(\rho), \mathsf{nil})$ with endpoint $\Phi(\rho)$.

In the binary-extension clause, write the source endpoint as

$$z = (a \odot_H \rho) +_{\mathsf{TC}(H)} (b \odot_H \tau).$$

The induction hypothesis gives the target tail bracket with endpoint $\Phi(\tau)$. The source clause supplies $\mathsf{Dens}_H(\rho)$, nonnegativity of a and b, and the same local unit-sum comparison. By Definition 221.3, $\mathsf{Dens}_K(\Phi(\rho))$. The binary bracketing clause over K therefore builds the endpoint

$$(a \odot_K \Phi(\rho)) +_{\mathsf{TC}(K)} (b \odot_K \Phi(\tau)).$$

The displayed linearity identity rewrites this target endpoint as $\Phi(z)$. Thus the binary target bracket matches the entrywise image spine and has endpoint $\Phi(z)$.

The induction supplies the target bracketing witness for the whole source witness, and the global readback was already rebuilt. Repacking these two rows by Definition 220.4 gives

$$\mathsf{DensAffSpine}_K(\Phi_* xs, \lambda, \Phi(\rho_{\mathrm{mix}})).$$

Applying Definition 220.6 to this target density affine spine gives $\mathsf{Dens}_K(\Phi(\rho_{\mathrm{mix}}))$. □

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine density preservation`

Theorem 221.9 (QuantumChannel identity channel is CPTP)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier, and let $\mathrm{id}_{\mathsf{TC}(H)} : \mathsf{TC}(H) \to \mathsf{TC}(H)$ be the identity function on the trace-class carrier supplied by the $\mathsf{OperatorIdeal}^{\uparrow}$ dependency of chapter 220. Then*

$$\mathsf{QChan}_{H,H}(\mathrm{id}_{\mathsf{TC}(H)}).$$

Moreover every carried density matrix is sent to the same carried density-matrix endpoint:

$$\mathsf{Dens}_H(\rho) \Longrightarrow \mathrm{id}_{\mathsf{TC}(H)}(\rho) = \rho \wedge \mathsf{Dens}_H(\mathrm{id}_{\mathsf{TC}(H)}(\rho)).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelSingleton identity channel cptp`

Proof. The trace-class carrier $\mathsf{TC}(H)$ is a module carrier over the scalar certificate used by the trace-class operator-ideal surface. Applying Definition 48.61 with $M = \mathsf{TC}(H)$ gives the module identity certificate for $\mathrm{id}_{\mathsf{TC}(H)}$. Read through Definition 48.1, this is exactly the carried $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(H))$ map-code required as the first row of Definition 221.2.

For complete positivity, let A be a finite ancilla Hilbert carrier and let X be a positive trace-class operator on $A \otimes H$. The amplified identity map is the identity on the trace-class carrier over $A \otimes H$:

$$(\mathrm{id}_A \otimes \mathrm{id}_{\mathsf{TC}(H)})(X) = X.$$

The input X is already positive trace-class on $A \otimes H$, and the target channel also has Hilbert carrier H. Hence the complete-positivity row of Definition 221.2 holds.

For trace preservation, let $T \in \mathsf{TC}(H)$. Since the map is the identity on $\mathsf{TC}(H)$,

$$\mathrm{Tr}_H(\mathrm{id}_{\mathsf{TC}(H)}(T)) = \mathrm{Tr}_H(T).$$

Thus the linear-map row, complete-positivity row, and trace-preservation row are precisely the three clauses of Definition 221.2, so

$$\mathsf{QChan}_{H,H}(\mathrm{id}_{\mathsf{TC}(H)})$$

holds.

Now assume $\mathsf{Dens}_H(\rho)$. The identity equation gives $\mathrm{id}_{\mathsf{TC}(H)}(\rho) = \rho$. Applying Definition 221.3 to the channel just constructed gives

$$\mathsf{Dens}_H(\mathrm{id}_{\mathsf{TC}(H)}(\rho)),$$

which is the asserted density-matrix output clause. □

Theorem 221.10 (QuantumChannel composition associativity law)**.** *Let H, K, L, and J be* $\mathsf{Hilbert}^{\uparrow}$ *carriers with trace-class spaces* $\mathsf{TC}(H)$, $\mathsf{TC}(K)$, $\mathsf{TC}(L)$, *and* $\mathsf{TC}(J)$. *Write* $\sim_{\mathsf{TC}(J)}$ *for the classifier on the final trace-class module inherited from the operator-ideal certificate. If*

$$\mathsf{QChan}_{H,K}(\Phi), \qquad \mathsf{QChan}_{K,L}(\Psi), \qquad \mathsf{QChan}_{L,J}(\Theta),$$

then both bracketings of the triple composite are carried by $\mathsf{QuantumChannel}^{\uparrow}(H, J)$*:*

$$\mathsf{QChan}_{H,J}((\Theta \circ \Psi) \circ \Phi) \qquad \textit{and} \qquad \mathsf{QChan}_{H,J}(\Theta \circ (\Psi \circ \Phi)).$$

Their underlying map-code endpoints are related by the pointwise $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(J))$ *classifier:*

$$(\Theta \circ \Psi) \circ \Phi \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(J))} \Theta \circ (\Psi \circ \Phi).$$

Equivalently, every carried trace-class endpoint $T : \mathsf{TC}(H)$ *satisfies*

$$((\Theta \circ \Psi) \circ \Phi)(T) \sim_{\mathsf{TC}(J)} (\Theta \circ (\Psi \circ \Phi))(T).$$

Moreover, every carried density-matrix input is sent to carried density-matrix outputs by both bracketings:

$$\mathsf{Dens}_H(\rho) \Longrightarrow \mathsf{Dens}_J(((\Theta \circ \Psi) \circ \Phi)(\rho)) \wedge \mathsf{Dens}_J((\Theta \circ (\Psi \circ \Phi))(\rho)).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine composition assoc`

Proof. Apply Definition 221.4 to Φ and Ψ. This gives

$$\mathsf{QChan}_{H,L}(\Psi \circ \Phi).$$

Applying the same theorem to $\Psi \circ \Phi$ and Θ gives

$$\mathsf{QChan}_{H,J}(\Theta \circ (\Psi \circ \Phi)).$$

In the other bracketing, first apply Definition 221.4 to Ψ and Θ, obtaining

$$\mathsf{QChan}_{K,J}(\Theta \circ \Psi).$$

Applying the same theorem to Φ and $\Theta \circ \Psi$ gives

$$\mathsf{QChan}_{H,J}((\Theta \circ \Psi) \circ \Phi).$$

By Definition 221.2, these two carrier conclusions include the carried $\mathsf{LinMap}^{\uparrow}$ map-code row, complete positivity for every finite ancilla, and trace preservation on $\mathsf{TC}(H)$.

It remains to compare the two carried map-code endpoints. Unpack the three channel hypotheses by Definition 221.2. Their first rows are carried $\mathsf{LinMap}^{\uparrow}$ map-codes, read concretely as the module-linear packages of Definition 48.59 through Definition 48.1. The trace-class carriers are module carriers over the common scalar source inherited from the $\mathsf{OperatorIdeal}^{\uparrow}$ and $\mathsf{Hilbert}^{\uparrow}$ dependency surfaces cited in chapter 220. Applying Definition 48.62 with

$$M = \mathsf{TC}(H), \qquad N = \mathsf{TC}(K), \qquad P = \mathsf{TC}(L), \qquad Q = \mathsf{TC}(J),$$

and with $f = \Phi$, $g = \Psi$, and $k = \Theta$, gives the pointwise $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(J))$ classifier comparison

$$(\Theta \circ \Psi) \circ \Phi \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(J))} \Theta \circ (\Psi \circ \Phi).$$

This is exactly the classifier specified in Definition 48.49: it is pointwise comparison in the final trace-class classifier, together with the two carried map-code endpoints already supplied by the two channel-carrier conclusions above.

Concretely, let T be a carried trace-class endpoint of $\mathsf{TC}(H)$. The output-closure rows of the three input channel map-codes make $\Phi(T)$ carried in $\mathsf{TC}(K)$, $\Psi(\Phi(T))$ carried in $\mathsf{TC}(L)$, and $\Theta(\Psi(\Phi(T)))$ carried in $\mathsf{TC}(J)$. Both bracketed composites evaluate to this same endpoint:

$$((\Theta \circ \Psi) \circ \Phi)(T) = \Theta(\Psi(\Phi(T))) = (\Theta \circ (\Psi \circ \Phi))(T).$$

Classifier reflexivity for the final trace-class module therefore gives

$$((\Theta \circ \Psi) \circ \Phi)(T) \sim_{\mathsf{TC}(J)} (\Theta \circ (\Psi \circ \Phi))(T),$$

which is the displayed pointwise form.

Finally assume $\mathsf{Dens}_H(\rho)$. Applying Definition 221.3 to the channel $\mathsf{QChan}_{H,J}((\Theta \circ \Psi) \circ \Phi)$ gives

$$\mathsf{Dens}_J(((\Theta \circ \Psi) \circ \Phi)(\rho)).$$

Applying the same lemma to $\mathsf{QChan}_{H,J}(\Theta \circ (\Psi \circ \Phi))$ gives

$$\mathsf{Dens}_J((\Theta \circ (\Psi \circ \Phi))(\rho)).$$

These are the two asserted density-output clauses. □

Definition 221.11 (Unitary trace-class conjugation map)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier and let $U : H \to H$ be an endpoint carried by the $\mathsf{UnitaryGroup}^{\uparrow}(H)$ carrier of section 219.1. Write $U^{-1} : H \to H$ for the inverse endpoint supplied by the same unitary automorphism row. For $T \in \mathsf{TC}(H)$ define the unitary trace-class conjugation expression by*

$$\mathrm{Ad}_U^{\mathsf{TC}}(T) := U \circ T \circ U^{-1}.$$

The expression is read in the bounded-operator composition ring over H from Definition 213.1; its trace-class output closure is the first carrier row proved in Definition 221.12.

Theorem 221.12 (Unitary conjugation is a QuantumChannel)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier. If $U : H \to H$ is carried by the $\mathsf{UnitaryGroup}^{\uparrow}(H)$ automorphism carrier and U^{-1} is its carried inverse, then the conjugation map of Definition 221.11 is carried by $\mathsf{QuantumChannel}^{\uparrow}(H, H)$:*

$$\mathsf{QChan}_{H,H}(\mathrm{Ad}_U^{\mathsf{TC}}).$$

Consequently every carried density matrix is sent to a carried density matrix:

$$\mathsf{Dens}_H(\rho) \Longrightarrow \mathsf{Dens}_H(\mathrm{Ad}_U^{\mathsf{TC}}(\rho)).$$

Proof. Unpack the $\mathsf{UnitaryGroup}^{\uparrow}$ carrier cited in section 219.1. The unitary witness supplies bounded $\mathsf{LinMap}^{\uparrow}(H, H)$ endpoints U and U^{-1}, the two inverse equations against the Hilbert identity, and the inner-product preservation row identifying U^{-1} with the adjoint-side action of U. Hence both endpoints are carried bounded operators in the ambient operator surface Op_H of Definition 213.1.

First prove trace-class output closure. Let $T \in \mathsf{TC}(H)$. Apply the right absorption half of Definition 213.5 to the carried bounded operator U^{-1} and the trace-class operator T. This gives

$T \circ U^{-1} \in \mathsf{TC}(H)$. Apply the left absorption half of the same theorem to the carried bounded operator U and this trace-class operator. The result is

$$U \circ T \circ U^{-1} \in \mathsf{TC}(H),$$

which is output closure for $\mathrm{Ad}_U^{\mathsf{TC}}$.

The same bounded-composition rows give the linear-map package. Source-classifier descent follows from the operator-ideal classifier transport row, since composing on the left by the fixed carried bounded operator U and on the right by the fixed carried bounded operator U^{-1} preserves the pointwise bounded-operator classifier. For carried $T, S \in \mathsf{TC}(H)$ and a carried real scalar a, bilinearity of bounded-operator composition over the trace-class module gives

$$\mathrm{Ad}_U^{\mathsf{TC}}(T +_{\mathsf{TC}(H)} S) = \mathrm{Ad}_U^{\mathsf{TC}}(T) +_{\mathsf{TC}(H)} \mathrm{Ad}_U^{\mathsf{TC}}(S)$$

and

$$\mathrm{Ad}_U^{\mathsf{TC}}(a \odot_H T) = a \odot_H \mathrm{Ad}_U^{\mathsf{TC}}(T).$$

The zero row is the same calculation at the trace-class zero operator. These are the output-closure, descent, additive, scalar, and zero rows of Definition 48.59, read through the concrete $\mathsf{LinMap}^{\uparrow}$ carrier in Definition 48.1. Thus $\mathrm{Ad}_U^{\mathsf{TC}}$ carries the required linear-map row in Definition 221.2.

For complete positivity, let A be a finite ancilla Hilbert carrier and let X be a positive trace-class operator on $A \otimes H$. Put

$$V_A := \mathrm{id}_A \otimes U, \qquad V_A^{-1} := \mathrm{id}_A \otimes U^{-1}.$$

The tensor row for Hilbert carriers makes V_A a carried unitary automorphism of $A \otimes H$ with inverse V_A^{-1}. The amplified conjugation map is the corresponding bounded conjugation:

$$(\mathrm{id}_A \otimes \mathrm{Ad}_U^{\mathsf{TC}})(X) = V_A \circ X \circ V_A^{-1}.$$

Trace-class membership of this amplified output follows from Definition 213.5 on $A \otimes H$. For positivity, evaluate the quadratic-form predicate at an arbitrary carried vector z of $A \otimes H$. The unitary inverse-adjoint row gives

$$\langle V_A \circ X \circ V_A^{-1} z, z\rangle = \langle X(V_A^{-1} z), V_A^{-1} z\rangle.$$

Since X is positive and $V_A^{-1} z$ is again a carried Hilbert endpoint, the right side is nonnegative. Therefore the amplified output is positive trace-class on $A \otimes H$. As A and X were arbitrary, $\mathrm{Ad}_U^{\mathsf{TC}}$ is completely positive.

For trace preservation, let $T \in \mathsf{TC}(H)$. The cyclic trace row for one trace-class factor and one carried bounded factor gives

$$\begin{aligned}
\mathrm{Tr}_H(\mathrm{Ad}_U^{\mathsf{TC}}(T)) &= \mathrm{Tr}_H(U \circ (T \circ U^{-1})) \\
&= \mathrm{Tr}_H((T \circ U^{-1}) \circ U) \\
&= \mathrm{Tr}_H(T \circ (U^{-1} \circ U)) \\
&= \mathrm{Tr}_H(T \circ \mathrm{id}_H) \\
&= \mathrm{Tr}_H(T).
\end{aligned}$$

The last two equalities use the inverse equation supplied by the unitary automorphism row and the bounded-operator identity law.

The carried linear-map row, complete-positivity row, and trace-preservation row are precisely the clauses of Definition 221.2; hence

$$\mathsf{QChan}_{H,H}(\mathrm{Ad}_U^{\mathsf{TC}})$$

holds. If $\mathsf{Dens}_H(\rho)$, applying Definition 221.3 to this channel gives

$$\mathsf{Dens}_H(\mathrm{Ad}_U^{\mathsf{TC}}(\rho)),$$

which is the asserted density-matrix endpoint preservation. □

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelUnitaryConjugation channel`

Theorem 221.13 (QuantumChannel identity composition unit laws)**.** *Let H and K be* $\mathsf{Hilbert}^{\uparrow}$ *carriers with trace-class spaces* $\mathsf{TC}(H)$ *and* $\mathsf{TC}(K)$*. Let* $\mathrm{id}_{\mathsf{TC}(H)}$ *and* $\mathrm{id}_{\mathsf{TC}(K)}$ *be the identity functions on these trace-class carriers, and write* $\sim_{\mathsf{TC}(K)}$ *for the target trace-class classifier inherited from the* $\mathsf{OperatorIdeal}^{\uparrow}$ *dependency surface. If*

$$\mathsf{QChan}_{H,K}(\Phi),$$

then both unit composites are carried by $\mathsf{QuantumChannel}^{\uparrow}(H,K)$*:*

$$\mathsf{QChan}_{H,K}(\Phi \circ \mathrm{id}_{\mathsf{TC}(H)}) \qquad \textit{and} \qquad \mathsf{QChan}_{H,K}(\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi).$$

Moreover both unit composites are related to Φ by the pointwise $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))$ *classifier:*

$$\Phi \circ \mathrm{id}_{\mathsf{TC}(H)} \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))} \Phi \qquad \textit{and} \qquad \mathrm{id}_{\mathsf{TC}(K)} \circ \Phi \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))} \Phi.$$

Equivalently, every carried trace-class endpoint $T \in \mathsf{TC}(H)$ satisfies

$$(\Phi \circ \mathrm{id}_{\mathsf{TC}(H)})(T) \sim_{\mathsf{TC}(K)} \Phi(T) \qquad \textit{and} \qquad (\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi)(T) \sim_{\mathsf{TC}(K)} \Phi(T).$$

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelSingleton identity composition unit laws`
Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelAffineMixtureSpine unit laws`

Proof. Apply Definition 221.9 to H and to K. This gives

$$\mathsf{QChan}_{H,H}(\mathrm{id}_{\mathsf{TC}(H)}) \qquad \text{and} \qquad \mathsf{QChan}_{K,K}(\mathrm{id}_{\mathsf{TC}(K)}).$$

Applying Definition 221.4 first to $\mathrm{id}_{\mathsf{TC}(H)}$ and Φ gives

$$\mathsf{QChan}_{H,K}(\Phi \circ \mathrm{id}_{\mathsf{TC}(H)}).$$

Applying the same theorem to Φ and $\mathrm{id}_{\mathsf{TC}(K)}$ gives

$$\mathsf{QChan}_{H,K}(\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi).$$

These are the two carried quantum-channel clauses.

It remains to compare the underlying map-code endpoints. Unpack $\mathsf{QChan}_{H,K}(\Phi)$ by Definition 221.2. Its first row carries the $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))$ map-code of Definition 48.1. The trace-class carriers are module carriers over the scalar certificate inherited from the $\mathsf{OperatorIdeal}^{\uparrow}$ and $\mathsf{Hilbert}^{\uparrow}$ dependency surfaces cited in chapter 220. Applying Definition 48.63 with

$$M = \mathsf{TC}(H), \qquad N = \mathsf{TC}(K), \qquad f = \Phi,$$

gives the two pointwise $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K))$ classifier comparisons

$$\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))} \Phi \qquad \text{and} \qquad \Phi \circ \mathrm{id}_{\mathsf{TC}(H)} \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(K))} \Phi.$$

For the displayed pointwise form, let T be a carried trace-class endpoint of $\mathsf{TC}(H)$. The output-closure row of the carried $\mathsf{LinMap}^{\uparrow}$ map-code for Φ gives that $\Phi(T)$ is carried in $\mathsf{TC}(K)$. The identity equations give

$$(\Phi \circ \mathrm{id}_{\mathsf{TC}(H)})(T) = \Phi(T) \qquad \text{and} \qquad (\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi)(T) = \Phi(T).$$

Classifier reflexivity for the target trace-class module therefore gives

$$(\Phi \circ \mathrm{id}_{\mathsf{TC}(H)})(T) \sim_{\mathsf{TC}(K)} \Phi(T) \qquad \text{and} \qquad (\mathrm{id}_{\mathsf{TC}(K)} \circ \Phi)(T) \sim_{\mathsf{TC}(K)} \Phi(T).$$

By Definition 48.49, these pointwise target-classifier comparisons are exactly the underlying $\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H), \mathsf{TC}(K$ classifier relations. □

Theorem 221.14 (Unitary conjugation channel composition law)**.** *Let H be a $\mathsf{Hilbert}^{\uparrow}$ carrier. Let $U, V : H \to H$ be endpoints carried by the $\mathsf{UnitaryGroup}^{\uparrow}(H)$ automorphism carrier, with carried inverses U^{-1} and V^{-1}. Let $W := U \circ V$ be their unitary-group product endpoint, and let $W^{-1} := V^{-1} \circ U^{-1}$ be the inverse endpoint supplied by the product row. Then the composite conjugation map and the product-unitary conjugation map are both carried quantum channels:*

$$\mathsf{QChan}_{H,H}(\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}}) \qquad \textit{and} \qquad \mathsf{QChan}_{H,H}(\mathrm{Ad}_W^{\mathsf{TC}}).$$

Moreover the composite channel endpoint is classified by the product-unitary endpoint:

$$\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}} \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(H))} \mathrm{Ad}_W^{\mathsf{TC}}.$$

Equivalently, writing $\sim_{\mathsf{TC}(H)}$ for the trace-class classifier inherited from the operator-ideal surface, every carried trace-class endpoint $T \in \mathsf{TC}(H)$ satisfies

$$(\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}})(T) \sim_{\mathsf{TC}(H)} \mathrm{Ad}_{U \circ V}^{\mathsf{TC}}(T).$$

Consequently every carried density matrix is sent to carried density-matrix endpoints by both representatives:

$$\mathsf{Dens}_H(\rho) \Longrightarrow \mathsf{Dens}_H((\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}})(\rho)) \wedge \mathsf{Dens}_H(\mathrm{Ad}_W^{\mathsf{TC}}(\rho)).$$

Proof. The $\mathsf{UnitaryGroup}^{\uparrow}(H)$ automorphism carrier cited in section 219.1 is a group of Hilbert automorphisms. Thus its product row carries $W = U \circ V$, and the inverse row identifies the carried inverse of W with $V^{-1} \circ U^{-1}$. Applying Definition 221.12 to U, to V, and to W gives

$$\mathsf{QChan}_{H,H}(\mathrm{Ad}_U^{\mathsf{TC}}), \qquad \mathsf{QChan}_{H,H}(\mathrm{Ad}_V^{\mathsf{TC}}), \qquad \mathsf{QChan}_{H,H}(\mathrm{Ad}_W^{\mathsf{TC}}).$$

Apply Definition 221.4 with $\Phi = \mathrm{Ad}_V^{\mathsf{TC}}$ and $\Psi = \mathrm{Ad}_U^{\mathsf{TC}}$. This gives the carried composite channel

$$\mathsf{QChan}_{H,H}(\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}}).$$

Together with the displayed W clause, this proves the two quantum-channel carrier conclusions.

It remains to identify the endpoints. Let T be a carried endpoint of $\mathsf{TC}(H)$. By Definition 221.11,

$$(\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}})(T) = U \circ (V \circ T \circ V^{-1}) \circ U^{-1}.$$

The bounded-operator composition ring over H from Definition 213.1 is associative on carried endpoints, and Definition 213.5 supplies the trace-class carrier rows for each intermediate conjugation. Hence the displayed endpoint is classified in the trace-class carrier with

$$(U \circ V) \circ T \circ (V^{-1} \circ U^{-1}).$$

The product inverse row gives $W^{-1} = V^{-1} \circ U^{-1}$, while $W = U \circ V$ by definition. Therefore

$$(U \circ V) \circ T \circ (V^{-1} \circ U^{-1}) = W \circ T \circ W^{-1} = \mathrm{Ad}_W^{\mathsf{TC}}(T).$$

Classifier reflexivity and classifier transport in the trace-class operator-ideal carrier give

$$(\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}})(T) \sim_{\mathsf{TC}(H)} \mathrm{Ad}_W^{\mathsf{TC}}(T).$$

Since T was arbitrary, Definition 48.49 packages these pointwise trace-class comparisons, together with the two carried linear-map rows included in the two channel carrier conclusions by Definition 221.2, as

$$\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}} \sim_{\mathsf{LinMap}^{\uparrow}(\mathsf{TC}(H),\mathsf{TC}(H))} \mathrm{Ad}_W^{\mathsf{TC}}.$$

Finally assume $\mathsf{Dens}_H(\rho)$. Applying Definition 221.3 to the composite channel gives

$$\mathsf{Dens}_H((\mathrm{Ad}_U^{\mathsf{TC}} \circ \mathrm{Ad}_V^{\mathsf{TC}})(\rho)).$$

Applying the same lemma to $\mathsf{QChan}_{H,H}(\mathrm{Ad}_W^{\mathsf{TC}})$ gives

$$\mathsf{Dens}_H(\mathrm{Ad}_W^{\mathsf{TC}}(\rho)).$$

These are the asserted density-matrix endpoint clauses. □

Lean4 ✓ `BEDC.Derived.QuantumChannelUp.QuantumChannelUnitaryConjugation composition law`

Closure status for $\mathsf{NameCert}_{\mathsf{QuantumChannel}^{\uparrow}}$.

Constructive story: A quantum channel from a carried Hilbert source H to a carried Hilbert target K is built by taking a $\mathsf{LinMap}^{\uparrow}$ code between the two trace-class carriers and adding the two CPTP rows: complete positivity under every finite ancilla and trace preservation on every trace-class endpoint. The carrier accepts only maps with that linear row, complete-positivity row, and trace-preservation row, while the classifier compares channels pointwise through the trace-class and linear-map classifiers and keeps the same density-matrix image, composition, affine-mixture, identity, and unitary-conjugation ledgers. The source therefore covers trace-class linear maps between $\mathsf{DensityMatrix}^{\uparrow}$ surfaces, the pattern records density-matrix image closure, composition closure and associativity, finite convex mixture closure, identity-channel unit laws, and unitary conjugation, and the ledger keeps the underlying $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{OperatorIdeal}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, and $\mathsf{UnitaryGroup}^{\uparrow}$ rows visible. Since the dependency classifiers and pointwise trace-class comparisons are equivalence relations and CPTP rows are stable under composition, convex combination, identity, and unitary conjugation as displayed, an admitted channel supplies the carrier witness, the classifier is reflexive, symmetric, and transitive, and classified replacements remain carried channels. A map row h lies in the signature gap of a $\mathsf{QuantumChannel}^{\uparrow}$ token p when the source-domain accepts its linear trace-class map and CPTP ledger, the signature relation pairs it with an answer channel and evidence ledger, and token introduction names that answer as p; unfolded, h sends every carried density matrix to the carried density matrix and channel behavior encoded by p. No standard quantum-information bridge is exported here. The chapter registers this CPTP-map construction under the name $\mathsf{QuantumChannel}^{\uparrow}$; a channel is a displayed linear trace-class map with positivity and trace ledgers, with no Stinespring dilation, external channel category, or host quantum-information primitive introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{QuantumChannel}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The obligation scope displayed in this chapter consists of the CPTP carrier, density-matrix image, composition closure and associativity, finite convex mixture closure, finite density-mixture preservation, identity channel, identity unit laws, unitary conjugation channel, and unitary-conjugation composition law over the $\mathsf{DensityMatrix}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{OperatorIdeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{UnitaryGroup}^{\uparrow}$, and BHist surfaces.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{QuantumChannel}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.QuantumChannelUp.QuantumChannelUnitaryConjugation\_composition\_law`

Bridge status: none

Not claimed: This chapter does not claim Stinespring dilation, full quantum information theory, a standard quantum-information bridge, or bridge verification.

Upgrade path: No further paper-axis upgrade is required for the mature $\mathsf{QuantumChannel}^{\uparrow}$ package displayed here.

Chapter 222

A Concrete Naming Certificate for $\mathsf{Entanglement}^{\uparrow}$

The entanglement interface $\mathsf{Entanglement}^{\uparrow}$ packages the structure obstruction of a bipartite quantum state to factor as a tensor product of pure states, certified via Schmidt rank or entanglement entropy. It depends on $\mathsf{NameCert}_{\mathsf{QuantumState}^{\uparrow}}$ (chapter 217) and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87).

222.1 Carrier definition

Definition 222.1 (EntanglementUp BHist source surface)**.** *An* $\mathsf{Entanglement}^{\uparrow}$ *BHist source surface consists of a* $\mathsf{QuantumState}^{\uparrow}$ *row for the displayed bipartite state,* $\mathsf{TensorProduct}^{\uparrow}$ *factor rows for the two displayed factors, a bipartite state endpoint, a factorization-obstruction witness for that endpoint,* hsame *transport rows for the state and factor endpoints, and* Pkg *provenance for all displayed rows. The obstruction row is part of the certified source surface; it is not a host-level negation over all possible decompositions.*

Lean4 (definition) `BEDC.Derived.EntanglementUp.EntanglementSourceSurface`

Theorem 222.2 (Entanglement source factor boundary)**.** *Consumers of the* $\mathsf{Entanglement}^{\uparrow}$ *source surface may read only the two displayed factor rows, the bipartite endpoint row, the factorization-obstruction witness, the* hsame *transport rows, and the* Pkg *provenance from Definition 222.1. No Schmidt-rank completeness theorem, entropy criterion, or classification of all bipartite states is included in this boundary.*

Lean4 ✓ `BEDC.Derived.EntanglementUp.EntanglementSourceSurface factor boundary`

Proof. Unpack the source surface as a finite BHist package. The $\mathsf{QuantumState}^{\uparrow}$ row supplies the carried bipartite endpoint, and the two $\mathsf{TensorProduct}^{\uparrow}$ rows name the displayed factor histories read by downstream tensor consumers.

Project the obstruction row and the hsame transport rows from the same package. Repacking these projections through Pkg gives exactly the visible consumer boundary, while completeness principles about Schmidt rank or entropy would require rows absent from the displayed source surface. □

Lean4 ✓ `BEDC.Derived.EntanglementUp.EntanglementBHistSourceSurface factor boundary`

Theorem 222.3 (Entanglement obstruction transport stability)**.** *Let two* Entanglement$^{\uparrow}$ *BHist source surfaces have* hsame*-related bipartite endpoints,* hsame*-related factor endpoints, the same displayed factorization-obstruction row transported through the package, and the same* Pkg *provenance. Then consumers of the two surfaces read the same obstruction boundary.*

The stable boundary is only the displayed obstruction row together with its transport and provenance data. It does not classify Schmidt rank, compute entanglement entropy, or decide completeness of all tensor-product factorizations.

Lean4 ✓ `BEDC.Derived.EntanglementUp.EntanglementBHistSourceSurface obstruction transport stability`

Proof. Unpack the two source surfaces using Definition 222.1. Their visible data consist of the bipartite endpoint row, the two factor rows, the obstruction row, hsame transports for the state and factor endpoints, and Pkg provenance.

Use the assumed hsame rows to transport the bipartite and factor endpoints inside the same package provenance. Because the displayed obstruction row is also transported through that package, the consumer sees one obstruction boundary rather than two independent host-level negations.

Reapply Definition 222.2. That boundary permits consumers to read exactly the transported obstruction, endpoint, factor, transport, and provenance rows. Since Schmidt-rank completeness and entropy classification are absent from the source surface, the stability claim does not depend on them. □

222.2 The certificate

Theorem 222.4 (EntanglementUp NameCert obligation surface)**.** *The* Entanglement$^{\uparrow}$ *NameCert obligation surface for Definition 222.1 is the package containing its* QuantumState$^{\uparrow}$ *endpoint row, the two* TensorProduct$^{\uparrow}$ *factor rows, the factorization-obstruction row, the* hsame *transport rows, and the* Pkg *provenance. Certificate consumers may demand those rows and no stronger entanglement invariant.*

Lean4 ✓ `BEDC.Derived.EntanglementUp.EntanglementBHistSourceSurface namecert obligation surface`

Proof. Start from the source factor boundary of Definition 222.2. It already separates the state endpoint, factor rows, obstruction witness, transport rows, and provenance rows.

Repack those rows into the NameCert fields: carrier from the state endpoint, dependencies from QuantumState$^{\uparrow}$ and TensorProduct$^{\uparrow}$, stability from the hsame transports, and ledger provenance from Pkg. Since no row supplies a complete Schmidt decomposition or entropy comparison, the certificate closes only this displayed obligation surface. □

Closure status for NameCert$_{\text{Entanglement}^{\uparrow}}$.

Constructive story: An Entanglement$^{\uparrow}$ packet is generated from a QuantumStateUp bipartite endpoint row, TensorProductUp factor endpoint rows, a displayed factorization-obstruction witness, componentwise hsame transport for state and factors, finite route rows, Pkg provenance, and local naming. The classifier reads entanglement as an obstruction surface carried by the same finite BHist packet: source factors are exposed, the obstruction transports along the displayed state and factor rows, and the NameCert surface repacks carrier, classifier, stability, and ledger provenance. The ledger story is quantum-structural but finite: no complete Schmidt decomposition, entropy comparison, Hilbert-space quotient, or host tensor equality is added beyond the displayed obstruction route.

Theory closure: TheoryGate(NameCert$_{\text{Entanglement}^{\uparrow}}$, seed)

Scope closed: This chapter binds the BHist source-surface definition and the source-factor-boundary, obstruction-transport-stability, and NameCert-obligation theorems for Entanglement$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{Entanglement}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim complete Schmidt decompositions, entropy comparisons, host tensor-factor equality, or quantum-state data beyond the displayed source and obstruction rows.

Upgrade path: To reach obligationClosure, the obstruction carrier and transport-stability theorem must be assembled into a checked packet-level closure statement.

Chapter 223

A Concrete Naming Certificate for $\mathsf{NewtonIteration}^{\uparrow}$

The Newton-iteration interface $\mathsf{NewtonIteration}^{\uparrow}$ packages the iterative scheme $x_{n+1} = x_n - F(x_n)/F'(x_n)$ for finding zeros of a differentiable map, with quadratic convergence on a contraction neighbourhood. It depends on $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ (chapter 122) and $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ (chapter 90).

223.1 Carrier definition

Definition 223.1 (Newton-iteration finite step carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *derivative source row and a* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *normed-source row for the same displayed point context. A* $\mathsf{NewtonIteration}^{\uparrow}$ *carrier row is the finite* BHist *ledger recording the source point answer, the derivative answer row at that point, an inverse-row witness for the displayed derivative answer, the next-step answer row, and the* Cont *witnesses that place the step computation inside the derivative and Banach source ledgers.*

The carrier records one finite Newton step or a finite list of such displayed steps. It does not assert convergence, completeness of the ambient space, a contraction theorem, or a radius of validity.

Lean4 (definition) `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier`

Definition 223.2 (Newton-iteration contraction classifier)**.** *Two rows of Definition 223.1 are classified as the same* $\mathsf{NewtonIteration}^{\uparrow}$ *step exactly when they have the same source point up to* hsame*, the derivative rows are transported through* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$*, the inverse-row witnesses are matched as visible answer histories, and the next-step answer rows are related by* hsame *inside the same* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *source context.*

The classifier is generated by derivative-source transport, Banach-source transport, inverse-row transport, next-step history transport, and finite concatenation of displayed step rows. It contains no convergence or completeness generator.

Lean4 (definition) `BEDC.Derived.NewtonIterationUp.NewtonIterationContractionClassifier`

223.2 The certificate

Theorem 223.3 (Newton-iteration Banach and derivative source scope)**.** *Every* $\mathsf{NewtonIteration}^{\uparrow}$ *carrier row has exactly two source certificates: the derivative source row from* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$

and the normed-source row from $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$*. The point, derivative, inverse-row, and next-step data are finite answer histories attached to those sources by* hsame*,* Cont*, and* Pkg *witnesses.*

Proof. Unpack Definition 223.1. The derivative and Banach certificates are explicit source fields, while the source point, derivative answer, inverse-row witness, and next-step answer are the finite displayed step ledger.

The classifier of Definition 223.2 can transport only those fields. Its source moves use the two named NameCert classifiers, and its computational moves use the displayed hsame, Cont, and Pkg witnesses, so no convergence or completeness datum enters the scope. □

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier banach derivative source scope`

Theorem 223.4 (Newton-iteration step stability)**.** *Classified* $\mathsf{NewtonIteration}^{\uparrow}$ *step rows remain classified after transporting the derivative source through* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$*, transporting the Banach source through* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$*, and replacing the visible source point, inverse-row witness, or next-step answer by an* hsame*-related row.*

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier step endpoint transport` ↪ variant `BEDC.Derived.NewtonIterationUp.NewtonIterationStep stability`

Proof. First transport the source certificates. The derivative source gives the derivative-row comparison, and the Banach source gives the point and next-step context in which the row is read.

Next transport the displayed step data. The source point and next-step rows use hsame endpoint replacement; the inverse-row witness is carried as a visible answer history; and Cont repacks the transported fields into the same finite computation ledger. The generated classifier then supplies the classified step row. □

Theorem 223.5 (Newton-iteration obligation package)**.** *The* $\mathsf{NewtonIteration}^{\uparrow}$ *chapter exports a finite obligation package consisting of the step carrier, the contraction classifier, the derivative and Banach source certificates, and ledger exactness for the displayed Newton step row. It does not claim convergence or completeness.*

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier semantic name certificate`
Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationCarrier obligation package`

Proof. Build the package from a carried step row and a classifier witness. The carrier supplies the source point, derivative answer, inverse-row witness, next-step answer, and the Cont rows placing them under the two source certificates.

Ledger exactness follows by inverting the carrier and classifier constructors. Every accepted datum is one of the two source certificates, one of the finite step answer histories, or one of the named hsame, Cont, Pkg, or NameCert transport witnesses. Hence the package exposes only the displayed finite Newton step obligation. □

Theorem 223.6 (Newton-iteration scoped kernel dependency boundary)**.** *The* $\mathsf{NewtonIteration}^{\uparrow}$ *obligation package is scoped exactly by the* $\mathsf{Derivative}^{\uparrow}$ *source row, the* $\mathsf{Banach}^{\uparrow}$ *source row, the finite* BHist *step ledger, the inverse-row witness, the next-step answer row, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *transport witnesses.*

Equivalently, every obligation row exported by Definition 223.5 is read from the carrier of Definition 223.1, classified by Definition 223.2, and bounded by the source-scope and stability rows of Definition 223.3 and Definition 223.4. Convergence, completeness, radius data, and host Newton data are outside this carrier.

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier scoped kernel dependency boundary`

Proof. Start with an exported obligation row. By Definition 223.5, it is either one of the two source certificates, one of the finite step answer histories, or one of the displayed transport witnesses used to read that finite step.

Apply Definition 223.1 to identify the only carrier fields: the derivative source row, the Banach source row, the source point answer, the derivative answer, the inverse-row witness, the next-step answer, and the finite BHist ledger connecting those rows by Cont. Apply Definition 223.2 to identify the only classifier moves: source transport, inverse-row transport, next-step transport, and finite concatenation of displayed step rows.

The source boundary is then fixed by Definition 223.3; there are no further source certificates beyond $\mathsf{Derivative}^{\uparrow}$ and $\mathsf{Banach}^{\uparrow}$. The admissible replacements are fixed by Definition 223.4; they use only hsame, Cont, Pkg, and NameCert transport witnesses already visible in the carrier.

Therefore the dependency boundary is exactly the named kernel surface. Any convergence theorem, ambient completeness field, contraction radius, or host-level Newton recurrence would require data not present in the carrier or classifier, so those rows are not part of the scoped obligation package. □

Closure status for $\mathsf{NameCert}_{\mathsf{NewtonIteration}^{\uparrow}}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{NewtonIteration}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridged scope is the finite step ledger over $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$, the inverse-row witness, next-step history, BHist rows, hsame, Cont, Pkg, displayed source certificate rows, and the semantic name-certificate package.

Constructive story: A $\mathsf{NewtonIteration}^{\uparrow}$ packet is built by choosing the displayed derivative and Banach source certificates, reading one finite Newton step through the point, derivative, inverse-row, and next-step histories, and repacking those rows through the visible hsame, Cont, Pkg, and NameCert witnesses.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{NewtonIteration}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not claim convergence, ambient completeness, a contraction theorem, or a radius of validity.

Upgrade path: No further paper-side theory-axis upgrade remains for the finite Newton-step packet.

Theorem 223.7 (Newton-iteration finite-step concatenation closure)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *derivative source row D and a* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *normed-source row B for the same displayed point context. Let R_1 and R_2 be accepted* $\mathsf{NewtonIteration}^{\uparrow}$ *carrier rows of Definition 223.1 over this same source pair. Write the source and next-step answer rows of R_1 as x_0 and x_1, and those of R_2 as y_1 and x_2. Let Λ_1 and Λ_2 be their displayed finite step ledgers, including the derivative-answer rows, inverse-row witnesses, and the* Cont *witnesses placing each displayed Newton step inside D and B.*

If $\mathsf{hsame}(x_1, y_1)$ *and* $\Lambda_{12} : \mathsf{BHist}$ *is displayed with*

$$\mathsf{Cont}(\Lambda_1, \Lambda_2, \Lambda_{12}),$$

then the displayed concatenated row R_{12} over D and B is an accepted $\mathsf{NewtonIteration}^{\uparrow}$ *carrier row. Its source-point answer is x_0, its next-step answer is x_2, and its finite step ledger is exactly the concatenated ledger Λ_{12}. The derivative-answer and inverse-witness subledgers of R_{12} are the visible finite lists obtained by keeping the R_1 subledgers before the R_2 subledgers after transporting the splice endpoint along* $\mathsf{hsame}(x_1, y_1)$.

Proof. Unpack the carrier of Definition 223.1. The row R_1 supplies a finite displayed Newton-step ledger from x_0 to x_1 under the derivative source D and the Banach source B. The row R_2 supplies a finite displayed Newton-step ledger from y_1 to x_2 under the same two sources. Both ledgers are finite BHist rows, and their derivative-answer rows, inverse-row witnesses, next-step rows, and source-containment witnesses are already among the accepted carrier fields.

Use the splice comparison $\mathsf{hsame}(x_1, y_1)$ to read the source endpoint of R_2 as the next-step endpoint of R_1. This is exactly the endpoint replacement allowed by Definition 223.4: the derivative and Banach source certificates remain D and B, while the visible source point of the second row is transported through the displayed hsame witness. No analytic Newton equation, convergence datum, completeness datum, or radius condition is introduced by this transport.

Now concatenate the two finite ledgers by the displayed continuation row $\mathsf{Cont}(\Lambda_1, \Lambda_2, \Lambda_{12})$. Since Cont is the finite continuation relation on BHist, the result is again a finite BHist ledger. The first segment records exactly the step data already accepted in R_1, and the second segment records exactly the transported step data already accepted in R_2. At the splice, the outgoing answer of the first segment and the incoming answer of the second segment are identified by the given $\mathsf{hsame}(x_1, y_1)$ witness, so the displayed list has a single source endpoint x_0 and a single final next-step endpoint x_2.

The internal Cont witnesses remain valid after concatenation. Where a witness is wholly inside one segment, it is inherited from the corresponding accepted carrier row. Where a witness crosses the displayed grouping of the two ledgers, Definition 4.56 identifies the two possible groupings up to hsame, and continuation result transport repacks the same finite history as Λ_{12}. Thus every derivative-source and Banach-source containment row required by the carrier definition is present in the concatenated display.

Finally apply the finite-concatenation generator in the classifier of Definition 223.2. It classifies the two accepted displayed step rows, after the splice transport, as one accepted finite Newton-iteration row. Repacking these fields gives R_{12} with source point x_0, next-step answer x_2, and finite step ledger Λ_{12}, as claimed. □

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier finite step concatenation closure`

↪ variant `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier finite step ledger concat closure`

Theorem 223.8 (Newton-iteration splice source determinacy)**.** *Let R_{12} and R'_{12} be accepted concatenated* $\mathsf{NewtonIteration}^{\uparrow}$ *carrier rows over the same* $\mathsf{NameCert}_{\mathsf{Derivative}^{\uparrow}}$ *source row D, the same* $\mathsf{NameCert}_{\mathsf{Banach}^{\uparrow}}$ *source row B, the same initial endpoint x_0, the same final endpoint x_2, and the same displayed splice witness $\sigma : \mathsf{hsame}(x_1, y_1)$. Suppose their concatenation ledgers Λ_{12} and Λ'_{12} are related by* hsame *and arise from displayed continuation rows*

$$\mathsf{Cont}(\Lambda_1, \Lambda_2, \Lambda_{12}) \qquad \textit{and} \qquad \mathsf{Cont}(\Lambda'_1, \Lambda'_2, \Lambda'_{12})$$

whose two segments are accepted Newton step ledgers over D and B.

Then R_{12} and R'_{12} have the same source-boundary projection. Their derivative source is D, their Banach source is B, their inverse-row subledger lists are read as the same displayed finite lists up to the hsame *transport of the concatenation ledgers, their next-step endpoint is x_2, and their finite ledger provenance is classified by the Newton-iteration contraction classifier of Definition 223.2.*

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier splice source determinacy`

Proof. Apply Definition 223.7 to both displayed concatenations. Each accepted concatenated row is therefore obtained by repacking the same derivative source D, the same Banach source B, the

same initial endpoint x_0, the same final endpoint x_2, and the same splice comparison σ into the carrier of Definition 223.1.

The carrier definition exposes no hidden source boundary. Its source projection consists only of the derivative source, the Banach source, the inverse-row answer histories, the next-step endpoint, and the finite Cont provenance attached to those rows. Thus two rows with the same displayed sources and endpoints can differ at the source boundary only by the listed ledger rows.

Use the hypothesis $\mathsf{hsame}(\Lambda_{12}, \Lambda'_{12})$ to transport the continuation result. The continuation result transport repacks the Cont witnesses for the two displayed concatenations into the same finite history boundary, and Definition 223.4 transports the segment data through the shared splice witness σ.

Finally read the transported rows through the classifier of Definition 223.2. Its generators identify derivative-source transport, Banach-source transport, inverse-row transport, next-step history transport, and finite concatenation, so the derivative source, Banach source, inverse-row subledger list, next-step endpoint, and finite ledger provenance have the same classified source-boundary projection.

No convergence datum, completeness datum, contraction radius, or analytic Newton theorem is introduced in this comparison. The statement is only a determinacy result for the finite BHist source boundary already present in the accepted carrier rows. □

Theorem 223.9 (Newton-iteration finite-prefix restriction carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Derivative}^\uparrow}$ *derivative source row D and a* $\mathsf{NameCert}_{\mathsf{Banach}^\uparrow}$ *normed-source row B for the same displayed point context. Let R_{n+k} be an accepted* $\mathsf{NewtonIteration}^\uparrow$ *carrier row of Definition 223.1 over D and B whose finite Newton ledger $\Lambda_{n+k} : \mathsf{BHist}$ is displayed as a prefix ledger followed by a tail ledger:*

$$\mathsf{Cont}(\Lambda_n, \Lambda_k, \Lambda_{n+k}).$$

Assume that the displayed prefix ledger Λ_n contains exactly the first n source-point rows, next-step rows, function-value rows, derivative-answer rows, inverse-row witnesses, and derivative-nonzero denominator witnesses read from R_{n+k}, with endpoint rows x_0 and x_n. Then the row R_n obtained by keeping D, B, x_0, x_n, and the displayed prefix subledgers is an accepted $\mathsf{NewtonIteration}^\uparrow$ *carrier row. In particular, finite restriction to the first n Newton recurrence steps preserves the iteration rows, the function-value rows, and the derivative-nonzero ledger without adding convergence, completeness, a contraction theorem, or a radius datum.*

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier finite prefix restriction`

Proof. Unpack the accepted carrier row R_{n+k} using Definition 223.1. Its public data are the two source certificates D and B, the visible source-point and next-step histories, the derivative answer rows, the inverse-row witnesses for the displayed derivative answers, and the Cont witnesses placing the displayed Newton computations inside the derivative and Banach source ledgers. The accepted row contains no analytic convergence field and no ambient completeness field.

The displayed continuation

$$\mathsf{Cont}(\Lambda_n, \Lambda_k, \Lambda_{n+k})$$

exhibits Λ_n as a finite initial subledger of the accepted finite ledger. Since Cont is generated only by the finite right-recursive continuation rules of Definition 4.10, every row of Λ_n is one of the visible rows already appearing in Λ_{n+k} before the tail Λ_k is read. Thus the first n source-point rows, next-step rows, function-value rows, derivative-answer rows, inverse-row witnesses, and derivative-nonzero denominator witnesses are inherited as finite BHist rows from the accepted packet.

The source certificates do not change under restriction. The derivative rows in the prefix are still scoped by D, because they are the same derivative-answer and nonzero-denominator rows that R_{n+k} placed under the derivative source. The point and next-step rows in the prefix are still scoped by B, because the Banach source containment witnesses are among the same retained Cont rows. If an endpoint of the retained prefix is represented by an hsame-transported history, Definition 223.4 repacks the same visible source point, inverse-row witness, and next-step answer without changing the two source certificates.

It remains only to check that the retained ledger is a Newton-iteration carrier ledger rather than an arbitrary subhistory. By the hypothesis on Λ_n, each retained step is one of the first n displayed Newton recurrence steps from R_{n+k}: it carries its source point, function value, derivative answer, inverse-row witness, nonzero-denominator witness, and next-step answer. The containment witnesses for those rows are inherited from the longer carrier, and no witness from the discarded tail Λ_k is required to read a retained recurrence step. Repacking these retained fields gives exactly the carrier row described in Definition 223.1 over the same pair D, B.

The classifier of Definition 223.2 permits only source transport, inverse-row transport, next-step history transport, and finite concatenation of displayed step rows. Restricting to the first displayed segment uses none of the tail-specific data and introduces no additional generator. Therefore the prefix row R_n is accepted as a $\mathsf{NewtonIteration}^{\uparrow}$ carrier row, with finite ledger Λ_n and endpoints x_0, x_n. □

Lean4 ✓ `BEDC.Derived.NewtonIterationUp.NewtonIterationBHistCarrier finite prefix restriction carrier`

Chapter 224

A Concrete Naming Certificate for $\mathsf{Interpolation}^{\uparrow}$

The polynomial-interpolation interface $\mathsf{Interpolation}^{\uparrow}$ packages, for a finite set of selected nodes and target values, the polynomial row whose displayed evaluations hit those targets. It depends on $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

224.1 Carrier definition

Definition 224.1 (Interpolation BHist node carrier)**.** *An* $\mathsf{Interpolation}^{\uparrow}$ *carrier row is a finite* BHist *package consisting of:*

1. *a* $\mathsf{FinSet}^{\uparrow}$ *finite-spine membership ledger selecting the interpolation nodes;*
2. *for every selected node, a carried target-value row with its* BHist *endpoint;*
3. *a* $\mathsf{Poly}^{\uparrow}$ *candidate row whose coefficient spine is carried by the polynomial certificate;*
4. *for every selected node, a polynomial-evaluation row comparing the candidate row at that node with the displayed target value; and*
5. *a sample ledger recording the* hsame*,* Cont*, and* Pkg *provenance used by those membership, target-value, polynomial, and evaluation rows.*

The carrier is the finite package itself; it is not a host polynomial function, a quotient representative, a field-completeness witness, or a uniqueness claim over an external field.

Theorem 224.2 (Interpolation sample ledger surface)**.** *Every accepted sample in the carrier of Definition 224.1 is readable from only the* $\mathsf{FinSet}^{\uparrow}$ *membership row for the selected node, the* $\mathsf{Poly}^{\uparrow}$ *evaluation row at that node, the* BHist *endpoints for the node, target value, and polynomial candidate, the displayed* hsame *comparisons, the displayed* Cont *routes, and the displayed* Pkg *provenance.*

No accepted sample exposes a host evaluation function, a quotient polynomial class, field completeness, a global interpolation algorithm, or uniqueness over an external field.

Lean4 ✓ `BEDC.Derived.InterpolationUp.InterpolationSampleLedger surface`

Proof. Unpack the carrier row of Definition 224.1. A sample is accepted only when its node occurs in the displayed finite-spine membership ledger and when the candidate polynomial has the displayed evaluation row at that same node.

Project the two dependency certificates. The finite-set side contributes only membership in the selected finite spine, while the polynomial side contributes only the named evaluation row and the coefficient-spine carrier row already present in the package.

The remaining data are bookkeeping rows: the node endpoint, target-value endpoint, candidate-polynomial endpoint, hsame comparisons, Cont routes, and Pkg provenance. Since the carrier contains no other constructor, no host evaluation function, quotient row, completeness witness, global algorithm, or external uniqueness field can be read from an accepted sample. □

Theorem 224.3 (Interpolation evaluation stability)**.** *Let two interpolation carrier rows share the same* $\mathsf{FinSet}^{\uparrow}$ *selected-node spine and the same* $\mathsf{Poly}^{\uparrow}$ *candidate surface up to displayed* hsame *transport. If each selected node endpoint, target-value endpoint, and polynomial endpoint row is transported by the displayed* hsame *comparisons and the corresponding* Cont/Pkg *routes, then the interpolation evaluation ledger is preserved sample by sample.*

Equivalently, every transported selected node reads the same membership row and the same target-hit evaluation row through the transported polynomial endpoint.

Lean4 ✓ `BEDC.Derived.InterpolationUp.InterpolationEvaluationLedger sample transport`

Proof. Fix an accepted sample in the first carrier row. By Definition 224.2, the sample is completely described by finite-set membership, a polynomial evaluation row, the three visible endpoints, and the displayed transport provenance.

Transport the selected node through the finite-set classifier rows. The membership ledger is stable because the node endpoint is carried along the displayed hsame comparison and the finite-spine row is the same selected surface.

Transport the candidate polynomial and target value through their endpoint comparisons. The $\mathsf{Poly}^{\uparrow}$ evaluation row is stable under the displayed polynomial endpoint transport and target-value transport, so the target-hit comparison is rebuilt at the transported sample.

The converse transport uses the same rows in the opposite direction, using symmetry of the displayed hsame comparisons and the reverse listed provenance routes. Hence the evaluation ledger is preserved sample by sample. □

Theorem 224.4 (Interpolation NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Interpolation}^{\uparrow}}$ *surface consists exactly of the carrier row of Definition 224.1, the classifier that compares two packages by the same selected-node membership rows, candidate polynomial rows, target-value rows, sample ledgers, and evaluation rows, the stability row of Definition 224.3, the sample ledger surface of Definition 224.2, and the exactness rows saying that every accepted package has all displayed selected samples and every displayed selected sample is read from those rows.*

This is a finite BHist *obligation surface over* $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.InterpolationUp.InterpolationNameCert obligation surface`

Proof. Start with the carrier row. Its fields list exactly the finite selected-node spine, target values, candidate polynomial row, sample ledger, and evaluation rows, so it supplies the source predicate for the local certificate.

Define the classifier by fieldwise comparison of those visible rows. Reflexive, symmetric, and transitive classifier witnesses are obtained by the corresponding hsame ledger laws on endpoints and by the already displayed classifier rows from the $\mathsf{FinSet}^{\uparrow}$ and $\mathsf{Poly}^{\uparrow}$ dependency certificates.

The stability obligation is precisely Definition 224.3. The ledger and exactness obligations are precisely Definition 224.2 together with the carrier definition: an accepted package contains no

sample except one read through the finite membership and evaluation rows, and each listed sample is accepted by those rows. □

Theorem 224.5 (Interpolation downstream threshold package)**.** Poly$^{\uparrow}$ *and* FinSet$^{\uparrow}$ *consumers may cite the interpolation carrier, classifier, stability, sample-ledger, and exactness rows of Definition 224.4. Such a citation gives only the finite* BHist *package of selected nodes, target values, candidate polynomial rows, evaluation rows, and visible* hsame/Cont/Pkg *provenance.*

It gives no host polynomial function, no quotient representative, no field completeness principle, and no uniqueness statement over external fields.

```
Lean4 ✓  BEDC.Derived.InterpolationUp.InterpolationDownstreamThresholdPackage boundary
  ↪ variant  BEDC.Derived.InterpolationUp.InterpolationDownstreamThresholdPackage threshold surface
  ↪ variant  BEDC.Derived.InterpolationUp.InterpolationDownstreamThreshold surface
```

Proof. Unpack the obligation surface from Definition 224.4. The rows available to a downstream consumer are the five displayed certificate rows: carrier, classifier, stability, sample ledger, and exactness.

Project those rows to a Poly$^{\uparrow}$ consumer. The consumer sees the candidate polynomial endpoint and the evaluation rows already carried by the polynomial certificate, together with their hsame/Cont/Pkg provenance.

Project the same rows to a FinSet$^{\uparrow}$ consumer. The consumer sees the selected finite-spine membership ledger and the node endpoints, again with only the displayed provenance rows.

Since neither projection adds a constructor to the interpolation carrier, the consumer receives no host function, quotient representative, completeness principle, or external-field uniqueness statement. The package is exactly the finite BHist threshold surface stated above. □

224.2 The certificate

Closure status for NameCert$_{\text{Interpolation}^{\uparrow}}$**.**

Constructive story: InterpolationUp is a finite selected-node spine over FinSet$^{\uparrow}$, target-value rows, a Poly$^{\uparrow}$ candidate row, hsame, Cont, and Pkg provenance. The displayed sample, evaluation, NameCert, and downstream-threshold rows bind that spine to BEDC histories only, so the chapter exports no host polynomial function and no field-completeness claim.

Theory closure: TheoryGate(NameCert$_{\text{Interpolation}^{\uparrow}}$, publicClosed)

Scope closed: The visible scope is the finite selected-node spine, target-value rows, Poly$^{\uparrow}$ candidate row, FinSet$^{\uparrow}$ membership ledger, hsame, Cont, and Pkg provenance recorded by the local carrier and sample ledger.

Formal verification: FormalStatus(NameCert$_{\text{Interpolation}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InterpolationUp.InterpolationNameCert\_obligation\_surface`

Bridge status: none

Not claimed: The chapter does not close host polynomial functions, quotient representatives, field completeness, global interpolation algorithms, or external uniqueness.

Upgrade path: The next bridge obligation is a checked Interpolation$^{\uparrow}$ standard bridge over the same finite-node and polynomial-evaluation rows.

Theorem 224.6 (Interpolation empty selection has empty evaluation ledger)**.** *Let I be an* Interpolation$^{\uparrow}$ *carrier row in the sense of Definition 224.1. Suppose that the displayed* FinSet$^{\uparrow}$ *selected-node membership ledger of I has no entries: no history n :* BHist *occurs as a selected node in that finite-spine ledger. Then I has no accepted sample. Consequently, its polynomial-evaluation ledger has no sample-indexed row, and the sample-ledger surface of I is empty.*

Proof. Assume, toward contradiction, that I has an accepted sample at a node n. By Definition 224.2, every accepted sample is read through the $\mathsf{FinSet}^{\uparrow}$ membership row for its selected node and the $\mathsf{Poly}^{\uparrow}$ evaluation row at that same node. In particular, the accepted sample exposes a selected-node membership entry for n in the displayed finite-spine ledger of I.

This contradicts the empty-ledger hypothesis. Hence no accepted sample exists. The only polynomial-evaluation rows admitted as sample rows by Definition 224.1 are the rows indexed by selected nodes and read together with the corresponding membership rows. Since there is no selected-node membership entry, there is no sample index from which such an evaluation row can be read. Therefore the polynomial-evaluation ledger contains no sample-indexed row, and the sample-ledger surface is empty. □

Lean4 ✓ `BEDC.Derived.InterpolationUp.InterpolationBHistNodeCarrier empty selection empty evaluation ledger`

Chapter 225

A Concrete Naming Certificate for $\mathsf{Approximation}^{\uparrow}$

The best-approximation interface $\mathsf{Approximation}^{\uparrow}$ packages, for a continuous function on a compact carrier, the polynomial of bounded degree minimising the supremum-norm error (Weierstrass / Chebyshev). It depends on $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ (chapter 130) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

225.1 Carrier definition

Theorem 225.1 (ApproximationUp carrier obligation surface)**.** *The* $\mathsf{Approximation}^{\uparrow}$ *carrier surface is a* BHist *packet whose continuous-source row is certified by* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*, whose polynomial-candidate row is certified by* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*, whose comparison row is* hsame*, whose transport rows are* Cont *ledgers, and whose finite error ledger records the displayed approximation error data. The carrier does not expose a supremum object or any choice data.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationFiniteErrorLedger carrier surface`

Proof. Read the carrier through the ten-field roadmap template:

1. source: the BHist input carrying the compact continuous-map source;
2. carrier: the accepted continuous endpoint supplied by $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$;
3. pattern: the polynomial candidate supplied by $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$;
4. classifier: componentwise hsame between source, candidate, and error endpoints;
5. stability: Cont transport for every exposed endpoint;
6. ledger: the finite error ledger;
7. exactness: each error row is attached to one displayed candidate and one displayed source;
8. consumer: polynomial approximation consumers read only these rows;
9. boundary: no supremum witness is exported;
10. provenance: no choice data is added beyond the two cited NameCert sources.

These ten rows are all carried by named histories and finite ledgers. Therefore the carrier surface is a BEDC packet rather than an external analytic minimisation object. □

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket obligation surface`

Theorem 225.2 (ApproximationUp polynomial consumer window)**.** *Every* $\mathsf{Approximation}^{\uparrow}$ *polynomial consumer reads a* BHist *source through* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*, a candidate row through* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*,* hsame *comparison rows,* Cont *transport rows, and the finite error ledger. Its permitted window is the finite candidate, degree, endpoint, and error data displayed by the packet, with no supremum row and no choice data.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket polynomial consumer window`

Proof. The consumer first projects the continuous map from $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ and the candidate polynomial from $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$. Both projections remain histories in the same BHist packet.

It then reads the hsame classifier and the Cont transport ledgers. These rows allow the candidate and error endpoints to move together without replacing the source certificate.

Finally the consumer reads the finite error ledger. Since the ledger is finite, the consumer can inspect recorded error rows directly; no supremum witness, selection functional, or choice data is part of the exposed window. □

225.2 The certificate

Theorem 225.3 (ApproximationUp compact continuous source boundary)**.** *The* $\mathsf{Approximation}^{\uparrow}$ *source boundary for a compact continuous input is exactly the* BHist *packet combining* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*,* Cont *transport,* hsame *comparison, and the finite error ledger. Compactness and continuity are consumed only through the continuous-map certificate row, and the boundary exports no supremum or choice data.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket compact continuous source boundary`

Proof. Use the ten-field roadmap template with the continuous certificate as the source side: source BHist, continuous carrier, polynomial pattern, hsame classifier, Cont stability, finite error ledger, endpoint exactness, polynomial consumer, no-supremum boundary, and no-choice provenance.

The compact continuous hypothesis is therefore not a separate analytic carrier. It is the continuous-map certificate row already present in $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$, transported by Cont and compared by hsame.

The polynomial side is read through $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$. The finite error ledger relates the two sides at recorded endpoints only, so the source boundary remains finite and certificate-local. □

Theorem 225.4 (ApproximationUp error ledger exactness)**.** *For* $\mathsf{Approximation}^{\uparrow}$*, the finite error ledger is exact relative to the* BHist *source certified by* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$*, the candidate certified by* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*, the* hsame *classifier, and the* Cont *transport rows: every ledger entry names one source endpoint, one polynomial endpoint, and one error endpoint, and every exposed error comparison is one of these finite entries. No supremum row or choice data is part of the exactness claim.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket error ledger exactness`

Proof. Project the source, candidate, classifier, and transport rows from the same certificate packet. The ten fields are the source, carrier, pattern, classifier, stability, ledger, exactness, consumer, no-supremum boundary, and no-choice provenance rows.

For an error entry already in the finite ledger, exactness is immediate from its recorded endpoints: it contains the source endpoint, the polynomial endpoint, and the named error endpoint.

Conversely, an exposed approximation error comparison is visible to consumers only by passing through the finite ledger row. Thus there is no hidden supremum-derived error endpoint and no unrecorded choice data. □

Theorem 225.5 (ApproximationUp finite error-ledger consumer determinacy)**.** *For* $\mathsf{Approximation}^{\uparrow}$*, two consumer reads of the same finite error-ledger entry over the same* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *source row and the same* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *candidate row classify to the same source endpoint, polynomial endpoint, and error endpoint under* hsame*. The* Cont *transport rows carry the visible source and candidate rows to those endpoints, and the consumer surface exposes no supremum row or choice row.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationFiniteErrorLedger consumer determinacy`
↪ variant `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket finite error ledger consumer determinacy`

Proof. Apply Definition 225.4 to the first consumer read. The finite ledger entry names a source endpoint, a polynomial endpoint, and an error endpoint, and the read exposes no endpoint outside that recorded triple.

Apply the same exactness theorem to the second consumer read. Because the ledger entry is the same recorded finite entry, the second read has the same three named endpoints.

Use the shared ledger-entry identity to identify the source endpoint, the polynomial endpoint, and the error endpoint under hsame. The visible Cont rows transport only the already recorded source and candidate rows, so no supremum-derived value or choice-selected witness can be read by the consumer. □

Theorem 225.6 (ApproximationUp no-choice polynomial window stability)**.** *Transport the displayed* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *polynomial-candidate row, and one finite error-ledger entry by the chapter's* hsame *classifier rows and finite* Cont *transport rows. The transported read preserves the same* $\mathsf{Approximation}^{\uparrow}$ *polynomial consumer window. It still exposes only the source endpoint, polynomial endpoint, error endpoint, and finite ledger entry, with no supremum object and no choice row.*

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket no choice polynomial window stability`

Proof. Apply Definition 225.4 before transport. The original consumer window is therefore the displayed finite ledger entry together with its source endpoint, polynomial endpoint, and error endpoint.

Apply the same exactness theorem after transporting the continuous-source row, polynomial-candidate row, and finite ledger entry along the chapter's hsame and Cont rows. Exactness again reads only the transported source endpoint, polynomial endpoint, error endpoint, and ledger entry.

Finally use Definition 225.5. Since both reads are over the same finite error-ledger entry up to the displayed transport rows, determinacy identifies the exposed endpoints under hsame. The polynomial consumer window is stable, and no supremum object or choice-selected row is introduced. □

Theorem 225.7 (ApproximationUp NameCert obligation inventory)**.** *The* $\mathsf{Approximation}^{\uparrow}$ NameCert *obligation inventory consists of the* BHist *source row,* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^{\uparrow}}$ *source certificate,* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *candidate certificate,* hsame *classifier,* Cont *stability transport, finite error ledger,*

ledger exactness, polynomial consumer window, no-supremum boundary, and no-choice provenance. These are the only obligations exported by the certificate surface.

Lean4 ✓ `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket namecert obligation inventory`

Proof. List the ten obligations in order: source row, continuous carrier row, polynomial pattern row, hsame classifier row, Cont stability row, finite error ledger row, exactness row, consumer row, no-supremum boundary row, and no-choice provenance row.

The first two rows come from $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$, and the polynomial row comes from $\mathsf{NameCert}_{\mathsf{Poly}^\uparrow}$. The classifier and stability rows are BEDC transport data over the same BHist endpoints.

The final four rows restrict consumers to finite recorded error data. Hence the inventory closes the approximation certificate surface without adding a supremum object, a best-candidate selector, or any choice data. □

Theorem 225.8 (ApproximationUp public certificate export)**.** *Every approximation consumer reads exactly the finite error-ledger surface: the* $\mathsf{NameCert}_{\mathsf{ContinuousMap}^\uparrow}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Poly}^\uparrow}$ *candidate row, the* BHist *source packet, the* hsame *classifier, finite* Cont *transports, source endpoint, polynomial endpoint, error endpoint, finite ledger entry, and no-choice provenance.*

The public certificate exports no supremum object, best-candidate selector, host function equality, or choice row.

Proof. Project the accepted packet through Definition 225.1. The carrier exposes the continuous-map source certificate, polynomial-candidate certificate, BHist packet, classifier, transport, endpoint, ledger, and provenance rows.

Apply Definition 225.2 and Definition 225.3. These keep the consumer window on the displayed polynomial endpoint and continuous source endpoint, without importing a host function-equality row.

Next use Definition 225.4 and Definition 225.5. They identify every readable approximation value with the finite ledger entry and its source, polynomial, and error endpoints.

Finally apply Definition 225.6 and Definition 225.7. The exported certificate is therefore exactly the displayed finite error-ledger surface, and there is no coordinate for a supremum object, best-candidate selector, host function equality, or choice row. □

Closure status for $\mathsf{NameCert}_{\mathsf{Approximation}^\uparrow}$**.**

Constructive story: An approximation packet is generated by taking a compact continuous-map source through $\mathsf{ContinuousMap}^\uparrow$, a bounded-degree polynomial candidate through $\mathsf{Poly}^\uparrow$, and a finite error ledger that names the source endpoint, candidate endpoint, and error endpoint being compared. The carrier accepts only this finite BHist packet with its hsame comparison and Cont transport rows; a supremum object, best-candidate selector, or choice-produced minimizer has no slot in the accepted data. Two approximation packets classify together when the continuous source, polynomial candidate, and recorded error endpoints transport componentwise through the displayed hsame and continuation rows. The source specification is the compact continuous-map certificate surface, the pattern specification is the polynomial-candidate row together with recorded approximation-error comparisons, and the ledger keeps every finite error entry, consumer window, endpoint exactness row, and no-choice provenance row visible. The five name-certificate obligations follow from an admitted packet for carrier inhabitation, the component classifiers inherited from the two dependency certificates, and ledger exactness, which repacks transported source, polynomial, and error endpoints as the same approximation surface. A packet history h lies in the signature gap of an $\mathsf{Approximation}^\uparrow$ token p when the source-domain accepts its continuous source and polynomial-candidate rows, the signature relation pairs it with an answer approximation packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, p records only the candidate and finite error rows actually present in the ledger. The chapter registers this finite error-ledger construction under the name $\mathsf{Approximation}^\uparrow$; it introduces no supremum attainment theorem, no best-polynomial selection functional, and no choice data.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Approximation}^\uparrow}$, publicClosed)

Scope closed: The public surface binds ContinuousMapUp, PolynomialUp, BHist, hsame, Cont, the endpoint rows, no-choice provenance, and the finite error ledger displayed by the approximation certificate surface.

Formal verification: FormalStatus(NameCert$_{\text{Approximation}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.ApproximationUp.ApproximationCarrierPacket\_obligation\_surface`

Bridge status: none

Not claimed: This chapter does not close supremum attainment, best-candidate selection, or choice data.

Upgrade path: Bridged closure requires a bridge theorem for the exported finite error-ledger certificate.

Chapter 226

A Concrete Naming Certificate for $\mathsf{Fft}^{\uparrow}$

The Fast-Fourier-transform interface $\mathsf{Fft}^{\uparrow}$ packages the $O(n \log n)$ divide-and-conquer evaluation of the discrete Fourier transform on length-n data when n has small prime factors. It depends on $\mathsf{NameCert}_{\mathsf{Fourier}^{\uparrow}}$ (chapter 124) and $\mathsf{NameCert}_{\mathsf{Complex}^{\uparrow}}$ (chapter 39).

226.1 Carrier definition

Definition 226.1 (FFT BHist source packet)**.** *An* $\mathsf{Fft}^{\uparrow}$ *source packet is a finite* BHist *schedule carrying a* $\mathsf{Complex}^{\uparrow}$ *scalar row, a* $\mathsf{Fourier}^{\uparrow}$ *transform row, a finite* ProbeBundle *of butterfly stages,* InBundle *membership witnesses for every scheduled stage, and a factorization ledger naming the split of the transform length. The carrier accepts exactly those packets whose complex scalar rows and Fourier rows are accepted by their dependency certificates and whose stage rows transport through the same* hsame *and* Cont *evidence.*

Theorem 226.2 (FFT carrier butterfly obligation)**.** *Every accepted* $\mathsf{Fft}^{\uparrow}$ *carrier row projects to a finite butterfly schedule: each stage is a* BHist *row in the displayed* ProbeBundle*, each membership witness is an* InBundle *row, and each butterfly continuation is carried by* Cont *from the* $\mathsf{Complex}^{\uparrow}$ *scalar dependency and the* $\mathsf{Fourier}^{\uparrow}$ *transform dependency. Conversely, those rows repack as the FFT carrier.*

```
Lean4 ✓  BEDC.Derived.FftUp.FftBHistSourcePacket butterfly schedule obligation
Lean4 ✓  BEDC.Derived.FftUp.FftBHistSourcePacket carrier butterfly obligation
```

Proof. Project the $\mathsf{Complex}^{\uparrow}$ and $\mathsf{Fourier}^{\uparrow}$ dependency rows from the packet. They supply the scalar and transform histories used by every scheduled stage.

Read the finite schedule through the ProbeBundle field. Each butterfly row is certified by an InBundle witness, so the schedule is finite at the BEDC surface and does not depend on a host array traversal.

For the converse direction, place the dependency rows, stage membership rows, and butterfly continuations into the packet constructor. The common hsame and Cont evidence transports the stage rows and yields the carried $\mathsf{Fft}^{\uparrow}$ endpoint. □

Theorem 226.3 (FFT factorization classifier stability obligation)**.** *The factorization classifier row of an* $\mathsf{Fft}^{\uparrow}$ *packet is stable under accepted replacement of the complex scalar, Fourier transform,*

and finite butterfly schedule rows. If two packets compare by the displayed hsame *evidence, then the split-length ledger, the stage membership witnesses, and the butterfly continuations classify the same FFT factorization surface.*

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket factorization classifier stability`

Proof. Transport the scalar row through $\mathsf{NameCert}_{\mathsf{Complex}^{\uparrow}}$ and the transform row through $\mathsf{NameCert}_{\mathsf{Fourier}^{\uparrow}}$. These two dependency transports fix the source histories on which the finite schedule is read.

Next transport every scheduled butterfly stage along the same packet comparison. The InBundle witnesses keep the stage list inside the finite ProbeBundle, while Cont transports the butterfly output rows.

The factorization ledger is stored with those stage rows. Repacking the transported dependencies, schedule, and ledger gives the same classifier surface for the target FFT packet. □

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket factorization classifier stability obligation`

Theorem 226.4 (FFT ledger exactness obligation)**.** *The* $\mathsf{Fft}^{\uparrow}$ *ledger consists exactly of the* $\mathsf{NameCert}_{\mathsf{Complex}^{\uparrow}}$ *dependency row, the* $\mathsf{NameCert}_{\mathsf{Fourier}^{\uparrow}}$ *dependency row, the finite* ProbeBundle *schedule, the* InBundle *stage witnesses, the butterfly continuation rows, the factorization ledger rows, and their* hsame *and* Cont *transports. It excludes analytic error estimates, floating-point bounds, asymptotic runtime claims, and standard bridge rows.*

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket ledger exactness obligation`

Proof. Coverage reads any accepted FFT packet into the two dependency rows, the finite schedule, the stage membership witnesses, the butterfly continuations, and the factorization ledger.

Soundness repacks exactly those rows. The scalar and transform dependencies justify the input histories, while InBundle and Cont justify the finite schedule and every butterfly output.

Completeness is the absence of further ledger coordinates. Error estimates, floating-point bounds, asymptotic analysis, and standard bridge data are not fields of the packet, so they cannot be consumed by this certificate. □

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket factorization ledger transport determinacy`

Theorem 226.5 (FFT root threshold unblock surface)**.** *The rows of Definition 226.1, Definition 226.2, Definition 226.3, and Definition 226.4 form the dependency-ready finite-history surface for* $\mathsf{Fft}^{\uparrow}$*. Downstream numerical-analysis certificates may consume the complex dependency, Fourier dependency, finite butterfly schedule, factorization ledger, and exact exclusion of analytic error or bridge data, but must provide any such estimates or bridges outside the FFT packet.*

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket root threshold unblock surface`

Proof. The definition fixes the finite packet and the two dependency certificates. The butterfly obligation turns the packet into carried BHist stage rows over a certified finite schedule.

The factorization stability obligation supplies the classifier transport for the split-length ledger and butterfly continuations. The ledger exactness obligation then states that no analytic estimate or standard bridge row is available inside the packet.

Together these rows expose the concrete FFT source surface needed by later certificates while keeping numerical-analysis obligations separate. □

226.2 The certificate

Theorem 226.6 (FFT schedule public NameCert export)**.** *The source packet of Definition 226.1, the butterfly carrier obligation of Definition 226.2, the factorization classifier stability obligation of Definition 226.3, the ledger exactness obligation of Definition 226.4, and the root threshold surface of Definition 226.5 together export the public* $\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$ *finite schedule interface.*

Consumers may read the $\mathsf{NameCert}_{\mathsf{Complex}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Fourier}^\uparrow}$ *dependencies, the finite* ProbeBundle *schedule, the* InBundle *stage witnesses, the butterfly continuation rows, the factorization ledger, and the* hsame/Cont *transport rows. Analytic error estimates, floating-point bounds, asymptotic runtime claims, and standard bridge rows are not part of this certificate.*

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket schedule public namecert export`

Proof. The source packet fixes the two dependency certificates and the finite ProbeBundle schedule. Its membership rows and butterfly continuations are the only stage data exposed to the BEDC surface.

Apply the butterfly carrier obligation to recover the finite stage witnesses and their Cont rows from any accepted packet. Apply the factorization classifier stability obligation to transport the split-length ledger and the butterfly rows through the displayed hsame comparison.

The ledger exactness obligation states that the readable ledger consists exactly of the two dependency rows, the schedule, the stage witnesses, the butterfly continuations, the factorization ledger, and their transport evidence. The root threshold surface repacks those rows as the public $\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$ interface, while analytic estimates, floating-point bounds, asymptotic runtime claims, and bridge rows remain unavailable. □

Lean4 ✓ `BEDC.Derived.FftUp.FftBHistSourcePacket public namecert export`

Theorem 226.7 (FFT standard schema bridge boundary)**.** *The public finite FFT schedule interface of Definition 226.6 supplies the standard FFT schema bridge boundary exactly through the* $\mathsf{Complex}^\uparrow$ *and* $\mathsf{Fourier}^\uparrow$ *dependency rows, the finite* ProbeBundle *schedule,* InBundle *stage witnesses, butterfly continuation rows, factorization ledger, and* hsame/Cont *transport rows.*

The bridge boundary exports no analytic error estimate, floating-point bound, asymptotic runtime claim, or operation-optimality claim.

Proof. Project the public schedule interface through Definition 226.6. The consumer-visible rows are the two dependency certificates, the finite schedule, stage witnesses, butterfly continuations, factorization ledger, and transport evidence.

Apply Definition 226.2 to read every scheduled stage as a finite ProbeBundle member with an InBundle witness. Then use Definition 226.3 to transport the split-length ledger and butterfly rows along the displayed hsame and Cont surface.

Finally apply Definition 226.4 and Definition 226.5. These rows exhaust the standard FFT schema boundary supplied by the packet, while analytic error estimates, floating-point bounds, asymptotic runtime claims, and operation-optimality claims remain outside the bridge boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$**.**

Constructive story: An FFT packet is presented by the ComplexUp and FourierUp dependency certificates, a finite probe-bundle schedule, displayed stage membership witnesses, butterfly continuation rows, factorization ledger rows, and the transport rows that make those finite rows readable as the public $\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$ surface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$, maturePackageClosed)

Scope closed: The mature surface is the finite FFT schedule, public $\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$ export rows, standard schema bridge boundary, factorization classifier, ledger exactness rows, transport determinacy rows, length-one identity surface, schedule-stage exhaustion, and length-one input-classifier theorem over the ComplexUp and FourierUp dependencies.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Fft}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.FftUp.FftBHistSourcePacket\_public\_namecert\_export`

Bridge status: paperBridge

Not claimed: The chapter does not close analytic error bounds, floating-point bounds, asymptotic runtime claims, operation-optimality claims, or schedule completeness beyond the displayed finite bridge.

Upgrade path: No further paper-side theory grade remains for this chapter; bridgeChecked status is a separate verification-axis obligation.

Definition 226.8 (FFT length-one identity surface)**.** *For an accepted* $\mathsf{Fft}^\uparrow$ *source packet of Definition 226.1, write* c *for its* $\mathsf{Complex}^\uparrow$ *scalar row,* F *for its* $\mathsf{Fourier}^\uparrow$ *transform row,* x *for the carrier row produced from* c *and* F*,* β *for the scheduled butterfly row,* ν *for the factorization row,* λ *for the ledger row,* y *for the endpoint row,* σ *for the stage name, and* Π *for the finite schedule. The predicate* $\mathsf{FftLenOneId}(P, x, y)$ *holds when the following rows are displayed:*

- *the schedule has length one,* $\mathsf{BLEN}(\Pi) = 1$*;*
- *the carrier membership row of Definition 226.2 reads* σ *as the unique scheduled stage and reads that stage back as the input row* x*;*
- *the singleton butterfly row supplied by* $\mathsf{NameCert}_{\mathsf{Fourier}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{Complex}^\uparrow}$ *classifies the butterfly ledger with the input row,* $\lambda \sim_{\mathsf{Complex}^\uparrow} x$*;*
- *the length-one factorization ledger is neutral on that ledger, so the endpoint row classifies with the ledger row,* $y \sim_{\mathsf{Complex}^\uparrow} \lambda$*.*

This surface contains no analytic FFT equality, host array equality, floating-point estimate, asymptotic claim, or standard bridge row.

Lemma 226.9 (FFT length-one schedule stage exhaustion)**.** *Let* P *be an accepted* $\mathsf{Fft}^\uparrow$ *source packet of Definition 226.1 with finite schedule* Π*. If* $\mathsf{BLEN}(\Pi) = 1$*, then every scheduled butterfly stage read by the carrier obligation is the single stage named by the packet membership row. In particular, the packet exposes no second butterfly stage and no tail-stage membership row.*

Proof. Apply Definition 226.2 to the accepted packet. This gives the displayed schedule membership row and the butterfly continuation rows inside the finite $\mathsf{ProbeBundle}$ schedule.

The length-one hypothesis and Definition 6.6 identify Π with a singleton bundle. Then Definition 6.7 identifies the member supplied by the carrier obligation with that singleton head. A tail membership would be a membership row in Bnil, which is impossible by the same singleton reading. Hence the carrier has exactly the one scheduled stage named by the packet membership row. □

Theorem 226.10 (FFT length-one schedule classifies with the input row)**.** *Let* P *be an accepted* $\mathsf{Fft}^\uparrow$ *source packet of Definition 226.1. If* $\mathsf{FftLenOneId}(P, x, y)$ *holds for its input row* x *and endpoint row* y*, then the FFT output endpoint is classified with the input row:* $y \sim_{\mathsf{Complex}^\uparrow} x$*.*

Proof. Read the accepted packet through Definition 226.2. The packet yields the $\mathsf{Complex}^\uparrow$ scalar dependency, the $\mathsf{Fourier}^\uparrow$ transform dependency, the finite schedule membership row, the singleton butterfly continuation, and the continuation rows that lead to the endpoint.

By the first row of Definition 226.8, the schedule has length one. The exhaustion lemma Definition 226.9 therefore removes every possible tail stage: the butterfly continuation seen by the carrier obligation is the unique scheduled row, and its stage readback is the input row x.

The singleton butterfly row in Definition 226.8 classifies the butterfly ledger with the input row, giving $\lambda \sim_{\mathsf{Complex}^{\uparrow}} x$. Next apply Definition 226.4. The ledger contains exactly the two dependency rows, the singleton schedule membership row, the butterfly continuation, the factorization row, and their displayed transports; there is no further stage or hidden analytic row that can change the endpoint classification.

The neutral length-one factorization row in Definition 226.8 gives $y \sim_{\mathsf{Complex}^{\uparrow}} \lambda$. Transitivity of the $\mathsf{Complex}^{\uparrow}$ classifier supplied by the dependency certificate then composes $y \sim_{\mathsf{Complex}^{\uparrow}} \lambda$ with $\lambda \sim_{\mathsf{Complex}^{\uparrow}} x$, yielding $y \sim_{\mathsf{Complex}^{\uparrow}} x$. □

Chapter 227

A Concrete Naming Certificate for $\mathsf{Quadrature}^{\uparrow}$

The numerical-quadrature interface $\mathsf{Quadrature}^{\uparrow}$ packages a finite weighted sum approximating an integral on a compact interval, classified by exactness degree (trapezoid, Simpson, Gauss-Legendre). It depends on $\mathsf{NameCert}_{\mathsf{Integral}^{\uparrow}}$ (chapter 123) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

227.1 Carrier definition

Definition 227.1 (Quadrature carried rule source row)**.** *A carried* $\mathsf{Quadrature}^{\uparrow}$ *rule source row is the* BHist*-visible tuple*

$$(xs, \alpha, \omega, \mathcal{I}_Q)$$

where xs *is the* $\mathsf{FinSet}^{\uparrow}$ *node spine, each node endpoint* α_i *and weight endpoint* ω_i *is carried by the scalar endpoint rows, and* $\mathcal{I}_Q$ *is the endpoint map supplied by the* $\mathsf{Integral}^{\uparrow}$ *polynomial row on the fixed compact interval. The polynomial inputs to the row are finite* $\mathsf{ListCarrier}$ *coefficient codes. Ordering choices for the node spine, numerical approximation choices, and convergence data are not carrier fields of the rule; when they are used, they are recorded only by ledger rows attached to the source tuple.*

227.2 The certificate

Definition 227.2 (Quadrature finite weighted exactness degree)**.** *Fix a scalar carrier* R *with classifier* $\sim_R$*, zero endpoint* 0_R*, addition* $+$*, multiplication* $\cdot$*, canonical polynomial trim* trim_R*, and Horner evaluation* $\mathsf{Eval}_{\alpha,R}$ *as in Definition 50.133. A finite weighted* $\mathsf{Quadrature}^{\uparrow}$ *rule over* R *is a tuple*

$$Q = (xs, \alpha, \omega, \mathcal{I}_Q)$$

where xs *is the finite* $\mathsf{FinSet}^{\uparrow}$ *index spine for the nodes,* α_i *and* ω_i *are carried scalar endpoints for each* $i : \mathsf{Pos}(xs)$*, and* $\mathcal{I}_Q(p)$ *is the scalar endpoint supplied by the* $\mathsf{Integral}^{\uparrow}$ *row for the polynomial code* p *on the fixed compact interval. Its quadrature sum on a finite coefficient spine* $p : \mathsf{ListCarrier}(R)$ *is*

$$\mathsf{QSum}_Q(p) := \mathsf{fold}_{+,\mathsf{Pos}(xs)}(i \mapsto \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p)).$$

The pointwise exactness predicate is

$$\mathsf{QExact}_Q(p) \iff \mathsf{QSum}_Q(p) \sim_R \mathcal{I}_Q(p).$$

For a unary degree bound $n : \mathsf{Nat}^{\uparrow}$*, define*

$$\mathsf{PolyDegLe}_R(p, n) \iff \forall k : \mathsf{Nat}^{\uparrow}.\ \mathsf{NatUnaryStrictPrefix}(n, k) \implies \mathsf{trim}_R(p)[k] \sim_R 0_R.$$

The quadrature exactness-degree predicate is

$$\mathsf{QuadratureExactUpTo}_R(Q, n) \iff \forall p : \mathsf{ListCarrier}(R).\ \mathsf{PolyDegLe}_R(p, n) \implies \mathsf{QExact}_Q(p).$$

Finally, the degree-bound comparison used by this $\mathsf{Quadrature}^{\uparrow}$ *classifier is*

$$\mathsf{DegBoundLe}(e, d) \iff \forall k : \mathsf{Nat}^{\uparrow}.\ \mathsf{NatUnaryStrictPrefix}(d, k) \implies \mathsf{NatUnaryStrictPrefix}(e, k).$$

This is the unary BEDC reading of the ordinary inequality $e \le d$*: every coefficient index above* d *is also above* e*.*

Theorem 227.3 (Quadrature carrier scope obligation)**.** *For the* $\mathsf{Quadrature}^{\uparrow}$ *certificate described by Definition 227.1 and Definition 227.2, the carrier scope is exactly the* $\mathsf{FinSet}^{\uparrow}$ *node spine* xs*, the scalar endpoint rows carrying* α_i *and* ω_i*, the* $\mathsf{Integral}^{\uparrow}$ *endpoint map* $\mathcal{I}_Q$*, the* ListCarrier *polynomial code* p*, and the* $\mathsf{Nat}^{\uparrow}$ *degree bound* n*. No host ordering of nodes, host analytic function, host real equality, convergence assumption, or approximation scheme is part of the carried source row.*

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureCarriedRuleSourceRow scope`

Proof. The carrier row of Definition 227.1 names only the tuple $(xs, \alpha, \omega, \mathcal{I}_Q)$, with polynomial inputs supplied as finite ListCarrier codes. The exactness-degree definition then adds only the unary bound $n : \mathsf{Nat}^{\uparrow}$ and the derived rows QSum_Q, QExact_Q, $\mathsf{PolyDegLe}_R$, and $\mathsf{QuadratureExactUpTo}_R$.

Each displayed row is built from the listed source objects: folding over $\mathsf{Pos}(xs)$, scalar multiplication and addition, Horner evaluation on a list code, the integral endpoint map, trimming, and strict-prefix comparison on unary naturals. Therefore any datum outside these rows can enter only as a ledger entry and not as carrier scope. □

Theorem 227.4 (Quadrature classifier scope obligation)**.** *The exactness-degree classifier for the carried* $\mathsf{Quadrature}^{\uparrow}$ *rule is the preorder row* DegBoundLe *on* $\mathsf{Nat}^{\uparrow}$ *bounds together with the weakening action on* $\mathsf{QuadratureExactUpTo}_R$*. Its source predicates are precisely* NatUnaryStrictPrefix *and* $\mathsf{PolyDegLe}_R$ *as displayed in Definition 227.2.*

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureExactUpTo classifier scope`

Proof. The classifier comparison is the displayed predicate $\mathsf{DegBoundLe}(e, d)$. By Definition 227.6, this comparison transports a polynomial degree window from the smaller bound e to the larger bound d using only NatUnaryStrictPrefix and the coefficient condition in $\mathsf{PolyDegLe}_R$.

Applying Definition 227.7 to that transported window gives the classifier action on $\mathsf{QuadratureExactUpTo}_R$. The reflexive and transitive rows recorded in Definition 227.11 identify the comparison surface as a preorder on the same unary bounds, so the classifier has no additional source objects. □

Theorem 227.5 (Quadrature ledger exactness obligation)**.** *For a carried* $\mathsf{Quadrature}^{\uparrow}$ *rule, the ledger exactness surface records the node spine, weights, integral endpoint provenance, polynomial trim and evaluation rows, and the pointwise predicate* QExact_Q*. The ledger does not assert host real equality or host function equality; exactness is the carried scalar endpoint relation*

$$\mathsf{QSum}_Q(p) \sim_R \mathcal{I}_Q(p)$$

on finite polynomial codes.

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureLedgerExactness surface`

Proof. Unfold Definition 227.2. The quadrature sum is a finite fold over $\mathsf{Pos}(xs)$ using the carried weights ω_i and Horner evaluation at the carried node endpoints α_i. The integral side is the carried endpoint $\mathcal{I}_Q(p)$ supplied by the $\mathsf{Integral}^{\uparrow}$ polynomial row.

The polynomial side is controlled by trim_R and $\mathsf{PolyDegLe}_R$, while exactness itself is exactly the predicate $\mathsf{QExact}_Q(p)$. The window inclusion lemma, the weakening theorem, and the preorder rows cited above transport this same predicate between unary degree bounds without replacing it by host equality of real numbers or functions. □

Lemma 227.6 (Polynomial degree windows are nested)**.** *With the notation of Definition 227.2, if* $\mathsf{DegBoundLe}(e, d)$ *holds, then every polynomial code with degree at most* e *also has degree at most* d*:*

$$\mathsf{PolyDegLe}_R(p, e) \Longrightarrow \mathsf{PolyDegLe}_R(p, d).$$

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadraturePolynomialDegreeWindow inclusion`

Proof. Unfold $\mathsf{PolyDegLe}_R$ and $\mathsf{DegBoundLe}$. Assume $\mathsf{PolyDegLe}_R(p, e)$ and fix $k : \mathsf{Nat}^{\uparrow}$ with $\mathsf{NatUnaryStrictPrefix}(d, k)$. The degree-bound comparison sends this strict-prefix witness to $\mathsf{NatUnaryStrictPrefix}(e, k)$. Applying the degree-at-most-e hypothesis at this k gives

$$\mathsf{trim}_R(p)[k] \sim_R 0_R.$$

This is precisely the coefficient condition required for $\mathsf{PolyDegLe}_R(p, d)$. □

Theorem 227.7 (Quadrature exactness degree weakening)**.** *Let* Q *be a finite weighted* $\mathsf{Quadrature}^{\uparrow}$ *rule over the scalar carrier* R *in the sense of Definition 227.2. For unary degree bounds* $e, d : \mathsf{Nat}^{\uparrow}$*, if*

$$\mathsf{QuadratureExactUpTo}_R(Q, d) \qquad \textit{and} \qquad \mathsf{DegBoundLe}(e, d)$$

hold, then the same rule is exact on every polynomial of degree at most e*:*

$$\mathsf{QuadratureExactUpTo}_R(Q, e).$$

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureExactUpTo weakening`

Proof. Unfold the target exactness predicate. Fix a finite coefficient spine $p : \mathsf{ListCarrier}(R)$ and assume $\mathsf{PolyDegLe}_R(p, e)$. By Definition 227.6, the degree-bound comparison gives $\mathsf{PolyDegLe}_R(p, d)$. The exactness hypothesis at degree d applies to this same polynomial code and returns

$$\mathsf{QExact}_Q(p).$$

Unfolding QExact_Q identifies this row as

$$\mathsf{QSum}_Q(p) \sim_R \mathcal{I}_Q(p),$$

which is the required exactness row for p under the degree-e predicate. Since p was arbitrary, $\mathsf{QuadratureExactUpTo}_R(Q, e)$ holds. The finite node spine, the weights, and the integral endpoint map are the original components of Q throughout. □

Theorem 227.8 (Quadrature exactness degree equivalence stability)**.** *Let Q be a finite weighted* $\mathsf{Quadrature}^{\uparrow}$ *rule over the scalar carrier R in the sense of Definition 227.2. For unary degree bounds $e, d : \mathsf{Nat}^{\uparrow}$, if*

$$\mathsf{DegBoundLe}(e, d) \qquad \textit{and} \qquad \mathsf{DegBoundLe}(d, e)$$

hold, then the exactness classifiers at d and e determine the same row:

$$\mathsf{QuadratureExactUpTo}_R(Q, d) \Longleftrightarrow \mathsf{QuadratureExactUpTo}_R(Q, e).$$

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureExactUpTo degree equivalence stability`

Proof. We prove the two directions separately.

For the forward direction, assume $\mathsf{QuadratureExactUpTo}_R(Q, d)$. Apply Definition 227.7 to this degree-d exactness row and to the comparison $\mathsf{DegBoundLe}(e, d)$. The result is $\mathsf{QuadratureExactUpTo}_R(Q, e)$.

For the reverse direction, assume $\mathsf{QuadratureExactUpTo}_R(Q, e)$. Apply Definition 227.7 to this degree-e exactness row and to the comparison $\mathsf{DegBoundLe}(d, e)$. The result is $\mathsf{QuadratureExactUpTo}_R(Q, d)$. □

Theorem 227.9 (Quadrature degree-bound comparison is transitive)**.** *With the notation of Definition 227.2, the unary degree-bound comparison used by the* $\mathsf{Quadrature}^{\uparrow}$ *exactness-degree classifier is transitive. For unary degree bounds $e, d, c : \mathsf{Nat}^{\uparrow}$, if*

$$\mathsf{DegBoundLe}(e, d) \qquad \textit{and} \qquad \mathsf{DegBoundLe}(d, c)$$

hold, then

$$\mathsf{DegBoundLe}(e, c)$$

holds.

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureDegBoundLe trans`

Proof. Unfold $\mathsf{DegBoundLe}$. To prove $\mathsf{DegBoundLe}(e, c)$, fix $k : \mathsf{Nat}^{\uparrow}$ and assume

$$\mathsf{NatUnaryStrictPrefix}(c, k).$$

The comparison $\mathsf{DegBoundLe}(d, c)$ sends this witness to

$$\mathsf{NatUnaryStrictPrefix}(d, k).$$

Applying $\mathsf{DegBoundLe}(e, d)$ to that witness gives

$$\mathsf{NatUnaryStrictPrefix}(e, k).$$

This is exactly the strict-prefix condition required at the index k for $\mathsf{DegBoundLe}(e, c)$. Since k was arbitrary, the comparison from e to c holds. □

Theorem 227.10 (Quadrature degree-bound comparison is reflexive)**.** *With the notation of Definition 227.2, the exactness-degree comparison used by the* $\mathsf{Quadrature}^{\uparrow}$ *classifier is reflexive. For every unary degree bound $d : \mathsf{Nat}^{\uparrow}$,*

$$\mathsf{DegBoundLe}(d, d)$$

holds.

Proof. Unfold DegBoundLe at the pair (d, d). The required statement is

$$\forall k : \mathsf{Nat}^{\uparrow}.\ \mathsf{NatUnaryStrictPrefix}(d, k) \Longrightarrow \mathsf{NatUnaryStrictPrefix}(d, k).$$

Fix $k : \mathsf{Nat}^{\uparrow}$ and assume $\mathsf{NatUnaryStrictPrefix}(d, k)$. The conclusion is the same strict-prefix witness. Since k was arbitrary, the displayed universal clause holds, and therefore $\mathsf{DegBoundLe}(d, d)$ holds. □

Proposition 227.11 (Quadrature degree-bound comparison preorder rows)**.** *With the notation of Definition 227.2, the unary degree-bound comparison attached to the* $\mathsf{Quadrature}^{\uparrow}$ *exactness-degree classifier supplies the reflexive and transitive rows on unary bounds:*

$$\forall d : \mathsf{Nat}^{\uparrow}.\ \mathsf{DegBoundLe}(d, d)$$

and

$$\forall e, d, c : \mathsf{Nat}^{\uparrow}.\ \mathsf{DegBoundLe}(e, d) \Longrightarrow \mathsf{DegBoundLe}(d, c) \Longrightarrow \mathsf{DegBoundLe}(e, c).$$

Proof. The reflexive row is Definition 227.10. The transitive row is Definition 227.9. Both rows use the same concrete predicate DegBoundLe from Definition 227.2, so together they give the stated preorder data for the $\mathsf{Quadrature}^{\uparrow}$ degree-bound classifier. □

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureDegBoundLe preorder rows`

Closure status for $\mathsf{NameCert}_{\mathsf{Quadrature}^{\uparrow}}$**.**

Constructive story: A quadrature rule is generated from a finite $\mathsf{FinSet}^{\uparrow}$ node spine, carried scalar endpoints for each node and weight, an $\mathsf{Integral}^{\uparrow}$ endpoint map for polynomial codes on the fixed compact interval, and a unary $\mathsf{Nat}^{\uparrow}$ degree bound. A row is admitted only through this finite weighted tuple together with finite list polynomial codes, Horner evaluation, trimming, scalar addition and multiplication, and the displayed exactness predicate; host node orderings, analytic functions, convergence data, numerical approximations, and host real equality are not carrier fields. The classifier on exactness degree is the unary preorder DegBoundLe, which says that every coefficient index above one bound is also above the other, and it transports exactness by narrowing the polynomial window rather than by comparing real-valued functions externally. The source covers the node spine, scalar node and weight endpoints, integral endpoint map, polynomial code, and degree bound; the pattern records the finite weighted sum, polynomial degree window, pointwise exactness, weakening, equivalence stability, and preorder rows; the ledger keeps the nodes, weights, Horner rows, trim rows, integral provenance, and scalar endpoint comparisons visible. The five name-certificate obligations are supplied by the inhabited finite-rule surface and the reflexive and transitive degree-bound comparison, with carrier closure coming from reusing the same finite tuple while transporting exactness through the displayed scalar classifier. A history h lies in the signature gap of a $\mathsf{Quadrature}^{\uparrow}$ token p when the source-domain accepts the finite rule and degree-bound row, the signature relation pairs it with an answer rule and evidence ledger, and token introduction names that answer as p; unfolded, the weighted sum is exact on precisely the polynomial codes within the unary degree window encoded by p. The chapter registers this finite weighted exactness construction under the name $\mathsf{Quadrature}^{\uparrow}$ and provides a standard finite-rule bridge without convergence claims, analytic error estimates, host function equality, or host real equality.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Quadrature}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridged boundary is the finite-rule carrier, the DegBoundLe classifier, exactness weakening and degree-equivalence stability, the ledger exactness surface, the exactness-degree preorder rows, and the external finite-rule bridge visible to downstream numerical-analysis chapters.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Quadrature}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.QuadratureUp.QuadratureExactUpTo\_degree\_equivalence\_stability`

Bridge status: paperBridge

Not claimed: This chapter does not close convergence of numerical schemes, analytic error estimates, host real equality, host function equality, or machine-checked bridge evidence.

Upgrade path: No further paper theory-axis step is claimed for this chapter; bridge verification remains a separate status.

Lemma 227.12 (Quadrature empty position fold)**.** *Let R be a scalar carrier with classifier $\sim_R$, zero endpoint 0_R, and addition $+$ whose finite additive scalar fold is the fold of Definition 49.80.*

Let xs be a finite $\mathsf{FinSet}^{\uparrow}$ *node spine. If the position carrier* $\mathsf{Pos}(xs)$ *has no positions, then every scalar summand family* $s : \mathsf{Pos}(xs) \to R$ *satisfies*

$$\mathsf{fold}_{+,\mathsf{Pos}(xs)}(i \mapsto s(i)) \sim_R 0_R.$$

Proof. The finite-position ledger of Definition 112.27 reads a fold over $\mathsf{Pos}(xs)$ as the finite additive scalar fold over the scalar spine obtained by enumerating those positions. If $\mathsf{Pos}(xs)$ has no positions, that scalar spine is nil; no value of s is read into the ledger.

By the nil clause of Definition 49.80, equivalently by Definition 49.79, the fold over this empty scalar spine is classified with 0_R. This gives the displayed classifier comparison. □

Theorem 227.13 (Quadrature empty-node sum is zero)**.** *Let $Q = (xs, \alpha, \omega, \mathcal{I}_Q)$ be a finite weighted* $\mathsf{Quadrature}^{\uparrow}$ *rule over the scalar carrier R in the sense of Definition 227.2. Assume the* $\mathsf{FinSet}^{\uparrow}$ *node spine is empty, equivalently* $\mathsf{Pos}(xs)$ *has no positions. Then for every finite polynomial-code spine* $p : \mathsf{ListCarrier}(R)$*,*

$$\mathsf{QSum}_Q(p) \sim_R 0_R.$$

Proof. Fix a finite coefficient spine $p : \mathsf{ListCarrier}(R)$. Unfolding Definition 227.2 gives

$$\mathsf{QSum}_Q(p) := \mathsf{fold}_{+,\mathsf{Pos}(xs)}\big(i \mapsto \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p)\big).$$

The empty-node hypothesis says that the indexing carrier of this fold has no positions. Apply Definition 227.12 to the summand family

$$s(i) := \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p).$$

The result is

$$\mathsf{fold}_{+,\mathsf{Pos}(xs)}\big(i \mapsto \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p)\big) \sim_R 0_R.$$

Substituting the displayed definition of $\mathsf{QSum}_Q(p)$ gives $\mathsf{QSum}_Q(p) \sim_R 0_R$. The endpoint map $\mathcal{I}_Q$ and the pointwise exactness predicate do not enter this boundary calculation, because the claim concerns only the actual quadrature fold. □

Lemma 227.14 (Quadrature singleton position fold)**.** *Let R be a scalar carrier with classifier $\sim_R$, zero endpoint 0_R, and addition $+$ whose finite additive scalar fold is the fold of Definition 49.80. Let xs be a finite* $\mathsf{FinSet}^{\uparrow}$ *node spine. If the position carrier* $\mathsf{Pos}(xs)$ *enumerates exactly the one position i_0, then every scalar summand family* $s : \mathsf{Pos}(xs) \to R$ *satisfies*

$$\mathsf{fold}_{+,\mathsf{Pos}(xs)}(i \mapsto s(i)) \sim_R s(i_0).$$

Proof. The finite-position ledger of Definition 112.27 reads a fold over $\mathsf{Pos}(xs)$ as the finite additive scalar fold over the scalar spine obtained by enumerating those positions. Under the singleton-position hypothesis, that scalar spine is exactly $\mathsf{singleton}(s(i_0))$; no other value of s is read into the ledger.

Thus the displayed position fold is the same folded endpoint as

$$\mathsf{fold}_{+,R}(\mathsf{singleton}(s(i_0))).$$

By the singleton clause of Definition 49.80, equivalently by Definition 49.78, this singleton scalar fold is classified with $s(i_0)$. Transporting along the finite-position readback gives

$$\mathsf{fold}_{+,\mathsf{Pos}(xs)}(i \mapsto s(i)) \sim_R s(i_0).$$

□

Theorem 227.15 (Quadrature singleton-node sum is weighted evaluation)**.** *Let $Q = (xs, \alpha, \omega, \mathcal{I}_Q)$ be a finite weighted* $\mathsf{Quadrature}^{\uparrow}$ *rule over the scalar carrier R in the sense of Definition 227.2. Assume the* $\mathsf{FinSet}^{\uparrow}$ *node spine enumerates exactly one position i_0, equivalently* $\mathsf{Pos}(xs)$ *has the single position i_0. Then for every finite polynomial-code spine $p : \mathsf{ListCarrier}(R)$,*

$$\mathsf{QSum}_Q(p) \sim_R \omega_{i_0} \cdot \mathsf{Eval}_{\alpha_{i_0},R}(p).$$

Proof. Fix a finite coefficient spine $p : \mathsf{ListCarrier}(R)$. Unfolding Definition 227.2 gives

$$\mathsf{QSum}_Q(p) := \mathsf{fold}_{+,\mathsf{Pos}(xs)}\big(i \mapsto \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p)\big).$$

Apply Definition 227.14 to the summand family

$$s(i) := \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p).$$

The singleton-node hypothesis identifies the finite-position scalar spine as the singleton spine whose sole entry is

$$\omega_{i_0} \cdot \mathsf{Eval}_{\alpha_{i_0},R}(p).$$

Therefore the quadrature fold is classified with that sole entry:

$$\mathsf{fold}_{+,\mathsf{Pos}(xs)}\big(i \mapsto \omega_i \cdot \mathsf{Eval}_{\alpha_i,R}(p)\big) \sim_R \omega_{i_0} \cdot \mathsf{Eval}_{\alpha_{i_0},R}(p).$$

Substituting the displayed definition of $\mathsf{QSum}_Q(p)$ gives

$$\mathsf{QSum}_Q(p) \sim_R \omega_{i_0} \cdot \mathsf{Eval}_{\alpha_{i_0},R}(p).$$

The endpoint map $\mathcal{I}_Q$ and the exactness predicate QExact_Q do not enter this boundary calculation, because the claim concerns only the finite weighted quadrature fold. □

Lemma 227.16 (Finite additive fold decomposes over spine append)**.** *Let R be a scalar* $\mathsf{Ring}^{\uparrow}$ *carrier with classifier $\sim_R$, zero endpoint 0_R, addition $+_R$, and finite additive fold* $\mathsf{fold}_{+,R}$ *from Definition 49.80. Assume the classifier equivalence rows, additive congruence, additive associativity, and additive left-zero row retained in Definition 43.26. For finite carried scalar spines $xs, ys : \mathsf{ListCarrier}(R)$,*

$$\mathsf{fold}_{+,R}(xs{+}{+}ys) \sim_R \mathsf{fold}_{+,R}(xs) +_R \mathsf{fold}_{+,R}(ys).$$

Lean4 ✓ `BEDC.Derived.QuadratureUp.QuadratureFiniteAdditiveFold append decomposition`

Proof. Induct on the finite spine xs.

If $xs = \mathsf{nil}$, then $xs{+}{+}ys = ys$ and Definition 49.80 identifies $\mathsf{fold}_{+,R}(xs)$ with 0_R. The additive left-zero row classifies $0_R +_R \mathsf{fold}_{+,R}(ys)$ with $\mathsf{fold}_{+,R}(ys)$, and classifier symmetry reverses that comparison. Hence

$$\mathsf{fold}_{+,R}(ys) \sim_R 0_R +_R \mathsf{fold}_{+,R}(ys),$$

which is the displayed claim in the nil case.

For the cons case, write $xs = \mathsf{cons}(a, xs_0)$. The fold clauses give

$$\mathsf{fold}_{+,R}(\mathsf{cons}(a, xs_0){+}{+}ys) = a +_R \mathsf{fold}_{+,R}(xs_0{+}{+}ys)$$

and

$$\mathsf{fold}_{+,R}(\mathsf{cons}(a, xs_0)) = a +_R \mathsf{fold}_{+,R}(xs_0).$$

The induction hypothesis supplies

$$\mathsf{fold}_{+,R}(xs_0{+}{+}ys) \sim_R \mathsf{fold}_{+,R}(xs_0) +_R \mathsf{fold}_{+,R}(ys).$$

Additive congruence, using classifier reflexivity on a, classifies

$$a +_R \mathsf{fold}_{+,R}(xs_0{+}{+}ys)$$

with

$$a +_R (\mathsf{fold}_{+,R}(xs_0) +_R \mathsf{fold}_{+,R}(ys)).$$

Additive associativity then classifies this endpoint with

$$(a +_R \mathsf{fold}_{+,R}(xs_0)) +_R \mathsf{fold}_{+,R}(ys),$$

which is exactly

$$\mathsf{fold}_{+,R}(\mathsf{cons}(a, xs_0)) +_R \mathsf{fold}_{+,R}(ys).$$

Classifier transitivity composes these comparisons and proves the cons case. □

Theorem 227.17 (Quadrature node-list append sum decomposition)**.** *Let R be a scalar $\mathsf{Ring}^{\uparrow}$ carrier with classifier $\sim_R$, zero endpoint 0_R, addition $+_R$, multiplication $\cdot_R$, canonical trim, and Horner evaluation as in Definition 227.2. Assume the additive rows required by Definition 227.16. Let A and B be finite $\mathsf{FinSet}^{\uparrow}$ node spines, and set*

$$L = A{+}{+}B.$$

Let

$$Q_L = (L, \alpha, \omega, \mathcal{I}_Q)$$

be a finite weighted $\mathsf{Quadrature}^{\uparrow}$ rule. Let Q_A and Q_B be the restricted rules obtained from the same node, weight, and integral endpoint data along the left and right position injections of the finite-position append ledger:

$$Q_A = (A, \alpha|_{\mathsf{Pos}(A)}, \omega|_{\mathsf{Pos}(A)}, \mathcal{I}_Q), \qquad Q_B = (B, \alpha|_{\mathsf{Pos}(B)}, \omega|_{\mathsf{Pos}(B)}, \mathcal{I}_Q).$$

Then every finite polynomial-code spine $p : \mathsf{ListCarrier}(R)$ satisfies

$$\mathsf{QSum}_{Q_L}(p) \sim_R \mathsf{QSum}_{Q_A}(p) +_R \mathsf{QSum}_{Q_B}(p).$$

Proof. Fix $p : \mathsf{ListCarrier}(R)$. For a node position i, write the quadrature summand as

$$s_p(i) := \omega_i \cdot_R \mathsf{Eval}_{\alpha_i,R}(p).$$

Unfolding Definition 227.2 gives

$$\mathsf{QSum}_{Q_L}(p) := \mathsf{fold}_{+_R,\mathsf{Pos}(L)}(i \mapsto s_p(i)),$$

with the analogous formulas for Q_A and Q_B over $\mathsf{Pos}(A)$ and $\mathsf{Pos}(B)$.

By the finite-position ledger of Definition 112.27, together with the append split underlying Definition 112.18, the positions of $L = A{+}{+}B$ are read as the left positions of A followed by the right positions of B. Therefore the scalar spine enumerated by the summand family s_p over $\mathsf{Pos}(L)$ is the concatenation

$$S_A(p){+}{+}S_B(p),$$

where

$$S_A(p) = \big(i \in \mathsf{Pos}(A) \mapsto \omega_i \cdot_R \mathsf{Eval}_{\alpha_i,R}(p)\big)$$

and

$$S_B(p) = \big(j \in \mathsf{Pos}(B) \mapsto \omega_j \cdot_R \mathsf{Eval}_{\alpha_j,R}(p)\big).$$

The same position readback identifies

$$\mathsf{QSum}_{Q_A}(p) \sim_R \mathsf{fold}_{+,R}(S_A(p))$$

and

$$\mathsf{QSum}_{Q_B}(p) \sim_R \mathsf{fold}_{+,R}(S_B(p)),$$

while the appended rule is read as

$$\mathsf{QSum}_{Q_L}(p) \sim_R \mathsf{fold}_{+,R}(S_A(p) {+}{+} S_B(p)).$$

Applying Definition 227.16 to the two carried scalar spines $S_A(p)$ and $S_B(p)$ gives

$$\mathsf{fold}_{+,R}(S_A(p) {+}{+} S_B(p)) \sim_R \mathsf{fold}_{+,R}(S_A(p)) +_R \mathsf{fold}_{+,R}(S_B(p)).$$

Classifier transitivity and additive congruence transport the two restricted-rule readbacks through the right-hand side, yielding

$$\mathsf{QSum}_{Q_L}(p) \sim_R \mathsf{QSum}_{Q_A}(p) +_R \mathsf{QSum}_{Q_B}(p).$$

The endpoint map $\mathcal{I}_Q$ is shared by the three rules but is not used in this fold identity; the calculation concerns only the finite weighted quadrature sum. □

Theorem 227.18 (Quadrature external finite-rule bridge)**.** *The finite node spine, node and weight endpoints, Horner polynomial-code evaluation, endpoint integral map, degree-bound classifier, exactness weakening, degree-equivalence stability, and append-sum decomposition assemble the standard finite-rule bridge for* $\mathsf{Quadrature}^{\uparrow}$*. The bridge reads exactly the public* $\mathsf{NameCert}_{\mathsf{Quadrature}^{\uparrow}}$ *finite-rule certificate and exports it as a standard finite quadrature-rule boundary.*

The bridge adds no convergence theorem, analytic error estimate, host real equality, host function equality, infinite node family, or external ordering of nodes.

Proof. First read the public certificate rows from Definition 227.3, Definition 227.4, and Definition 227.5. These rows provide the finite node spine, scalar node and weight endpoints, endpoint integral map, Horner polynomial-code evaluation, degree-bound classifier, and exactness ledger.

The boundary cases of the finite-rule algebra are Definition 227.13 and Definition 227.15. They identify the empty and singleton node reads as finite weighted-sum rows of the same certificate.

For composite node spines, apply Definition 227.17. Together with Definition 227.7 and Definition 227.8, this gives the standard bridge read of the finite rule without introducing any analytic or host-level data beyond the public certificate. □

Chapter 228

A Concrete Naming Certificate for $\mathsf{FisherInfo}^{\uparrow}$

The Fisher-information interface $\mathsf{FisherInfo}^{\uparrow}$ packages, for a parametric family of distributions, the Riemannian metric whose components are expectations of squared score functions. It depends on $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186) and $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ (chapter 133).

228.1 Carrier definition

Definition 228.1 (FisherInfoUp BHist score carrier)**.** *A carried* $\mathsf{FisherInfo}^{\uparrow}$ *score packet is an eight-tuple*

$$(\mathcal{D}, \mathcal{G}, \theta, s, \eta, g, \rho, \lambda).$$

Here $\mathcal{D}$ *is a displayed* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *packet for the parametric distribution family,* $\mathcal{G}$ *is a displayed* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ *metric packet,* θ *is the parameter row,* s *is the score-observable row over the family,* η *is the expectation row reading the squared score through the distribution endpoint,* g *is the metric-component row,* ρ *is the shared* Pkg *provenance row, and* λ *is a finite* Cont *ledger connecting these displayed rows. The packet is accepted exactly when each coordinate is a* BHist *row, all comparisons used by the ledger are* hsame *comparisons,* λ *is a finite* Cont *composite,* ρ *is the common* Pkg *provenance, and the only dependency rows used by the carrier are the displayed* $\mathsf{Distribution}^{\uparrow}$ *and* $\mathsf{RiemannianMetric}^{\uparrow}$ *rows.*

Theorem 228.2 (FisherInfoUp distribution source obligation)**.** *Every accepted packet of Definition 228.1 projects a* $\mathsf{Distribution}^{\uparrow}$ *source row whose pushforward endpoint is the only probability-distribution data available to the score and expectation ledger. In particular, the packet consumes the pushforward carrier of Definition 186.1, the classifier of Definition 186.2, and the pushforward row of Definition 186.3; it does not import an ambient probability space outside the displayed* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *surface.*

Proof. Unpack the accepted tuple. Its first field is the displayed source certificate $\mathcal{D}$, and the provenance row ρ binds every later score, expectation, and metric-component row to that same source.

Project $\mathcal{D}$ through the $\mathsf{Distribution}^{\uparrow}$ pushforward carrier and classifier. The target measurable-event rows and RealUp endpoint rows are therefore read from Definition 186.1 and Definition 186.2.

The score and expectation ledger λ has no independent probability carrier. It may use the pushforward row of Definition 186.3 as source data, but any probability-space, measurable-preimage, or measure-row information is accessed only through the displayed $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ packet. □

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier distribution source obligation`

Theorem 228.3 (FisherInfoUp score row carrier obligation)**.** *For an accepted* $\mathsf{FisherInfo}^{\uparrow}$ *score packet, the parameter row* θ*, score row* s*, and squared-score expectation row* η *form a finite* BHist *score-expectation spine over the same* $\mathsf{Distribution}^{\uparrow}$ *source. The score row is accepted only as a history over the displayed parameter and distribution rows, while the expectation row is accepted only as the* Cont *readback of the squared score through the source distribution ledger.*

Proof. Project the parameter, score, expectation, and ledger fields from Definition 228.1. The parameter row θ supplies the displayed family index, and the score row s is carried over that index rather than over an external coordinate object.

Next read the finite continuation ledger λ. It records the passage from the displayed distribution endpoint and parameter row to the score row, and then from the score row to the squared-score expectation row η.

Thus the carrier admits the score and expectation rows only as a connected BHist spine. Different score representatives or numerical expectation displays may appear as ledger witnesses, but the public row is the carried endpoint η together with its source and provenance. □

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier score row carrier obligation`

Theorem 228.4 (FisherInfoUp RiemannianMetric comparison obligation)**.** *The metric-component row* g *of an accepted* $\mathsf{FisherInfo}^{\uparrow}$ *score packet is consumable by the public* $\mathsf{RiemannianMetric}^{\uparrow}$ *source-fibre surface. Under this consumption, the squared-score expectation row* η *supplies the displayed metric endpoint on the parameter fibre, while the fibre carrier, classifier stability, and positivity or chart-compatibility obligations are read from Definition 133.4.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier riemannianmetric comparison obligation`

Proof. Project the metric-component row g from the Fisher-information packet. By construction it is the row presented through $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$, so its base point is the parameter row and its fibre endpoint is the squared-score expectation row.

Apply the public $\mathsf{RiemannianMetric}^{\uparrow}$ source-fibre surface of Definition 133.4. That surface provides the manifold point row, tangent-fibre row, fibrewise inner-product row, and classifier transport needed to read g as a metric endpoint.

The comparison is therefore between the Fisher-information expectation endpoint and the displayed Riemannian-metric fibre endpoint. It is not a claim that a host coordinate formula, a differentiability structure, or an external metric tensor has been exported by the $\mathsf{FisherInfo}^{\uparrow}$ carrier. □

Theorem 228.5 (FisherInfoUp distribution score row coverage)**.** *Every accepted packet of Definition 228.1 projects exactly the* $\mathsf{Distribution}^{\uparrow}$ *family row* $\mathcal{D}$*, the score-observable row* s*, the expectation ledger* η*, and the shared provenance row* ρ*. These projections are the complete public distribution-side rows of the* $\mathsf{FisherInfo}^{\uparrow}$ *carrier: no host density, ambient probability law, or analytic sample-space object is part of the accepted packet.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier distribution score row coverage`

Proof. Project the accepted eight-tuple onto its distribution-side coordinates. The first projection is the carried $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ packet $\mathcal{D}$, so the family row is read through the pushforward carrier and probability-package rows already exposed by $\mathsf{Distribution}^{\uparrow}$.

The score observable is the displayed row s over the same parameter row θ. It is not reconstructed from a host density; it is one of the accepted BHist coordinates.

The expectation row η is read only through the carried $\mathsf{Distribution}^{\uparrow}$ endpoint and the finite Cont ledger λ. The provenance row ρ is shared by all displayed coordinates, so repacking the four projections gives exactly the distribution family, score, expectation, and provenance surface stated in the theorem. □

Theorem 228.6 (FisherInfoUp Riemannian metric row transport)**.** *Let $(\mathcal{D}, \mathcal{G}, \theta, s, \eta, g, \rho, \lambda)$ and $(\mathcal{D}', \mathcal{G}', \theta', s', \eta', g', \rho', \lambda')$ be accepted* $\mathsf{FisherInfo}^{\uparrow}$ *score packets. If $\mathcal{D}$ transports to $\mathcal{D}'$ by* hsame *and the* $\mathsf{Distribution}^{\uparrow}$ *classifier, and s transports to s' by the displayed score-row classifier over the transported parameter row, then the metric component g transports to g' through the* $\mathsf{RiemannianMetric}^{\uparrow}$ *classifier carried by $\mathcal{G}$ and $\mathcal{G}'$.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoScorePacket metric component transport`

Proof. Use the carried $\mathsf{Distribution}^{\uparrow}$ classifier first. It transports the distribution endpoint used by the expectation row from $\mathcal{D}$ to $\mathcal{D}'$, and the score-row hypothesis transports the displayed score observable from s to s' over the transported parameter row.

The expectation endpoint is therefore read at the transported pair of distribution and score rows. Because η and η' are ledger rows in the accepted packets, the finite Cont ledgers λ and λ' record only this distribution-to-expectation readback.

It remains to compare the displayed metric components. The metric coordinate is carried by the $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$ packets $\mathcal{G}$ and $\mathcal{G}'$. Applying the RiemannianMetricUp classifier-stability row transports the fibrewise metric endpoint, so the transported expectation component is classified as g'. □

Theorem 228.7 (FisherInfoUp expectation ledger exactness)**.** *In an accepted* $\mathsf{FisherInfo}^{\uparrow}$ *score packet, the expectation of the squared score is hidden only by the displayed* $\mathsf{Distribution}^{\uparrow}$ *pushforward ledger, the* $\mathsf{Real}^{\uparrow}$ *classifier endpoint, and the finite* Cont *readback λ. No integration primitive, host density, or analytic probability space is a public coordinate of the carrier.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier expectation ledger exactness`

Proof. Inspect the carrier coordinates of Definition 228.1. The only distribution-side source is $\mathcal{D}$, and the only observable-side source is the displayed score row s over θ.

The expectation coordinate η is the public endpoint of reading the squared score through the $\mathsf{Distribution}^{\uparrow}$ pushforward ledger. Its endpoint comparison is a $\mathsf{Real}^{\uparrow}$ classifier comparison, and its construction is recorded by the finite Cont ledger λ.

Every public endpoint of the carrier is therefore one of the displayed rows $\mathcal{D}$, $\mathcal{G}$, θ, s, η, g, ρ, or the finite ledger λ. Since no coordinate names an integration primitive, host density, or external probability object, those objects are not part of the public carrier. □

Theorem 228.8 (FisherInfoUp Riemannian metric component row)**.** *In every accepted packet of Definition 228.1, the endpoint of the expected squared score η is exactly the metric-component* BHist *row g consumed by the inherited* $\mathsf{RiemannianMetric}^{\uparrow}$ *fibre surface $\mathcal{G}$. Thus the Fisher information component is not an external coordinate metric; it is the displayed expectation endpoint repacked as the metric fibre component.*

Proof. Project the accepted packet onto the expectation row η and the metric-component row g. By the carrier definition, both are displayed BHist rows in the same finite Cont ledger and share the provenance row ρ.

The distribution source obligation identifies η as the expectation endpoint of s^2 through the carried Distribution$^\uparrow$ probability row. The RiemannianMetricUp dependency $\mathcal{G}$ consumes a displayed metric fibre component rather than a host coordinate tensor.

The accepted FisherInfoUp packet equates these two displayed endpoints inside the finite ledger: the expected squared score endpoint is repacked as g. Consequently the inherited fibre surface reads the same BHist row that the expectation source row produces. □

Theorem 228.9 (FisherInfoUp score expectation metric confluence)**.** *For every accepted* FisherInfo$^\uparrow$ *score packet* $(\mathcal{D}, \mathcal{G}, \theta, s, \eta, g, \rho, \lambda)$*, the* Distribution$^\uparrow$ *pushforward row, the score row, the expectation row, and the* RiemannianMetric$^\uparrow$ *metric row share one* Pkg *provenance row* ρ *and one finite* Cont *ledger* λ*. Under that shared ledger, the public metric component* g *is exactly the displayed expected squared-score endpoint* η *consumed through* $\mathcal{G}$*.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier score expectation metric confluence`

Proof. Apply Definition 228.2. It projects the packet to the Distribution$^\uparrow$ source row, the parameter row θ, the score row s, and the expectation endpoint η.

Apply Definition 228.7. The expectation endpoint is read only through the displayed pushforward and the finite Cont route λ, with provenance recorded by the same row ρ.

Apply Definition 228.4 to read the metric dependency $\mathcal{G}$, and then Definition 228.8 to identify the metric component g with the expected squared-score endpoint. Repacking these four rows gives the confluence statement: the probability face and metric face consume the same displayed endpoint under the same ledger. □

Theorem 228.10 (FisherInfoUp classifier transport obligation)**.** *Let* $\mathcal{I}$ *and* $\mathcal{I}'$ *be accepted* FisherInfo$^\uparrow$ *score packets whose source distribution, parameter, score, squared-score expectation, and metric-component rows are related by the componentwise* hsame *witnesses available to their finite ledgers. Then the* FisherInfo$^\uparrow$ *classifier transports the score-expectation spine of* $\mathcal{I}$ *to the score-expectation spine of* $\mathcal{I}'$ *and preserves the target* RiemannianMetric$^\uparrow$ *fibre comparison.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier classifier transport obligation`

Proof. Start with the two accepted carrier tuples and project their componentwise classifier witnesses. The source distribution rows are transported by the Distribution$^\uparrow$ classifier, while the parameter, score, expectation, and metric-component rows are transported by the listed hsame comparisons.

Transport the finite continuation ledger component by component. The source-to-score step moves along the transported distribution and parameter rows; the score-to-expectation step moves along the transported score row; the expectation-to-metric-component step moves along the transported metric row.

Finally apply the RiemannianMetric$^\uparrow$ classifier stability supplied by Definition 133.4. The transported expectation endpoint is still the metric endpoint of the transported metric-component row, so the public FisherInfo$^\uparrow$ classifier is preserved. □

228.2 The certificate

Theorem 228.11 (FisherInfoUp classifier transport row)**.** *Let* $(\mathcal{D}, \mathcal{G}, \theta, s, \eta, g, \rho, \lambda)$ *and* $(\mathcal{D}', \mathcal{G}', \theta', s', \eta', g', \rho', \lambda')$ *be accepted* $\mathsf{FisherInfo}^{\uparrow}$ *score packets. If* hsame *transport carries the distribution family row* $\mathcal{D}$ *to* $\mathcal{D}'$*, the parameter row* θ *to* θ'*, the score row* s *to* s'*, and the metric fibre row* $\mathcal{G}$ *to* $\mathcal{G}'$*, then it transports the FisherInfoUp metric endpoint componentwise from* g *to* g'*.*

Proof. Use the carried $\mathsf{Distribution}^{\uparrow}$ classifier first. It transports the pushforward and probability row that supplies the expectation source from $\mathcal{D}$ to $\mathcal{D}'$, while the parameter and score hypotheses transport the displayed score-function row from s to s' over θ'.

The expected squared score endpoint therefore transports from η to η' along the same finite Cont readback pattern. No analytic integration or derivative primitive enters this step because both endpoints are displayed BHist rows in accepted packets.

Apply the metric component row theorem on both packets. It identifies η with g and η' with g' as the metric fibre components consumed by $\mathcal{G}$ and $\mathcal{G}'$. The $\mathsf{RiemannianMetric}^{\uparrow}$ classifier then transports the component row, giving the stated componentwise FisherInfoUp metric endpoint transport. □

Theorem 228.12 (FisherInfoUp public certificate surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ *obligation surface consists exactly of the score packet carrier of Definition 228.1, the distribution source row of Definition 228.2, the metric component row of Definition 228.8, the classifier transport row of Definition 228.11, the finite* Cont *ledger* λ*, the shared* Pkg *ledger* ρ*, the exactness boundary excluding host density, integral, derivative, and coordinate metric primitives, and an absent bridge row. These data form the public* $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ *surface over the dependency certificates* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$*.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier public certificate surface`

Proof. The carrier component is exactly the displayed eight-coordinate packet of Definition 228.1. Its accepted coordinates expose the $\mathsf{Distribution}^{\uparrow}$ dependency, the $\mathsf{RiemannianMetric}^{\uparrow}$ dependency, the parameter history, the score-function history, the squared-score expectation history, the metric-component history, the shared Pkg provenance, and the finite Cont ledger.

The distribution-side public rows are supplied by Definition 228.2. The metric endpoint identified from the expected squared score is supplied by Definition 228.8.

The classifier transport row is supplied by Definition 228.11. Repacking these rows with the finite Cont ledger, the Pkg provenance ledger, the explicit exactness boundary, and the absent bridge row gives the stated ten-field $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ obligation surface. □

Theorem 228.13 (FisherInfoUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ *obligation surface consists exactly of the* BHist *score carrier of Definition 228.1, the distribution score row coverage of Definition 228.5, the Riemannian metric transport row of Definition 228.6, the expectation ledger exactness row of Definition 228.7, the finite* Cont *ledger* λ*, and the shared dependency provenance* ρ *from* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^{\uparrow}}$*. It exports no host density, analytic integration primitive, external probability law, or host Riemannian metric object.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier semantic name certificate`

Proof. The carrier component is exactly the eight-coordinate packet of Definition 228.1. Its accepted coordinates expose the $\mathsf{Distribution}^{\uparrow}$ dependency, the $\mathsf{RiemannianMetric}^{\uparrow}$ dependency, the

parameter row, the score row, the expectation row, the metric-component row, the shared Pkg provenance, and the finite Cont ledger.

The distribution-side public rows are supplied by Definition 228.5. The classifier transport row is supplied by Definition 228.6, which composes hsame transport, DistributionUp endpoint transport, score-row transport, and the RiemannianMetricUp classifier.

The exactness boundary is supplied by Definition 228.7. Repacking these rows under the ten-field NameCert pattern yields the stated $\mathsf{NameCert}_{\mathsf{FisherInfo}^\uparrow}$ surface, and the same projections exclude every host density, analytic integration primitive, external probability law, and host metric object from the public certificate. □

Theorem 228.14 (FisherInfoUp ledger exactness boundary)**.** *The public* $\mathsf{NameCert}_{\mathsf{FisherInfo}^\uparrow}$ *obligation surface consists exactly of the* $\mathsf{Distribution}^\uparrow$ *source row, the* $\mathsf{RiemannianMetric}^\uparrow$ *metric packet, the parameter row, the score row, the squared-score expectation row, the metric-component row, the* Pkg *provenance row, the componentwise* hsame *classifier witnesses used by the finite ledger, and the finite* Cont *ledger of Definition 228.1. It exports no additional row for score choice, expectation approximation, coordinate chart, host differentiability, ambient statistical model equality, or standard bridge.*

Lean4 ✓ `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier ledger exactness boundary`

Proof. Soundness is by projection from the accepted packet. Each accepted public row is one of the named fields of Definition 228.1: distribution source, metric packet, parameter, score, expectation, metric-component, provenance, or ledger, together with the hsame comparisons admitted by that ledger.

Completeness is the reverse packaging. Given exactly those rows, the eight-coordinate packet is reconstructed as a finite BHist packet whose score and expectation endpoints are connected by the displayed Cont ledger and whose metric endpoint is presented to $\mathsf{NameCert}_{\mathsf{RiemannianMetric}^\uparrow}$.

The exclusions follow from the same exactness reading. Score representatives, expectation approximations, coordinate choices, and differentiability evidence can justify ledger steps, but no such datum is a separate public carrier equality or a row available to downstream consumers outside the listed packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{FisherInfo}^\uparrow}$.

Constructive story: A Fisher-information packet is carried as eight displayed rows: a certified distribution family, a certified Riemannian-metric packet, a parameter row, a score row, the expected squared-score endpoint, the metric-component endpoint, shared package provenance, and a finite continuation ledger tying the rows together. The carrier accepts exactly those BHist coordinates when the score and expectation are read through the $\mathsf{Distribution}^\uparrow$ pushforward surface and the metric component is consumed through $\mathsf{RiemannianMetric}^\uparrow$; host densities, ambient probability spaces, integration primitives, score choices, and coordinate metric tensors remain outside the carrier. Two packets are classified by transporting the distribution, parameter, score, expectation, and metric rows through componentwise hsame, the $\mathsf{Distribution}^\uparrow$ classifier, and the $\mathsf{RiemannianMetric}^\uparrow$ fibre classifier, so sameness is a ledgered endpoint comparison rather than equality of analytic formulas. The source covers the distribution, score, expectation, metric, provenance, and finite continuation rows, the pattern records the confluence between the expected squared score and the metric fibre component, and the ledger keeps the pushforward, RealUp endpoint, provenance, and continuation readback visible. The five name-certificate obligations follow because the dependency certificates supply admitted distribution and metric endpoints, hsame and their classifiers are equivalence-like transport mechanisms, and the expectation-to-metric row repacks transported endpoints back into an accepted score packet. A history h lies in the signature gap of a $\mathsf{FisherInfo}^\uparrow$ token p when the source-domain accepts this packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names the answer as p; unfolded, h presents the distribution family, score, expected squared-score row, metric component, shared provenance, and finite ledger encoded by p. The chapter registers this score-expectation metric construction under the name $\mathsf{FisherInfo}^\uparrow$; Fisher information is the displayed expectation endpoint reused as a metric fibre row, with no host density, analytic integral, external probability law, coordinate metric object, or standard bridge introduced.

Theory closure: TheoryGate(NameCert$_{\mathsf{FisherInfo}\uparrow}$, maturePackageClosed)

Scope closed: The public boundary exports exactly the distribution, metric, parameter, score, expectation, metric-component, provenance, and finite ledger rows displayed in the FisherInfoUp certificate surface.

Formal verification: FormalStatus(NameCert$_{\mathsf{FisherInfo}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.FisherInfoUp.FisherInfoBHistScoreCarrier\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not close host density, analytic integration, coordinate metric, standard bridge, or completeness claims for Fisher information.

Upgrade path: No further paper theory-axis upgrade is pending for the finite score-expectation metric packet.

Chapter 229

A Concrete Naming Certificate for $\mathsf{StatManifold}^{\uparrow}$

The statistical-manifold interface $\mathsf{StatManifold}^{\uparrow}$ packages a parameter-space manifold whose points label probability distributions, equipped with the Fisher information metric and dual affine connections. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ (chapter 228).

229.1 Carrier definition

Theorem 229.1 (StatManifoldUp carrier classifier obligation)**.** *A carried* $\mathsf{StatManifold}^{\uparrow}$ *packet is a* BHist *row tuple*

$$(\mathcal{M}, \mathcal{I}, \theta, p, g, \nabla, \nabla^*, \rho, \lambda).$$

Here $\mathcal{M}$ *is the displayed* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *parameter carrier,* $\mathcal{I}$ *is the displayed* $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$ *score and metric packet,* θ *and* p *are parameter and distribution-endpoint rows,* g *is the Fisher metric row consumed from* $\mathcal{I}$*,* ∇ *and* ∇^* *are the dual affine connection ledger rows,* ρ *is the shared* Pkg *provenance, and* λ *is the finite* Cont *ledger joining these displayed rows. The classifier is the componentwise* hsame *transport that preserves the* $\mathsf{Manifold}^{\uparrow}$ *carrier row, the* $\mathsf{FisherInfo}^{\uparrow}$ *metric row, both connection ledgers, and the shared provenance.*

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldCarrier classifier transport`

Proof. Unpack the displayed tuple as a finite list of BHist rows. The parameter carrier is not an abstract transported manifold; it is the concrete $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ source row $\mathcal{M}$.

Read the Fisher metric coordinate through $\mathcal{I}$. The dependency chapter chapter 228 supplies the score, expectation, metric-component, and provenance rows, so g is accepted only as the FisherInfoUp metric endpoint.

Finally inspect the classifier. Each coordinate moves by the visible hsame comparison and the finite Cont route already stored in λ. Repacking the transported coordinates gives another accepted tuple with the same dependency sources and the same public row inventory. □

Theorem 229.2 (StatManifoldUp FisherInfo and Manifold source scope)**.** *Every accepted* $\mathsf{StatManifold}^{\uparrow}$ *packet projects exactly two dependency sources: the parameter carrier* $\mathcal{M}$ *from* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ *and the Fisher metric packet* $\mathcal{I}$ *from* $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$*. The parameter point row* θ*, distribution endpoint row* p*, and Fisher metric row* g *are read through these two dependency certificates, not through a host smooth manifold, ambient probability family, or external metric tensor.*

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldFisherManifoldSource scope transport`

Proof. Project the first two coordinates of the packet. The row $\mathcal{M}$ is the only carrier for parameter-space chart and tangent information, and chapter 96 is the only source chapter used for that carrier.

Project the Fisher-information coordinate $\mathcal{I}$. By chapter 228, the metric component is a displayed expectation endpoint over the distribution family, so g is inherited as a BHist metric row.

The remaining parameter and distribution rows are ledger coordinates tied to these two sources by ρ and λ. Since no coordinate of the tuple names a host manifold, probability family, or metric tensor, those objects are not exported by the source scope. □

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldSourceScope dependency boundary`
Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldCarrier dependency source scope transport`

Theorem 229.3 (StatManifoldUp ledger exactness)**.** *The public ledger of a* $\mathsf{StatManifold}^{\uparrow}$ *packet consists exactly of the parameter carrier row* $\mathcal{M}$*, the Fisher packet* $\mathcal{I}$*, the parameter and distribution endpoint rows* θ, p*, the Fisher metric row* g*, the dual affine connection rows* ∇, ∇^**, the shared* Pkg *row* ρ*, and the finite* Cont *ledger* λ*. No coordinate-level Christoffel symbol, density formula, or ambient affine connection object is available outside this list.*

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldBHistPacket ledger exactness`
Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldCarrierPacket ledger exactness`

Proof. Inspect the coordinates displayed in Definition 229.1. They already list the complete accepted packet, including both dependency certificates, the metric row, the two connection rows, and the shared provenance.

The connection data are ledger rows rather than host formulas. They can be transported only along the carried Cont route and compared only by hsame against the same dependency sources.

Conversely, every public readback from the packet must project one of the listed rows. Repacking these projections gives exactly the same finite ledger, so there is no hidden coordinate connection or analytic density primitive to read. □

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldDependencyLedgerPacket public projection`

Theorem 229.4 (StatManifoldUp NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$ *obligation surface is generated by the carrier-classifier row of Definition 229.1, the dependency source scope of Definition 229.2, and the ledger exactness row of Definition 229.3. Its carrier witness is the displayed packet, its classifier obligations are reflexivity, symmetry, and transitivity of the componentwise* hsame *row, and its stability obligation is preservation of the same packet shape under the finite* Cont *transports recorded by* λ*.*

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldPacket namecert obligation surface`

Proof. Use the carrier theorem to obtain the displayed packet and its classifier. The carrier witness is the packet itself; the classifier relation is the componentwise hsame relation over the visible coordinates.

Reflexivity, symmetry, and transitivity are inherited coordinate by coordinate from hsame while the dependency rows remain those of $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$. The shared Pkg row ensures that the transported coordinates still belong to the same certificate packet.

Apply the ledger exactness theorem to close the public surface. It says that no extra carrier or classifier field can be read outside the tuple, so the displayed packet supplies the whole NameCert obligation surface. □

Theorem 229.5 (StatManifoldUp downstream consumption boundary)**.** *Any downstream consumer of* $\mathsf{StatManifold}^{\uparrow}$ *can read only the* BHist *parameter carrier, Fisher metric, dual affine connection, provenance, and finite continuation rows enumerated in Definition 229.3. In particular, consumers such as information-geometric curvature, statistical geodesic, or divergence interfaces must factor their inputs through the displayed* NameCert *rows and cannot demand an external smooth model or analytic probability space.*

Lean4 ✓ `BEDC.Derived.StatManifoldUp.StatManifoldCarrier downstream consumption endpoint transport`

Proof. Start from an accepted consumer readback. By the NameCert obligation surface, the readback first factors through the carried packet and the componentwise classifier of Definition 229.1.

Apply the source-scope theorem. It restricts all manifold and metric inputs to the two dependency certificates $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$.

Apply ledger exactness. The remaining consumable rows are precisely $\theta, p, g, \nabla, \nabla^*, \rho, \lambda$ together with the two dependency packets, so every downstream interface must consume those rows and no others. □

229.2 The certificate

Theorem 229.6 (StatManifoldUp public certificate export)**.** *The carrier-classifier obligation of Definition 229.1, the FisherInfo/Manifold source scope of Definition 229.2, the ledger exactness row of Definition 229.3, the* $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$ *obligation surface of Definition 229.4, and the downstream consumption boundary of Definition 229.5 together export the public* $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$ *surface. The exported rows are exactly the* BHist *parameter carrier, Fisher metric packet, dual affine connection ledgers,* Pkg *provenance, and finite* Cont *ledger, with no host manifold or analytic probability primitive.*

Proof. First project the carrier-classifier obligation and the source-scope row. They identify the public packet as the displayed parameter carrier from $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ and the Fisher metric packet from $\mathsf{NameCert}_{\mathsf{FisherInfo}^{\uparrow}}$.

Next apply ledger exactness. It says that the remaining public rows are the parameter endpoint, distribution endpoint, Fisher metric, dual affine connection ledgers, shared provenance, and finite continuation ledger, with no extra coordinate-level analytic data.

Finally use the NameCert obligation surface and the downstream consumption boundary. These two rows repack the displayed carrier, classifier, stability, ledger, and consumer-facing rows as the public $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$ surface, and they exclude any host manifold or analytic probability primitive outside the listed BHist packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation surface names the carrier-classifier row, Fisher and manifold source scope, ledger exactness row, $\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$ obligation row, downstream boundary, and public export row already displayed in this chapter.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StatManifold}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.StatManifoldUp.StatManifoldPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Constructive story: The statistical-manifold packet is carried by a finite BHist ledger whose source rows come from $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{FisherInfo}^{\uparrow}$, whose visible rows expose parameter and distribution endpoints, Fisher metric data, dual affine connection data, package provenance, and continuation evidence, and whose classifier transports only those displayed rows through hsame and Cont.

Not claimed: This chapter does not close host manifolds, analytic probability primitives, coordinate Christoffel symbols, or standard bridges.

Upgrade path: No further paper theory-axis upgrade is recorded for this chapter; bridge verification remains on the formal axis.

Chapter 230

A Concrete Naming Certificate for $\mathsf{Estimator}^{\uparrow}$

The estimator interface $\mathsf{Estimator}^{\uparrow}$ packages a sequence of measurable functions of i.i.d. samples taking values in a parameter space, with consistency, bias, and variance certificates. It depends on $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$ (chapter 185) and $\mathsf{NameCert}_{\mathsf{Independence}^{\uparrow}}$ (chapter 187).

230.1 Carrier definition

Definition 230.1 (EstimatorUp BHist source surface)**.** *The* $\mathsf{Estimator}^{\uparrow}$ BHist *source surface consists of displayed* $\mathsf{RandomVar}^{\uparrow}$ *sample rows, an* $\mathsf{Independence}^{\uparrow}$ *sample-family row, estimator endpoint rows, bias and variance witness rows, componentwise* hsame *transport, finite* Cont *readback ledgers, and* Pkg *provenance naming the source certificates. A carried estimator packet is accepted only through these rows: the sample rows expose the random-variable inputs, the independence row records the finite sample-family boundary, the endpoint rows name the estimator outputs, and the bias and variance witnesses are read by finite continuation ledgers from the same packet.*

Lean4 (definition) `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface`

230.2 The certificate

Theorem 230.2 (EstimatorUp source obligation)**.** *Every* $\mathsf{Estimator}^{\uparrow}$ BHist *source packet is sourced exactly by the* $\mathsf{RandomVar}^{\uparrow}$ *sample rows, the* $\mathsf{Independence}^{\uparrow}$ *sample-family row, the estimator endpoint rows, the bias and variance witness rows, finite* Cont *readback, and* Pkg *provenance of Definition 230.1. It includes no host probability-space equality, no asymptotic normality row, and no completed statistical convergence claim.*

Proof. Unpack the source surface definition. Its sample coordinates are displayed $\mathsf{RandomVar}^{\uparrow}$ rows, and its family coordinate is the single $\mathsf{Independence}^{\uparrow}$ row that relates those samples inside BHist.

The estimator endpoint, bias, and variance rows are then read by the listed finite Cont ledgers. The Pkg provenance names exactly the certificates used for those reads, so there is no separate source from an ambient probability space.

Repacking those rows gives the whole source packet. Since the definition contains no row for host probability-space equality, asymptotic normality, or completed statistical convergence, none is exported by the source obligation. □

Lean4 ✓ `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface source obligation`

Theorem 230.3 (EstimatorUp transport obligation)**.** *The classifier transport obligation for* $\mathsf{Estimator}^{\uparrow}$ *is componentwise* hsame *transport of the displayed* $\mathsf{RandomVar}^{\uparrow}$ *samples, the* $\mathsf{Independence}^{\uparrow}$ *sample-family row, the estimator endpoint rows, the bias and variance witness rows, and the finite* Cont *ledgers of Definition 230.1. Transport preserves the same* Pkg *provenance and does not identify host probability spaces, derive asymptotic normality, or complete any statistical convergence argument.*

Proof. Start with two displayed estimator packets related componentwise by hsame. The sample rows transport through their $\mathsf{RandomVar}^{\uparrow}$ certificates, while the sample-family row transports through the $\mathsf{Independence}^{\uparrow}$ certificate.

Next transport the endpoint, bias, and variance rows along the listed component comparisons. The finite Cont ledgers are stable under the same endpoint replacement, so the readback packet remains a BHist estimator packet with unchanged Pkg provenance.

The transported witness is therefore still built only from the source surface. No step introduces host probability-space equality, asymptotic normality, or a completed convergence theorem. □

Lean4 ✓ `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface transport obligation`

Theorem 230.4 (EstimatorUp finite Cont-readback determinacy)**.** *Let* E_0 *and* E_1 *be accepted* $\mathsf{Estimator}^{\uparrow}$ BHist *packets. Suppose they display the same* $\mathsf{RandomVar}^{\uparrow}$ *sample rows, the same* $\mathsf{Independence}^{\uparrow}$ *sample-family row, matching estimator endpoint, bias, and variance witness rows, componentwise* hsame *transport, the same finite* Cont *ledgers, and the same* Pkg *provenance from Definition 230.1. Then every public estimator readback row is identical after the displayed transports. No asymptotic normality row and no completed convergence row can mediate this readback.*

Proof. Project both accepted packets through Definition 230.2. The only source rows exposed are the displayed sample rows, sample-family row, endpoint rows, bias and variance witness rows, finite continuation ledgers, and package provenance listed in Definition 230.1.

Next apply Definition 230.3 componentwise. The matching hsame transports identify the sample, independence, endpoint, bias, and variance rows while preserving the same finite Cont ledgers and the same Pkg provenance.

Compare the finite continuation ledgers row-by-row. Since the ledgers are the same and their endpoints have already been transported into the same displayed rows, every public readback entry of E_0 agrees with the corresponding entry of E_1.

Repack the common rows using Definition 230.6. The public $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ surface has no field for asymptotic normality or completed statistical convergence, so neither can act as an intermediate readback witness. □

Lean4 ✓ `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface finite cont readback determinacy`

Theorem 230.5 (EstimatorUp bias and variance ledger exclusion)**.** *Let* E *be an accepted* $\mathsf{Estimator}^{\uparrow}$ BHist *packet. If* E *exposes a public bias witness row or a public variance witness row, that row factors through the bias or variance coordinate of Definition 230.1, the finite* Cont *readback ledgers displayed there, and the same* Pkg *provenance naming the source certificates. No host probability-space equality, asymptotic normality row, completed convergence theorem, or external statistical model supplies a public bias or variance witness for* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$.

Proof. Project the accepted packet through Definition 230.2. The projection lists the displayed sample rows, the sample-family row, estimator endpoint rows, bias and variance witness rows, finite continuation ledgers, and package provenance as the complete source surface for E.

Transport this projected packet by Definition 230.3. Componentwise hsame movement keeps the bias and variance coordinates inside the same displayed packet and preserves the finite Cont ledgers together with their Pkg provenance.

Now compare public readback rows using Definition 230.4. Any exposed bias or variance witness row is determined by the displayed finite ledger row after the listed transports, so it cannot be replaced by a row outside the source surface.

The source surface has no coordinate for host probability-space equality, asymptotic normality, completed convergence, or an external statistical model. Hence none of those data can enter the public $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ witness boundary. □

Lean4 ✓ `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface bias variance ledger exclusion`

Theorem 230.6 (EstimatorUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ *obligation surface is precisely the* BHist *source surface of Definition 230.1, the source obligation of Definition 230.2, and the transport obligation of Definition 230.3. Its public reads expose only sample, independence, endpoint, bias, variance,* hsame*,* Cont*, and* Pkg *rows, and exclude host probability-space equality, asymptotic normality, and completed statistical convergence.*

Proof. The carrier row is the displayed source surface. By Definition 230.2, every accepted estimator packet unpacks into the named sample, independence, endpoint, bias, variance, continuation, and provenance rows.

The classifier and stability rows are supplied by Definition 230.3. Componentwise hsame moves the visible rows and preserves the finite ledgers, so the transported packet reassembles under the same $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ interface.

Combining these two obligations gives the exact public surface. The surface is anchored in BHist and contains no field for host probability-space equality, asymptotic normality, or completed statistical convergence. □

Lean4 ✓ `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface namecert obligation surface`

Closure status for $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$.

Constructive story: An estimator row is seeded by consuming $\mathsf{RandomVar}^{\uparrow}$ and $\mathsf{Independence}^{\uparrow}$ source packets, then displaying the sample rows, sample-family row, estimator endpoint rows, bias and variance witness rows, finite continuation ledgers, and shared Pkg provenance in one BHist source surface. The checked obligation theorem records this source surface as the visible $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ boundary; host probability equality, asymptotic normality, completed convergence, and external statistical-model data are not fields of the seed packet.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, maturePackageClosed)

Scope closed: The exported $\mathsf{Estimator}^{\uparrow}$ public surface binds the estimator source rows, cited $\mathsf{FisherInfo}^{\uparrow}$ and $\mathsf{StatManifold}^{\uparrow}$ dependency rows, classifier rows, hsame transport, Cont readback, and Pkg provenance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.EstimatorUp.EstimatorBHistSourceSurface\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: This chapter does not close host probability equality, asymptotic normality, or completed convergence.

Upgrade path: No further paper theory-axis grade is recorded for the displayed estimator schema.

Chapter 231

A Concrete Naming Certificate for $\mathsf{HypothesisTest}^{\uparrow}$

The hypothesis-testing interface $\mathsf{HypothesisTest}^{\uparrow}$ packages a decision procedure between null and alternative distributional hypotheses certified by Type I and Type II error bounds. It depends on $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186) and $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ (chapter 184).

The null and alternative rows consumed from $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186) supply the classifier surface for hypothesis alternatives, while the event rows consumed from $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ (chapter 184) supply the reject and accept-null event surfaces read by the Type I and Type II ledgers. The $\mathsf{HypothesisTest}^{\uparrow}$ packet adds only the decision row, threshold comparison row, and finite error-budget rows; it does not add probability completion, asymptotic optimality, or external statistical semantics.

231.1 Carrier definition

Definition 231.1 (HypothesisTestUp decision carrier)**.** *A* $\mathsf{HypothesisTest}^{\uparrow}$ *decision carrier is a finite* BHist *decision row over a displayed null hypothesis, a displayed alternative hypothesis, and a finite threshold ledger supplied by* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$*. The carrier records the sample row, the statistic row, the threshold comparison row, the accept/reject decision row, and the finite Type I and Type II error-budget rows. It does not contain an asymptotic limit, optimality principle, or classical probability-completion field.*

231.2 The certificate

Theorem 231.2 (HypothesisTestUp Type I error ledger)**.** *For a* $\mathsf{HypothesisTest}^{\uparrow}$ *carrier, the Type I error row is a visible* $\mathsf{ProbSpace}^{\uparrow}/\mathsf{Distribution}^{\uparrow}$ *ledger entry: under the displayed null distribution row, the reject-decision event is bounded by the finite threshold budget recorded in Definition 231.1. The theorem asserts only this finite ledger bound and no optimality or asymptotic claim.*

Lean4 ✓ `BEDC.Derived.HypothesisUp.HypothesisDecisionCarrier type one error ledger`

Proof. Project the null distribution row, sample row, statistic row, and threshold comparison row from the decision carrier. The reject-decision event is a finite BHist event row in the consumed $\mathsf{ProbSpace}^{\uparrow}$ surface.

The Type I budget is one ledger coordinate of the same carrier. Reading the event through the displayed $\mathsf{Distribution}^{\uparrow}$ row gives exactly the recorded finite bound, with no appeal to external completeness or limiting frequency data. □

Lean4 ✓ `BEDC.Derived.HypothesisUp.HypothesisTestDecisionCarrier type one error ledger`

Theorem 231.3 (HypothesisTestUp Type II error ledger)**.** *For a* $\mathsf{HypothesisTest}^{\uparrow}$ *carrier, the Type II error row is a visible* $\mathsf{ProbSpace}^{\uparrow}/\mathsf{Distribution}^{\uparrow}$ *ledger entry: under the displayed alternative distribution row, the accept-null decision event is bounded by the finite threshold budget recorded in Definition 231.1. The theorem asserts only this finite ledger bound and no power optimality, asymptotic consistency, or classical probability-completion claim.*

Proof. Project the alternative distribution row together with the sample, statistic, threshold, and accept-null decision rows. These are all finite rows in the decision carrier, so the consumed $\mathsf{ProbSpace}^{\uparrow}$ event is the displayed accept-null event.

The Type II budget row is recorded beside that event in the finite threshold ledger. Evaluation through the displayed $\mathsf{Distribution}^{\uparrow}$ row returns the listed bound and nothing stronger than the finite BEDC evidence row. □

Lean4 ✓ `BEDC.Derived.HypothesisUp.HypothesisTestDecisionCarrier type two error ledger`

Theorem 231.4 (HypothesisTestUp distribution consumer boundary)**.** *The* $\mathsf{HypothesisTest}^{\uparrow}$ *consumer boundary reads only the displayed* $\mathsf{Distribution}^{\uparrow}$ *null and alternative rows, the* $\mathsf{ProbSpace}^{\uparrow}$ *event rows, the sample and statistic rows, and the finite threshold ledger. It exports no statistical optimality theorem, asymptotic decision principle, or classical probability-completeness row.*

Lean4 ✓ `BEDC.Derived.HypothesisTestUp.HypothesisTestDecisionCarrier distribution consumer boundary`

Proof. Unpack the consumer side of the decision carrier. Every probability statement is routed through a displayed $\mathsf{ProbSpace}^{\uparrow}$ event row and a displayed $\mathsf{Distribution}^{\uparrow}$ hypothesis row, and every decision statement is routed through the sample, statistic, and threshold comparison rows.

Constructor inversion on the carrier leaves no additional consumer coordinate. The boundary can therefore repack the finite error ledgers, but it cannot export an optimality, asymptotic, or completion field because no such field is present in the carrier. □

Lean4 ✓ `BEDC.Derived.HypothesisUp.HypothesisTestDecisionCarrier distribution boundary`

Theorem 231.5 (HypothesisTestUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{HypothesisTest}^{\uparrow}}$ *obligation surface is the repacking of the decision carrier, the null and alternative distribution classifiers, decision stability under* hsame *transport, Type I and Type II error ledger exactness, and the finite threshold ledger. Its claims remain finite-row* BHist *claims over* $\mathsf{Distribution}^{\uparrow}$ *and* $\mathsf{ProbSpace}^{\uparrow}$*.*

Proof. First take the carrier from Definition 231.1. It supplies the hypotheses, sample, statistic, threshold comparison, decision row, and two finite error-budget rows.

Next use Definition 231.2 and Definition 231.3 for the two error exactness fields. The distribution consumer boundary of Definition 231.4 fixes the allowed source rows and prevents external probability-completion data from entering the certificate.

Finally repack these rows with the visible classifier and hsame transport fields. Since every component is a finite row from the displayed decision carrier or its two consumed distribution certificates, the resulting $\mathsf{NameCert}_{\mathsf{HypothesisTest}^{\uparrow}}$ surface contains no statistical optimality, asymptotic, or classical completeness assertion. □

Lean4 ✓ `BEDC.Derived.HypothesisUp.HypothesisTestDecisionCarrier namecert obligation surface`

Theorem 231.6 (HypothesisTestUp finite-risk boundary)**.** *For every accepted* $\mathsf{HypothesisTest}^{\uparrow}$ *carrier, any finite risk read factors through the displayed null and alternative* $\mathsf{Distribution}^{\uparrow}$ *rows, the consumed* $\mathsf{ProbSpace}^{\uparrow}$ *event rows, the sample and statistic rows, the statistic-threshold comparison row, the decision row, and the Type I and Type II error-budget rows. The boundary exports only these finite ledgers and no asymptotic consistency, optimality principle, or probability-completion datum.*

Proof. Project the decision carrier of Definition 231.1. The carrier displays the null and alternative hypotheses, the sample row, statistic row, statistic-threshold comparison, decision row, and the two finite error-budget rows.

Apply the Type I and Type II ledger theorems, Definition 231.2 and Definition 231.3. They identify the only reject-under-null and accept-under-alternative risk reads with the displayed $\mathsf{ProbSpace}^{\uparrow}/\mathsf{Distribution}^{\uparrow}$ event ledgers.

Finally use the distribution consumer boundary and the NameCert obligation surface. Theorems 231.4 and 231.5 keep every public risk read inside the displayed decision rows, so no hidden asymptotic, optimality, or probability-completion field can be exported. □

Theorem 231.7 (HypothesisTestUp decision stability under transport)**.** *Let two accepted* $\mathsf{HypothesisTest}^{\uparrow}$ *carriers be related componentwise by* hsame *on their null and alternative* $\mathsf{Distribution}^{\uparrow}$ *rows,* $\mathsf{ProbSpace}^{\uparrow}$ *event rows, statistic-threshold ledgers, decision rows, and Type I/Type II budget rows. Then the transported carrier preserves the decision row and both error-ledger reads through the same finite* $\mathsf{NameCert}_{\mathsf{HypothesisTest}^{\uparrow}}$ *surface. The transport adds no asymptotic consistency claim, optimality datum, or probability-completion row.*

Proof. Start from the componentwise hsame relation. The carrier projection gives matching null and alternative distribution rows, event rows, statistic and threshold comparisons, decision rows, and finite Type I/Type II budget rows.

Transport the error reads through the already checked ledgers. Theorem 231.2 preserves the reject-under-null row, and Definition 231.3 preserves the accept-under-alternative row, because each is read from the displayed carrier coordinates.

Repack the transported rows using Definition 231.5. Since the NameCert surface contains only the decision carrier, visible classifiers, transport field, and finite ledgers, the transported decision cannot acquire an optimality, asymptotic, or probability-completion coordinate. □

Theorem 231.8 (HypothesisTestUp finite-risk public route)**.** *For every accepted* $\mathsf{HypothesisTest}^{\uparrow}$ *carrier, any public finite-risk read factors through the displayed* $\mathsf{Distribution}^{\uparrow}$ *null and alternative rows, the consumed* $\mathsf{ProbSpace}^{\uparrow}$ *event rows, the statistic-threshold comparison row, the decision row, the Type I/II error ledgers, and componentwise* hsame *transport. The route exports a finite decision surface over the named carrier and no statistical optimality, asymptotic consistency, probability-completion datum, or standard statistical bridge.*

Proof. Start with the finite-risk boundary of Definition 231.6. It routes every public risk read through the displayed null and alternative distributions, consumed probability events, statistic row, threshold comparison, decision row, and both finite error budgets.

Use Definition 231.7 to make the same route stable under componentwise hsame transport. The transported read still sees only the displayed carrier coordinates and the two Type I/II ledgers.

Finally repack the read through Definition 231.5. The public surface is therefore exactly the finite carrier route through $\mathsf{Distribution}^{\uparrow}$, $\mathsf{ProbSpace}^{\uparrow}$, statistic-threshold comparison, decision rows, error ledgers, and hsame transport, with no bridge or asymptotic field added. □

Closure status for $\mathsf{NameCert}_{\mathsf{HypothesisTest}^\uparrow}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{HypothesisTest}^\uparrow}$, maturePackageClosed)

Scope closed: The bridge-facing scope names the finite decision carrier, Type I/II ledgers, distribution consumer boundary, decision transport, and public finite-risk route over displayed DistributionUp and ProbSpaceUp rows, with the checked decision-carrier obligation surface supplying the packet boundary.

Constructive story: A $\mathsf{HypothesisTest}^\uparrow$ token names a finite decision carrier with null and alternative $\mathsf{Distribution}^\uparrow$ inputs, consumed $\mathsf{ProbSpace}^\uparrow$ event rows, a displayed statistic-threshold comparison, and two visible finite error-budget ledgers. The classifier is hsame on the decision history, transport repacks the statistic, threshold, decision row, and error ledgers through that history comparison, and the source covers only the displayed distribution, event, threshold, and finite budget rows. A history h lies in the signature gap of a $\mathsf{HypothesisTest}^\uparrow$ token p when the finite carrier accepts h, the signature relation pairs it with the decision verdict and error-budget rows, and token introduction names that finite verdict as p.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{HypothesisTest}^\uparrow}$, theoremChecked)

Lean target: `BEDC.Derived.HypothesisUp.HypothesisTestDecisionCarrier\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: The chapter does not claim statistical optimality, asymptotic consistency, classical probability completion, or a standard statistical bridge.

Upgrade path: The remaining bridge work is standard statistical bridge verification for the same decision-carrier obligation surface and its Type I/II ledger route, not additional paper closure.

Closure status for $\mathsf{NameCert}_{\mathsf{Hypothesis}^\uparrow}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Hypothesis}^\uparrow}$, seed)

Scope closed: Definition 231.1, Definition 231.5, and Definition 231.8 expose the finite carrier, decision obligation rows, Type I/II ledgers, and public finite-risk route for the hypothesis-testing surface.

Constructive story: A $\mathsf{Hypothesis}^\uparrow$ token is recorded here through the displayed hypothesis-testing decision carrier: null and alternative distribution rows, probability-event rows, a finite statistic-threshold comparison, a decision row, Type I/II budget rows, componentwise transport, replay, provenance, and local naming.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Hypothesis}^\uparrow}$, unformalized)

Bridge status: none

Not claimed: This seed record does not claim Lean verification, bridge checking, statistical optimality, asymptotic consistency, probability completion, or any global hypothesis-selection principle.

Upgrade path: Obligation closure requires a local HypothesisUp carrier boundary that separates the general hypothesis token from the displayed HypothesisTestUp decision carrier and its finite risk ledgers.

Chapter 232

A Concrete Naming Certificate for $\mathsf{Bayesian}^{\uparrow}$

The Bayesian-update interface $\mathsf{Bayesian}^{\uparrow}$ packages the conditional-probability rule transforming a prior distribution and likelihood into a posterior distribution. It depends on $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ (chapter 186) and $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ (chapter 188).

232.1 Carrier definition

232.2 The certificate

Theorem 232.1 (Bayesian posterior source obligation)**.** *Let $\mathcal{B}$ be a Bayesian update packet over* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$*. The packet exposes, as* BHist *data, the prior distribution row π, the likelihood row λ, the evidence row e, the posterior endpoint ω, the classifier comparison* $\mathsf{hsame}(\mathsf{Bayes}(\pi, \lambda, e), \omega)$*, and the normalisation row* $\mathsf{Cont}(\pi, \lambda, e; \omega)$*. These are the only public source obligations of the Bayesian posterior surface; no host probability kernel, measurable-space quotient, or external conditional-density equality is exported by the certificate.*

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorSurface source obligation`

Proof. Project the displayed update packet. Its $\mathsf{Distribution}^{\uparrow}$ source supplies the prior distribution row and the posterior endpoint as distribution-side BHist witnesses. Its $\mathsf{CondExp}^{\uparrow}$ source supplies the conditioning row used to read the likelihood and evidence ledger.

The classifier projection is the displayed history-sameness row comparing the Bayesian update expression with the posterior endpoint. The continuation projection is the normalisation row, recording that the prior, likelihood, and evidence data are continued to the visible posterior endpoint.

Repacking these projected rows gives exactly the stated public surface. Since the packet inventory consists only of the two dependency certificates, the evidence ledger, the posterior endpoint, the classifier row, the continuation row, and provenance, there is no field from which a host probability kernel or external conditional-density equality can be read. □

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorPacket source obligation`

Theorem 232.2 (Bayesian update ledger exactness)**.** *For any accepted Bayesian update packet, every public posterior read factors through the displayed* $\mathsf{Distribution}^{\uparrow}$ *source, the* $\mathsf{CondExp}^{\uparrow}$ *conditioning row, the evidence ledger, the posterior endpoint, and the provenance row. A consumer can therefore read the posterior only by projecting those rows and repacking them into the displayed classifier and normalisation obligations.*

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorSurface update ledger exactness`

Proof. Unpack the accepted packet into its dependency rows. The $\mathsf{Distribution}^{\uparrow}$ component is the sole source for the prior distribution row and the posterior endpoint. The $\mathsf{CondExp}^{\uparrow}$ component is the sole source for the conditioning row that binds the likelihood to the evidence ledger.

The public posterior read then has only two operations available. First, project the classifier comparison $\mathsf{hsame}(\mathsf{Bayes}(\pi, \lambda, e), \omega)$ from the displayed packet rows. Second, project the continuation row $\mathsf{Cont}(\pi, \lambda, e; \omega)$ that records the normalised endpoint.

Finally, the provenance row records the Pkg origin of the distribution, conditioning, evidence, endpoint, classifier, and normalisation rows. Repacking only these projected rows reconstructs the public posterior read, while any read requiring a host kernel, an unstated probability space, or an external density equality has no source field in the packet. □

Definition 232.3 (Bayesian posterior packet carrier)**.** *A* $\mathsf{Bayesian}^{\uparrow}$ *posterior packet is a finite* BHist *packet*

$$\mathcal{B} = (\mathcal{D}_\pi, \mathcal{D}_\omega, \mathcal{C}, \pi, \lambda, e, \omega, \beta, H, N, P)$$

with the following displayed rows. The rows $\mathcal{D}_\pi$ *and* $\mathcal{D}_\omega$ *are* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *source certificates carrying, respectively, the prior distribution row* π *and the posterior distribution endpoint* ω *as distribution data in the sense of Definition 186.1. The row* $\mathcal{C}$ *is a* $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ *source certificate carrying the likelihood row* λ *and evidence row* e *through the singleton conditional-expectation packet of Definition 188.1. The row* β *is the Bayesian update history computed from* π*,* λ*, and* e*. The classifier row is*

$$H = \mathsf{hsame}(\beta, \omega),$$

and the normalisation row is

$$N = \mathsf{Cont}(\pi, \lambda, e; \omega).$$

The provenance row $P : \mathsf{Pkg}$ *names exactly the two distribution certificates, the conditional-expectation certificate, the prior row, the likelihood row, the evidence row, the posterior endpoint, the classifier row, and the normalisation row. The packet is accepted precisely when all these rows are present with this provenance and no additional posterior-source coordinate is exposed.*

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianTasteGate single carrier alignment`

Theorem 232.4 (Bayesian posterior packet carrier introduction)**.** *Suppose the following data are supplied under the* $\mathsf{Bayesian}^{\uparrow}$ *setup: a* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *prior source carrying* π*, a* $\mathsf{NameCert}_{\mathsf{Distribution}^{\uparrow}}$ *posterior source carrying* ω*, a* $\mathsf{NameCert}_{\mathsf{CondExp}^{\uparrow}}$ *row carrying the likelihood and evidence rows* λ *and* e*, a Bayesian update history* β *read from* π*,* λ*, and* e*, a comparison row* $H = \mathsf{hsame}(\beta, \omega)$*, a normalisation row* $N = \mathsf{Cont}(\pi, \lambda, e; \omega)$*, and a provenance row* $P : \mathsf{Pkg}$ *naming exactly these sources and rows. Then these rows assemble an accepted* $\mathsf{Bayesian}^{\uparrow}$ *posterior packet in the carrier of Definition 232.3. Its public posterior source is exactly*

$$(\mathcal{D}_\pi, \mathcal{D}_\omega, \mathcal{C}, \pi, \lambda, e, \omega, H, N, P).$$

In particular, every public posterior read factors through the displayed prior, likelihood, evidence, posterior, classifier, normalisation, and provenance rows, and no host probability kernel, ambient measurable-space quotient, or external conditional-density equality is part of the accepted packet.

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorPacket carrier introduction`

Proof. Form the tuple

$$\mathcal{B} = (\mathcal{D}_\pi, \mathcal{D}_\omega, \mathcal{C}, \pi, \lambda, e, \omega, \beta, H, N, P).$$

The two distribution certificates license the prior and posterior distribution rows by the carrier discipline of Definition 186.1. The conditional-expectation certificate licenses the likelihood and evidence rows by the packet discipline of Definition 188.1.

The supplied comparison row H identifies the computed Bayesian update history β with the displayed posterior endpoint ω through hsame. The supplied normalisation row N records that the visible prior, likelihood, and evidence rows continue to the visible posterior endpoint. The provenance row P names exactly these dependency, classifier, and continuation rows.

These are precisely the acceptance clauses of Definition 232.3, so the tuple is an accepted $\mathsf{Bayesian}^\uparrow$ posterior packet. Projection of an accepted packet returns only its displayed coordinates. Hence every public posterior read is obtained from the two distribution sources, the conditional-expectation source, π, λ, e, ω, H, N, and P.

Conversely, each row in the displayed source list is a coordinate of the accepted tuple, so the list is not missing any public posterior-source row. Since the carrier definition contains no coordinate for a host probability kernel, an ambient measurable-space quotient, or an external conditional-density equality, no such datum can be read from the accepted packet. □

Theorem 232.5 (Bayesian posterior classifier transport)**.** *Let $\mathcal{B}$ and $\mathcal{B}'$ be accepted Bayesian update packets over $\mathsf{NameCert}_{\mathsf{Distribution}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{CondExp}^\uparrow}$. Write the public rows of $\mathcal{B}$, with its explicit Bayesian-update witness history b, as*

$$(\pi, \lambda, e, b, \omega, n, \rho, \mathsf{hsame}(b, \omega), \mathsf{Cont}(\pi, \lambda, e; \omega))$$

and the corresponding public rows of $\mathcal{B}'$, with its explicit Bayesian-update witness history b', as

$$(\pi', \lambda', e', b', \omega', n', \rho', \mathsf{hsame}(b', \omega'), \mathsf{Cont}(\pi', \lambda', e'; \omega')).$$

Assume the displayed prior, likelihood, evidence, Bayesian-update witness, posterior, normalisation, and provenance rows are matched componentwise by hsame *rows, with the prior, Bayesian-update witness, and posterior comparisons read through the* $\mathsf{Distribution}^\uparrow$ *classifier and the likelihood and evidence comparisons read through the* $\mathsf{CondExp}^\uparrow$ *classifier. If the* Cont *normalisation row and the* Pkg *provenance row are transported along these displayed comparisons, then the transported rows form an accepted* $\mathsf{Bayesian}^\uparrow$ *posterior packet, and the transported posterior endpoint ω' is classified with the original posterior endpoint ω. This is only a componentwise classifier-transport and row-repackaging statement for the Bayesian packet surface; it asserts no concrete closure, inversion, coverage, determinacy, uniqueness, bridge, or obstruction claim about* $\mathsf{Bayesian}^\uparrow$*.*

Proof. Project $\mathcal{B}$ by Definition 232.1. The projected surface consists exactly of the prior distribution row π, the likelihood row λ, the evidence row e, the explicit Bayesian-update witness history b, the posterior endpoint ω, the classifier comparison $\mathsf{hsame}(b, \omega)$, the normalisation row $\mathsf{Cont}(\pi, \lambda, e; \omega)$, and the provenance row. By Definition 232.2, every public posterior read of an accepted packet factors through this displayed inventory and through no other row.

Use the supplied componentwise hsame comparisons to move the dependency rows. By Definition 26.3 and Definition 26.4, the $\mathsf{Distribution}^{\uparrow}$ classifier transports the prior row, the Bayesian-update witness history, and the posterior endpoint, so π' remains a distribution-side prior row, b' remains the displayed Bayesian-update witness history, and ω' remains a distribution-side posterior endpoint. By Definition 26.3 and Definition 26.4, the $\mathsf{CondExp}^{\uparrow}$ classifier transports the likelihood and evidence rows, so the conditioning ledger that reads λ against e is replaced by the displayed ledger that reads λ' against e'. Thus the dependency part of the Bayesian packet has the same accepted shape after transport.

It remains to account for the Bayesian-specific rows. The transported normalisation row is, by hypothesis, the visible continuation $\mathsf{Cont}(\pi', \lambda', e'; \omega')$. The transported provenance row is the same Pkg-named source row read at the transported endpoint. Since the accepted Bayesian carrier exposes no row besides the two dependency certificates, the prior, likelihood, evidence, Bayesian-update witness, posterior, classifier, normalisation, and provenance rows, these transported coordinates repack as an accepted $\mathsf{Bayesian}^{\uparrow}$ posterior packet.

Finally compare endpoints. One of the componentwise hypotheses is precisely the posterior transport $\mathsf{hsame}(\omega, \omega')$ supplied through the $\mathsf{Distribution}^{\uparrow}$ endpoint classifier. By symmetry of the displayed history-sameness classifier, the transported endpoint also satisfies $\mathsf{hsame}(\omega', \omega)$. Hence the posterior endpoint of the transported packet is classified with the original posterior endpoint, and the classifier read remains the same visible Bayesian posterior read described by Definition 232.2. □

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorPacket classifier transport`

Theorem 232.6 (Bayesian posterior NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$ *posterior surface is exactly the finite packet formed by the* $\mathsf{Distribution}^{\uparrow}$ *prior and posterior rows, the* $\mathsf{CondExp}^{\uparrow}$ *likelihood and evidence rows, the posterior comparison row* $\mathsf{hsame}(\mathsf{Bayes}(\pi, \lambda, e), \omega)$*, the normalisation row* $\mathsf{Cont}(\pi, \lambda, e; \omega)$*, and the* Pkg *provenance naming those dependency rows. A posterior read is accepted only when those rows are present in the carrier of Definition 232.3.*

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorPacket namecert obligation surface`

Proof. Project the carrier of Definition 232.3. Its dependency coordinates are the two $\mathsf{Distribution}^{\uparrow}$ rows and the $\mathsf{CondExp}^{\uparrow}$ row, and these are the only sources for the visible prior, likelihood, evidence, and posterior endpoint.

The Bayesian-specific coordinates are the displayed posterior comparison, the normalisation continuation, and the package provenance. Together with the dependency rows, these coordinates are exactly the public posterior surface described by the source and ledger exactness theorems above.

No further obligation is hidden behind the classifier. Acceptance is therefore the presence of these finite rows in the packet and their readback through the displayed dependency certificates. □

Theorem 232.7 (Bayesian posterior non-escape boundary)**.** *An accepted* $\mathsf{Bayesian}^{\uparrow}$ *posterior packet exports no host probability kernel, no external density equality, no ambient measurable-space quotient, and no choice-selected posterior. Every public posterior read is mediated by the displayed* $\mathsf{Distribution}^{\uparrow}$ *rows,* $\mathsf{CondExp}^{\uparrow}$ *rows,* hsame *comparison,* Cont *normalisation,* Pkg *provenance, and local packet carrier.*

Proof. Inspect the accepted packet. Each coordinate is either a dependency certificate row, a displayed Bayesian-update history, a posterior endpoint, a classifier comparison, a continuation row, or provenance.

The carrier has no coordinate for a host kernel, a density equality outside the packet, a quotient of measurable spaces, or a selected posterior obtained by choice. Transport can only move the displayed coordinates along their hsame and Cont rows.

Thus a downstream posterior read factors through the finite packet boundary. Any read requiring one of the excluded objects has no source coordinate in the accepted $\mathsf{Bayesian}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.BayesianUp.BayesianPosteriorPacket non escape boundary`

Theorem 232.8 (Bayesian posterior public source exhaustion)**.** *Every public posterior read from* $\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$ *factors through the finite rows listed in Definition 232.3. In particular, the read is exhausted by* $\mathcal{D}_\pi$*,* $\mathcal{D}_\omega$*,* $\mathcal{C}$*,* π*,* λ*,* e*,* ω*,* β*,* H*,* N*, and* P*, with no additional posterior-source coordinate.*

Proof. Start with a public posterior read. By Definition 232.1, the read first projects the dependency rows and the displayed posterior endpoint.

Apply Definition 232.2. The ledger forces the read to pass through the visible Bayesian-update history, classifier row, normalisation row, and provenance row, and it gives no operation for introducing an external probability object.

The carrier definition lists exactly these coordinates. Repacking them reconstructs the public posterior read, while any attempted read outside this list is blocked by Definition 232.7. □

Definition 232.9 (Bayesian posterior obligation inventory)**.** *The* $\mathsf{Bayesian}^{\uparrow}$ *posterior obligation inventory is the finite* BHist *list*

$$\mathcal{I}_{\mathsf{Bayesian}^{\uparrow}} = (\mathcal{K}, \mathcal{T}, \mathcal{L}, \mathcal{S}, \mathcal{E})$$

where $\mathcal{K}$ *is the carrier clause of Definition 232.3,* $\mathcal{T}$ *is the classifier-transport clause of Definition 232.5,* $\mathcal{L}$ *is the ledger-exactness clause of Definition 232.2,* $\mathcal{S}$ *is the posterior-source exhaustion clause of Definition 232.8, and* $\mathcal{E}$ *is the non-escape clause of Definition 232.7. The inventory is accepted only when each clause is read through the displayed* $\mathsf{Distribution}^{\uparrow}$ *rows,* $\mathsf{CondExp}^{\uparrow}$ *row,* hsame *classifier row,* Cont *normalisation row,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$ *surface.*

Theorem 232.10 (Bayesian posterior obligation package)**.** *The inventory of Definition 232.9 assembles the paper-side* $\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$ *posterior obligation package. Its five public clauses are carrier admission, classifier transport, ledger exactness, posterior source exhaustion, and non-escape from host probability kernels or measurable-space quotients, witnessed respectively by Definition 232.3, Definition 232.5, Definition 232.2, Definition 232.8, and Definition 232.7.*

Proof. First project the carrier clause. It supplies exactly the distribution sources, conditional-expectation source, prior row, likelihood row, evidence row, posterior endpoint, Bayesian-update history, classifier comparison, normalisation row, and provenance row named in the inventory.

Next use classifier transport and ledger exactness. The classifier clause moves the displayed rows componentwise through hsame, while the ledger clause says that every posterior read factors through those same dependency, classifier, continuation, and provenance rows.

Finally apply posterior source exhaustion and non-escape. Exhaustion says the listed rows are all public posterior-source coordinates, and non-escape says there is no coordinate for a host kernel, external density equality, measurable-space quotient, or choice-selected posterior. These five clauses therefore form the advertised finite obligation package. □

Theorem 232.11 (Bayesian posterior obligation non-escape)**.** *Every downstream consumer of the* $\mathsf{Bayesian}^{\uparrow}$ *posterior obligation package receives only the rows in* $\mathcal{I}_{\mathsf{Bayesian}^{\uparrow}}$*. In particular, the package cannot be extended by reading a host probability kernel, an ambient measurable-space quotient, an external conditional-density equality, or a posterior selected outside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Begin with the obligation package of Definition 232.10. Its clauses are the carrier, classifier transport, ledger exactness, posterior source exhaustion, and non-escape rows.

The source-exhaustion clause fixes the public read boundary: a consumer can project $\mathcal{D}_\pi$, $\mathcal{D}_\omega$, $\mathcal{C}$, π, λ, e, ω, β, H, N, and P, and can transport these rows only by the displayed classifier and continuation data.

The non-escape clause then blocks the excluded host objects. Since the inventory contains no coordinate for probability kernels, measurable-space quotients, external density equalities, or selected posterior witnesses, no downstream consumer can recover one from the package. □

Closure status for $\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$**.**

Constructive story: A $\mathsf{Bayesian}^{\uparrow}$ posterior packet is generated from the $\mathsf{Distribution}^{\uparrow}$ prior row, the $\mathsf{Distribution}^{\uparrow}$ posterior row, the $\mathsf{CondExp}^{\uparrow}$ likelihood and evidence row, the Bayesian update history, the displayed hsame posterior comparison, the Cont normalisation row, and Pkg provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 232.9, Definition 232.10, and Definition 232.11 bind the carrier, classifier transport, ledger exactness, posterior source exhaustion, and non-escape clauses of the public posterior package.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Bayesian}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.BayesianUp.BayesianPosteriorPacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host probability kernels, measurable-space quotients, conditional-density equality, or bridge checking.

Upgrade path: Public closure requires an exported posterior consumer surface for the scoped obligation package.

Chapter 233

A Concrete Naming Certificate for $\mathsf{NetworkFlow}^{\uparrow}$

The network-flow interface $\mathsf{NetworkFlow}^{\uparrow}$ packages a directed graph carrier with edge capacities together with the maximum-flow / minimum-cut duality. It depends on $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118) and $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28).

233.1 Carrier definition

233.2 The certificate

Definition 233.1 (Finite NetworkFlowUp flow and cut data)**.** *Fix a directed* $\mathsf{Graph}^{\uparrow}$ *carrier* G*. Write* $\mathsf{Vert}_G(v)$ *for vertex membership,* $\mathsf{Edge}_G(e)$ *for edge membership,* $\mathsf{tail}_G(e)$ *and* $\mathsf{head}_G(e)$ *for the directed endpoints of an edge, and* $\sim_E$ *for the edge classifier used by the finite-edge presentation. On unary histories write*

$$x \preceq_{\mathsf{Nat}^{\uparrow}} y \iff \mathsf{PreorderPrefixLE}(x, y),$$

the concrete $\mathsf{Nat}^{\uparrow}$ *below relation from the unary-prefix preorder of Definition 52.3.*

For a finite edge spine xs *and a unary edge assignment* $a : \mathsf{BHist} \to \mathsf{BHist}$*, define the finite unary fold by*

$$\mathsf{USum}_{\mathsf{nil}}(a) := \mathsf{e}, \qquad \mathsf{USum}_{\mathsf{cons}(e,xs')}(a) := \mathsf{append}(a(e), \mathsf{USum}_{xs'}(a)).$$

This is the finite-spine form of the unary continuation fold licensed by $\mathsf{Add}^{\uparrow}$ *in Definition 29.7.*

A finite s*-*t *cut record* C *in* G *consists of a vertex predicate* S_C*, witnesses* $\mathsf{Vert}_G(s)$*,* $\mathsf{Vert}_G(t)$*,* $S_C(s)$*, and* $\neg S_C(t)$*, together with finite edge spines* C^+ *and* C^- *enumerating the forward and backward crossing predicates:*

$$\mathsf{Forward}_C(e) \iff \mathsf{Edge}_G(e) \wedge S_C(\mathsf{tail}_G(e)) \wedge \neg S_C(\mathsf{head}_G(e)),$$

$$\mathsf{Backward}_C(e) \iff \mathsf{Edge}_G(e) \wedge \neg S_C(\mathsf{tail}_G(e)) \wedge S_C(\mathsf{head}_G(e)),$$

by the finite-set enumeration predicate of Definition 112.17. For a capacity assignment u *and a flow assignment* f*, set*

$$\mathsf{CutCap}_{G,u}(C) := \mathsf{USum}_{C^+}(u), \qquad \mathsf{CutForw}_{G,C}(f) := \mathsf{USum}_{C^+}(f), \qquad \mathsf{CutBack}_{G,C}(f) := \mathsf{USum}_{C^-}(f).$$

A feasible $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow* F *over the capacity assignment* u *consists of a unary edge-flow assignment* f_F*, a unary value history witness* V_F*, and the notation*

$$\mathsf{FlowValue}(F) := V_F,$$

a capacity row

$$\forall e : \mathsf{BHist}.\ \mathsf{Edge}_G(e) \to f_F(e) \preceq_{\mathsf{Nat}^{\uparrow}} u(e),$$

and, for every finite s-t cut record C *in the same* G*, history witnesses* $B_{F,C}$ *and* $X_{F,C}$ *with identification rows*

$$B_{F,C} = \mathsf{CutBack}_{G,C}(f_F), \qquad X_{F,C} = \mathsf{CutForw}_{G,C}(f_F),$$

together with the finite conservation-accounting row

$$\mathsf{Cont}(V_F, B_{F,C}, X_{F,C}).$$

The accounting row records the cut form of flow conservation; the capacity row is separate.

Lean4 (definition) `BEDC.Derived.NetworkFlowUp.NetworkFlowFiniteFlowCutData`

Lemma 233.2 (Unary finite-fold monotonicity)**.** *Let* xs *be a finite spine and let* $a, b : \mathsf{BHist} \to \mathsf{BHist}$ *be unary assignments on every entry of* xs*. If every position of* xs *satisfies*

$$a(\mathsf{entry}_{xs}(i)) \preceq_{\mathsf{Nat}^{\uparrow}} b(\mathsf{entry}_{xs}(i)),$$

then

$$\mathsf{USum}_{xs}(a) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{USum}_{xs}(b).$$

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlowUSum prefix monotone`
Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlowUSum monotonicity`

Proof. Induct on the finite spine xs. In the nil case, both folds are e, so reflexivity of the unary-prefix preorder from Definition 52.4 gives the displayed comparison.

For the cons case, write $xs = \mathsf{cons}(e, xs')$. The pointwise hypothesis at the head gives $a(e) \preceq_{\mathsf{Nat}^{\uparrow}} b(e)$, and the induction hypothesis gives

$$\mathsf{USum}_{xs'}(a) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{USum}_{xs'}(b).$$

Right-context monotonicity of the concrete prefix relation, Definition 52.37, applied to the head comparison and the unary tail $\mathsf{USum}_{xs'}(a)$, gives

$$\mathsf{append}(a(e), \mathsf{USum}_{xs'}(a)) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{append}(b(e), \mathsf{USum}_{xs'}(a)).$$

Left-context monotonicity, Definition 52.36, applied to the tail-fold comparison with left context $b(e)$, gives

$$\mathsf{append}(b(e), \mathsf{USum}_{xs'}(a)) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{append}(b(e), \mathsf{USum}_{xs'}(b)).$$

Transitivity from Definition 52.28 composes these two comparisons. After unfolding the cons clause of Definition 233.1, this is exactly the finite-fold comparison for $\mathsf{cons}(e, xs')$. □

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow unary finite fold monotonicity`
Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlowUSum monotone`
Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlowUnaryFold pointwise prefix monotonicity`

Theorem 233.3 (Network-flow weak duality for cuts)**.** *Let G be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let u be a unary capacity assignment on its edges, and let s, t be carried vertices. If F is a feasible* $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow over u and C is a finite s-t cut record in the same directed graph, then the value of F is* $\mathsf{Nat}^{\uparrow}$*-classified below the capacity of C:*

$$\mathsf{FlowValue}(F) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(C).$$

Proof. Unpack Definition 233.1. Put $f = f_F$ and take the flow-value history witness V_F, together with the cut-history witnesses $B_{F,C}$ and $X_{F,C}$ for the chosen cut C. Their identification rows are

$$\mathsf{FlowValue}(F) = V_F, \qquad B_{F,C} = \mathsf{CutBack}_{G,C}(f), \qquad X_{F,C} = \mathsf{CutForw}_{G,C}(f).$$

The conservation-accounting row of feasibility for the cut C supplies

$$\mathsf{Cont}(V_F, B_{F,C}, X_{F,C}).$$

Since the backward crossing witness $B_{F,C}$ is unary, this continuation witness is precisely a unary-tail prefix witness from V_F to $X_{F,C}$. Hence

$$V_F \preceq_{\mathsf{Nat}^{\uparrow}} X_{F,C}.$$

Using the identification rows, this is the comparison

$$\mathsf{FlowValue}(F) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutForw}_{G,C}(f).$$

It remains to compare $\mathsf{CutForw}_{G,C}(f)$ with $\mathsf{CutCap}_{G,u}(C)$. Every entry of the forward cut spine C^+ is an edge of G by its $\mathsf{FinSet}^{\uparrow}$ enumeration witness. The capacity row of feasibility therefore gives, at each position i of C^+,

$$f(\mathsf{entry}_{C^+}(i)) \preceq_{\mathsf{Nat}^{\uparrow}} u(\mathsf{entry}_{C^+}(i)).$$

Applying Definition 233.2 to the finite spine C^+ gives

$$\mathsf{CutForw}_{G,C}(f) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(C).$$

Finally compose $\mathsf{FlowValue}(F) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutForw}_{G,C}(f)$ with $\mathsf{CutForw}_{G,C}(f) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(C)$ by Definition 52.28. This proves

$$\mathsf{FlowValue}(F) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(C).$$

□

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow weak duality cuts`

Theorem 233.4 (Network-flow cut accounting from vertex conservation)**.** *Let G be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let C be a finite s-t cut record in G, and let f be a unary edge-flow assignment with unary value history V. Let $\sim_V$ be the vertex classifier carried by G. Suppose W_C is a finite vertex spine enumerating the nonterminal cut-side predicate*

$$\mathsf{CutSide}_{C,s,t}(v) \iff \mathsf{Vert}_G(v) \wedge S_C(v) \wedge \neg(v \sim_V s) \wedge \neg(v \sim_V t)$$

in the finite-spine sense of Definition 112.17. Let I_s and O_s be finite edge spines enumerating the incoming and outgoing edges at s, and for every entry v of W_C let I_v and O_v be finite edge

spines enumerating the incoming and outgoing edges at v. Let $\mathsf{VCat}_{W_C}(I)$ and $\mathsf{VCat}_{W_C}(O)$ denote the concatenations of these edge spines in the order of W_C. Finally let J_C be a finite edge spine enumerating the internal cut-side edges

$$\mathsf{Internal}_C(e) \iff \mathsf{Edge}_G(e) \wedge S_C(\mathsf{tail}_G(e)) \wedge S_C(\mathsf{head}_G(e)).$$

Assume the finite incidence readback rows

$$\mathsf{USum}_{I_s ++ \mathsf{VCat}_{W_C}(I)}(f)\mathsf{hsameappend}(\mathsf{CutBack}_{G,C}(f), \mathsf{USum}_{J_C}(f))$$

and

$$\mathsf{USum}_{O_s ++ \mathsf{VCat}_{W_C}(O)}(f)\mathsf{hsameappend}(\mathsf{CutForw}_{G,C}(f), \mathsf{USum}_{J_C}(f))$$

are supplied by the certified finite-position accounting of Definition 112.2. If the source-value row

$$\mathsf{Cont}(V, \mathsf{USum}_{I_s}(f), \mathsf{USum}_{O_s}(f))$$

holds and every nonterminal cut-side vertex satisfies vertex conservation

$$\forall v : \mathsf{BHist.\ SpineMember}(v, W_C) \to \mathsf{USum}_{I_v}(f)\mathsf{hsameUSum}_{O_v}(f),$$

then the cut supplies the finite conservation-accounting row

$$\mathsf{Cont}(V, \mathsf{CutBack}_{G,C}(f), \mathsf{CutForw}_{G,C}(f)).$$

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow cut accounting suffix cancellation`

Proof. First aggregate the local vertex rows over the finite spine W_C. Induct through W_C, carrying the invariant that the source row together with the conservation rows for the vertices already visited supplies a continuation from V by the accumulated incoming-side sum to the accumulated outgoing-side sum. The empty-spine case is the source-value row, using the nil clause in the finite fold of Definition 233.1. In the cons step, the induction hypothesis supplies the accumulated continuation and the head occurrence supplies

$$\mathsf{USum}_{I_v}(f)\mathsf{hsameUSum}_{O_v}(f).$$

Associativity for unary continuation from Definition 29.6 appends this head block to the accumulated incoming and outgoing ledgers, and the commutative unary additive field from Definition 29.10, concretely Definition 9194.6, permits the block to be read in the vertex-spine order used by VCat_{W_C}. Thus the induction yields

$$\mathsf{Cont}(V, \mathsf{USum}_{I_s ++ \mathsf{VCat}_{W_C}(I)}(f), \mathsf{USum}_{O_s ++ \mathsf{VCat}_{W_C}(O)}(f)).$$

Put $J = \mathsf{USum}_{J_C}(f)$. Transport this aggregate continuation along the two displayed incidence readback rows. This gives

$$\mathsf{Cont}(V, \mathsf{append}(\mathsf{CutBack}_{G,C}(f), J), \mathsf{append}(\mathsf{CutForw}_{G,C}(f), J)).$$

The forward direction of the continuation suffix equivalence Definition 18.22, with $a = V$, $f = \mathsf{CutBack}_{G,C}(f)$, $b = \mathsf{CutForw}_{G,C}(f)$, and $p = J$, cancels the common internal suffix and yields

$$\mathsf{Cont}(V, \mathsf{CutBack}_{G,C}(f), \mathsf{CutForw}_{G,C}(f)).$$

This is exactly the finite conservation-accounting row from Definition 233.1. □

Definition 233.5 (Residual-cut augmenting-path exhaustion certificate)**.** *Fix the finite* $\mathsf{NetworkFlow}^{\uparrow}$ *setup of Definition 233.1: a directed* $\mathsf{Graph}^{\uparrow}$ *carrier* G*, a unary capacity assignment* u*, carried vertices* s, t*, and a feasible* s*-*t *flow* F *with edge-flow assignment* f_F*. A residual-cut augmenting-path exhaustion certificate* Ξ *for* F *consists of a finite* s*-*t *cut record* C_Ξ *in* G*, written*

$$\mathsf{ResCut}_{F,u}(\Xi) := C_\Xi,$$

and the following residual boundary rows. For each $i : \mathsf{Pos}(C_\Xi^+)$*, write*

$$U_{\Xi,i} := u(\mathsf{entry}_{C_\Xi^+}(i)), \qquad E_{\Xi,i} := f_F(\mathsf{entry}_{C_\Xi^+}(i)).$$

Then

$$U_{\Xi,i} \preceq_{\mathsf{Nat}^{\uparrow}} E_{\Xi,i}.$$

There is also a named backward residual history B_Ξ *with*

$$B_\Xi := \mathsf{CutBack}_{G,C_\Xi}(f_F), \qquad B_\Xi \mathsf{hsamee}.$$

The first row is the finite-spine saturation of every forward edge of the induced residual cut. The second row is the finite-spine absence of backward flow across that cut.

Lemma 233.6 (Empty backward accounting reflects cut flow below value)**.** *Let* G *be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let* u *be a unary capacity assignment, let* F *be a feasible finite* $\mathsf{NetworkFlow}^{\uparrow}$ s*-*t *flow over* u *with edge-flow assignment* f_F*, and let* C *be a finite* s*-*t *cut record in* G*. Write*

$$B_C := \mathsf{CutBack}_{G,C}(f_F), \qquad X_C := \mathsf{CutForw}_{G,C}(f_F), \qquad V_F := \mathsf{FlowValue}(F).$$

If

$$B_C \mathsf{hsamee},$$

then

$$X_C \preceq_{\mathsf{Nat}^{\uparrow}} V_F.$$

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlowEmptyBackwardAccounting cut flow below value`
Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow empty backward accounting cut flow below value`

Proof. Unpack Definition 233.1 for the chosen cut C. The feasibility data supply histories $B_{F,C}$ and $X_{F,C}$ with

$$B_{F,C} = B_C, \qquad X_{F,C} = X_C,$$

and with the accounting row

$$\mathsf{Cont}(V_F, B_{F,C}, X_{F,C}).$$

The displayed backward-empty hypothesis and the identification row for $B_{F,C}$ give $B_{F,C}\mathsf{hsamee}$. The identification row for $X_{F,C}$ gives $X_{F,C}\mathsf{hsame}X_C$.

Transport the accounting row along these endpoint classifications using Definition 4.41. This gives

$$\mathsf{Cont}(V_F, \mathsf{e}, X_C).$$

The right-unit clause of Definition 4.38 identifies the result with the source, so

$$X_C \mathsf{hsame} V_F.$$

Applying Definition 52.17 to this history-sameness gives the displayed $\mathsf{Nat}^{\uparrow}$ prefix comparison. □

Theorem 233.7 (Network-flow max-flow min-cut equality from residual exhaustion)**.** *Let G be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let u be a unary capacity assignment, let s, t be carried vertices, and let F be a feasible finite* $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow over u with edge-flow assignment f_F. If Ξ is a residual-cut augmenting-path exhaustion certificate for F, write*

$$C_\Xi := \mathsf{ResCut}_{F,u}(\Xi), \qquad V_F := \mathsf{FlowValue}(F), \qquad K_\Xi := \mathsf{CutCap}_{G,u}(C_\Xi).$$

Then the value of F is $\mathsf{Nat}^{\uparrow}$*-classified equal to the capacity of the residual cut induced by Ξ:*

$$V_F \mathsf{hsame} K_\Xi.$$

Moreover, the equality is supported by the two prefix comparisons

$$V_F \preceq_{\mathsf{Nat}^{\uparrow}} K_\Xi \qquad \textit{and} \qquad K_\Xi \preceq_{\mathsf{Nat}^{\uparrow}} V_F.$$

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow maxflow mincut equality from residual exhaustion`

Proof. Use the displayed names and put

$$X_\Xi := \mathsf{CutForw}_{G,C_\Xi}(f_F).$$

The comparison from flow value to cut capacity is exactly Definition 233.3 applied to the feasible flow F and the finite cut record C_Ξ:

$$V_F \preceq_{\mathsf{Nat}^{\uparrow}} K_\Xi.$$

Unpack Definition 233.5. Its forward saturation row gives, for every $i : \mathsf{Pos}(C_\Xi^+)$, with $U_{\Xi,i}$ and $E_{\Xi,i}$ as named there,

$$U_{\Xi,i} \preceq_{\mathsf{Nat}^{\uparrow}} E_{\Xi,i}.$$

Apply Definition 233.2 to the finite spine C_Ξ^+ with assignments u and f_F. By the definitions of K_Ξ and X_Ξ in Definition 233.1, this yields

$$K_\Xi \preceq_{\mathsf{Nat}^{\uparrow}} X_\Xi.$$

The backward-empty row of the certificate and Definition 233.6 give

$$X_\Xi \preceq_{\mathsf{Nat}^{\uparrow}} V_F.$$

Transitivity of the concrete unary prefix preorder from Definition 52.28 composes these two comparisons and gives

$$K_\Xi \preceq_{\mathsf{Nat}^{\uparrow}} V_F.$$

The two displayed prefix comparisons now face in opposite directions. Applying Definition 52.30 gives

$$V_F \mathsf{hsame} K_\Xi.$$

Both endpoints are unary: the source is the flow-value witness of feasibility, and the target is the finite unary fold defining cut capacity. Therefore Definition 28.27 reads this history-sameness as the claimed $\mathsf{Nat}^{\uparrow}$ classification equality. □

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow residual exhaustion value capacity hsame`
Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow residual exhaustion cut value hsame`

Theorem 233.8 (Network-flow equality implies optimality)**.** *Let G be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let u be a unary capacity assignment, and let s, t be carried vertices. Let F be a feasible finite* $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow over u, and let C be a finite s-t cut record in G. If*

$$\mathsf{FlowValue}(F)\mathsf{hsameCutCap}_{G,u}(C),$$

then F is maximal among feasible finite s-t flows and C is minimal among finite s-t cuts: for every feasible finite $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow F' over u and every finite s-t cut record D in G,*

$$\mathsf{FlowValue}(F') \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{FlowValue}(F) \qquad \textit{and} \qquad \mathsf{CutCap}_{G,u}(C) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(D).$$

Proof. Write

$$V := \mathsf{FlowValue}(F), \qquad K := \mathsf{CutCap}_{G,u}(C).$$

The displayed equality gives $V\mathsf{hsame}K$. By symmetry of history-sameness from Definition 3.8, this also gives $K\mathsf{hsame}V$. Applying Definition 52.17 yields

$$K \preceq_{\mathsf{Nat}^{\uparrow}} V.$$

Let F' be any feasible finite $\mathsf{NetworkFlow}^{\uparrow}$ s-t flow over u. Applying weak duality, Definition 233.3, to F' and the fixed cut C gives

$$\mathsf{FlowValue}(F') \preceq_{\mathsf{Nat}^{\uparrow}} K.$$

Compose this comparison with $K \preceq_{\mathsf{Nat}^{\uparrow}} V$ by Definition 52.28. Since $V = \mathsf{FlowValue}(F)$, the result is

$$\mathsf{FlowValue}(F') \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{FlowValue}(F).$$

Let D be any finite s-t cut record in G. Applying weak duality to the fixed feasible flow F and the cut D gives

$$V \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(D).$$

Compose $K \preceq_{\mathsf{Nat}^{\uparrow}} V$ with this comparison by Definition 52.28. Since $K = \mathsf{CutCap}_{G,u}(C)$, the result is

$$\mathsf{CutCap}_{G,u}(C) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(D).$$

The two comparisons are exactly the displayed maximality and minimality clauses. □

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow equality implies optimality`

Corollary 233.9 (Network-flow residual exhaustion optimality)**.** *Let G be a directed* $\mathsf{Graph}^{\uparrow}$ *carrier, let u be a unary capacity assignment, and let s, t be carried vertices. Let F be a feasible finite* $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow over u with edge-flow assignment f_F. If Ξ is a residual-cut augmenting-path exhaustion certificate for F, write*

$$C_{\Xi} := \mathsf{ResCut}_{F,u}(\Xi).$$

Then F is maximal among feasible finite s-t flows and C_{Ξ} is minimal among finite s-t cuts: for every feasible finite $\mathsf{NetworkFlow}^{\uparrow}$ *s-t flow F' over u and every finite s-t cut record D in G,*

$$\mathsf{FlowValue}(F') \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{FlowValue}(F) \qquad \textit{and} \qquad \mathsf{CutCap}_{G,u}(C_{\Xi}) \preceq_{\mathsf{Nat}^{\uparrow}} \mathsf{CutCap}_{G,u}(D).$$

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow residual exhaustion optimality`

Proof. Put

$$V_F := \mathsf{FlowValue}(F), \qquad K_\Xi := \mathsf{CutCap}_{G,u}(C_\Xi).$$

By Definition 233.7, the residual exhaustion certificate supplies

$$V_F \mathsf{hsame} K_\Xi.$$

Apply Definition 233.8 to the feasible flow F and the finite cut record C_Ξ. For each feasible finite s-t flow F' over u and each finite s-t cut record D in G, it gives

$$\mathsf{FlowValue}(F') \preceq_{\mathsf{Nat}^\uparrow} \mathsf{FlowValue}(F) \qquad \text{and} \qquad \mathsf{CutCap}_{G,u}(C_\Xi) \preceq_{\mathsf{Nat}^\uparrow} \mathsf{CutCap}_{G,u}(D).$$

These are exactly the maximal-flow and minimal-cut clauses for the residual cut induced by Ξ. □

Lemma 233.10 (Finite unary fold of the constant empty assignment)**.** *Fix a finite spine xs and define*

$$a_{\mathsf{e}}(e) := \mathsf{e} \qquad \textit{for every } e : \mathsf{BHist}.$$

Then

$$\mathsf{USum}_{xs}(a_{\mathsf{e}}) = \mathsf{e}.$$

Proof. Induct on the finite spine xs. In the nil case, the defining nil clause of Definition 233.1 gives

$$\mathsf{USum}_{\mathsf{nil}}(a_{\mathsf{e}}) = \mathsf{e}.$$

For the cons case, write $xs = \mathsf{cons}(e, xs')$. Unfolding the cons clause of Definition 233.1 gives

$$\mathsf{USum}_{\mathsf{cons}(e,xs')}(a_{\mathsf{e}}) = \mathsf{append}(a_{\mathsf{e}}(e), \mathsf{USum}_{xs'}(a_{\mathsf{e}})).$$

By definition of a_{e} and the induction hypothesis, this becomes

$$\mathsf{USum}_{\mathsf{cons}(e,xs')}(a_{\mathsf{e}}) = \mathsf{append}(\mathsf{e}, \mathsf{e}).$$

By the append presentation of continuation from Definition 4.10, the left-unit clause of Definition 4.38 identifies $\mathsf{append}(\mathsf{e}, \mathsf{e})$ with e. Hence

$$\mathsf{USum}_{\mathsf{cons}(e,xs')}(a_{\mathsf{e}}) = \mathsf{e}.$$

This closes the induction. □

Theorem 233.11 (Zero edge-flow is feasible at zero value)**.** *Let G be a directed $\mathsf{Graph}^\uparrow$ carrier, let u be a unary capacity assignment on its edges, and let s, t be carried vertices. Define the zero edge-flow assignment by*

$$f_0(e) := \mathsf{e} \qquad \textit{for every } e : \mathsf{BHist},$$

and define the value witness by

$$V_{F_0} := \mathsf{e}.$$

Then the flow datum F_0 with edge-flow assignment f_0 and value history V_{F_0} is a feasible $\mathsf{NetworkFlow}^\uparrow$ s-t flow over u. More precisely, for every finite s-t cut record C in G, one may take

$$B_{F_0,C} := \mathsf{e}, \qquad X_{F_0,C} := \mathsf{e},$$

and all rows required by Definition 233.1 hold.

Lean4 ✓ `BEDC.Derived.NetworkFlowUp.NetworkFlow zero edge flow feasible`

Proof. Unfold feasibility from Definition 233.1. We must verify the capacity row and the cut-accounting row.

For the capacity row, fix $e : \mathsf{BHist}$ and assume $\mathsf{Edge}_G(e)$. Because u is a unary capacity assignment on edges, the history $u(e)$ lies in the concrete unary history preorder carrier. Therefore Definition 52.19 gives

$$\mathsf{e} \preceq_{\mathsf{Nat}^\uparrow} u(e).$$

Since $f_0(e) = \mathsf{e}$, this is exactly

$$f_0(e) \preceq_{\mathsf{Nat}^\uparrow} u(e).$$

So the capacity row holds for every carried edge.

Now fix a finite s-t cut record C in G. Apply Definition 233.10 to the backward and forward cut spines with the constant assignment f_0. Using the definitions of $\mathsf{CutBack}_{G,C}$ and $\mathsf{CutForw}_{G,C}$ from Definition 233.1, this gives

$$\mathsf{CutBack}_{G,C}(f_0) = \mathsf{e}, \qquad \mathsf{CutForw}_{G,C}(f_0) = \mathsf{e}.$$

Hence the chosen witnesses satisfy the required identification rows

$$B_{F_0,C} = \mathsf{CutBack}_{G,C}(f_0), \qquad X_{F_0,C} = \mathsf{CutForw}_{G,C}(f_0).$$

It remains to verify the conservation-accounting row. With the chosen value and cut histories, this row is

$$\mathsf{Cont}(V_{F_0}, B_{F_0,C}, X_{F_0,C}) = \mathsf{Cont}(\mathsf{e}, \mathsf{e}, \mathsf{e}).$$

The left-unit clause of Definition 4.38 gives exactly

$$\mathsf{Cont}(\mathsf{e}, \mathsf{e}, \mathsf{e}).$$

Thus the required accounting row holds for every finite cut record C.

Both the capacity row and the cut-accounting row are therefore satisfied, so F_0 is a feasible $\mathsf{NetworkFlow}^\uparrow$ s-t flow over u with zero edge-flow, zero value witness, and trivial cut-history witnesses. □

Theorem 233.12 (Zero feasible network flow has minimum value)**.** *Let G be a directed $\mathsf{Graph}^\uparrow$ carrier, let u be a unary capacity assignment on its edges, and let s, t be carried vertices. Define the zero edge-flow assignment by*

$$f_0(e) := \mathsf{e} \qquad \textit{for every } e : \mathsf{BHist},$$

and let F_0 be the feasible $\mathsf{NetworkFlow}^\uparrow$ s-t flow over u supplied by Definition 233.11, with value witness

$$V_{F_0} := \mathsf{e}.$$

Then F_0 has minimum value among feasible finite s-t flows over u: for every feasible finite $\mathsf{NetworkFlow}^\uparrow$ s-t flow F over u,

$$\mathsf{FlowValue}(F_0) \preceq_{\mathsf{Nat}^\uparrow} \mathsf{FlowValue}(F).$$

Proof. Unpack the feasible-flow datum of Definition 233.1 for the arbitrary feasible flow F. Its value witness is a unary history, and by notation

$$\mathsf{FlowValue}(F) = V_F.$$

Since V_F lies in the concrete unary history preorder carrier, Definition 52.19 gives

$$\mathsf{e} \preceq_{\mathsf{Nat}^\uparrow} V_F.$$

Using the value-witness definition of the zero flow from Definition 233.11,

$$\mathsf{FlowValue}(F_0) = V_{F_0} = \mathsf{e}.$$

Transporting the left endpoint along this identification and the right endpoint along $\mathsf{FlowValue}(F) = V_F$ gives

$$\mathsf{FlowValue}(F_0) \preceq_{\mathsf{Nat}^\uparrow} \mathsf{FlowValue}(F).$$

The quantified flow F was arbitrary among feasible finite s-t flows over u, so the zero feasible flow is minimum for the concrete $\mathsf{Nat}^\uparrow$ prefix order on flow values. □

Closure status for $\mathsf{NameCert}_{\mathsf{NetworkFlow}^\uparrow}$**.**

Constructive story: A $\mathsf{NetworkFlow}^\uparrow$ packet is generated from finite BHist rows for a directed graph, unary capacity assignment, source and target endpoints, feasible-flow witnesses, and finite cut witnesses. The flow value and cut-capacity reads are not external graph-optimization objects; they are Cont folds over displayed edge spines whose summands are unary $\mathsf{Nat}^\uparrow$ histories. The classifier compares accepted packets by hsame on graph, capacity, flow, cut, and value rows, while Pkg records the consumed $\mathsf{Graph}^\uparrow$, $\mathsf{Nat}^\uparrow$, and additive-fold dependencies. Thus the max-flow/min-cut surface is a finite ledger of histories and routes, with no hidden residual network or host optimization oracle.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{NetworkFlow}^\uparrow}$, maturePackageClosed)

Scope closed: Definition 233.1, Definition 233.2, Definition 233.3, Definition 233.4, Definition 233.7, Definition 233.11, and Definition 233.12 bind the public finite flow-cut export: residual-exhaustion max-flow/min-cut equality, zero edge-flow feasibility, zero feasible minimum value, BHist ledger rows, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert rows displayed in the chapter.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{NetworkFlow}^\uparrow}$, theoremChecked)

Lean target: `BEDC.Derived.NetworkFlowUp.NetworkFlow\_maxflow\_mincut\_equality\_from\_residual\_exhaustion`

Bridge status: paperBridge

Origin: human

Not claimed: It does not claim a host graph algorithm, residual-network completeness, ambient linear programming duality, or equality of external flow objects.

Upgrade path: No further theory-axis upgrade remains beyond maintaining bridge and readback audits for the finite residual-exhaustion and cut-certificate surface.

Chapter 234

A Concrete Naming Certificate for $\mathsf{Matching}^{\uparrow}$

The graph-matching interface $\mathsf{Matching}^{\uparrow}$ packages a subset of edges in a graph carrier with no shared vertex, together with the maximum-matching / minimum-vertex-cover duality on bipartite graphs. It depends on $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

234.1 Carrier definition

234.2 The certificate

Definition 234.1 (Matching carrier and finite edge subset)**.** *Fix a* $\mathsf{Graph}^{\uparrow}$ *carrier* G*. Write* $\mathsf{Vert}_G(v)$ *for vertex membership,* $\mathsf{Edge}_G(e)$ *for edge membership,* $\mathsf{Inc}_G(v, e)$ *for incidence of a vertex with an edge, and* $\sim_E$ *for the edge classifier used by the* $\mathsf{FinSet}^{\uparrow}$ *presentation of graph edges. For an edge predicate* $M : \mathsf{BHist} \to \mathsf{Prop}$*, define*

$$\mathsf{MatchingEdgeSet}_G(M) \iff (\forall e : \mathsf{BHist}.\ M(e) \to \mathsf{Edge}_G(e)) \wedge (\forall e, e', v : \mathsf{BHist}.\ M(e) \wedge M(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{I}$$

Thus a matching edge predicate is a graph-edge subset whose selected edges have no shared incident vertex except along the edge classifier. For edge predicates N *and* M*, define*

$$\mathsf{FinSetEdgeSubset}_{G,\sim_E}(N, M) \iff \exists xs : \mathsf{HistSpine}.\ \mathsf{FinSetSpineEnumerates}_{\mathsf{Edge}_G,\sim_E}(xs, N) \wedge \forall e : \mathsf{BHist}.\ N(e) \to M($$

The first component is the finite enumeration witness supplied by the $\mathsf{FinSet}^{\uparrow}$ *machinery of Definition 112.17; the second component is ordinary edge-subset inclusion into* M*.*

Lean4 (definition) `BEDC.Derived.MatchingUp.MatchingEdgeSet`
Lean4 (definition) `BEDC.Derived.MatchingUp.FinSetEdgeSubset`

Theorem 234.2 (Matching finite-subset closure)**.** *Let* G *be a* $\mathsf{Graph}^{\uparrow}$ *carrier with edge classifier* $\sim_E$*. If* $M, N : \mathsf{BHist} \to \mathsf{Prop}$ *satisfy*

$$\mathsf{MatchingEdgeSet}_G(M) \qquad \textit{and} \qquad \mathsf{FinSetEdgeSubset}_{G,\sim_E}(N, M),$$

then

$$\mathsf{MatchingEdgeSet}_G(N).$$

Equivalently, every $\mathsf{FinSet}^{\uparrow}$ *edge subset of a* $\mathsf{Matching}^{\uparrow}$ *edge set is again a* $\mathsf{Matching}^{\uparrow}$ *edge set in the same* $\mathsf{Graph}^{\uparrow}$ *carrier.*

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet finite subset closed`

Proof. Unpack Definition 234.1. The matching hypothesis for M supplies two rows: first, every M-edge is a graph edge of G; second, any two M-edges incident to the same carried vertex are classified by $\sim_E$ as the same edge. The finite-subset hypothesis supplies a finite spine xs with

$$\mathsf{FinSetSpineEnumerates}_{\mathsf{Edge}_G,\sim_E}(xs, N)$$

and an inclusion row

$$\forall e : \mathsf{BHist}.\ N(e) \to M(e).$$

The spine witness records that N is the $\mathsf{FinSet}^{\uparrow}$ edge subset; the hereditary argument uses the displayed inclusion row.

To prove the graph-edge row for N, fix e and assume $N(e)$. The inclusion row gives $M(e)$, and the graph-edge row for M gives $\mathsf{Edge}_G(e)$.

To prove the no-shared-vertex row for N, fix e, e', v and assume

$$N(e) \wedge N(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e').$$

The inclusion row gives $M(e)$ and $M(e')$. Keeping the same vertex and incidence witnesses, apply the no-shared-vertex row for M to obtain

$$e \sim_E e'.$$

These two rows are exactly $\mathsf{MatchingEdgeSet}_G(N)$ by Definition 234.1. □

Theorem 234.3 (Matching compatible union closure)**.** *Let G be a $\mathsf{Graph}^{\uparrow}$ carrier with edge classifier $\sim_E$. Let $M, N : \mathsf{BHist} \to \mathsf{Prop}$ be edge predicates, and define the pointwise union predicate $U : \mathsf{BHist} \to \mathsf{Prop}$ by*

$$U(e) \iff M(e) \vee N(e).$$

Assume

$$\mathsf{MatchingEdgeSet}_G(M) \qquad \textit{and} \qquad \mathsf{MatchingEdgeSet}_G(N),$$

and assume the cross-incident compatibility condition

$$\forall e, e', v : \mathsf{BHist}.\ ((M(e) \wedge N(e')) \vee (N(e) \wedge M(e'))) \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e') \to e \sim_E e'.$$

Then

$$\mathsf{MatchingEdgeSet}_G(U).$$

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet compatible union closed`

Proof. Unpack Definition 234.1. The matching hypotheses for M and N each supply a graph-edge row and a no-shared-vertex row.

For the graph-edge row of U, fix $e : \mathsf{BHist}$ and assume $U(e)$. By the defining display for U, either $M(e)$ or $N(e)$ holds. In the first case, the graph-edge row for M gives $\mathsf{Edge}_G(e)$. In the second case, the graph-edge row for N gives $\mathsf{Edge}_G(e)$.

For the no-shared-vertex row of U, fix $e, e', v : \mathsf{BHist}$ and assume

$$U(e) \wedge U(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e').$$

The two U-memberships split into four cases. If $M(e)$ and $M(e')$ hold, the no-shared-vertex row for M, together with the same vertex and incidence witnesses, gives $e \sim_E e'$. If $N(e)$ and $N(e')$ hold, the no-shared-vertex row for N gives $e \sim_E e'$.

It remains to handle the two cross cases. If $M(e)$ and $N(e')$ hold, the left disjunct in the cross-incident compatibility hypothesis applies to the same e, e', v and gives $e \sim_E e'$. If $N(e)$ and $M(e')$ hold, the right disjunct applies directly and gives $e \sim_E e'$. Thus every pair of U-selected edges incident to the same carried vertex is classified by $\sim_E$ as the same edge.

The graph-edge row and the no-shared-vertex row are precisely $\mathsf{MatchingEdgeSet}_G(U)$ by Definition 234.1. □

Theorem 234.4 (Empty edge predicate matching)**.** *Let G be a $\mathsf{Graph}^\uparrow$ carrier with vertex predicate Vert_G, edge predicate Edge_G, incidence predicate Inc_G, and edge classifier $\sim_E$. Let $Z : \mathsf{BHist} \to \mathsf{Prop}$ be an edge-selection predicate satisfying*

$$\forall e : \mathsf{BHist}.\ Z(e) \to \bot.$$

Then

$$\mathsf{MatchingEdgeSet}_G(Z).$$

In particular, the empty predicate $M_\varnothing(e) \iff \bot$ is a $\mathsf{Matching}^\uparrow$ edge set in G.

Proof. Unpack Definition 234.1. The matching claim has two rows: graph-edge support for every selected edge, and the no-shared-vertex implication for pairs of selected edges.

For graph-edge support, fix $e : \mathsf{BHist}$ and assume $Z(e)$. The displayed emptiness row gives $\bot$, and hence gives $\mathsf{Edge}_G(e)$.

For the no-shared-vertex row, fix $e, e', v : \mathsf{BHist}$ and assume

$$Z(e) \wedge Z(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e').$$

The first component gives $Z(e)$, so the displayed emptiness row again gives a contradiction. Therefore the required conclusion $e \sim_E e'$ follows. These two vacuous rows are exactly $\mathsf{MatchingEdgeSet}_G(Z)$.

Taking $Z = M_\varnothing$, the defining equivalence $M_\varnothing(e) \iff \bot$ supplies $M_\varnothing(e) \to \bot$ for every e, so the displayed result applies to the empty edge predicate. □

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet e0 empty absurd predicate`

Theorem 234.5 (Singleton edge predicate matching)**.** *Let G be a $\mathsf{Graph}^\uparrow$ carrier with edge classifier $\sim_E$, and let $\mathsf{cert}_E : \mathsf{NameCert}(\mathsf{Edge}_G, \sim_E)$ be the edge naming certificate in the sense of Definition 9.7. Fix a carried edge $e_\star : \mathsf{BHist}$ such that*

$$\mathsf{Edge}_G(e_\star).$$

Define the edge predicate $M_{e_\star} : \mathsf{BHist} \to \mathsf{Prop}$ by

$$M_{e_\star}(e) \iff e \sim_E e_\star.$$

Then

$$\mathsf{MatchingEdgeSet}_G(M_{e_\star}).$$

In particular, the $\sim_E$-class of any carried edge is a $\mathsf{Matching}^\uparrow$ edge set in G.

Proof. Unpack Definition 234.1. To prove $\mathsf{MatchingEdgeSet}_G(M_{e_\star})$, it is enough to prove the graph-edge row and the no-shared-vertex row.

For the graph-edge row, fix $e : \mathsf{BHist}$ and assume $M_{e_\star}(e)$. By definition of $M_{e_\star}$, this means

$$e \sim_E e_\star.$$

The symmetry field of the naming certificate from Definition 9.7 reverses this comparison and gives

$$e_\star \sim_E e.$$

Apply the carrier-transport field of the same certificate to the carried-edge witness $\mathsf{Edge}_G(e_\star)$. This transports edge membership along $e_\star \sim_E e$ and yields

$$\mathsf{Edge}_G(e).$$

Thus every $M_{e_\star}$-selected edge is a graph edge of G.

For the no-shared-vertex row, fix $e, e', v : \mathsf{BHist}$ and assume

$$M_{e_\star}(e) \wedge M_{e_\star}(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e').$$

Project the first two components. By the definition of $M_{e_\star}$, they give

$$e \sim_E e_\star \qquad \text{and} \qquad e' \sim_E e_\star.$$

Use symmetry from Definition 9.7 on the second comparison to obtain

$$e_\star \sim_E e'.$$

Now apply classifier transitivity from Definition 9.8 to the comparisons $e \sim_E e_\star$ and $e_\star \sim_E e'$. This yields

$$e \sim_E e'.$$

The vertex and incidence witnesses are retained from the hypothesis but are not needed further, because every selected edge lies in the same classifier class of $e_\star$.

The graph-edge row and the no-shared-vertex row are exactly the two clauses of $\mathsf{MatchingEdgeSet}_G(M_{e_\star})$ in Definition 234.1. □

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet singleton edge predicate`
Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet singleton classifier closed`

Theorem 234.6 (Matching augmentation symmetric-difference decomposition)**.** *Let G be a $\mathsf{Graph}^\uparrow$ carrier with vertex predicate Vert_G, edge predicate Edge_G, incidence predicate Inc_G, and edge classifier $\sim_E$. For two finite $\mathsf{Matching}^\uparrow$ edge predicates M, N in G, the symmetric-difference ledger decomposes into carried edge rows: each displayed edge e has $\mathsf{Edge}_G(e)$, an endpoint-incidence witness row through Inc_G, and one of the two finite membership certificates $M(e)$ or $N(e)$ but not both. The ledger contains no unrecorded host edge set beyond these BHist rows.*

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingAugmentation symmetric difference decomposition`

Proof. Read the finite edge-subset rows for M and N from Definition 234.1. Each selected edge is a carried $\mathsf{Graph}^{\uparrow}$ edge, and each pair of selected incident edges is governed by the no-shared-vertex row.

Construct the symmetric-difference ledger by scanning the two finite membership ledgers. An edge in exactly one ledger is copied with its carried edge witness; an edge in both ledgers is omitted from the toggled surface and retained only as the classifier comparison explaining the cancellation.

The endpoint-incidence witnesses are the incidence rows already stored by the $\mathsf{Graph}^{\uparrow}$ carrier. Because the decomposition stores membership side, carried edge status, incidence, and classifier comparisons explicitly, no external host edge set is introduced. □

Theorem 234.7 (Matching augmenting edge toggle closure)**.** *Let M be a $\mathsf{Matching}^{\uparrow}$ edge predicate in a $\mathsf{Graph}^{\uparrow}$ carrier G, and let $e_\star : \mathsf{BHist}$ be a carried edge. Suppose the singleton predicate $M_{e_\star}(e) \iff e \sim_E e_\star$ is incident-disjoint from M except along the edge classifier $\sim_E$. Then toggling the singleton predicate into M gives another $\mathsf{MatchingEdgeSet}_G$: the resulting predicate is the compatible union of M with the singleton edge predicate, with classifier-equal overlap cancelled by the same finite toggle ledger.*

Proof. First apply Definition 234.5 to the carried edge $e_\star$. This gives the singleton matching predicate whose selected edges are exactly the $\sim_E$-class of $e_\star$.

Next use the incident-disjointness hypothesis to verify compatibility with M. Whenever a vertex is incident to one edge selected by M and one edge selected by the singleton predicate, the hypothesis collapses the two edges by $\sim_E$, which is precisely the compatibility condition needed by Definition 234.3.

Finally apply the compatible-union closure theorem and read the finite toggle ledger from Definition 234.6. Edges in the classifier-equal overlap are cancelled by the toggle ledger, and all remaining selected edges keep their $\mathsf{Graph}^{\uparrow}$ carried-edge and incidence rows. □

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet toggle singleton compatible union closed`

Theorem 234.8 (Matching bipartite cover consumer boundary)**.** *A bipartite cover consumer of the finite augmenting surface may read only the finite edge subset, the no-shared-vertex row of Definition 234.1, the incidence* BHist *rows of* $\mathsf{Graph}^{\uparrow}$*, the carried graph rows, and the* $\mathsf{FinSet}^{\uparrow}$ *provenance of the finite ledger. It may not read an ambient host edge set, an uncarried vertex quotient, or any matching predicate not presented by the displayed finite* BHist *ledger.*

Proof. The symmetric-difference and toggle theorems expose the finite matching data as listed rows: carried edges, incidence witnesses, membership side, classifier comparisons, and no-shared-vertex certificates.

A bipartite cover construction uses exactly those rows to decide which endpoints are covered by selected edges and which alternating steps are available. The $\mathsf{FinSet}^{\uparrow}$ provenance bounds the search to the displayed finite ledger, while the $\mathsf{Graph}^{\uparrow}$ incidence rows provide all endpoint reads.

Thus the consumer boundary is the finite BEDC ledger itself. Since every edge and vertex access is mediated by BHist and the graph certificate, there is no permission to inspect an ambient host graph or an unrecorded edge collection. □

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet bipartite cover consumer boundary`

Theorem 234.9 (Matching abstract sub-predicate closure)**.** *Let G be a $\mathsf{Graph}^{\uparrow}$ carrier with edge classifier $\sim_E$. Let $M, N : \mathsf{BHist} \to \mathsf{Prop}$ be edge predicates. If*

$$\mathsf{MatchingEdgeSet}_G(M)$$

and

$$\forall e : \mathsf{BHist}.\ N(e) \to M(e),$$

then

$$\mathsf{MatchingEdgeSet}_G(N).$$

Thus the matching condition is hereditary under ordinary predicate inclusion; no finite-spine enumeration of N is required.

Lean4 ✓ `BEDC.Derived.MatchingUp.MatchingEdgeSet abstract subpredicate closed`

Proof. Unpack Definition 234.1. The matching hypothesis for M supplies the graph-edge row

$$\forall e : \mathsf{BHist}.\ M(e) \to \mathsf{Edge}_G(e)$$

and the no-shared-vertex row

$$\forall e, e', v : \mathsf{BHist}.\ M(e) \wedge M(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e') \to e \sim_E e'.$$

The second hypothesis supplies the inclusion row from N into M.

For the graph-edge row of N, fix $e : \mathsf{BHist}$ and assume $N(e)$. The inclusion row gives $M(e)$, and the graph-edge row for M gives $\mathsf{Edge}_G(e)$.

For the no-shared-vertex row of N, fix $e, e', v : \mathsf{BHist}$ and assume

$$N(e) \wedge N(e') \wedge \mathsf{Vert}_G(v) \wedge \mathsf{Inc}_G(v, e) \wedge \mathsf{Inc}_G(v, e').$$

Projecting the first two components gives $N(e)$ and $N(e')$. The inclusion row turns these into $M(e)$ and $M(e')$. Keeping the same vertex and incidence witnesses, apply the no-shared-vertex row for M to obtain

$$e \sim_E e'.$$

The graph-edge row and the no-shared-vertex row are exactly $\mathsf{MatchingEdgeSet}_G(N)$ by Definition 234.1. □

Theorem 234.10 (Matching standard finite-edge bridge)**.** *The public finite-edge-subset matching certificate bridges to the standard finite matching interface exactly through the displayed* $\mathsf{Graph}^{\uparrow}$ *carrier,* $\mathsf{FinSet}^{\uparrow}$ *finite ledger,* BHist *edge predicates, incidence rows, no-shared-vertex classifier, augmentation and toggle rows, and bipartite-cover consumer boundary.*

The bridge exposes finite selected edges, carried incidence witnesses, classifier comparisons for shared vertices, compatible augmentation toggles, and the public cover-side consumer boundary. It exposes no ambient host edge set, maximum-matching optimality theorem, vertex-cover duality theorem, or external graph representation.

Proof. Start with Definition 234.2. It binds the selected edge predicate to the displayed $\mathsf{Graph}^{\uparrow}$ carrier and the $\mathsf{FinSet}^{\uparrow}$ finite ledger, so every selected edge read is a carried graph-edge read.

Next combine the closure rows. Use Definition 234.3, Definition 234.4, and Definition 234.5. These rows give the finite empty, singleton, and compatible-union entry points for the standard finite matching interface.

Now add the consumer operations. Apply Definition 234.6, Definition 234.7, and Definition 234.8. They keep alternating augmentation, finite toggling, and the bipartite-cover read boundary inside the same edge predicate, incidence, and classifier ledger.

Finally apply Definition 234.9. It shows that sub-predicate reads remain matching reads without adding an unrecorded host edge set. The listed rows are therefore exactly the finite-edge standard interface available from the public certificate, and the excluded graph-theory objects have no coordinate in the packet. □

Theorem 234.11 (Matching alternating-cover consumer example)**.** *Let G be a displayed* $\mathsf{Graph}^{\uparrow}$ *carrier, and let M be a finite* $\mathsf{FinSet}^{\uparrow}$ *edge predicate satisfying* $\mathsf{MatchingEdgeSet}_G(M)$*. An alternating finite edge path together with a bipartite-cover side row consumes only the selected edge predicate, the displayed incidence rows, the edge classifier, the augmentation toggle rows, and the* Pkg/NameCert *provenance already exposed by the public matching certificate.*

The resulting consumer packet is again a finite BHist *surface. It records the selected path edges, incidence witnesses, membership-side rows, classifier comparisons, toggle ledger, cover-side rows, and provenance rows. It does not claim maximum matching optimality or vertex-cover duality.*

Proof. First bind the selected edge predicate to the public finite carrier. Apply Definition 234.2. Every edge read by the alternating path is therefore a carried $\mathsf{Graph}^{\uparrow}$ edge with a finite $\mathsf{FinSet}^{\uparrow}$ provenance row.

Next expose the alternating path ledger. Use Definition 234.6 to split the path steps into selected and unselected membership-side reads, and then apply Definition 234.7 to keep the toggle surface inside the same matching predicate and edge classifier.

Now add the cover-side consumer. Apply Definition 234.8. It restricts the cover read to selected edges, incidence rows, no-shared-vertex classifier comparisons, carried graph rows, and finite ledger provenance.

Finally apply Definition 234.10. The bridge packages the alternating path, toggle, and cover-side reads as one finite BHist consumer surface. Since the packet contains no coordinate for an optimality theorem or a duality theorem, neither conclusion is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{Matching}^{\uparrow}}$**.**

Constructive story: A matching is generated inside a displayed $\mathsf{Graph}^{\uparrow}$ carrier by choosing an edge predicate and then bounding the chosen edges with a $\mathsf{FinSet}^{\uparrow}$ finite-spine witness. The carrier accepts a predicate only when every selected history is a graph edge and any two selected edges incident to the same carried vertex collapse through the graph edge classifier; predicates with uncarried edges or unclassified shared vertices are excluded. Two matching presentations are compared through the edge classifier and the finite-subset or compatible-union ledgers, so a singleton edge class, a finite subpredicate, and a compatible toggle all remain inside the same graph-certified surface rather than becoming host edge sets. The source is the finite edge subset over the graph carrier, the pattern records hereditary subset closure, compatible union closure, empty and singleton edge predicates, augmentation toggles, and the bipartite-cover consumer boundary, and the ledger keeps selected edges, incidence witnesses, membership side, finite enumeration, and classifier comparisons visible. The five name-certificate obligations are supplied by the empty or singleton carried edge examples for nonemptiness, by the edge certificate for reflexivity, symmetry, and transitivity, and by finite-subset and compatible-union closure for repacking classified selected edges as matchings. A history h lies in the signature gap of a $\mathsf{Matching}^{\uparrow}$ token p when the source-domain accepts its finite edge predicate, the signature relation pairs it with an answer matching and evidence ledger, and the token-introduction relation names that answer as p; concretely, every edge selected by h is a carried graph edge and any shared-vertex conflict is resolved exactly as p records. The chapter registers this finite incidence construction under the name $\mathsf{Matching}^{\uparrow}$; maximum matching, vertex-cover duality, external graph-theory bridges, and ambient host edge sets remain outside the scoped certificate.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Matching}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public finite-edge-subset matching certificate and its standard finite-edge bridge bind the finite edge subset, incidence, compatibility, augmentation, toggle, and bipartite-cover consumer rows to the displayed $\mathsf{Graph}^{\uparrow}$ carrier, $\mathsf{FinSet}^{\uparrow}$ finite-subset witness, BHist edge predicates, and edge classifier.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Matching}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MatchingUp.MatchingEdgeSet\_finite\_subset\_closed`

Bridge status: paperBridge

Not claimed: Maximum matching, vertex-cover duality, and ambient host edge sets are not claimed by this chapter.

Upgrade path: No further paper-side theory closure upgrade remains for this chapter; formal bridge checking remains a separate verification-axis task.

Chapter 235

A Concrete Naming Certificate for $\mathsf{LPDuality}^{\uparrow}$

The linear-programming-duality interface $\mathsf{LPDuality}^{\uparrow}$ packages a primal/dual pair of linear programs together with strong-duality and complementary-slackness certificates over an ordered field. It depends on $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ (chapter 208) and $\mathsf{NameCert}_{\mathsf{Polytope}^{\uparrow}}$ (chapter 209).

235.1 Carrier definition

235.2 The certificate

Definition 235.1 (Finite $\mathsf{LPDuality}^{\uparrow}$ ordered-field feasibility row)**.** *An* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field consists of finite row-position and column-position carriers* I *and* J*, a scalar carrier* F *equipped with the* $\mathsf{Field}^{\uparrow}$ *operations and classifier of chapter 45, and a* $\mathsf{TotalOrder}^{\uparrow}$ *comparison on the same scalar carrier and classifier as in chapter 54. Write* $+_F$*,* $\cdot_F$*,* 0_F*,* $\sim_F$*, and* $\preceq_F$ *for these data, with* $u \preceq_F v$ *meaning that* u *is less than or classifier-equal to* v*. The nonnegative scalar predicate is*

$$\mathsf{NonNeg}_F(a) \iff 0_F \preceq_F a.$$

The scalar order rows used by the certificate are classifier stability of $\preceq_F$*,*

$$u \sim_F u' \wedge v \sim_F v' \wedge u \preceq_F v \Longrightarrow u' \preceq_F v',$$

left and right multiplication monotonicity by nonnegative scalars,

$$\mathsf{NonNeg}_F(a) \wedge u \preceq_F v \Longrightarrow (a \cdot_F u \preceq_F a \cdot_F v) \wedge (u \cdot_F a \preceq_F v \cdot_F a),$$

and finite-sum monotonicity over every finite position carrier K*,*

$$\Big(\forall k \in K.\ r_k \preceq_F s_k\Big) \Longrightarrow \sum_{k \in K} r_k \preceq_F \sum_{k \in K} s_k.$$

For coefficients $A : I \times J \to F$*, right-hand side* $b : I \to F$*, and cost vector* $c : J \to F$*, define*

$$\alpha_i(x) := \sum_{j \in J} A_{ij} \cdot_F x_j, \qquad \beta_j(y) := \sum_{i \in I} y_i \cdot_F A_{ij}.$$

The finite distributivity and interchange row records the classifier comparison

$$\sum_{j\in J} \beta_j(y) \cdot_F x_j \sim_F \sum_{i\in I} y_i \cdot_F \alpha_i(x).$$

The primal and dual feasible carriers, read as the row descriptions of the corresponding $\mathsf{Polytope}^{\uparrow}$ *feasible sets over the convex substrate of chapter 208 and chapter 209, are*

$$\mathsf{PrFeas}_{A,b}(x) \iff \Big(\forall j \in J.\ \mathsf{NonNeg}_F(x_j)\Big) \wedge \Big(\forall i \in I.\ \alpha_i(x) \preceq_F b_i\Big)$$

and

$$\mathsf{DuFeas}_{A,b,c}(y) \iff \Big(\forall i \in I.\ \mathsf{NonNeg}_F(y_i)\Big) \wedge \Big(\forall j \in J.\ c_j \preceq_F \beta_j(y)\Big).$$

The objective endpoints are

$$\mathsf{PrObj}_{A,c}(x) := \sum_{j\in J} c_j \cdot_F x_j, \qquad \mathsf{DuObj}_b(y) := \sum_{i\in I} y_i \cdot_F b_i.$$

Theorem 235.2 (LPDuality root obligation surface)**.** *The root certificate surface for* $\mathsf{LPDuality}^{\uparrow}$ *consists of a* $\mathsf{ConvexSet}^{\uparrow}$ *feasible-region carrier,* $\mathsf{Field}^{\uparrow}$ *scalar objective rows,* $\mathsf{Polytope}^{\uparrow}$ *face and witness rows,* $\mathsf{TotalOrder}^{\uparrow}$ *comparison rows,* hsame *classifier transport,* Cont *ledger movement, and* Pkg *provenance. Every admitted dual-certificate row projects to these fields: primal and dual feasibility are read from the feasible-region and polytope rows, scalar objective endpoints are read from the ordered-field rows, comparisons are read from the total-order rows, and all transport is recorded by the displayed* hsame*,* Cont*, and* Pkg *ledgers. No host linear-programming primitive, ambient matrix equality, or quotient vector space is exported by this surface.*

Proof. Project an admitted dual-certificate row through Definition 235.1. The finite row and column carriers, feasible predicates, scalar sums, and objective endpoints are exactly the displayed certificate fields.

The feasible-region and face witnesses are read through the cited $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{Polytope}^{\uparrow}$ certificates, while scalar operations and objective comparisons are read through the $\mathsf{Field}^{\uparrow}$ and $\mathsf{TotalOrder}^{\uparrow}$ rows. Classifier movement uses the explicit hsame stability rows, and ledger movement uses the displayed Cont and Pkg provenance rows.

Repacking these projections gives a finite BHist surface with no additional constructor. Since the definition exposes no host optimization solver, matrix equality primitive, or quotient-space row, every admitted dual-certificate row is exhausted by the listed BEDC fields. □

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityFiniteOrderedFieldFeasibilityRow root obligation surface`

Theorem 235.3 (LPDuality feasible weak duality)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. If* x *is primal feasible and* y *is dual feasible,*

$$\mathsf{PrFeas}_{A,b}(x) \wedge \mathsf{DuFeas}_{A,b,c}(y),$$

then the primal objective value at x *is less than or classifier-equal to the dual objective value at* y*:*

$$\mathsf{PrObj}_{A,c}(x) \preceq_F \mathsf{DuObj}_b(y).$$

Equivalently, the $\mathsf{TotalOrder}^{\uparrow}$ *comparison between the two objective endpoints cannot select the strict-right branch.*

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityFeasibleWeakDuality prefix order`

Proof. Unpack the feasibility predicates of Definition 235.1. From primal feasibility, for each row position $i \in I$ there is a constraint comparison

$$\alpha_i(x) \preceq_F b_i,$$

and from dual feasibility there is a nonnegativity witness $\mathsf{NonNeg}_F(y_i)$. Multiplication monotonicity by the nonnegative scalar y_i gives

$$y_i \cdot_F \alpha_i(x) \preceq_F y_i \cdot_F b_i.$$

Finite-sum monotonicity over I yields

$$\sum_{i \in I} y_i \cdot_F \alpha_i(x) \preceq_F \sum_{i \in I} y_i \cdot_F b_i.$$

The right-hand side is $\mathsf{DuObj}_b(y)$ by definition.

From dual feasibility, for each column position $j \in J$ there is a comparison

$$c_j \preceq_F \beta_j(y),$$

and from primal feasibility there is a nonnegativity witness $\mathsf{NonNeg}_F(x_j)$. Right multiplication monotonicity by the nonnegative scalar x_j gives

$$c_j \cdot_F x_j \preceq_F \beta_j(y) \cdot_F x_j.$$

Finite-sum monotonicity over J yields

$$\sum_{j \in J} c_j \cdot_F x_j \preceq_F \sum_{j \in J} \beta_j(y) \cdot_F x_j.$$

The left-hand side is $\mathsf{PrObj}_{A,c}(x)$ by definition.

The finite distributivity and interchange row gives the classifier comparison

$$\sum_{j \in J} \beta_j(y) \cdot_F x_j \sim_F \sum_{i \in I} y_i \cdot_F \alpha_i(x).$$

Classifier stability of $\preceq_F$, applied to reflexivity at the left endpoint of this comparison, turns it into the order comparison

$$\sum_{j \in J} \beta_j(y) \cdot_F x_j \preceq_F \sum_{i \in I} y_i \cdot_F \alpha_i(x).$$

Composing the three displayed comparisons by transitivity of the $\mathsf{TotalOrder}^{\uparrow}$ order gives

$$\mathsf{PrObj}_{A,c}(x) \preceq_F \mathsf{DuObj}_b(y).$$

This is exactly the weak-duality comparison for the feasible primal and dual witnesses. □

Corollary 235.4 (LPDuality weak-duality equality gives optimality)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Suppose x is primal feasible and y is dual feasible, and suppose their objective endpoints are equal under the scalar classifier:*

$$\mathsf{PrFeas}_{A,b}(x) \wedge \mathsf{DuFeas}_{A,b,c}(y), \qquad \mathsf{PrObj}_{A,c}(x) \sim_F \mathsf{DuObj}_b(y).$$

Then x is primal optimal and y is dual optimal in the row sense:

$$\forall x'.\ \mathsf{PrFeas}_{A,b}(x') \Longrightarrow \mathsf{PrObj}_{A,c}(x') \preceq_F \mathsf{PrObj}_{A,c}(x),$$

and

$$\forall y'.\ \mathsf{DuFeas}_{A,b,c}(y') \Longrightarrow \mathsf{DuObj}_b(y) \preceq_F \mathsf{DuObj}_b(y').$$

Proof. For the primal optimality clause, fix x' with $\mathsf{PrFeas}_{A,b}(x')$. Applying Definition 235.3 to x' and the given dual feasible witness y gives

$$\mathsf{PrObj}_{A,c}(x') \preceq_F \mathsf{DuObj}_b(y).$$

The scalar classifier is reflexive at $\mathsf{PrObj}_{A,c}(x')$, and symmetry of the displayed classifier equality gives

$$\mathsf{DuObj}_b(y) \sim_F \mathsf{PrObj}_{A,c}(x).$$

The classifier-stability row for $\preceq_F$ in Definition 235.1 transports the right endpoint of the weak-duality comparison, yielding

$$\mathsf{PrObj}_{A,c}(x') \preceq_F \mathsf{PrObj}_{A,c}(x).$$

Since x' was arbitrary, the first universal clause follows.

For the dual optimality clause, fix y' with $\mathsf{DuFeas}_{A,b,c}(y')$. Applying Definition 235.3 to the given primal feasible witness x and y' gives

$$\mathsf{PrObj}_{A,c}(x) \preceq_F \mathsf{DuObj}_b(y').$$

The displayed classifier equality gives

$$\mathsf{PrObj}_{A,c}(x) \sim_F \mathsf{DuObj}_b(y),$$

and reflexivity of the scalar classifier holds at $\mathsf{DuObj}_b(y')$. The same classifier-stability row transports the left endpoint of the weak-duality comparison, yielding

$$\mathsf{DuObj}_b(y) \preceq_F \mathsf{DuObj}_b(y').$$

Since y' was arbitrary, the second universal clause follows. □

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityWeakDualityEquality optimality`

Theorem 235.5 (LPDuality complementary slackness gives objective equality)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Suppose x is primal feasible and y is dual feasible,*

$$\mathsf{PrFeas}_{A,b}(x) \wedge \mathsf{DuFeas}_{A,b,c}(y),$$

and suppose the two complementary-slackness product families are classifier-equal termwise:

$$\forall j \in J.\ c_j \cdot_F x_j \sim_F \beta_j(y) \cdot_F x_j, \qquad \forall i \in I.\ y_i \cdot_F \alpha_i(x) \sim_F y_i \cdot_F b_i.$$

Then the primal and dual objective endpoints are classifier-equal,

$$\mathsf{PrObj}_{A,c}(x) \sim_F \mathsf{DuObj}_b(y).$$

Moreover, x is primal optimal and y is dual optimal in the row sense:

$$\forall x'.\ \mathsf{PrFeas}_{A,b}(x') \Longrightarrow \mathsf{PrObj}_{A,c}(x') \preceq_F \mathsf{PrObj}_{A,c}(x),$$

and

$$\forall y'.\ \mathsf{DuFeas}_{A,b,c}(y') \Longrightarrow \mathsf{DuObj}_b(y) \preceq_F \mathsf{DuObj}_b(y').$$

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityComplementarySlackness objective equality`

Proof. For each column position $j \in J$, order reflexivity gives

$$c_j \cdot_F x_j \preceq_F c_j \cdot_F x_j \qquad \text{and} \qquad \beta_j(y) \cdot_F x_j \preceq_F \beta_j(y) \cdot_F x_j.$$

Transporting these reflexive comparisons by the classifier-stability row for $\preceq_F$ and by the displayed column slack equality, in both directions, gives

$$c_j \cdot_F x_j \preceq_F \beta_j(y) \cdot_F x_j \qquad \text{and} \qquad \beta_j(y) \cdot_F x_j \preceq_F c_j \cdot_F x_j.$$

Finite-sum monotonicity over J therefore yields the opposing comparisons

$$\sum_{j \in J} c_j \cdot_F x_j \preceq_F \sum_{j \in J} \beta_j(y) \cdot_F x_j, \qquad \sum_{j \in J} \beta_j(y) \cdot_F x_j \preceq_F \sum_{j \in J} c_j \cdot_F x_j.$$

Antisymmetry of the ordered-field order gives the classifier equality

$$\mathsf{PrObj}_{A,c}(x) \sim_F \sum_{j \in J} \beta_j(y) \cdot_F x_j.$$

The same argument over the row positions uses the displayed row slack equality. For each $i \in I$, classifier stability transports the two reflexive order comparisons into

$$y_i \cdot_F \alpha_i(x) \preceq_F y_i \cdot_F b_i \qquad \text{and} \qquad y_i \cdot_F b_i \preceq_F y_i \cdot_F \alpha_i(x).$$

Finite-sum monotonicity over I, followed by antisymmetry, gives

$$\sum_{i \in I} y_i \cdot_F \alpha_i(x) \sim_F \mathsf{DuObj}_b(y).$$

The finite distributivity and interchange row in Definition 235.1 supplies

$$\sum_{j \in J} \beta_j(y) \cdot_F x_j \sim_F \sum_{i \in I} y_i \cdot_F \alpha_i(x).$$

Transitivity of the scalar classifier composes the three displayed classifier equalities into

$$\mathsf{PrObj}_{A,c}(x) \sim_F \mathsf{DuObj}_b(y).$$

The feasibility hypotheses and this objective equality are precisely the hypotheses of Definition 235.4. Applying that corollary gives the stated primal and dual optimality clauses. □

Theorem 235.6 (LPDuality dual feasibility binary convex closure)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $y, y' : I \to F$ *be dual feasible witnesses, and let* $\lambda, \mu : F$ *be scalar coefficients such that*

$$\mathsf{DuFeas}_{A,b,c}(y) \wedge \mathsf{DuFeas}_{A,b,c}(y') \wedge \mathsf{NonNeg}_F(\lambda) \wedge \mathsf{NonNeg}_F(\mu) \wedge (\lambda +_F \mu) \sim_F 1_F.$$

Define $\eta : I \to F$ *componentwise by*

$$\eta_i := \lambda \cdot_F y_i +_F \mu \cdot_F y'_i \qquad (i \in I).$$

Then

$$\mathsf{DuFeas}_{A,b,c}(\eta).$$

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityDualFeasibility binary convex closure`

Proof. Unpack the two dual-feasibility hypotheses from Definition 235.1. They give

$$\forall i \in I.\ \mathsf{NonNeg}_F(y_i), \qquad \forall i \in I.\ \mathsf{NonNeg}_F(y'_i),$$

and

$$\forall j \in J.\ c_j \preceq_F \beta_j(y), \qquad \forall j \in J.\ c_j \preceq_F \beta_j(y').$$

We verify the two clauses of $\mathsf{DuFeas}_{A,b,c}(\eta)$.

First fix $i \in I$. Since $\mathsf{NonNeg}_F(y_i)$ and $\mathsf{NonNeg}_F(y'_i)$ mean $0_F \preceq_F y_i$ and $0_F \preceq_F y'_i$, left multiplication monotonicity by the nonnegative scalars λ and μ gives

$$\lambda \cdot_F 0_F \preceq_F \lambda \cdot_F y_i, \qquad \mu \cdot_F 0_F \preceq_F \mu \cdot_F y'_i.$$

Apply finite-sum monotonicity over a two-point carrier to these two comparisons. This yields

$$(\lambda \cdot_F 0_F) +_F (\mu \cdot_F 0_F) \preceq_F (\lambda \cdot_F y_i) +_F (\mu \cdot_F y'_i).$$

The field rows from chapter 45 identify the left endpoint with 0_F, using zero multiplication and the additive unit law. By the definition of η_i, the right endpoint is η_i. Classifier stability of $\preceq_F$ therefore gives

$$0_F \preceq_F \eta_i.$$

Thus $\mathsf{NonNeg}_F(\eta_i)$ holds for every $i \in I$.

Next fix $j \in J$. Dual feasibility of y and y' gives

$$c_j \preceq_F \beta_j(y), \qquad c_j \preceq_F \beta_j(y').$$

Left multiplication monotonicity by the nonnegative scalars λ and μ yields

$$\lambda \cdot_F c_j \preceq_F \lambda \cdot_F \beta_j(y), \qquad \mu \cdot_F c_j \preceq_F \mu \cdot_F \beta_j(y').$$

Finite-sum monotonicity over a two-point carrier gives

$$(\lambda \cdot_F c_j) +_F (\mu \cdot_F c_j) \preceq_F (\lambda \cdot_F \beta_j(y)) +_F (\mu \cdot_F \beta_j(y')).$$

On the left, distributivity and the coefficient-sum hypothesis give the classifier chain

$$(\lambda \cdot_F c_j) +_F (\mu \cdot_F c_j) \sim_F (\lambda +_F \mu) \cdot_F c_j \sim_F 1_F \cdot_F c_j \sim_F c_j.$$

On the right, expand the definition of β_j and use distributivity, associativity, and finite-sum compatibility with the scalar classifier from chapter 45:

$$(\lambda \cdot_F \beta_j(y)) +_F (\mu \cdot_F \beta_j(y')) \sim_F \sum_{i \in I} (\lambda \cdot_F y_i) \cdot_F A_{ij} +_F \sum_{i \in I} (\mu \cdot_F y'_i) \cdot_F A_{ij}$$

and hence

$$(\lambda \cdot_F \beta_j(y)) +_F (\mu \cdot_F \beta_j(y')) \sim_F \sum_{i \in I} (\lambda \cdot_F y_i +_F \mu \cdot_F y'_i) \cdot_F A_{ij} = \beta_j(\eta).$$

Classifier stability of $\preceq_F$ transports the displayed order comparison along these left and right classifier equalities, yielding

$$c_j \preceq_F \beta_j(\eta).$$

Thus the dual constraint clause holds for every $j \in J$.

We have shown both

$$\forall i \in I.\ \mathsf{NonNeg}_F(\eta_i)$$

and

$$\forall j \in J.\ c_j \preceq_F \beta_j(\eta).$$

By the definition of dual feasibility in Definition 235.1, this is exactly

$$\mathsf{DuFeas}_{A,b,c}(\eta).$$

□

Theorem 235.7 (B-516: $\mathsf{LPDuality}^{\uparrow}$ primal feasibility binary convex closure)**.** *Let F be the ordered-field scalar interface carried by a finite $\mathsf{LPDuality}^{\uparrow}$ row certificate as in Definition 235.1. Let J be the finite column index object, let I_0 be any finite family of certified primal rows, let*

$$A : I_0 \times J \to F, \qquad b : I_0 \to F$$

be the row-coefficient and right-hand-side data, and let

$$x, x' : J \to F$$

be two primal vectors. Write

$$\mathsf{Row}_i(z) := \sum_{j \in J} A_{ij} \cdot_F z_j$$

for the finite row evaluation, and define

$$\mathsf{PrFeas}^{I_0}_{A,b}(z) \quad :\Longleftrightarrow \quad \forall i \in I_0,\ \mathsf{Row}_i(z) \preceq_F b_i.$$

Assume

$$\mathsf{PrFeas}^{I_0}_{A,b}(x), \qquad \mathsf{PrFeas}^{I_0}_{A,b}(x'),$$

and let $\alpha, \beta : F$ satisfy

$$\mathsf{NonNeg}_F(\alpha), \qquad \mathsf{NonNeg}_F(\beta), \qquad \alpha +_F \beta \sim_F 1_F.$$

Define the componentwise binary affine mixture

$$\lambda_j := \alpha \cdot_F x_j +_F \beta \cdot_F x'_j, \qquad j \in J.$$

The finite row certificate records the row-affine-linearity comparison for this mixture:

$$\mathsf{Row}_i(\lambda) \sim_F \alpha \cdot_F \mathsf{Row}_i(x) +_F \beta \cdot_F \mathsf{Row}_i(x') \qquad (i \in I_0).$$

The scalar order portion of the same certificate records binary order-addition monotonicity, the two-point finite-sum monotonicity instance of Definition 235.1:

$$p \preceq_F q \wedge r \preceq_F s \Longrightarrow p +_F r \preceq_F q +_F s.$$

Then

$$\mathsf{PrFeas}^{I_0}_{A,b}(\lambda).$$

Moreover, the closure is row-local and coefficient-sign-free: no hypothesis of the form $\mathsf{NonNeg}_F(A_{ij})$ is required for any row coefficient.

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityPrimalFeasibilityBinaryConvexClosure`

Proof. Fix a row $i \in I_0$. By the definition of λ, field distributivity, commutativity of scalar multiplication, and the finite-sum linearity certificate over the finite column object J recorded by the row-affine-linearity field displayed in the theorem statement,

$$\begin{aligned}\mathsf{Row}_i(\lambda) &= \sum_{j\in J} A_{ij} \cdot_F (\alpha \cdot_F x_j +_F \beta \cdot_F x'_j)\\ &\sim_F \sum_{j\in J} (\alpha \cdot_F (A_{ij} \cdot_F x_j) +_F \beta \cdot_F (A_{ij} \cdot_F x'_j))\\ &\sim_F \alpha \cdot_F \sum_{j\in J} A_{ij} \cdot_F x_j +_F \beta \cdot_F \sum_{j\in J} A_{ij} \cdot_F x'_j\\ &= \alpha \cdot_F \mathsf{Row}_i(x) +_F \beta \cdot_F \mathsf{Row}_i(x').\end{aligned}$$

The two feasibility assumptions give

$$\mathsf{Row}_i(x) \preceq_F b_i, \qquad \mathsf{Row}_i(x') \preceq_F b_i.$$

Since α and β are nonnegative, the multiplication-monotonicity row of Definition 235.1 yields

$$\alpha \cdot_F \mathsf{Row}_i(x) \preceq_F \alpha \cdot_F b_i, \qquad \beta \cdot_F \mathsf{Row}_i(x') \preceq_F \beta \cdot_F b_i.$$

The binary order-addition monotonicity row displayed in the theorem statement gives

$$\alpha \cdot_F \mathsf{Row}_i(x) +_F \beta \cdot_F \mathsf{Row}_i(x') \preceq_F \alpha \cdot_F b_i +_F \beta \cdot_F b_i.$$

By right distributivity and the convex-weight certificate,

$$\alpha \cdot_F b_i +_F \beta \cdot_F b_i \sim_F (\alpha +_F \beta) \cdot_F b_i \sim_F 1_F \cdot_F b_i \sim_F b_i.$$

The classifier-stability row for $\preceq_F$ recorded in Definition 235.1, applied to the row-evaluation classifier comparison above and to the final scalar classifier comparison, yields

$$\mathsf{Row}_i(\lambda) \preceq_F b_i.$$

Because $i \in I_0$ was arbitrary, $\mathsf{PrFeas}^{I_0}_{A,b}(\lambda)$ follows. The proof used only finite-sum linearity, commutative-field distributivity, ordered-field monotonicity under nonnegative scalar multiplication, additive monotonicity of the order through the displayed two-point finite-sum row, and classifier stability for $\preceq_F$ from Definition 235.1. The entries A_{ij} were never compared with 0_F. Hence the closure is local in the chosen row ledger I_0 and does not require any coefficient-sign side condition. □

Theorem 235.8 (LPDuality feasible-region face exhaustion)**.** *Every displayed feasible-region face row read by an* $\mathsf{LPDuality}^{\uparrow}$ *consumer is generated by either the primal binary convex closure row of Definition 235.7 or the dual binary convex closure row of Definition 235.6, together with the ordered-field prefix order and the finite* BHist *ledger of Definition 235.1. The consumer surface has no coordinate for host convex geometry, ambient polyhedra, topological faces, separation theorems, or external linear-programming objects.*

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityFeasibleRegion face exhaustion`

Proof. Start with a displayed feasible-region face row in the $\mathsf{LPDuality}^{\uparrow}$ consumer surface. The finite ordered-field row of Definition 235.1 presents such a row only through the primal feasibility predicate, the dual feasibility predicate, the ordered-field prefix comparison, and the finite BHist ledger.

For a primal face row, apply Definition 235.7. It shows that binary convex motion inside any certified finite family of primal rows is generated by the carried field operations, order monotonicity, classifier stability, and the displayed finite-sum ledger.

For a dual face row, apply Definition 235.6. The same finite ordered-field rows generate the nonnegative dual coordinates and the dual constraint comparisons, again without leaving the displayed ledger.

The remaining comparison between primal and dual consumer rows is the weak-duality prefix-order theorem Definition 235.3. It relates the two generated surfaces only through the ordered-field prefix order. Since every cited row is drawn from the finite BHist ledger, no host convex geometry or external linear-programming object is available to generate an additional feasible-region face. □

Lemma 235.9 (LPDuality primal objective binary affine readback)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $x, x' : J \to F$ *be primal vectors, let* $\alpha, \beta : F$ *be scalar coefficients, and define* $\lambda : J \to F$ *componentwise by*

$$\lambda_j := \alpha \cdot_F x_j +_F \beta \cdot_F x'_j \qquad (j \in J).$$

Then the primal objective is affine over this binary mixture:

$$\mathsf{PrObj}_{A,c}(\lambda) \sim_F \alpha \cdot_F \mathsf{PrObj}_{A,c}(x) +_F \beta \cdot_F \mathsf{PrObj}_{A,c}(x').$$

Proof. Expand the objective endpoint from Definition 235.1. By the definition of λ, distributivity in the carried $\mathsf{Field}^{\uparrow}$ row, commutativity and associativity of multiplication, and finite-sum compatibility with the scalar classifier, one has

$$\begin{aligned}
\mathsf{PrObj}_{A,c}(\lambda) &= \sum_{j\in J} c_j \cdot_F (\alpha \cdot_F x_j +_F \beta \cdot_F x'_j) \\
&\sim_F \sum_{j\in J} \big(\alpha \cdot_F (c_j \cdot_F x_j) +_F \beta \cdot_F (c_j \cdot_F x'_j)\big) \\
&\sim_F \alpha \cdot_F \sum_{j\in J} c_j \cdot_F x_j +_F \beta \cdot_F \sum_{j\in J} c_j \cdot_F x'_j \\
&= \alpha \cdot_F \mathsf{PrObj}_{A,c}(x) +_F \beta \cdot_F \mathsf{PrObj}_{A,c}(x').
\end{aligned}$$

This is the asserted classifier equality. □

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityFiniteOrderedFieldFeasibilityRow primal objective binary affine readback`

Theorem 235.10 (LPDuality Farkas finite-alternative handoff)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Suppose the same finite coefficient rows* A, b, c *are equipped with a* $\mathsf{FarkasLemma}^{\uparrow}$ *packet from chapter 6185. Then the Farkas finite-alternative row supplies the nonnegative multiplier ledger consumed by the weak-duality comparison of Definition 235.3: feasibility branches become primal or dual feasible rows, and obstruction branches become the displayed multiplier comparison rows whose finite sums witness objective separation in the ordered-field ledger.*

Proof. Project the $\mathsf{LPDuality}^{\uparrow}$ row through Definition 235.1. The weak-duality theorem consumes exactly finite row and column carriers, ordered-field scalar operations, nonnegative scalar predicates, finite-sum monotonicity, and the distributivity-interchange ledger.

Project the $\mathsf{FarkasLemma}^{\uparrow}$ packet through Definition 6185.1. Its feasibility branch is already a finite row of inequalities over the same coefficient system, so classifier transport repacks it as the corresponding primal or dual feasibility row in the linear-programming surface.

In the obstruction branch, the Farkas packet supplies a nonnegative multiplier row and the coefficient-annihilation equations. The $\mathsf{PositiveCone}^{\uparrow}$ nonnegative witnesses give the scalar monotonicity hypotheses used in weak duality, while the finite-sum equations identify the multiplier sum with the objective endpoint comparison read by the $\mathsf{LPDuality}^{\uparrow}$ ledger.

Thus the handoff is row-for-row. The Farkas certificate contributes no optimizer, separation theorem, or strong-duality existence claim; it only names the finite multiplier ledger that the weak-duality comparison already consumes. □

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityFarkasAlternativeHandoff`

Theorem 235.11 (LPDuality optimal primal face binary convex closure)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $x, x' : J \to F$ *be primal feasible witnesses, let* $\tau : F$ *be a scalar endpoint, and suppose both witnesses lie in the same primal objective fiber:*

$$\mathsf{PrFeas}_{A,b}(x), \qquad \mathsf{PrFeas}_{A,b}(x'),$$

$$\mathsf{PrObj}_{A,c}(x) \sim_F \tau, \qquad \mathsf{PrObj}_{A,c}(x') \sim_F \tau.$$

Let $\alpha, \beta : F$ *satisfy*

$$\mathsf{NonNeg}_F(\alpha), \qquad \mathsf{NonNeg}_F(\beta), \qquad \alpha +_F \beta \sim_F 1_F,$$

and define the componentwise binary affine mixture

$$\lambda_j := \alpha \cdot_F x_j +_F \beta \cdot_F x'_j \qquad (j \in J).$$

Then λ *is primal feasible and remains in the same primal objective fiber:*

$$\mathsf{PrFeas}_{A,b}(\lambda), \qquad \mathsf{PrObj}_{A,c}(\lambda) \sim_F \tau.$$

Consequently, when τ *is the scalar endpoint certified as the primal optimum of the row, the certified primal optimal face at* τ *is closed under binary affine combinations with nonnegative coefficients whose sum is classifier-equal to* 1_F*.*

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityOptimalPrimalFace binary convex closure`

Proof. Unpack the two primal-feasibility hypotheses using Definition 235.1. They give

$$\forall j \in J.\ \mathsf{NonNeg}_F(x_j), \qquad \forall j \in J.\ \mathsf{NonNeg}_F(x'_j),$$

and

$$\forall i \in I.\ \alpha_i(x) \preceq_F b_i, \qquad \forall i \in I.\ \alpha_i(x') \preceq_F b_i.$$

First fix $j \in J$. Since $\mathsf{NonNeg}_F(x_j)$ and $\mathsf{NonNeg}_F(x'_j)$ mean $0_F \preceq_F x_j$ and $0_F \preceq_F x'_j$, multiplication monotonicity by the nonnegative scalars α and β gives

$$\alpha \cdot_F 0_F \preceq_F \alpha \cdot_F x_j, \qquad \beta \cdot_F 0_F \preceq_F \beta \cdot_F x'_j.$$

The two-point finite-sum monotonicity instance in Definition 235.1 yields

$$\alpha \cdot_F 0_F +_F \beta \cdot_F 0_F \preceq_F \alpha \cdot_F x_j +_F \beta \cdot_F x'_j.$$

The $\mathsf{Field}^{\uparrow}$ zero laws identify the left endpoint with 0_F, and the definition of λ_j identifies the right endpoint with λ_j. Classifier stability of $\preceq_F$ therefore gives

$$0_F \preceq_F \lambda_j.$$

Thus $\mathsf{NonNeg}_F(\lambda_j)$ holds for every $j \in J$.

For the row inequalities, apply Definition 235.7 to the finite row family I, with $\mathsf{Row}_i(z) = \alpha_i(z)$. The displayed row-constraint clauses for x and x', together with the same nonnegative coefficients and the classifier equality $\alpha +_F \beta \sim_F 1_F$, give

$$\forall i \in I.\ \alpha_i(\lambda) \preceq_F b_i.$$

Combining this row-constraint clause with the nonnegativity clause just proved is exactly

$$\mathsf{PrFeas}_{A,b}(\lambda)$$

by Definition 235.1.

It remains to read back the objective endpoint. By Definition 235.9,

$$\mathsf{PrObj}_{A,c}(\lambda) \sim_F \alpha \cdot_F \mathsf{PrObj}_{A,c}(x) +_F \beta \cdot_F \mathsf{PrObj}_{A,c}(x').$$

Scalar classifier congruence transports the two objective-fiber hypotheses through multiplication and addition, giving

$$\alpha \cdot_F \mathsf{PrObj}_{A,c}(x) +_F \beta \cdot_F \mathsf{PrObj}_{A,c}(x') \sim_F \alpha \cdot_F \tau +_F \beta \cdot_F \tau.$$

Distributivity, the coefficient-sum classifier equality, and the multiplicative unit law give

$$\alpha \cdot_F \tau +_F \beta \cdot_F \tau \sim_F (\alpha +_F \beta) \cdot_F \tau \sim_F 1_F \cdot_F \tau \sim_F \tau.$$

Transitivity of the scalar classifier composes the displayed classifier equalities into

$$\mathsf{PrObj}_{A,c}(\lambda) \sim_F \tau.$$

The final sentence is the specialization of the same statement to a scalar endpoint already certified as optimal for the row. □

Lemma 235.12 (LPDuality dual objective binary affine readback)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $y, y' : I \to F$ *be dual vectors, let* $\alpha, \beta : F$ *be scalar coefficients, and define* $\mu : I \to F$ *componentwise by*

$$\mu_i := \alpha \cdot_F y_i +_F \beta \cdot_F y'_i \qquad (i \in I).$$

Then the dual objective is affine over this binary mixture:

$$\mathsf{DuObj}_b(\mu) \sim_F \alpha \cdot_F \mathsf{DuObj}_b(y) +_F \beta \cdot_F \mathsf{DuObj}_b(y').$$

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityDualObjective binary affine readback`

Proof. Expand the dual objective endpoint from Definition 235.1. By the definition of μ, distributivity in the carried $\mathsf{Field}^{\uparrow}$ row, associativity and commutativity of multiplication, and finite-sum compatibility with the scalar classifier, one has

$$\begin{aligned}\mathsf{DuObj}_b(\mu) &= \sum_{i\in I}(\alpha \cdot_F y_i +_F \beta \cdot_F y'_i) \cdot_F b_i \\ &\sim_F \sum_{i\in I}\big(\alpha \cdot_F (y_i \cdot_F b_i) +_F \beta \cdot_F (y'_i \cdot_F b_i)\big) \\ &\sim_F \alpha \cdot_F \sum_{i\in I} y_i \cdot_F b_i +_F \beta \cdot_F \sum_{i\in I} y'_i \cdot_F b_i \\ &= \alpha \cdot_F \mathsf{DuObj}_b(y) +_F \beta \cdot_F \mathsf{DuObj}_b(y').\end{aligned}$$

This is the asserted classifier equality. □

Theorem 235.13 (LPDuality optimal dual face binary convex closure)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $y, y' : I \to F$ *be dual feasible witnesses, let* $\tau : F$ *be a scalar endpoint, and suppose both witnesses lie in the same dual objective fiber:*

$$\mathsf{DuFeas}_{A,b,c}(y), \qquad \mathsf{DuFeas}_{A,b,c}(y'),$$

$$\mathsf{DuObj}_b(y) \sim_F \tau, \qquad \mathsf{DuObj}_b(y') \sim_F \tau.$$

Let $\alpha, \beta : F$ *satisfy*

$$\mathsf{NonNeg}_F(\alpha), \qquad \mathsf{NonNeg}_F(\beta), \qquad \alpha +_F \beta \sim_F 1_F,$$

and define the componentwise binary affine mixture

$$\mu_i := \alpha \cdot_F y_i +_F \beta \cdot_F y'_i \qquad (i \in I).$$

Then μ *is dual feasible and remains in the same dual objective fiber:*

$$\mathsf{DuFeas}_{A,b,c}(\mu), \qquad \mathsf{DuObj}_b(\mu) \sim_F \tau.$$

Consequently, when τ *is the scalar endpoint certified as the dual optimum of the row, the certified dual optimal face at* τ *is closed under binary affine combinations with nonnegative coefficients whose sum is classifier-equal to* 1_F*.*

Proof. The feasibility statement is exactly the dual-feasibility binary convex closure of Definition 235.6, applied to the two feasible witnesses y, y' and to the coefficients α, β. Hence

$$\mathsf{DuFeas}_{A,b,c}(\mu).$$

It remains to read back the objective endpoint. By Definition 235.12,

$$\mathsf{DuObj}_b(\mu) \sim_F \alpha \cdot_F \mathsf{DuObj}_b(y) +_F \beta \cdot_F \mathsf{DuObj}_b(y').$$

Scalar classifier congruence transports the two objective-fiber hypotheses through multiplication and addition, giving

$$\alpha \cdot_F \mathsf{DuObj}_b(y) +_F \beta \cdot_F \mathsf{DuObj}_b(y') \sim_F \alpha \cdot_F \tau +_F \beta \cdot_F \tau.$$

Distributivity, the coefficient-sum classifier equality, and the multiplicative unit law give

$$\alpha \cdot_F \tau +_F \beta \cdot_F \tau \sim_F (\alpha +_F \beta) \cdot_F \tau \sim_F 1_F \cdot_F \tau \sim_F \tau.$$

Transitivity of the scalar classifier composes the displayed classifier equalities into

$$\mathsf{DuObj}_b(\mu) \sim_F \tau.$$

The final sentence is the specialization of the same statement to a scalar endpoint already certified as optimal for the dual row. □

Theorem 235.14 (LPDuality objective fiber sandwich closure)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $x, x' : J \to F$ *be primal feasible witnesses, let* $y, y' : I \to F$ *be dual feasible witnesses, and let* $\tau : F$ *be a scalar endpoint. Suppose weak duality gives the objective comparison for every displayed primal-dual pair, and suppose all four displayed objective endpoints lie in the same scalar fiber:*

$$\mathsf{PrObj}_{A,c}(x) \sim_F \tau, \qquad \mathsf{PrObj}_{A,c}(x') \sim_F \tau,$$

$$\mathsf{DuObj}_b(y) \sim_F \tau, \qquad \mathsf{DuObj}_b(y') \sim_F \tau.$$

Then the primal optimal-face closure row at τ *and the dual optimal-face closure row at* τ *are consumed by the same* τ*-fiber sandwich: every binary affine primal mixture of* x, x' *and every binary affine dual mixture of* y, y' *with nonnegative coefficients whose sum is classifier-equal to* 1_F *remains feasible, remains classifier-equal to* τ *on its own objective side, and sits between weak-duality comparisons whose endpoints are classifier-stable copies of* τ*.*

Lean4 ✓ `BEDC.Derived.LPDualityUp.LPDualityObjectiveFiber sandwich closure`

Proof. First apply Definition 235.3 to each displayed primal-dual pair. Classifier stability of $\preceq_F$ transports the primal and dual objective endpoints along the four fiber hypotheses, so each weak duality comparison becomes a comparison from a scalar endpoint classifier-equal to τ to a scalar endpoint classifier-equal to τ.

Next apply Definition 235.11 to the primal witnesses x, x' at the fiber endpoint τ. This gives primal feasibility and primal objective readback at τ for every allowed binary affine primal mixture.

Apply Definition 235.13 to the dual witnesses y, y' at the same fiber endpoint. This gives dual feasibility and dual objective readback at τ for every allowed binary affine dual mixture.

Finally use weak duality once more on the transported primal and dual mixtures. The two closure rows provide the objective endpoint equalities to τ, and classifier stability of the ordered-field order transports the comparison endpoints into the common τ fiber. Thus the primal and dual closure rows are consumed by one objective-fiber sandwich rather than by separate scalar certificates. □

Theorem 235.15 (LPDuality primal-dual affine fiber product closure)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let* $x, x' : J \to F$ *be primal feasible witnesses, let* $y, y' : I \to F$ *be dual feasible witnesses, and let* $\tau : F$ *be a scalar endpoint. Suppose all four objective endpoints lie in the same scalar fiber:*

$$\mathsf{PrObj}_{A,c}(x) \sim_F \tau, \qquad \mathsf{PrObj}_{A,c}(x') \sim_F \tau,$$

$$\mathsf{DuObj}_b(y) \sim_F \tau, \qquad \mathsf{DuObj}_b(y') \sim_F \tau.$$

Let $\alpha, \beta : F$ be nonnegative coefficients with $\alpha +_F \beta \sim_F 1_F$, and form the paired binary affine mixture

$$\lambda_j := \alpha \cdot_F x_j +_F \beta \cdot_F x'_j \qquad (j \in J), \qquad \mu_i := \alpha \cdot_F y_i +_F \beta \cdot_F y'_i \qquad (i \in I).$$

Then (λ, μ) is a feasible primal-dual pair, both objective endpoints remain classifier-equal to τ, and the weak-duality comparison between the mixed pair is a comparison between classifier-stable copies of τ.

Proof. Apply Definition 235.11 to the primal witnesses x, x' with endpoint τ and coefficients α, β. This gives the primal feasibility of λ and the readback $\mathsf{PrObj}_{A,c}(\lambda) \sim_F \tau$.

Apply Definition 235.13 to the dual witnesses y, y' with the same endpoint and coefficients. This gives the dual feasibility of μ and the readback $\mathsf{DuObj}_b(\mu) \sim_F \tau$.

Finally use Definition 235.14 on the same four witnesses and the same scalar fiber. The two closure rows give the paired feasible mixture, and weak duality for the mixed pair is transported along the two objective readbacks to a comparison whose endpoints are classifier-stable copies of τ. □

Theorem 235.16 (LPDuality weak-duality slackness optimality packet)**.** *Let an* $\mathsf{LPDuality}^{\uparrow}$ *row over an ordered field be given as in Definition 235.1. Let $x : J \to F$ be a primal feasible witness and let $y : I \to F$ be a dual feasible witness. Suppose the two complementary-slackness product families are classifier-equal termwise:*

$$\forall j \in J.\ c_j \cdot_F x_j \sim_F \beta_j(y) \cdot_F x_j, \qquad \forall i \in I.\ y_i \cdot_F \alpha_i(x) \sim_F y_i \cdot_F b_i.$$

Then the row carries a certified optimality packet: the objectives $\mathsf{PrObj}_{A,c}(x)$ and $\mathsf{DuObj}_b(y)$ are classifier-equal, x is primal optimal, and y is dual optimal. Moreover, writing $\tau := \mathsf{PrObj}_{A,c}(x)$, any further primal feasible optimal witness $x' : J \to F$ and any further dual feasible optimal witness $y' : I \to F$ whose objective endpoints are classifier-equal to τ enter the common objective-fiber sandwich at τ: every binary affine primal mixture of x, x' and every binary affine dual mixture of y, y' with nonnegative coefficients whose sum is classifier-equal to 1_F remains feasible, remains in its own τ-objective fiber, and is bounded by the weak-duality comparisons between classifier-stable copies of τ.

Proof. Apply Definition 235.5 to the feasible witnesses x and y and to the two displayed slackness families. This gives the scalar objective equality together with the primal optimality of x and the dual optimality of y.

The objective equality identifies $\mathsf{DuObj}_b(y)$ with the same fiber endpoint $\tau := \mathsf{PrObj}_{A,c}(x)$. Together with the assumed fiber readbacks for the feasible optimal witnesses x' and y', the four endpoints x, x', y, y' have weak-duality comparisons by Definition 235.3. Hence they satisfy the hypotheses of Definition 235.14. Applying that theorem gives the shared primal and dual binary-affine closure statement and the weak-duality sandwich over the common τ fiber. □

Closure status for $\mathsf{NameCert}_{\mathsf{LPDuality}^{\uparrow}}$.

Constructive story: A linear-programming duality row begins with finite row and column carriers, a $\mathsf{Field}^{\uparrow}$ scalar surface equipped with a $\mathsf{TotalOrder}^{\uparrow}$ comparison, and displayed coefficient, right-hand-side, and cost rows from which primal feasibility, dual feasibility, and objective endpoints are computed by finite sums. The carrier accepts only packets whose feasible-region rows come through $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{Polytope}^{\uparrow}$, whose scalar operations and comparisons come through the ordered-field surface, and whose weak-duality, complementary-slackness, face, and objective-fiber data are kept as finite BHist rows. Two accepted packets classify together by componentwise hsame transport of scalar endpoints, feasible witnesses, objective values, finite-sum ledgers, face witnesses, and consumer rows, never by ambient matrix

equality or quotient vector-space equality. The source specification is the finite ordered-field feasibility row plus the convex and polytope dependency rows, the pattern specification records weak-duality comparison and complementary-slackness equality, and the ledger keeps nonnegativity, finite-sum monotonicity, objective readbacks, convex closure, and face-fiber rows visible. The five name-certificate obligations are supplied by an admitted feasible packet, the inherited equivalence and order-stability rows, and the finite transport proofs that rebuild each primal, dual, objective, and ledger row after classified replacement. A packet history h lies in the signature gap of an LPDuality$^{\uparrow}$ token p when the source-domain accepts its ordered-field primal-dual surface, the signature relation pairs it with an answer duality packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the feasibility rows, weak-duality comparison, and any complementary-slackness equality are exactly those encoded by p. The chapter registers this finite ordered-field duality construction under the name LPDuality$^{\uparrow}$; it introduces no optimization solver, no strong-duality existence theorem, no separation theorem, and no standard bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{LPDuality}\uparrow}$, maturePackageClosed)

Chapter 236

A Concrete Naming Certificate for $\mathsf{ShortestPath}^{\uparrow}$

The shortest-path interface $\mathsf{ShortestPath}^{\uparrow}$ packages, on a weighted graph carrier with nonnegative weights, the path of minimum total weight between two vertices together with Dijkstra and Bellman-Ford correctness certificates. It depends on $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118) and $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$ (chapter 38).

236.1 Carrier definition

Definition 236.1 (Shortest-path weighted graph carrier)**.** *A* $\mathsf{ShortestPath}^{\uparrow}$ *carrier is a finite* BHist *weighted-graph packet. Its visible rows consist of vertex rows, directed or undirected edge rows, nonnegative* $\mathsf{Real}^{\uparrow}$ *weight rows attached to the displayed edges, source and target endpoint rows, a finite path ledger, and the* Pkg *provenance row that records which graph and weight packet the ledger reads from.*

The carrier does not include a completed metric space, an infinite graph, an unstated host ordering on vertices, or an external minimization oracle. Every comparison row is read from the finite graph packet, the $\mathsf{Real}^{\uparrow}$ *weight certificates, the endpoint rows, and the displayed path ledger.*

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier endpoint expanded boundary`
Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier source rows`

236.2 The certificate

Theorem 236.2 (Shortest-path visible path ledger)**.** *For any accepted* $\mathsf{ShortestPath}^{\uparrow}$ *packet, the readable path data are exactly the finite vertex sequence in the path ledger, the edge-incidence rows certifying that consecutive vertices are connected, the nonnegative* $\mathsf{Real}^{\uparrow}$ *weight rows for those edges, the source and target endpoint rows, and the* Pkg *provenance row tying the ledger to the weighted-graph carrier.*

No row of the certificate asserts an unseen edge, a hidden lower-weight path, a completed real metric, or a host-index equality between vertices.

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier visible path ledger`
↪ variant `BEDC.Derived.ShortestPathUp.ShortestPathVisiblePathLedger`

Proof. Unpack the weighted-graph carrier of Definition 236.1. The only graph rows it exports are the finite vertex rows, edge rows, endpoint rows, weight rows, path-ledger rows, and package provenance.

Read the path ledger pointwise. Each adjacent pair in the displayed vertex sequence is checked by one visible edge-incidence row, and each such edge contributes its displayed nonnegative $\mathsf{Real}^{\uparrow}$ weight row.

The source and target constraints are the endpoint rows at the first and last ledger positions. Since the carrier has no generator for unseen edges, completed metrics, host-index equalities, or external minimization oracles, the listed rows are exactly the visible path ledger. □

Theorem 236.3 (Shortest-path relaxation certificate scope)**.** *Dijkstra and Bellman-Ford readback for* $\mathsf{ShortestPath}^{\uparrow}$ *remains a finite* BHist *ledger obligation. The certificate surface consists of the weighted-graph carrier, the source and target endpoint rows, nonnegative* $\mathsf{Real}^{\uparrow}$ *edge-weight rows, finite relaxation rows comparing displayed path weights, predecessor or path-ledger rows, and the* Pkg *provenance row.*

The certificate does not assert an ambient choice of shortest path, a total ordering of all host vertices, an infinite relaxation process, or a completed real-analysis object.

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier relaxation certificate scope`

↪ variant `BEDC.Derived.ShortestPathUp.ShortestPathRelaxationCertificate scope`

Proof. Start from the carrier definition. It fixes a finite graph packet, a finite family of nonnegative $\mathsf{Real}^{\uparrow}$ weight rows, and the package provenance used by the path ledger.

For a Dijkstra readback, each settled-step claim is a row comparing visible candidate path weights over the finite frontier named by the packet. For a Bellman-Ford readback, each relaxation claim is a finite edge row together with the displayed before-and-after path-weight comparison.

In both readings the predecessor or path-ledger row supplies the reconstructed path, and Definition 236.2 identifies the readable endpoint and incidence rows. Thus the certificate surface is a finite BHist ledger obligation over the named graph and weight rows, with no ambient choice principle, host-vertex ordering, infinite process, or completed real object. □

Definition 236.4 (Shortest-path relaxation ledger carrier)**.** *A* $\mathsf{ShortestPath}^{\uparrow}$ *relaxation ledger carrier is a finite* BHist *packet over the weighted-graph carrier of Definition 236.1. Its displayed rows are the* $\mathsf{Graph}^{\uparrow}$ *vertex and edge rows, nonnegative* $\mathsf{Real}^{\uparrow}$ *edge-weight rows, before-and-after path-weight rows, predecessor rows, visible* Cont *relaxation rows, the* hsame *comparisons recording the transported packet equalities, and the* Pkg *provenance tying the relaxation ledger to the named graph and weight packet.*

The carrier records only finite relaxation evidence. It does not contain a host minimizer, a hidden vertex order, an infinite relaxation stream, or a completed metric assumption.

Lean4 (definition) `BEDC.Derived.ShortestPathUp.ShortestPathRelaxationLedgerCarrier`

Theorem 236.5 (Shortest-path relaxation continuation closure)**.** *Let a* $\mathsf{ShortestPath}^{\uparrow}$ *weighted-graph carrier display finite vertex rows, edge rows, nonnegative* $\mathsf{Real}^{\uparrow}$ *weight rows, endpoint rows, and path-ledger rows. If a transported relaxation packet also displays the before-and-after path-weight rows, predecessor rows, visible* Cont *relaxation rows, matching* hsame *comparisons, and the same* Pkg *provenance, then those rows repack as an accepted relaxation ledger carrier over the same weighted graph.*

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier relaxation cont closure`

Proof. Project the weighted-graph carrier rows. They give the finite vertex, edge, weight, endpoint, path-ledger, and provenance rows named in Definition 236.1.

Next read the transported relaxation packet. Its visible Cont rows produce the before-and-after path-weight rows and the predecessor rows, while the hsame comparisons identify the transported packets with the displayed source graph and weight rows.

The required carrier is obtained by repacking exactly these projected and transported rows into Definition 236.4. The Pkg provenance is unchanged, so the relaxation ledger remains attached to the original weighted-graph packet. □

Theorem 236.6 (Shortest-path visible relaxation NameCert surface)**.** *The visible path ledger of Definition 236.2 together with an accepted relaxation ledger carrier of Definition 236.4 supplies the finite* $\mathsf{NameCert}_{\mathsf{ShortestPath}^{\uparrow}}$ *surface for displayed Dijkstra or Bellman-Ford readback. The surface consists of endpoint visibility, edge-incidence visibility, nonnegative weight visibility, finite before-and-after path-weight comparisons, predecessor visibility, relaxation* Cont *rows,* hsame *transport comparisons, and* Pkg *provenance.*

It does not expose a host minimization principle, a hidden vertex order, an infinite relaxation process, or a completed metric-space assumption.

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier visible relaxation namecert surface`

Proof. Use Definition 236.2 to obtain the endpoint, incidence, nonnegative weight, path-ledger, and provenance rows from the visible path certificate.

Apply Definition 236.5 to the transported relaxation rows. This supplies the finite before-and-after path-weight rows, predecessor rows, visible Cont relaxation rows, and hsame transport comparisons over the same weighted graph.

Combining the two finite ledgers gives exactly the displayed $\mathsf{NameCert}_{\mathsf{ShortestPath}^{\uparrow}}$ surface. Since neither carrier has a generator for host minimizers, hidden vertex orderings, infinite relaxation streams, or completed metric objects, none of those assumptions is part of the certificate surface. □

Theorem 236.7 (Shortest-path finite edge exhaustion)**.** *Every accepted* $\mathsf{ShortestPath}^{\uparrow}$ *path-ledger step is exhausted by visible finite data: a displayed edge-incidence row, the source and target endpoint rows it connects, a finite* Cont *route through the carrier rows, and the* Pkg *provenance row that ties the step to the weighted-graph packet.*

Consequently the certificate has no hidden edge source. Any edge used by the accepted path is read from the finite BHist *carrier of Definition 236.1, not from a host graph outside the certificate.*

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier finite edge exhaustion`

Proof. Inspect the carrier constructors in Definition 236.1. The carrier exports only vertex rows, edge rows, nonnegative weight rows, endpoint rows, path-ledger rows, and the package provenance row.

Apply Definition 236.2 to a single adjacent ledger step. The step supplies its two displayed vertices, the incidence row between them, and the endpoint rows used by the ledger.

It remains to account for routing and provenance. The finite Cont route is the row-by-row traversal through those displayed carrier rows, and the Pkg row records that the traversal reads this weighted-graph packet. Since the carrier has no constructor for an unseen edge source, the listed rows exhaust the edge obligation. □

Theorem 236.8 (Shortest-path weight readback)**.** *For any accepted* $\mathsf{ShortestPath}^{\uparrow}$ *packet, the total weight of the displayed path is read only from the visible nonnegative* $\mathsf{Real}^{\uparrow}$ *edge-weight rows and the finite path-ledger summation rows.*

No total path weight may be supplied by an ambient metric, an unlisted edge weight, a host real-number accumulator, or an implicit minimization oracle.

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier weight readback`

Proof. Start with the visible ledger theorem. By Definition 236.2, every adjacent pair in the accepted vertex sequence has one displayed edge-incidence row and one displayed nonnegative $\mathsf{Real}^{\uparrow}$ weight row.

The summation rows are finite because the path ledger is finite in the weighted-graph carrier. Reading them in ledger order gives the total weight as the certificate's displayed finite sum of those edge-weight rows.

The carrier described in Definition 236.1 contains no completed metric object, no unlisted edge-weight generator, and no host accumulator. Thus the readback of total weight is exactly the finite $\mathsf{Real}^{\uparrow}$ row summation named by the certificate. □

Theorem 236.9 (Shortest-path relaxation soundness)**.** *A Dijkstra or Bellman-Ford relaxation row in an accepted* $\mathsf{ShortestPath}^{\uparrow}$ *packet can lower or preserve a displayed path-weight candidate only through visible rows: the relaxed edge row, its predecessor row, its endpoint rows, the relevant* hsame *identifications, the finite* Cont *route through the ledger, and the* Pkg *provenance row for the weighted-graph carrier.*

The relaxation certificate therefore cannot justify a candidate change by a hidden predecessor, a host-side vertex equality, an unrecorded edge weight, or an infinite relaxation process.

Lean4 ✓ `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier relaxation soundness`

Proof. Use Definition 236.3. It identifies a relaxation claim as a finite row comparing displayed before-and-after path-weight candidates over the named graph packet.

The row can mention an edge only through the carrier of Definition 236.1. Its predecessor and endpoint data are therefore the displayed predecessor row, endpoint rows, and edge-incidence row already present in the finite BHist packet.

Apply Definition 236.2 to reconstruct the candidate path segment. The required hsame identifications and finite Cont route are the visible transports that keep the predecessor, edge, and endpoint rows in the same ledger packet, while the Pkg row supplies provenance.

No remaining constructor can lower or preserve the displayed candidate: the certificate has no host-side equality source, no hidden predecessor row, no unrecorded weight row, and no infinite relaxation process. The relaxation is therefore sound exactly over the visible finite rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{ShortestPath}^{\uparrow}}$**.**

Constructive story: A shortest-path row is generated from a finite weighted graph packet by keeping the vertex rows, edge rows, nonnegative $\mathsf{Real}^{\uparrow}$ weight rows, endpoint rows, path ledger, relaxation rows, hsame transports, Cont routes, and Pkg provenance visible in the same BHist carrier. The obligation surface records only the finite ledger data available to Dijkstra or Bellman-Ford readback; it introduces no ambient minimizer, hidden vertex order, infinite relaxation stream, or completed metric-space object.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ShortestPath}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The scoped surface binds the weighted-graph carrier rows, endpoint rows, nonnegative $\mathsf{Real}^{\uparrow}$ weight rows, finite path-ledger rows, relaxation Cont rows, hsame transports, and Pkg provenance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ShortestPath}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ShortestPathUp.ShortestPathWeightedGraphCarrier\_visible\_path\_ledger`

Bridge status: none

Not claimed: The obligation surface does not close optimality over infinite graphs or negative-cycle completeness.
Upgrade path: The paper-axis treatment is mature; the remaining top formal upgrade is bridgeChecked verification.

Chapter 237

A Concrete Naming Certificate for $\mathsf{SpanningTree}^{\uparrow}$

The spanning-tree interface $\mathsf{SpanningTree}^{\uparrow}$ packages a maximal acyclic subgraph reaching every vertex of a connected graph carrier, with minimum-weight selection in the weighted case (Kruskal / Prim). It depends on $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ (chapter 118) and $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$ (chapter 119).

237.1 Carrier definition

Theorem 237.1 (SpanningTreeUp carrier obligation surface)**.** *The carrier of* $\mathsf{SpanningTree}^{\uparrow}$ *exposes only finite* BHist *rows over the two source certificates* $\mathsf{NameCert}_{\mathsf{Graph}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Tree}^{\uparrow}}$*. An accepted packet carries displayed vertex rows, graph-edge rows, tree-edge rows, a root row or root-free witness inherited from* $\mathsf{Tree}^{\uparrow}$*, incidence rows tying each tree edge to graph endpoints, reachability rows from the root branch when present, acyclicity rows, and* Pkg *provenance for the two dependency certificates.*

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrierPacket dependency surface`

Proof. Read the carrier through the named $\mathsf{Graph}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ certificates. The graph certificate supplies the visible vertex and edge rows, while the tree certificate supplies the acyclicity, root-branch, and tree-edge rows.

The spanning-tree carrier adds no ambient graph object. It records the incidence and reachability witnesses as finite BHist rows with their Pkg provenance, so every consumer-visible field is already present in the displayed carrier packet. □

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrier obligation surface`

Theorem 237.2 (SpanningTreeUp classifier obligation surface)**.** *The classifier for* $\mathsf{SpanningTree}^{\uparrow}$ *is componentwise* hsame *on the visible vertex, graph-edge, tree-edge, root, incidence, reachability, acyclicity, and provenance rows named in Definition 237.1. Transport along the classifier may use the* $\mathsf{Graph}^{\uparrow}$ *and* $\mathsf{Tree}^{\uparrow}$ *source classifiers, but it does not compare hidden host graphs, hidden edge sets, or unrecorded root choices.*

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeBHistCarrier classifier obligation`
Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrierPacket classifier obligation`

Proof. Project the two source classifiers from $\mathsf{NameCert}_{\mathsf{Graph}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Tree}^\uparrow}$. These transport the graph-edge rows and tree rows by the same hsame witnesses carried in the spanning-tree packet.

The remaining rows are finite ledger coordinates. Transporting incidence, reachability, acyclicity, root, and provenance rows componentwise preserves the carrier because each transported row still points to the same displayed dependency certificates. □

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeClassifier obligation surface`

Theorem 237.3 (SpanningTreeUp acyclic maximality obligation surface)**.** *Maximal acyclic reachability for* $\mathsf{SpanningTree}^\uparrow$ *is read only from the displayed tree-edge ledger, the finite incidence rows, the root or root-free branch inherited from* $\mathsf{Tree}^\uparrow$*, and finite* Cont *routes witnessing reachability. The obligation excludes any maximality proof that inspects a hidden graph equality, an unlisted edge, or an infinite search over ambient edges.*

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeAcyclicMaximality surface`
Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeAcyclicMaximality obligation surface`

Proof. Use the tree-edge ledger as the only candidate subgraph. Acyclicity is the visible row imported from the $\mathsf{Tree}^\uparrow$ certificate, and reachability is checked by finite Cont routes whose endpoints are the displayed vertex rows.

Maximality is therefore a ledger-readback statement. If an edge participates in the claim, it must already occur as a graph-edge row with incidence data and as a candidate tree-edge comparison row; otherwise the carrier has no constructor through which the edge can be read. □

Theorem 237.4 (SpanningTreeUp weight readback obligation surface)**.** *In the weighted case,* $\mathsf{SpanningTree}^\uparrow$ *compares spanning-tree candidates only through displayed* $\mathsf{Real}^\uparrow$ *edge-weight rows attached to the graph-edge ledger and through finite summation ledgers attached to the chosen tree-edge rows. No comparison may use an external minimizer, a hidden weight function, or an infinite family of candidate trees.*

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrierPacket weight readback obligation`

Proof. Read each weight from the visible graph-edge row. The $\mathsf{Real}^\uparrow$ source supplies the carrier for the displayed edge-weight value, and the spanning-tree packet records which tree-edge row consumes that value.

The total weight of a candidate is a finite summation ledger over those displayed rows. Comparing two candidates is therefore a comparison of two finite ledgers and their $\mathsf{Real}^\uparrow$ readbacks, with no extra optimization object outside the packet. □

Theorem 237.5 (SpanningTreeUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{SpanningTree}^\uparrow}$ *surface is assembled from the carrier rows of Definition 237.1, the classifier transport of Definition 237.2, the acyclic-reachability ledger of Definition 237.3, and the weighted readback rows of Definition 237.4. It explicitly excludes host graph equality, hidden edges, external minimization, and infinite graph data.*

Lean4 ✓ `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrier semantic name certificate`

Proof. Collect the four preceding obligation surfaces into one certificate packet. The carrier and classifier determine which histories are admissible and how they transport under hsame.

The maximality and weight clauses determine which ledger rows can be read by downstream algorithms such as Kruskal and Prim. Since each clause names only visible BHist, Cont, hsame, Pkg, $\mathsf{NameCert}_{\mathsf{Graph}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{Tree}^\uparrow}$, and $\mathsf{Real}^\uparrow$ rows, the assembled certificate has no entry point for the excluded host-level data. □

237.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{SpanningTree}^{\uparrow}}$.

Constructive story: A spanning-tree packet is read from the displayed graph and tree certificates by projecting vertex rows, graph-edge rows, tree-edge rows, incidence witnesses, root or root-free data, finite reachability routes, acyclicity evidence, and provenance. The classifier transports only those visible rows through hsame and the source certificate classifiers. In the weighted case, edge weights are read through displayed $\mathsf{Real}^{\uparrow}$ rows and finite summation ledgers over the chosen tree edges. The certificate therefore seeds the spanning-tree surface as a finite ledger package over $\mathsf{Graph}^{\uparrow}$, $\mathsf{Tree}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no hidden host graph, unlisted edge family, external minimizer, or infinite graph object.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SpanningTree}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The displayed $\mathsf{Graph}^{\uparrow}$, $\mathsf{Tree}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows, finite BHist edge and vertex ledgers, Cont reachability routes, hsame classifier transport, and Pkg provenance form the seeded paper scope.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SpanningTree}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SpanningTreeUp.SpanningTreeCarrier\_semantic\_name\_certificate`

Bridge status: none

Not claimed: Hidden graph equality, hidden edge sets, external minimizers, and infinite graph data are not claimed.

Upgrade path: Bridged closure requires a finite graph/tree bridge over edge-weight, summation-ledger, and $\mathsf{Real}^{\uparrow}$ consumer surfaces.

Chapter 238

A Concrete Naming Certificate for $\mathsf{SimplicialComplex}^{\uparrow}$

The simplicial-complex interface $\mathsf{SimplicialComplex}^{\uparrow}$ packages a finite collection of simplices closed under taking faces, with face-incidence and dimension-grading data. It depends on $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112) and $\mathsf{NameCert}_{\mathsf{Poset}^{\uparrow}}$ (chapter 53).

238.1 Carrier definition

238.2 The certificate

Definition 238.1 (SimplicialComplexUp finite face carrier)**.** *Fix a finite vertex source* $V : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_V$*. A* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carrier* K *over* $(V, \sim_V)$ *consists of a simplex-code source* $S_K : \mathsf{BHist} \to \mathsf{Prop}$ *with classifier* $\sim_K$*, a finite spine* $ks : \mathsf{HistSpine}$*, a carried-simplex predicate* $\mathsf{Simplex}_K : \mathsf{BHist} \to \mathsf{Prop}$*, a face-incidence relation*

$$\mathsf{Face}_K : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop},$$

and a dimension-grading row on carried simplices.

The finite-simplex row is

$$\mathsf{FinSetSpineEnumerates}_{S_K, \sim_K}(ks, \mathsf{Simplex}_K),$$

using the $\mathsf{FinSet}^{\uparrow}$ *enumeration predicate of Definition 112.17. The face-incidence row is the* $\mathsf{Poset}^{\uparrow}$ *relation on simplex codes supplied by Definition 53.2; in particular it includes the transitivity field*

$$\forall \rho\, \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Face}_K(\rho, \tau) \wedge \mathsf{Face}_K(\tau, \sigma) \to \mathsf{Face}_K(\rho, \sigma).$$

The simplicial closure row says that faces of carried simplices are carried:

$$\forall \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Simplex}_K(\sigma) \wedge \mathsf{Face}_K(\tau, \sigma) \to \mathsf{Simplex}_K(\tau).$$

Thus the carrier uses the finite inventory from chapter 112 and the transitive face-order row from chapter 53.

Lean4 (definition) `BEDC.Derived.SimplicialComplexUp.SimplicialComplexFiniteFaceCarrier`

Theorem 238.2 (Simplicial face-chain closure)**.** *Let K be a* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carrier over $(V, \sim_V)$ as in Definition 238.1. For histories $\rho, \tau, \sigma : \mathsf{BHist}$, if*

$$\mathsf{Simplex}_K(\sigma) \wedge \mathsf{Face}_K(\tau, \sigma) \wedge \mathsf{Face}_K(\rho, \tau),$$

then

$$\mathsf{Simplex}_K(\tau) \wedge \mathsf{Simplex}_K(\rho) \wedge \mathsf{Face}_K(\rho, \sigma).$$

In particular, a face of a face of a carried simplex is again carried by K and is a face of the original simplex.

```
Lean4 ✓  BEDC.Derived.SimplicialComplexUp.SimplicialComplexFace chain closure
  ↪variant  BEDC.Derived.SimplicialComplexUp.SimplicialFaceCarrier face chain closure
```

Proof. Unpack the carrier rows from Definition 238.1. The displayed hypotheses give the carried upper simplex $\mathsf{Simplex}_K(\sigma)$, the first face incidence $\mathsf{Face}_K(\tau, \sigma)$, and the second face incidence $\mathsf{Face}_K(\rho, \tau)$.

Apply the simplicial closure row to $\mathsf{Simplex}_K(\sigma)$ and $\mathsf{Face}_K(\tau, \sigma)$. This gives

$$\mathsf{Simplex}_K(\tau).$$

Apply the same closure row again to this carried simplex and $\mathsf{Face}_K(\rho, \tau)$. This gives

$$\mathsf{Simplex}_K(\rho).$$

The face-incidence relation is the $\mathsf{Poset}^{\uparrow}$ row of the carrier. Its transitivity field, cited in Definition 53.2, composes $\mathsf{Face}_K(\rho, \tau)$ with $\mathsf{Face}_K(\tau, \sigma)$ and yields

$$\mathsf{Face}_K(\rho, \sigma).$$

Combining the carried intermediate simplex, the carried lower simplex, and the composite face-incidence witness gives the displayed conjunction. □

Definition 238.3 (Simplicial face dimension grading row)**.** *Let K be a* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carrier over $(V, \sim_V)$ as in Definition 238.1. A face dimension grading row for K consists of a grading map*

$$\dim_K : \mathsf{BHist} \to \mathbb{N}$$

and the carried-face monotonicity field

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_K(\alpha) \wedge \mathsf{Simplex}_K(\beta) \wedge \mathsf{Face}_K(\alpha, \beta) \to \dim_K(\alpha) \leq \dim_K(\beta).$$

Thus the dimension comparison is asserted on the carried endpoints of the face relation supplied by the $\mathsf{Poset}^{\uparrow}$ *row.*

Theorem 238.4 (Simplicial face-chain dimension monotonicity)**.** *Let K be a* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carrier over $(V, \sim_V)$ as in Definition 238.1, equipped with a face dimension grading row $\dim_K$ in the sense of Definition 238.3. For histories $\rho, \tau, \sigma : \mathsf{BHist}$, if*

$$\mathsf{Simplex}_K(\sigma) \wedge \mathsf{Face}_K(\rho, \tau) \wedge \mathsf{Face}_K(\tau, \sigma),$$

then

$$\dim_K(\rho) \leq \dim_K(\tau) \wedge \dim_K(\tau) \leq \dim_K(\sigma) \wedge \dim_K(\rho) \leq \dim_K(\sigma).$$

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexFace dimension chain monotonicity`

Proof. Unpack the displayed hypothesis. Apply Definition 238.2, whose proof uses the simplicial closure row of Definition 238.1 and the transitive $\mathsf{Poset}^{\uparrow}$ face row of Definition 53.2. This gives

$$\mathsf{Simplex}_K(\tau) \wedge \mathsf{Simplex}_K(\rho) \wedge \mathsf{Face}_K(\rho, \sigma).$$

Apply the carried-face monotonicity field of Definition 238.3 to ρ and τ, using $\mathsf{Simplex}_K(\rho)$, $\mathsf{Simplex}_K(\tau)$, and $\mathsf{Face}_K(\rho, \tau)$. This yields

$$\dim_K(\rho) \leq \dim_K(\tau).$$

Apply the same field to τ and σ, using $\mathsf{Simplex}_K(\tau)$, $\mathsf{Simplex}_K(\sigma)$, and $\mathsf{Face}_K(\tau, \sigma)$. This yields

$$\dim_K(\tau) \leq \dim_K(\sigma).$$

Finally apply the same field to the composite face incidence $\mathsf{Face}_K(\rho, \sigma)$ together with the carried endpoints $\mathsf{Simplex}_K(\rho)$ and $\mathsf{Simplex}_K(\sigma)$. This yields

$$\dim_K(\rho) \leq \dim_K(\sigma).$$

The three displayed comparisons are exactly the claimed conjunction. □

Definition 238.5 (Simplicial intersection carrier rows)**.** *Let K and L be $\mathsf{SimplicialComplex}^{\uparrow}$ finite face carriers over the same finite vertex source $(V, \sim_V)$ as in Definition 238.1. Assume that both carriers use the same simplex-code source $S : \mathsf{BHist} \to \mathsf{Prop}$ with classifier $\sim_S$, and that their face-incidence rows are read through one displayed relation*

$$\mathsf{Face} : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop}.$$

The simplicial intersection predicate is

$$\mathsf{Simplex}_{K \cap L}(z) := \mathsf{Simplex}_K(z) \wedge \mathsf{Simplex}_L(z).$$

For a finite spine $js : \mathsf{HistSpine}$, the finite enumeration row for the intersection is

$$\mathsf{FinSetSpineEnumerates}_{S, \sim_S}(js, \mathsf{Simplex}_{K \cap L}),$$

in the sense of Definition 112.17. The inherited face relation is

$$\mathsf{Face}_{K \cap L}(\rho, \sigma) := \mathsf{Face}(\rho, \sigma).$$

Lean4 (definition) `BEDC.Derived.SimplicialComplexUp.SimplicialComplexIntersectionCarrier`

Theorem 238.6 (Simplicial intersection carrier is face closed)**.** *Let K and L share the simplex-code source, classifier, and face relation as in Definition 238.5. Let $js : \mathsf{HistSpine}$ satisfy*

$$\mathsf{FinSetSpineEnumerates}_{S, \sim_S}(js, \mathsf{Simplex}_{K \cap L}).$$

Then the intersection rows carry the finite enumeration, face closure, and inherited face transitivity:

$$\mathsf{FinSetSpineEnumerates}_{S, \sim_S}(js, \mathsf{Simplex}_{K \cap L}),$$

$$\forall \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Simplex}_{K \cap L}(\sigma) \wedge \mathsf{Face}_{K \cap L}(\tau, \sigma) \to \mathsf{Simplex}_{K \cap L}(\tau),$$

and

$$\forall \rho\, \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Face}_{K \cap L}(\rho, \tau) \wedge \mathsf{Face}_{K \cap L}(\tau, \sigma) \to \mathsf{Face}_{K \cap L}(\rho, \sigma).$$

Moreover, every two-step face chain in the intersection satisfies

$$\mathsf{Simplex}_{K \cap L}(\sigma) \wedge \mathsf{Face}_{K \cap L}(\tau, \sigma) \wedge \mathsf{Face}_{K \cap L}(\rho, \tau) \to \mathsf{Simplex}_{K \cap L}(\tau) \wedge \mathsf{Simplex}_{K \cap L}(\rho) \wedge \mathsf{Face}_{K \cap L}(\rho, \sigma).$$

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexIntersectionCarrier face chain closure`

Proof. The finite-enumeration row is exactly the displayed hypothesis, with the predicate named in Definition 238.5 and the enumeration predicate supplied by Definition 112.17.

For face closure, fix $\tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cap L}(\sigma) \wedge \mathsf{Face}_{K\cap L}(\tau, \sigma).$$

Unfolding the intersection predicate gives $\mathsf{Simplex}_K(\sigma)$ and $\mathsf{Simplex}_L(\sigma)$, and unfolding the inherited relation gives $\mathsf{Face}(\tau, \sigma)$. The simplicial closure row of K from Definition 238.1 gives $\mathsf{Simplex}_K(\tau)$. The same closure row for L gives $\mathsf{Simplex}_L(\tau)$. Pairing these two conclusions folds back to

$$\mathsf{Simplex}_{K\cap L}(\tau).$$

For inherited face transitivity, fix $\rho, \tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Face}_{K\cap L}(\rho, \tau) \wedge \mathsf{Face}_{K\cap L}(\tau, \sigma).$$

Unfold the inherited relation to read these as $\mathsf{Face}(\rho, \tau)$ and $\mathsf{Face}(\tau, \sigma)$. The face-incidence row of K is the $\mathsf{Poset}^{\uparrow}$ relation row from Definition 53.2 packaged by Definition 238.1; its transitivity field composes the two displayed face incidences and yields $\mathsf{Face}(\rho, \sigma)$. Folding the inherited relation gives $\mathsf{Face}_{K\cap L}(\rho, \sigma)$.

For the two-step chain statement, start with the displayed chain hypothesis. The face-closure row just proved gives $\mathsf{Simplex}_{K\cap L}(\tau)$ from the upper face incidence. Applying the same row again to $\mathsf{Simplex}_{K\cap L}(\tau)$ and $\mathsf{Face}_{K\cap L}(\rho, \tau)$ gives $\mathsf{Simplex}_{K\cap L}(\rho)$. The inherited transitivity row gives $\mathsf{Face}_{K\cap L}(\rho, \sigma)$. Combining these three conclusions proves the final conjunction. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexIntersection face chain closure`

Theorem 238.7 (Simplicial intersection inherits face dimension grading)**.** *Let K and L be* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carriers over the same finite vertex source $(V, \sim_V)$, sharing the simplex-code source, classifier, and face relation as in Definition 238.5. Let $d : \mathsf{BHist} \to \mathbb{N}$ be a common face-dimension grading map: its K-row and L-row are*

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_K(\alpha) \wedge \mathsf{Simplex}_K(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \le d(\beta),$$

and

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_L(\alpha) \wedge \mathsf{Simplex}_L(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \le d(\beta).$$

Then the intersection predicate and inherited face relation satisfy the face-dimension grading row

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_{K\cap L}(\alpha) \wedge \mathsf{Simplex}_{K\cap L}(\beta) \wedge \mathsf{Face}_{K\cap L}(\alpha, \beta) \to d(\alpha) \le d(\beta).$$

Moreover, every two-step face chain in the intersection satisfies

$$\mathsf{Simplex}_{K\cap L}(\sigma) \wedge \mathsf{Face}_{K\cap L}(\tau, \sigma) \wedge \mathsf{Face}_{K\cap L}(\rho, \tau) \to d(\rho) \le d(\tau) \wedge d(\tau) \le d(\sigma) \wedge d(\rho) \le d(\sigma).$$

Proof. For the one-step grading row, fix histories $\alpha, \beta : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cap L}(\alpha) \wedge \mathsf{Simplex}_{K\cap L}(\beta) \wedge \mathsf{Face}_{K\cap L}(\alpha, \beta).$$

Unfolding the intersection predicate from Definition 238.5 gives $\mathsf{Simplex}_K(\alpha)$, $\mathsf{Simplex}_L(\alpha)$, $\mathsf{Simplex}_K(\beta)$, and $\mathsf{Simplex}_L(\beta)$. Unfolding the inherited face relation gives $\mathsf{Face}(\alpha, \beta)$. The K-row of the common grading map, which is the carried-face monotonicity field of Definition 238.3 read through the shared relation, gives

$$d(\alpha) \leq d(\beta).$$

The L-row applies to the same unfolded face incidence and the L-endpoints, giving the identical comparison for the same map d. Hence the displayed intersection row holds.

For the two-step assertion, fix $\rho, \tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cap L}(\sigma) \wedge \mathsf{Face}_{K\cap L}(\tau, \sigma) \wedge \mathsf{Face}_{K\cap L}(\rho, \tau).$$

Unfolding gives $\mathsf{Simplex}_K(\sigma)$ and $\mathsf{Simplex}_L(\sigma)$, together with $\mathsf{Face}(\tau, \sigma)$ and $\mathsf{Face}(\rho, \tau)$. The simplicial closure row of Definition 238.1 gives $\mathsf{Simplex}_K(\tau)$ and $\mathsf{Simplex}_L(\tau)$, hence $\mathsf{Simplex}_{K\cap L}(\tau)$. Applying the same closure rows to $\mathsf{Face}(\rho, \tau)$ gives $\mathsf{Simplex}_K(\rho)$ and $\mathsf{Simplex}_L(\rho)$, hence $\mathsf{Simplex}_{K\cap L}(\rho)$. The transitivity field of the shared $\mathsf{Poset}^{\uparrow}$ face row from Definition 53.2, packaged by Definition 238.1, composes $\mathsf{Face}(\rho, \tau)$ with $\mathsf{Face}(\tau, \sigma)$ and gives $\mathsf{Face}(\rho, \sigma)$, which folds back to $\mathsf{Face}_{K\cap L}(\rho, \sigma)$.

Apply the inherited one-step grading row to (ρ, τ), to (τ, σ), and to (ρ, σ). These three applications give

$$d(\rho) \leq d(\tau),$$

$$d(\tau) \leq d(\sigma),$$

and

$$d(\rho) \leq d(\sigma).$$

Combining the three comparisons gives the claimed chain conjunction. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexIntersection face dimension grading`

Definition 238.8 (Simplicial union carrier rows)**.** *Let K and L be* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carriers over the same finite vertex source $(V, \sim_V)$ as in Definition 238.1. Assume that both carriers use the same simplex-code source $S : \mathsf{BHist} \to \mathsf{Prop}$ with classifier $\sim_S$, and that their face-incidence rows are read through one displayed relation*

$$\mathsf{Face} : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop}.$$

The simplicial union predicate is

$$\mathsf{Simplex}_{K\cup L}(z) := \mathsf{Simplex}_K(z) \vee \mathsf{Simplex}_L(z).$$

For a finite spine $js : \mathsf{HistSpine}$, the finite enumeration row for the union is

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(js, \mathsf{Simplex}_{K\cup L}),$$

in the sense of Definition 112.17. The inherited face relation is

$$\mathsf{Face}_{K\cup L}(\rho, \sigma) := \mathsf{Face}(\rho, \sigma).$$

Theorem 238.9 (Simplicial union carrier is face closed)**.** *Let K and L share the simplex-code source, classifier, and face relation as in Definition 238.8. Let $js : \mathsf{HistSpine}$ satisfy*

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(js, \mathsf{Simplex}_{K\cup L}).$$

Then the union rows carry the finite enumeration, face closure, and inherited face transitivity:

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(js, \mathsf{Simplex}_{K\cup L}),$$

$$\forall \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Simplex}_{K\cup L}(\sigma) \wedge \mathsf{Face}_{K\cup L}(\tau,\sigma) \to \mathsf{Simplex}_{K\cup L}(\tau),$$

and

$$\forall \rho\, \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Face}_{K\cup L}(\rho,\tau) \wedge \mathsf{Face}_{K\cup L}(\tau,\sigma) \to \mathsf{Face}_{K\cup L}(\rho,\sigma).$$

Moreover, every two-step face chain in the union satisfies

$$\mathsf{Simplex}_{K\cup L}(\sigma) \wedge \mathsf{Face}_{K\cup L}(\tau,\sigma) \wedge \mathsf{Face}_{K\cup L}(\rho,\tau) \to \mathsf{Simplex}_{K\cup L}(\tau) \wedge \mathsf{Simplex}_{K\cup L}(\rho) \wedge \mathsf{Face}_{K\cup L}(\rho,\sigma).$$

Proof. The finite-enumeration row is exactly the displayed hypothesis, with the predicate named in Definition 238.8 and the enumeration predicate supplied by Definition 112.17.

For face closure, fix $\tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cup L}(\sigma) \wedge \mathsf{Face}_{K\cup L}(\tau,\sigma).$$

Unfolding the union predicate gives either $\mathsf{Simplex}_K(\sigma)$ or $\mathsf{Simplex}_L(\sigma)$, and unfolding the inherited relation gives $\mathsf{Face}(\tau,\sigma)$. In the K case, the simplicial closure row of Definition 238.1 gives $\mathsf{Simplex}_K(\tau)$, hence $\mathsf{Simplex}_{K\cup L}(\tau)$. In the L case, the same closure row for L gives $\mathsf{Simplex}_L(\tau)$, hence again $\mathsf{Simplex}_{K\cup L}(\tau)$.

For inherited face transitivity, fix $\rho, \tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Face}_{K\cup L}(\rho,\tau) \wedge \mathsf{Face}_{K\cup L}(\tau,\sigma).$$

Unfold the inherited relation to read these as $\mathsf{Face}(\rho,\tau)$ and $\mathsf{Face}(\tau,\sigma)$. The face-incidence row of K is the $\mathsf{Poset}^{\uparrow}$ relation row from Definition 53.2 packaged by Definition 238.1; its transitivity field composes the two displayed face incidences and yields $\mathsf{Face}(\rho,\sigma)$. Folding the inherited relation gives $\mathsf{Face}_{K\cup L}(\rho,\sigma)$.

For the two-step chain statement, start with the displayed chain hypothesis. The face-closure row just proved gives $\mathsf{Simplex}_{K\cup L}(\tau)$ from the upper face incidence. Applying the same row again to $\mathsf{Simplex}_{K\cup L}(\tau)$ and $\mathsf{Face}_{K\cup L}(\rho,\tau)$ gives $\mathsf{Simplex}_{K\cup L}(\rho)$. The inherited transitivity row gives $\mathsf{Face}_{K\cup L}(\rho,\sigma)$. Combining these three conclusions proves the final conjunction. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion face chain closure`

Theorem 238.10 (Simplicial union append enumeration)**.** *Let K and L share the simplex-code source and classifier used for the simplicial union predicate in Definition 238.8. Let ks, ls :* $\mathsf{HistSpine}$ *be finite BEDC-history spines. If*

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(ks, \mathsf{Simplex}_K) \qquad \textit{and} \qquad \mathsf{FinSetSpineEnumerates}_{S,\sim_S}(ls, \mathsf{Simplex}_L)$$

hold, then the appended spine enumerates the simplicial union predicate:

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(ks{+}{+}ls, \mathsf{Simplex}_{K\cup L}).$$

Proof. Apply Definition 112.19 with the shared simplex-code source S, classifier $\sim_S$, finite spines ks and ls, and predicates $\mathsf{Simplex}_K$ and $\mathsf{Simplex}_L$. The two displayed enumeration hypotheses are exactly its two inputs, so it gives

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(ks{+}{+}ls, \lambda z.\ \mathsf{Simplex}_K(z) \vee \mathsf{Simplex}_L(z)).$$

By Definition 238.8, the predicate on the right is precisely $\mathsf{Simplex}_{K\cup L}$. Rewriting the displayed conclusion by this definition gives

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(ks{+}{+}ls, \mathsf{Simplex}_{K\cup L}),$$

which is the claimed appended enumeration row. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion append enumeration`

Theorem 238.11 (Simplicial union inherits face dimension grading)**.** *Let K and L be* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carriers over the same finite vertex source $(V, \sim_V)$, sharing the simplex-code source, classifier, and face relation as in Definition 238.8. Let $d : \mathsf{BHist} \to \mathbb{N}$ be a common face-dimension grading map: its K-row and L-row are*

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_K(\alpha) \wedge \mathsf{Simplex}_K(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \le d(\beta),$$

and

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_L(\alpha) \wedge \mathsf{Simplex}_L(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \le d(\beta).$$

Then the union predicate and inherited face relation satisfy the face-dimension grading row

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_{K\cup L}(\alpha) \wedge \mathsf{Simplex}_{K\cup L}(\beta) \wedge \mathsf{Face}_{K\cup L}(\alpha, \beta) \to d(\alpha) \le d(\beta).$$

Moreover, every two-step face chain in the union satisfies

$$\mathsf{Simplex}_{K\cup L}(\sigma) \wedge \mathsf{Face}_{K\cup L}(\tau, \sigma) \wedge \mathsf{Face}_{K\cup L}(\rho, \tau) \to$$

$$d(\rho) \le d(\tau) \wedge d(\tau) \le d(\sigma) \wedge d(\rho) \le d(\sigma).$$

Proof. The face-closure and inherited-transitivity rows for the union surface are the rows isolated in Definition 238.9. For the grading comparison, keep the branch of the upper simplex visible.

For the one-step grading row, fix histories $\alpha, \beta : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cup L}(\alpha) \wedge \mathsf{Simplex}_{K\cup L}(\beta) \wedge \mathsf{Face}_{K\cup L}(\alpha, \beta).$$

Unfolding Definition 238.8 gives $\mathsf{Face}(\alpha, \beta)$ and a branch for the upper endpoint β. If $\mathsf{Simplex}_K(\beta)$ holds, the simplicial closure row of K from Definition 238.1 gives $\mathsf{Simplex}_K(\alpha)$ from $\mathsf{Face}(\alpha, \beta)$. The K-grading row then gives $d(\alpha) \le d(\beta)$. If $\mathsf{Simplex}_L(\beta)$ holds, the same argument with the closure row of L gives $\mathsf{Simplex}_L(\alpha)$, and the L-grading row gives $d(\alpha) \le d(\beta)$. Thus the displayed union grading row holds.

For the two-step chain statement, fix $\rho, \tau, \sigma : \mathsf{BHist}$ and assume

$$\mathsf{Simplex}_{K\cup L}(\sigma) \wedge \mathsf{Face}_{K\cup L}(\tau, \sigma) \wedge \mathsf{Face}_{K\cup L}(\rho, \tau).$$

Unfolding the inherited relation gives $\mathsf{Face}(\tau, \sigma)$ and $\mathsf{Face}(\rho, \tau)$. Case-analyze the upper simplex branch $\mathsf{Simplex}_{K\cup L}(\sigma)$.

If $\mathsf{Simplex}_K(\sigma)$ holds, the closure row of K gives $\mathsf{Simplex}_K(\tau)$, and applying it again gives $\mathsf{Simplex}_K(\rho)$. The transitivity field of the shared $\mathsf{Poset}^{\uparrow}$ face row from Definition 53.2, packaged by Definition 238.1, composes the two face incidences and gives $\mathsf{Face}(\rho, \sigma)$. Applying the K-grading row to (ρ, τ), (τ, σ), and (ρ, σ) gives

$$d(\rho) \le d(\tau),$$

$$d(\tau) \le d(\sigma),$$

and

$$d(\rho) \leq d(\sigma).$$

If $\mathsf{Simplex}_L(\sigma)$ holds, the identical branch argument using the closure row of L gives $\mathsf{Simplex}_L(\tau)$ and $\mathsf{Simplex}_L(\rho)$; the same shared transitivity field gives $\mathsf{Face}(\rho, \sigma)$; and the L-grading row applied to the same three face incidences gives the same three displayed comparisons. Combining the three comparisons in either upper branch proves the chain conjunction. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion face dimension grading`

Lemma 238.12 (Simplicial union finite face-closed carrier inherits face dimension grading)**.** *Let K and L be* $\mathsf{SimplicialComplex}^{\uparrow}$ *finite face carriers over the same finite vertex source $(V, \sim_V)$, sharing the simplex-code source, classifier, and face relation as in Definition 238.8. Let $d : \mathsf{BHist} \to \mathbb{N}$ be a common face-dimension grading map: its K-row and L-row are*

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_K(\alpha) \wedge \mathsf{Simplex}_K(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \leq d(\beta),$$

and

$$\forall \alpha\, \beta : \mathsf{BHist}.\ \mathsf{Simplex}_L(\alpha) \wedge \mathsf{Simplex}_L(\beta) \wedge \mathsf{Face}(\alpha, \beta) \to d(\alpha) \leq d(\beta).$$

Let js : $\mathsf{HistSpine}$ *satisfy*

$$\mathsf{FinSetSpineEnumerates}_{S,\sim_S}(js, \mathsf{Simplex}_{K \cup L}),$$

and assume face closure and inherited transitivity:

$$\forall \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Simplex}_{K \cup L}(\sigma) \wedge \mathsf{Face}_{K \cup L}(\tau, \sigma) \to \mathsf{Simplex}_{K \cup L}(\tau),$$

$$\forall \rho\, \tau\, \sigma : \mathsf{BHist}.\ \mathsf{Face}_{K \cup L}(\rho, \tau) \wedge \mathsf{Face}_{K \cup L}(\tau, \sigma) \to \mathsf{Face}_{K \cup L}(\rho, \sigma).$$

For histories α, β : BHist*, if*

$$\mathsf{Simplex}_{K \cup L}(\alpha) \wedge \mathsf{Simplex}_{K \cup L}(\beta) \wedge \mathsf{Face}_{K \cup L}(\alpha, \beta),$$

then

$$d(\alpha) \leq d(\beta).$$

Moreover, for histories ρ, τ, σ : BHist*, if*

$$\mathsf{Simplex}_{K \cup L}(\sigma) \wedge \mathsf{Face}_{K \cup L}(\tau, \sigma) \wedge \mathsf{Face}_{K \cup L}(\rho, \tau),$$

then

$$d(\rho) \leq d(\tau) \wedge d(\tau) \leq d(\sigma) \wedge d(\rho) \leq d(\sigma).$$

Proof. Apply Definition 238.11. Its one-step and two-step conclusions are exactly the two graded comparison claims for the union predicate and inherited face relation over the same shared carrier rows from Definition 238.8. The finite and face-closed hypotheses identify the finite face-closed context in which this application is intended, and therefore the two displayed implications are the target inequalities. □

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion face dimension grading rows`

Lean4 ✓ `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion face dimension grading surface`

Closure status for $\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}$.

Constructive story: A simplicial complex is generated from a finite simplex-code spine together with a face relation supplied by the $\mathsf{Poset}^{\uparrow}$ row and finite enumeration supplied by $\mathsf{FinSet}^{\uparrow}$. The carrier accepts simplex histories listed by the finite spine and closes downward along displayed face incidences, while a code outside the enumeration or a face relation without the shared poset transitivity row is not part of this seed surface. Two presentations are compared through the shared simplex-code classifier, inherited face relation, and common dimension-grading row, so intersections and unions are built by pointwise conjunction or disjunction of carried simplex predicates rather than by an external geometric realization. The source is the finite face carrier over a fixed vertex source, the pattern records face-chain closure, dimension monotonicity, intersection closure, union closure, appended finite enumeration, and union grading rows, and the ledger keeps simplex codes, finite spines, face incidences, branches, and grading comparisons visible. The name-certificate obligations at this seed level are visible in the same rows: an accepted finite carrier gives the inhabited surface, the shared classifiers provide reflexive, symmetric, and transitive comparison, and face-chain, union, and intersection closure repack transported faces back into carried simplices. A history h lies in the signature gap of a $\mathsf{SimplicialComplex}^{\uparrow}$ token p when the source-domain accepts its finite face carrier, the signature relation pairs it with an answer carrier and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h lists the same finite simplex inventory, face-chain closure, and dimension-grading data encoded by p. The chapter registers this finite face-poset construction under the name $\mathsf{SimplicialComplex}^{\uparrow}$; homology, geometric realization, a full public simplicial-complex object, and a standard bridge are not introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature $\mathsf{SimplicialComplex}^{\uparrow}$ surface is the finite face-poset union and dimension-grading consumer interface over the carried simplex codes, face incidences, finite spines, BHist, hsame, Pkg, and NameCert rows displayed in this chapter.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SimplicialComplexUp.SimplicialComplexUnion\_face\_dimension\_grading\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close a full public simplicial-complex object, homology, geometric realization, or standard bridge.

Upgrade path: Only Lean-side bridge checking remains beyond the mature finite face-poset union and dimension-grading consumer surface.

Chapter 239

A Concrete Naming Certificate for $\mathsf{PersistentHom}^{\uparrow}$

The persistent-homology interface $\mathsf{PersistentHom}^{\uparrow}$ packages the bigraded module of homology groups of a filtered simplicial complex together with the persistence-diagram / barcode summary. It depends on $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ (chapter 98) and $\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}$ (chapter 238).

239.1 Carrier definition

Theorem 239.1 (PersistentHomUp carrier obligation surface)**.** *An accepted* $\mathsf{PersistentHom}^{\uparrow}$ *row is a finite* BHist *filtration packet over a displayed* $\mathsf{SimplicialComplex}^{\uparrow}$ *carrier together with* $\mathsf{Homology}^{\uparrow}$ *rows for the filtration stages. Its visible data consist of the finite index spine, the simplicial-complex packet at each index, the boundary maps between adjacent stages, the homology rows read from those complexes, the persistence maps induced by the boundary ledger, and the* Pkg *provenance row binding all of these entries into one named packet.*

Proof. Inspect the accepted BHist packet. The carrier row contains only the finite filtration spine, the stagewise $\mathsf{SimplicialComplex}^{\uparrow}$ packets, the $\mathsf{Homology}^{\uparrow}$ readback rows, the displayed persistence-map routes, and their common provenance.

Each projected row is already a BEDC history component rather than an ambient topological object. The finite spine supplies the index boundary, the simplicial-complex rows supply the face carriers at each stage, and the homology rows supply the cycle-boundary readbacks.

Repacking these projections gives exactly the carrier obligation surface: a finite filtration packet whose accepted rows are the displayed histories and no additional geometric realization, chain-complex library, or barcode object. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier obligation surface`

Theorem 239.2 (PersistentHomUp filtration classifier stability)**.** *If two accepted* $\mathsf{PersistentHom}^{\uparrow}$ *packets are related by the displayed classifier, then transport along their* hsame *rows and* Cont *routes preserves the finite filtration-index rows, the stagewise* $\mathsf{SimplicialComplex}^{\uparrow}$ *rows, the* $\mathsf{Homology}^{\uparrow}$ *readback rows, the persistence maps between stages, and the shared* Pkg *provenance.*

Proof. Unpack the classifier as componentwise history comparison. Its index component is an hsame row on the finite filtration spine, so transported endpoints keep the same displayed index boundary.

For each carried index, the classifier also contains the transported $\mathsf{SimplicialComplex}^{\uparrow}$ and $\mathsf{Homology}^{\uparrow}$ rows. Their source certificates remain the same named rows after transport because the classifier stores the endpoint histories rather than replacing them by external complexes.

Finally, inspect the Cont routes and Pkg row. The route entries identify the persistence maps between the transported stage rows, while the provenance entry is carried unchanged as the common package witness. These projections are precisely the advertised stability clauses. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier classifier stability`

Theorem 239.3 (PersistentHomUp simplicial homology source boundary)**.** *A downstream consumer of an accepted* $\mathsf{PersistentHom}^{\uparrow}$ *row may read only the source certificates for the displayed* $\mathsf{SimplicialComplex}^{\uparrow}$ *stages, the source certificates for the displayed* $\mathsf{Homology}^{\uparrow}$ *rows, and the finite filtration ledger showing how those rows are ordered and connected. It cannot read an unstated complex, an unstated boundary quotient, or a barcode row outside the displayed ledger.*

Proof. Project the consumer interface from the accepted carrier. The only named source certificates in the packet are the $\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}$ rows for the stages and the $\mathsf{NameCert}_{\mathsf{Homology}^{\uparrow}}$ rows for the associated homology readbacks.

The filtration ledger supplies the order relation on the finite index spine and the Cont routes connecting adjacent stages. Therefore every consumer-visible map is traced through a displayed history row and its package provenance.

Any row not listed in those projections has no constructor in the accepted packet. It is therefore outside the source boundary for the $\mathsf{PersistentHom}^{\uparrow}$ interface. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier source boundary`

Theorem 239.4 (PersistentHomUp filtration ledger exactness)**.** *The filtration ledger of an accepted* $\mathsf{PersistentHom}^{\uparrow}$ *row exposes exactly the finite filtration indices, the boundary maps between adjacent stages, the* $\mathsf{Homology}^{\uparrow}$ *rows computed from the displayed* $\mathsf{SimplicialComplex}^{\uparrow}$ *stages, the barcode summary rows read from those persistence maps, the* Cont *routes that witness stage transport, and the* Pkg *provenance that binds the packet.*

Proof. Read the ledger by constructor inspection. Its index entries are the finite filtration spine, and its stage entries are the displayed simplicial-complex and homology histories attached to those indices.

The boundary-map and persistence-map rows are exactly the Cont entries whose endpoints are adjacent stage histories. The barcode summary rows are ledger summaries of those same routes, so they do not introduce a separate external barcode carrier.

The remaining displayed row is the Pkg provenance. Combining these projections gives both directions of exactness: every listed component is visible in the ledger, and every ledger component is one of the listed rows. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier ledger exactness`

Theorem 239.5 (PersistentHomUp local NameCert surface)**.** *The local* NameCert *obligation surface for* $\mathsf{PersistentHom}^{\uparrow}$ *is assembled from the finite filtration carrier, the filtration-classifier stability row, the simplicial and homology source boundary, and the filtration-ledger exactness row. Thus a local persistent-homology name certificate records a carried* BHist *packet, classifier transport by* hsame *and* Cont*, source readback through* $\mathsf{SimplicialComplex}^{\uparrow}$ *and* $\mathsf{Homology}^{\uparrow}$*, and package provenance through* Pkg*.*

Proof. Use Definition 239.1 for the carried packet. It supplies the finite filtration spine, stage rows, homology rows, persistence maps, and package provenance.

Use Definition 239.2 for classifier transport and Definition 239.3 for the consumer-visible source rows. These two projections give the hsame and Cont movement required by the local certificate.

Use Definition 239.4 for the ledger field. Repacking the carrier, classifier, source, ledger, and provenance rows into the NameCert template gives the local obligation surface and does not assert a separate Lean theorem or standard bridge. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier local namecert surface`

239.2 The certificate

Theorem 239.6 (PersistentHomUp empty filtration spine ledger collapse)**.** *Let P be an accepted* $\mathsf{PersistentHom}^{\uparrow}$ *packet. Suppose that the finite filtration-index spine of P is empty, in the sense that no displayed index entry of P is carried by that spine. Then the filtration ledger of P has no stagewise* $\mathsf{SimplicialComplex}^{\uparrow}$ *packet row, no stagewise* $\mathsf{Homology}^{\uparrow}$ *readback row, no adjacent-stage boundary-map row, no persistence-map row, and no barcode-summary row. Apart from the* Pkg *provenance row, every persistence-indexed ledger component of P is empty.*

Proof. Use Definition 239.1 to read the accepted carrier. Its visible non-provenance data are the finite index spine, the $\mathsf{SimplicialComplex}^{\uparrow}$ packet at each carried index, the boundary maps between adjacent stages, the $\mathsf{Homology}^{\uparrow}$ rows read from those displayed complexes, and the persistence maps induced by the boundary ledger.

Use Definition 239.4 for the ledger side. It says that the filtration ledger exposes exactly the finite filtration indices, the adjacent-stage boundary maps, the $\mathsf{Homology}^{\uparrow}$ rows computed from the displayed $\mathsf{SimplicialComplex}^{\uparrow}$ stages, the barcode summary rows read from the persistence maps, the Cont routes witnessing stage transport, and the Pkg provenance binding the packet.

If a stagewise $\mathsf{SimplicialComplex}^{\uparrow}$ packet row were present, the carrier description would attach it to a displayed filtration index. This contradicts emptiness of the index spine. A $\mathsf{Homology}^{\uparrow}$ readback row is computed from such a displayed stage, so it cannot occur either. An adjacent-stage boundary-map row has adjacent stage endpoints, hence displayed stage rows and their carried indices; these are absent. A persistence-map row is induced by that adjacent-stage boundary ledger, so it has no source row once the boundary-map rows are absent. Finally, every barcode-summary row is read from the persistence maps by ledger exactness, and therefore no barcode-summary row remains.

Thus all index-dependent filtration, stage, homology, persistence-map, and barcode entries are empty. The only row not eliminated by the empty-spine hypothesis is the package provenance row, which records that the accepted packet is named but supplies no additional persistence-indexed content. □

Lean4 ✓ `BEDC.Derived.PersistentHomUp.PersistentHomFiltrationCarrier empty spine ledger collapse`

Closure status for $\mathsf{NameCert}_{\mathsf{PersistentHom}^{\uparrow}}$**.**

Constructive story: A $\mathsf{PersistentHom}^{\uparrow}$ packet is generated from a finite BHist filtration spine, stagewise $\mathsf{SimplicialComplex}^{\uparrow}$ rows, $\mathsf{Homology}^{\uparrow}$ readback rows, displayed persistence-map routes, and a barcode-facing ledger. Each stage is read as a history component, and each adjacent map is replayed through Cont rather than imported from an ambient chain-complex library. The classifier transports the index spine, stage packets, homology rows, and persistence routes by componentwise hsame, while Pkg names the simplicial and homology dependencies. Empty-spine collapse is therefore a visible packet degeneration: all indexed rows disappear and only provenance remains.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PersistentHom}^{\uparrow}}, \mathsf{obligation})$

Scope closed: This chapter binds the filtration carrier obligation surface, classifier stability, source-boundary, barcode ledger obligation, and empty-spine ledger collapse for $\mathsf{PersistentHom}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PersistentHom}^{\uparrow}}, \text{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim geometric realization, quotient homology classes beyond the displayed rows, persistence stability over metric barcodes, or external barcode equality.

Upgrade path: Scoped closure requires binding the listed obligations to their kernel primitives and exposing the resulting verification target for $\mathsf{PersistentHom}^{\uparrow}$.

Chapter 240

A Concrete Naming Certificate for $\mathsf{Mapper}^{\uparrow}$

The Mapper interface $\mathsf{Mapper}^{\uparrow}$ packages, for a continuous function from a topological space to a parameter range, the simplicial-complex skeleton built from clusterings of preimages of a finite cover. It depends on $\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}$ (chapter 238) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88).

240.1 Carrier definition

Definition 240.1 (Mapper cover-preimage carrier)**.** *A* $\mathsf{Mapper}^{\uparrow}$ *carrier is a finite* BHist *packet consisting of a* $\mathsf{Topology}^{\uparrow}$ *open-cover row, displayed preimage rows for the cover elements, clustering ledger rows on those preimages, incidence rows recording when clusters meet, and a* $\mathsf{SimplicialComplex}^{\uparrow}$ *skeleton row whose simplices are read from the incidence ledger. The packet also carries the visible endpoint data and* hsame/Cont/Pkg *provenance for the cover, preimage, cluster, and simplex rows.*

The carrier is the finite cover-preimage packet. It contains no host clustering algorithm, no metric convergence assertion, no arbitrary compactness principle for open covers, and no standard bridge object.

Lean4 ✓ `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier source readback`

Theorem 240.2 (Mapper cluster classifier stability)**.** *Let two* $\mathsf{Mapper}^{\uparrow}$ *carrier packets have open-cover rows, displayed preimage rows, and clustering ledger rows related by displayed* hsame *classifiers. If the incidence rows and simplicial skeleton row are read only from those transported cover, preimage, and cluster rows, then the transported packet is again an accepted* $\mathsf{Mapper}^{\uparrow}$ *carrier with the same cluster-incidence shape.*

Lean4 ✓ `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier cluster classifier stability`

Proof. Project the $\mathsf{Topology}^{\uparrow}$ dependency certificate. It transports the open-cover row and the displayed preimage rows attached to the cover elements.

Transport the clustering ledger rows along the same endpoint comparisons. The cluster rows retain their source preimages because the preimage endpoints are part of the transported cover packet.

Replay the incidence ledger on the transported clusters. Since the simplicial skeleton row is read from incidence and simplex rows already in the finite packet, it repacks over the transported data with the same shape. □

Theorem 240.3 (Mapper simplicial ledger exactness)**.** *For every accepted* $\mathsf{Mapper}^{\uparrow}$ *carrier, the simplicial skeleton ledger exposes exactly the cover row, preimage rows, cluster rows, incidence rows, and simplex rows listed in the finite packet. It does not expose a host clustering algorithm, metric convergence theorem, arbitrary open-cover compactness principle, or standard bridge claim.*

Lean4 ✓ `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier simplicial ledger exactness`

Proof. Inspect the carrier of Definition 240.1. Its accepted rows are cover, preimage, cluster, incidence, and skeleton rows, with their displayed provenance.

Project the skeleton row through the $\mathsf{SimplicialComplex}^{\uparrow}$ dependency certificate. The simplices are exactly those read from the incidence rows already present in the packet.

Since the packet has no constructor for algorithmic clustering, metric limits, compactness, or a bridge object, none of those host claims is exported by the simplicial ledger. □

Theorem 240.4 (Mapper NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Mapper}^{\uparrow}}$ *surface consists of the cover-preimage carrier of Definition 240.1, the cluster classifier over displayed* $\mathsf{Topology}^{\uparrow}$ *rows, the stability clause of Definition 240.2, the simplicial ledger exactness clause of Definition 240.3, and the source coverage assertion that every accepted Mapper row is read from the finite cover, preimage, cluster, incidence, and simplex rows.*

Lean4 ✓ `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier namecert obligation surface`

Proof. Use the cover-preimage carrier as the source predicate. It lists precisely the rows that may enter the local naming certificate.

The classifier is the displayed comparison of cover, preimage, and cluster rows. Its transport obligation is Definition 240.2.

The ledger exactness and source coverage obligations are supplied by Definition 240.3 and the carrier definition. Together they expose the Mapper skeleton as a finite BEDC packet and rule out host analytic or algorithmic assertions. □

Theorem 240.5 (Mapper topology boundary exclusions)**.** *The* $\mathsf{Mapper}^{\uparrow}$ *boundary supplies only the BEDC cover-preimage and simplicial skeleton surface over* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{SimplicialComplex}^{\uparrow}}$*. It does not assert host clustering algorithms, metric convergence, arbitrary open-cover compactness, or standard bridge claims.*

Proof. Read the boundary through Definition 240.4. The exported data are the carrier, classifier, stability, skeleton ledger, exactness, and source coverage rows.

Each exported row factors through the finite carrier of Definition 240.1. That carrier records only cover, preimage, cluster, incidence, and simplex rows with their displayed provenance.

Therefore the topology boundary is exactly the stated BEDC packet and carries none of the excluded host claims. □

Lean4 ✓ `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier topology boundary exclusions`

Theorem 240.6 (Mapper public export)**.** *The cluster-classifier stability, simplicial-ledger exactness,* $\mathsf{NameCert}_{\mathsf{Mapper}^{\uparrow}}$ *obligation surface, and topology-boundary exclusions form the public* $\mathsf{Mapper}^{\uparrow}$ *export over the cover-preimage carrier rows.*

The export consists only of the finite cover, preimage, cluster, incidence, simplex, transport, continuation, provenance, and local naming rows. It does not export persistent-homology completeness, an analytic cover-refinement theorem, or a host topological quotient.

Proof. Project the finite carrier of Definition 240.1. Its rows are the cover, preimage, clustering, incidence, simplicial skeleton, transport, continuation, provenance, and local naming rows.

Apply Definition 240.2 and Definition 240.3. These identify the accepted cluster transport and the exact simplicial ledger available from the packet.

Use Definition 240.4 and Definition 240.5 to repack those rows as the public naming boundary. Since the four cited rows all project from the same finite carrier, the excluded completeness, analytic refinement, and quotient claims are not exported. □

240.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{Mapper}^{\uparrow}}$.

Constructive story: MapperUp is presented by the cover-preimage carrier, the topology cover row, the simplicial-complex ledger, hsame, Cont, and Pkg provenance. These rows record finite cover membership and simplicial incidence over BEDC histories only, so the chapter does not export a host cover object or a persistent-homology completeness theorem.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Mapper}^{\uparrow}}$, publicClosed)

Scope closed: Definition 240.6 binds the cover-preimage carrier, cluster classifier, simplicial ledger exactness, NameCert obligation surface, and topology-boundary exclusions over $\mathsf{Topology}^{\uparrow}$, $\mathsf{SimplicialComplex}^{\uparrow}$, BHist, hsame, Cont, and Pkg.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Mapper}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MapperUp.MapperCoverPreimageCarrier\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: The chapter does not close host covers, persistent-homology completeness, or standard bridge data.

Upgrade path: Bridged closure requires a standard $\mathsf{Mapper}^{\uparrow}$ bridge over the finite cover-preimage carrier and simplicial ledger.

Chapter 241

A Concrete Naming Certificate for $\mathsf{ErrorCode}^{\uparrow}$

The error-correcting-code interface $\mathsf{ErrorCode}^{\uparrow}$ packages a subset of $\mathbb{F}_q^n$ at minimum Hamming distance d together with encoder, syndrome, and decoder data correcting up to $\lfloor (d-1)/2 \rfloor$ errors. It depends on $\mathsf{NameCert}_{\mathsf{Field}^{\uparrow}}$ (chapter 45) and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47).

241.1 Carrier definition

241.2 The certificate

Definition 241.1 (ErrorCode minimum-distance decoding interface)**.** *An* $\mathsf{ErrorCode}^{\uparrow}$ *certificate over the field certificate of chapter 45 and the vector-space certificate of chapter 47 carries the following metric data. Its ambient words are histories of the certified vector space* $\mathbb{F}_q^n$*. It has a codeword predicate* $\mathsf{Code}_{\mathcal{C}}(x)$*, a code classifier* $\rho_{\mathcal{C}}(x, y)$ *on codeword histories, and a Hamming-distance row*

$$\Delta_{\mathcal{C}}(x, y) \in \mathbb{N}.$$

The Hamming row is symmetric and satisfies the triangle inequality on ambient word histories. The minimum-distance field for a positive natural number d *is recorded in the constructive direction*

$$\mathsf{Code}_{\mathcal{C}}(x) \wedge \mathsf{Code}_{\mathcal{C}}(y) \wedge \Delta_{\mathcal{C}}(x, y) < d \Longrightarrow \rho_{\mathcal{C}}(x, y).$$

The decoding-radius field records the natural number

$$t = \lfloor (d-1)/2 \rfloor.$$

A word r *is within decoding radius* t *of a codeword* c *when* $\Delta_{\mathcal{C}}(c, r) \leq t$*.*

Lean4 (definition) `BEDC.Derived.ErrorCodeUp.ErrorCodeMinimumDistanceInterface`

Lemma 241.2 (Half minimum-distance radius bound)**.** *Let* d *be a positive natural number and let* $t = \lfloor (d-1)/2 \rfloor$*. Then* $2t < d$*.*

Proof. The floor relation gives $t \leq (d-1)/2$. Multiplying by 2 gives $2t \leq d-1$. Positivity of d gives $d-1 < d$. Thus $2t < d$. □

Theorem 241.3 (ErrorCode unique decoding radius)**.** *Let $\mathcal{C}$ be an* $\mathsf{ErrorCode}^{\uparrow}$ *certificate with Hamming-distance row $\Delta_{\mathcal{C}}$, codeword predicate* $\mathsf{Code}_{\mathcal{C}}$*, code classifier $\rho_{\mathcal{C}}$, positive minimum distance d, and decoding radius $t = \lfloor (d-1)/2 \rfloor$ as in Definition 241.1. Let c_1, c_2, and r be ambient word histories. If* $\mathsf{Code}_{\mathcal{C}}(c_1)$*,* $\mathsf{Code}_{\mathcal{C}}(c_2)$*, and*

$$\Delta_{\mathcal{C}}(c_1, r) \leq t \quad \textit{and} \quad \Delta_{\mathcal{C}}(c_2, r) \leq t,$$

then c_1 and c_2 are code-classifier equal:

$$\rho_{\mathcal{C}}(c_1, c_2).$$

Lean4 ✓ `BEDC.Derived.ErrorCodeUp.ErrorCode unique decoding radius`

Proof. The Hamming triangle row gives

$$\Delta_{\mathcal{C}}(c_1, c_2) \leq \Delta_{\mathcal{C}}(c_1, r) + \Delta_{\mathcal{C}}(r, c_2).$$

By symmetry, $\Delta_{\mathcal{C}}(r, c_2) = \Delta_{\mathcal{C}}(c_2, r)$, so the two radius bounds give

$$\Delta_{\mathcal{C}}(c_1, c_2) \leq t + t = 2t.$$

By Definition 241.2, $2t < d$. Hence

$$\Delta_{\mathcal{C}}(c_1, c_2) < d.$$

The minimum-distance field in Definition 241.1 sends two carried codeword histories at Hamming distance below d to a code-classifier witness. Applying that field to the codeword witnesses for c_1 and c_2 yields $\rho_{\mathcal{C}}(c_1, c_2)$. □

Lean4 ✓ `BEDC.Derived.ErrorCodeUp.ErrorCodeMetricReceivedWithinZero unique decoding empty`
Lean4 ✓ `BEDC.Derived.ErrorCodeUp.ErrorCodeMinimumDistanceInterface unique decoding radius`
Lean4 ✓ `BEDC.Derived.ErrorCodeUp.ErrorCodeSingleton unique decoding radius`

Corollary 241.4 (ErrorCode smaller-radius uniqueness)**.** *Let $\mathcal{C}$ be an* $\mathsf{ErrorCode}^{\uparrow}$ *certificate with Hamming-distance row $\Delta_{\mathcal{C}}$, codeword predicate* $\mathsf{Code}_{\mathcal{C}}$*, code classifier $\rho_{\mathcal{C}}$, positive minimum distance d, and decoding radius $t = \lfloor (d-1)/2 \rfloor$ as in Definition 241.1. Let s be a natural number with $s \leq t$. For ambient word histories c_1, c_2, and r, suppose* $\mathsf{Code}_{\mathcal{C}}(c_1)$ *and* $\mathsf{Code}_{\mathcal{C}}(c_2)$*, and suppose*

$$\Delta_{\mathcal{C}}(c_1, r) \leq s \quad \textit{and} \quad \Delta_{\mathcal{C}}(c_2, r) \leq s.$$

Then c_1 and c_2 are code-classifier equal:

$$\rho_{\mathcal{C}}(c_1, c_2).$$

Proof. Transitivity of the natural-number order composes the first radius bound with $s \leq t$ and gives

$$\Delta_{\mathcal{C}}(c_1, r) \leq t.$$

The same order-transitivity step composes the second radius bound with $s \leq t$ and gives

$$\Delta_{\mathcal{C}}(c_2, r) \leq t.$$

The two codeword witnesses and these two enlarged radius bounds are exactly the hypotheses of Definition 241.3. Applying that theorem yields $\rho_{\mathcal{C}}(c_1, c_2)$. □

Lean4 ✓ `BEDC.Derived.ErrorCodeUp.ErrorCode smaller radius uniqueness`

Closure status for $\mathsf{NameCert}_{\mathsf{ErrorCode}^{\uparrow}}$.

Constructive story: An $\mathsf{ErrorCode}^{\uparrow}$ packet is generated from BHist word rows over the displayed field and vector-space certificates, a codeword predicate, a code classifier, a Hamming-distance row, and a decoding-radius ledger. The minimum-distance and radius comparisons are read as finite natural-history inequalities, and the decoding conclusion is a classifier row rather than a host codeword equality. Transport by hsame preserves the carried words, distance rows, and received-word witnesses, while Cont records the route from received data to the classifier conclusion and Pkg records the field and vector-space sources. The unique-decoding surface is therefore the finite minimum-distance packet.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ErrorCode}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the minimum-distance decoding interface, half-radius lemma, unique-decoding theorem, zero-radius specialization, and smaller-radius uniqueness for $\mathsf{ErrorCode}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ErrorCode}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim an encoder implementation, syndrome decoding algorithm, probabilistic channel model, host vector equality, or full coding-theory optimality.

Upgrade path: Obligation closure requires Lean encodings of the metric interface, radius arithmetic, classifier conclusion, and the displayed uniqueness variants.

Chapter 242

A Concrete Naming Certificate for $\mathsf{Hash}^{\uparrow}$

The hash-function interface $\mathsf{Hash}^{\uparrow}$ packages a deterministic finite-output map with collision-resistance, preimage-resistance, and second-preimage-resistance certificates against a bounded adversary. It depends on $\mathsf{NameCert}_{\mathsf{Func}^{\uparrow}}$ (chapter 132) and $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ (chapter 112).

242.1 Carrier definition

242.2 The certificate

Definition 242.1 (Hash evaluation and success transcripts)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate as in section 242.1 and section 242.2. Its carrier data consist of a message carrier $\mathsf{Msg}_{\mathcal{H}}$ with message classifier $\sigma_{\mathcal{H}}$, a finite digest carrier $\mathsf{Dig}_{\mathcal{H}}$ with digest classifier $\rho_{\mathcal{H}}$ from the finite-output $\mathsf{FinSet}^{\uparrow}$ presentation of chapter 112, and a deterministic function row supplied by the $\mathsf{Func}^{\uparrow}$ substrate of chapter 132. Write*

$$\mathsf{HashEval}_{\mathcal{H}}(m, d)$$

for the row witness that m is a carried message, d is a carried digest, and the hash row of $\mathcal{H}$ evaluates m to the digest representative d.

For message histories x and x', define successful second-preimage transcript by

$$\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x') \iff \exists d, d' : \mathsf{BHist}.\ \mathsf{HashEval}_{\mathcal{H}}(x, d) \wedge \mathsf{HashEval}_{\mathcal{H}}(x', d') \wedge \neg\sigma_{\mathcal{H}}(x, x') \wedge \rho_{\mathcal{H}}(d', d).$$

Define successful collision transcript for the ordered pair (x, x') by

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \iff \exists d, d' : \mathsf{BHist}.\ \mathsf{HashEval}_{\mathcal{H}}(x, d) \wedge \mathsf{HashEval}_{\mathcal{H}}(x', d') \wedge \neg\sigma_{\mathcal{H}}(x, x') \wedge \rho_{\mathcal{H}}(d, d').$$

The two predicates use the same evaluation row; the digest-classifier orientation is the only difference.

Lean4 (definition) `BEDC.Derived.HashUp.HashEvalTranscript`

Theorem 242.2 (Hash evaluation transcript determinacy)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose hash row is the deterministic $\mathsf{Func}^{\uparrow}$ row carried by the certificate and whose digest endpoint classifier is the finite-output classifier $\rho_{\mathcal{H}}$ supplied by the $\mathsf{FinSet}^{\uparrow}$ dependency. For any message history m and digest histories d and d', two carried evaluations over the same hash row determine the same digest class:*

$$\mathsf{HashEval}_{\mathcal{H}}(m, d) \wedge \mathsf{HashEval}_{\mathcal{H}}(m, d') \Longrightarrow \rho_{\mathcal{H}}(d, d').$$

Proof. Unfold the evaluation row of Definition 242.1. The two hypotheses expose the same carried message row m, the same deterministic $\mathsf{Func}^{\uparrow}$ function row, and two digest endpoint rows d and d' produced by that row.

Project determinacy from the $\mathsf{Func}^{\uparrow}$ certificate. Since both evaluations read the same input history through the same finite Cont ledger and the same Pkg provenance, the function-row determinacy comparison identifies the two produced endpoint histories at the digest boundary.

Now transport that endpoint comparison through the finite-output $\mathsf{FinSet}^{\uparrow}$ classifier. The digest carrier row of $\mathcal{H}$ is exactly the finite-output row named in Definition 242.1, so classifier transport yields $\rho_{\mathcal{H}}(d, d')$.

Repack the evidence without changing the transcript: the message row, digest endpoint rows, BHist witnesses, Cont readback, and Pkg provenance are the rows already carried by the two $\mathsf{HashEval}_{\mathcal{H}}$ hypotheses. □

Lean4 ✓ `BEDC.Derived.HashUp.HashEvalTranscript determinacy`

Theorem 242.3 (Hash second-preimage success induces collision)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose finite-output digest classifier is supplied by its $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ component. For message histories x and x', every successful second-preimage transcript for base message x and returned message x' induces a successful collision transcript for the ordered pair (x, x') over the same hash row:*

$$\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x').$$

Lean4 ✓ `BEDC.Derived.HashUp.HashSecondPreimageSuccess induces collision`

Proof. Unfold Definition 242.1. A second-preimage success transcript gives digest histories d and d' with the two evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x', d'),$$

the message distinction witness $\neg\sigma_{\mathcal{H}}(x, x')$, and the digest-classifier comparison $\rho_{\mathcal{H}}(d', d)$. The digest classifier is the classifier of the finite-output naming certificate from chapter 112, so the classifier-symmetry field of Definition 9.7 reverses the displayed comparison and gives

$$\rho_{\mathcal{H}}(d, d').$$

Using the same digest witnesses d, d', the same two evaluation row witnesses, and the same message distinction witness, this is exactly the collision predicate over the same $\mathsf{HashEval}_{\mathcal{H}}$ row in Definition 242.1. □

Theorem 242.4 (Hash collision success is symmetric)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose message classifier $\sigma_{\mathcal{H}}$ and finite-output digest classifier $\rho_{\mathcal{H}}$ have the classifier-symmetry fields supplied by their naming-certificate components. For message histories x and x', every successful collision transcript for the ordered pair (x, x') induces a successful collision transcript for the ordered pair (x', x) over the same hash-evaluation row:*

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x).$$

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionSuccess symmetric`

Proof. Unfold Definition 242.1. A collision transcript for (x, x') gives digest histories d and d' with evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x', d'),$$

the message distinction witness $\neg\sigma_{\mathcal{H}}(x, x')$, and the digest comparison $\rho_{\mathcal{H}}(d, d')$.

The digest-classifier symmetry field from Definition 9.7 reverses the digest comparison to

$$\rho_{\mathcal{H}}(d', d).$$

For the reversed message distinction, suppose $\sigma_{\mathcal{H}}(x', x)$ held. The message-classifier symmetry field would give $\sigma_{\mathcal{H}}(x, x')$, contradicting the displayed witness $\neg\sigma_{\mathcal{H}}(x, x')$. Hence

$$\neg\sigma_{\mathcal{H}}(x', x).$$

Using the swapped digest witnesses d' and d, the two original evaluation row witnesses read in the opposite order, the reversed message distinction, and the reversed digest comparison, the definition repacks exactly as $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x)$ over the same $\mathsf{HashEval}_{\mathcal{H}}$ row. □

Theorem 242.5 (Hash compression round carrier)**.** *Each hash evaluation transcript in Definition 242.1 is a* BHist *packet over the* $\mathsf{Func}^{\uparrow}$ *deterministic row, the message carrier, the finite digest carrier, the* Cont *readback row, and the* Pkg *provenance row. The transcript exports no separate host bitstring computation.*

Lean4 ✓ `BEDC.Derived.HashUp.HashEvalTranscript compression round carrier`

Proof. Unfold Definition 242.1. A row $\mathsf{HashEval}_{\mathcal{H}}(m, d)$ contains a carried message endpoint, a carried digest endpoint, and the hash-function row supplied by the $\mathsf{Func}^{\uparrow}$ substrate.

Project determinacy from Definition 242.2. The two digest rows produced by the same message and function row are compared only through the finite digest classifier inherited from $\mathsf{FinSet}^{\uparrow}$.

Finally read the evaluation route through the displayed Cont readback and Pkg provenance. Repacking these rows gives the compression-round carrier as a BEDC transcript rather than as an external bitstring computation. □

Theorem 242.6 (Hash digest classifier stability)**.** *Transporting digest endpoints by the finite-output* $\mathsf{FinSet}^{\uparrow}$ *digest classifier preserves* $\mathsf{HashEval}_{\mathcal{H}}$*,* $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}$*, and* $\mathsf{HashCollisionSuccess}_{\mathcal{H}}$*. The preservation is a classifier transport of digest rows, not an equality of host strings.*

Lean4 ✓ `BEDC.Derived.HashUp.HashEvalTranscript digest classifier stability`

Proof. Start with an evaluation transcript and a digest-classifier edge supplied by the finite-output $\mathsf{FinSet}^{\uparrow}$ certificate. The digest endpoint remains in the digest carrier, and the same $\mathsf{Func}^{\uparrow}$ row and message carrier row still witness the evaluation.

For second-preimage success, unfold Definition 242.1. The transported digest row replaces the original digest witness while the two evaluation rows and the message-distinction witness remain the same.

For collision success, use the same unpacking together with the digest-classifier symmetry used in Definition 242.4. Repacking the transported digest witnesses preserves the two success predicates through the classifier boundary. □

Theorem 242.7 (Hash collision ledger boundary)**.** *The collision, second-preimage, and preimage-resistance ledgers of a* $\mathsf{Hash}^{\uparrow}$ *certificate may read only message-carrier rows, digest-carrier rows, function determinacy rows, classifier comparisons, and bounded adversary transcripts. They may not read external probability spaces, host bitstring equality, or unrecorded randomness.*

Proof. Unfold the transcript definition of Definition 242.1. Collision and second-preimage success are built from two evaluation rows, one message-classifier distinction, and one digest-classifier comparison.

Apply Definition 242.3 and Definition 242.4. These theorem blocks use only the evaluation rows, classifier symmetry, function determinacy, and the existing transcript witnesses.

The bounded adversary surface therefore has no additional ledger row to consult. Repacking the available witnesses gives the stated boundary for collision, second-preimage, and preimage-resistance ledgers. □

Theorem 242.8 (Hash collision transcript symmetry)**.** *Let* $\mathcal{H}$ *be a* $\mathsf{Hash}^{\uparrow}$ *certificate whose message classifier* $\sigma_{\mathcal{H}}$ *and finite-output digest classifier* $\rho_{\mathcal{H}}$ *have the classifier-symmetry fields supplied by their naming-certificate components. For message histories* x *and* x'*, every successful collision transcript for the ordered pair* (x, x') *induces a successful collision transcript for the ordered pair* (x', x) *over the same two hash-evaluation rows:*

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x).$$

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionTranscript symmetric`

Proof. Unfold Definition 242.1. A collision transcript for (x, x') gives digest histories d and d' with evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x', d'),$$

the message distinction witness $\neg\sigma_{\mathcal{H}}(x, x')$, and the digest comparison $\rho_{\mathcal{H}}(d, d')$.

The digest-classifier symmetry field from Definition 9.7, applied through the finite-output $\mathsf{FinSet}^{\uparrow}$ component cited in chapter 112, reverses the digest comparison to

$$\rho_{\mathcal{H}}(d', d).$$

For the reversed message distinction, suppose $\sigma_{\mathcal{H}}(x', x)$ held. The message-classifier symmetry field from the same naming-certificate discipline would give $\sigma_{\mathcal{H}}(x, x')$, contradicting $\neg\sigma_{\mathcal{H}}(x, x')$. Hence

$$\neg\sigma_{\mathcal{H}}(x', x).$$

Using the swapped digest witnesses d' and d, the two original evaluation row witnesses read in the opposite order, the reversed message distinction, and the reversed digest comparison, the definition repacks exactly as $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x)$ over the same two $\mathsf{HashEval}_{\mathcal{H}}$ rows. □

Theorem 242.9 (Hash collision success induces reversed second-preimage)**.** *Let* $\mathcal{H}$ *be a* $\mathsf{Hash}^{\uparrow}$ *certificate whose message classifier* $\sigma_{\mathcal{H}}$ *has the classifier-symmetry field supplied by its naming-certificate component. For message histories* x *and* x'*, every successful collision transcript for the ordered pair* (x, x') *induces a successful second-preimage transcript for base message* x' *and returned message* x *over the same two hash-evaluation rows:*

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x', x).$$

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionSuccess induces reversed second preimage`

Proof. Unfold Definition 242.1. A collision transcript for (x, x') gives digest histories d and d' with the two evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x', d'),$$

the message distinction witness $\neg\sigma_{\mathcal{H}}(x, x')$, and the digest comparison

$$\rho_{\mathcal{H}}(d, d').$$

To build the second-preimage transcript for (x', x), take the digest witness for the base message x' to be d' and the digest witness for the returned message x to be d. The two displayed evaluation row witnesses then occur in the required reversed order, and the required digest condition is still

$$\rho_{\mathcal{H}}(d, d'),$$

which is the collision digest comparison itself.

It remains only to reverse the message distinction. Suppose $\sigma_{\mathcal{H}}(x', x)$ held. The message-classifier symmetry field from Definition 9.7 would give $\sigma_{\mathcal{H}}(x, x')$, contradicting $\neg\sigma_{\mathcal{H}}(x, x')$. Hence

$$\neg\sigma_{\mathcal{H}}(x', x).$$

Using the swapped digest witnesses d' and d, the same two hash-evaluation rows, the reversed message distinction, and the unchanged digest comparison, the definition repacks exactly as $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x', x)$. □

Definition 242.10 (Hash collision-freeness)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate as in section 242.1 and section 242.2. For histories x and x', define*

$$\mathsf{CollFreeH}_{\mathcal{H}}(x, x') \iff \neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x').$$

Lean4 (definition) `BEDC.Derived.HashUp.HashCollisionFree`

Theorem 242.11 (Hash collision-freeness excludes second-preimage success)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose finite-output digest classifier is supplied by its $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ component. For message histories x and x', if*

$$\mathsf{CollFreeH}_{\mathcal{H}}(x, x') \wedge \mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$$

holds, then

$$\bot.$$

Proof. Unfold $\mathsf{CollFreeH}_{\mathcal{H}}(x, x')$, so it is enough to show $\neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$. By Definition 242.3, the assumed second-preimage success gives

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x').$$

This directly contradicts the displayed collision-freeness hypothesis, so the conjunction is inconsistent. □

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionFree excludes second preimage success`

Theorem 242.12 (Hash collision-freeness is symmetric)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose message classifier $\sigma_{\mathcal{H}}$ and finite-output digest classifier $\rho_{\mathcal{H}}$ have the classifier-symmetry fields supplied by their naming-certificate components. For message histories x and x', if*

$$\mathsf{CollFreeH}_{\mathcal{H}}(x, x')$$

holds, then

$$\mathsf{CollFreeH}_{\mathcal{H}}(x', x).$$

Proof. Assume

$$\mathsf{CollFreeH}_{\mathcal{H}}(x, x').$$

By Definition 242.10, this means

$$\neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x').$$

To prove $\mathsf{CollFreeH}_{\mathcal{H}}(x', x)$, it is enough by Definition 242.10 to show

$$\neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x).$$

Suppose instead that

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x)$$

held. Then Definition 242.4, applied with the ordered pair (x', x) in place of (x, x'), gives

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x').$$

This contradicts the displayed collision-freeness hypothesis. Therefore

$$\neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x', x),$$

and another use of Definition 242.10 yields

$$\mathsf{CollFreeH}_{\mathcal{H}}(x', x).$$

□

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionFree symmetric`

Theorem 242.13 (Hash collision success is irreflexive on the message)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose message classifier $\sigma_{\mathcal{H}}$ carries the reflexivity field supplied by its naming-certificate component. For every message history x, if*

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x)$$

holds, then

$$\bot.$$

Proof. Unfold Definition 242.1. A collision transcript for the diagonal pair (x, x) gives digest histories d and d' with the two evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x, d'),$$

the message distinction witness

$$\neg\sigma_{\mathcal{H}}(x, x),$$

and the digest comparison

$$\rho_{\mathcal{H}}(d, d').$$

The first evaluation row already exhibits x as a carried message of $\mathcal{H}$. Since the message classifier is supplied by a naming certificate, the reflexivity field from Definition 9.7 therefore gives

$$\sigma_{\mathcal{H}}(x, x).$$

This contradicts the displayed witness $\neg\sigma_{\mathcal{H}}(x, x)$. Hence no diagonal collision-success transcript can exist, and the assumption implies $\bot$. □

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionSuccess irreflexive on message`

Theorem 242.14 (Hash collision success induces same-direction second-preimage)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose finite-output digest classifier $\rho_{\mathcal{H}}$ carries the classifier-symmetry field supplied by its $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ component. For message histories x and x', every successful collision transcript for the ordered pair (x, x') induces a successful second-preimage transcript with base message x and returned message x' over the same two hash-evaluation rows:*

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x').$$

Lean4 ✓ `BEDC.Derived.HashUp.HashCollisionSuccess induces same direction second preimage`

Proof. Unfold Definition 242.1. A collision transcript for (x, x') gives digest histories d and d' with evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x', d'),$$

the message distinction witness

$$\neg\sigma_{\mathcal{H}}(x, x'),$$

and the digest comparison

$$\rho_{\mathcal{H}}(d, d').$$

The digest classifier is the classifier of the finite-output naming certificate from chapter 112. Its classifier-symmetry field, as recorded in Definition 9.7, reverses the displayed digest comparison and gives

$$\rho_{\mathcal{H}}(d', d).$$

Keep the same digest witnesses d and d'. The two hash-evaluation rows and the message distinction witness already occur in the order required for a second-preimage transcript with base message x and returned message x', and the reversed digest comparison is exactly the second-preimage digest condition in Definition 242.1. Repacking these witnesses gives

$$\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x').$$

□

Theorem 242.15 (Hash resistance success boundary)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose finite-output digest classifier $\rho_{\mathcal{H}}$ and message classifier $\sigma_{\mathcal{H}}$ are symmetric classifier fields supplied by the naming-certificate components of the certificate. Assume the digest classifier has the symmetry*

field used by Definition 242.14. For message histories x and x', the two transcript predicates over the same two evaluation rows are equivalent:

$$\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$$

and

$$\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x') \Longrightarrow \mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x').$$

Thus collision-freeness and second-preimage resistance share the same transcript boundary under the BEDC classifiers.

Proof. For the forward direction, assume $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$. Apply Definition 242.3. It uses the same two $\mathsf{HashEval}_{\mathcal{H}}$ rows, the same message-classifier distinction, and the digest comparison already carried by the second-preimage transcript, so it returns $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$ without changing the transcript boundary.

For the reverse direction, assume $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$. Apply Definition 242.14. The only transport it needs is the finite-output digest-classifier symmetry field from the $\mathsf{NameCert}_{\mathsf{FinSet}^{\uparrow}}$ component, while the message classifier and the two evaluation rows remain the same ordered pair. This returns $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$.

The two implications identify the successful transcript boundary. Negating the collision side or the second-preimage side therefore excludes the same successful pair of BEDC evaluation rows under the certificate classifiers. □

Theorem 242.16 (Hash resistance negated boundary equivalence)**.** *Let $\mathcal{H}$ be a $\mathsf{Hash}^{\uparrow}$ certificate whose finite-output digest classifier $\rho_{\mathcal{H}}$ and message classifier $\sigma_{\mathcal{H}}$ are symmetric classifier fields supplied by the naming-certificate components of the certificate. Assume the digest classifier has the symmetry field used by Definition 242.14. For message histories x and x', collision-freeness for the ordered pair is equivalent to the negation of second-preimage success:*

$$\mathsf{CollFreeH}_{\mathcal{H}}(x, x') \Longleftrightarrow \neg\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x').$$

Proof. Unfold Definition 242.10. The displayed claim becomes the equivalence between $\neg\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x$ and $\neg\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$ under the same certificate hypotheses.

For the forward direction, assume $\mathsf{CollFreeH}_{\mathcal{H}}(x, x')$ and suppose $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$ held. By Definition 242.3, the second-preimage transcript induces $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$, contradicting the unfolded collision-freeness hypothesis.

For the reverse direction, assume $\neg\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$. To show $\mathsf{CollFreeH}_{\mathcal{H}}(x, x')$, unfold Definition 242.10 and suppose $\mathsf{HashCollisionSuccess}_{\mathcal{H}}(x, x')$ held. By Definition 242.14, that collision transcript induces $\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x')$, contradicting the assumed negation. □

Theorem 242.17 (Hash transcript predicate mature coverage)**.** *For a $\mathsf{Hash}^{\uparrow}$ certificate $\mathcal{H}$, evaluation, collision success, second-preimage success, collision-freeness, resistance success, irreflexivity, and negated-boundary reads are all projections of the displayed message carrier, finite digest carrier, deterministic function row, message and digest classifiers,* Cont *readback, and* Pkg *provenance.*

The mature transcript surface exports these predicate rows and no probabilistic adversary, host bitstring computation, external complexity assumption, or randomized oracle model.

Proof. The evaluation rows are fixed by the deterministic carrier and readback surface of Definition 242.2. Collision reads are bounded by Definition 242.7 and transported by Definition 242.4.

The second-preimage and collision boundaries are related by Definition 242.3 and Definition 242.14. Collision-freeness is the negated transcript predicate of Definition 242.10, and the shared resistance boundary is the surface of Definition 242.15.

The negated boundary is recorded by Definition 242.16, while Definition 242.18 excludes the diagonal second-preimage transcript from the same message classifier. These results mention only the displayed message rows, finite digest rows, deterministic function row, classifiers, continuation readback, and provenance, so the transcript predicates have no exported coordinate for external cryptographic or computational assumptions. □

Closure status for $\mathsf{NameCert}_{\mathsf{Hash}^\uparrow}$**.**

Constructive story: A hash certificate is generated by combining a message carrier, a finite digest carrier from $\mathsf{FinSet}^\uparrow$, and a deterministic function row supplied by $\mathsf{Func}^\uparrow$, then recording each evaluation as a visible transcript from message history to digest history. The carrier accepts evaluation, collision, second-preimage, and collision-freeness rows only when the message and digest endpoints are carried, the function row supplies the evaluation ledger, and the message and digest classifiers supply the distinction or equality comparisons; unrecorded randomness, host bitstrings, and probability spaces are excluded. Two transcripts are compared by the message classifier, the finite digest classifier, and the deterministic function row, so reversing a collision or translating a second preimage into a collision uses classifier symmetry rather than external string equality. The source is the displayed evaluation transcript surface, the pattern records evaluation determinacy, collision symmetry, second-preimage-to-collision implications, collision-freeness, irreflexivity on the message, and shared resistance boundaries, and the ledger keeps both evaluations, both digest endpoints, the message-distinction witness, digest comparison, Cont readback, and Pkg provenance visible. The five name-certificate obligations are supplied by accepted transcript rows for carrier witnesses, by the message and digest naming certificates for reflexivity, symmetry, and transitivity, and by classifier-stability rows showing that transported digest or message endpoints preserve the success predicates. A history h lies in the signature gap of a $\mathsf{Hash}^\uparrow$ token p when the source-domain accepts its evaluation or resistance transcript, the signature relation pairs it with an answer transcript and evidence ledger, and the token-introduction relation names that answer as p; concretely, p records the same carried messages, finite digests, evaluation rows, and collision or second-preimage boundary. The chapter registers this deterministic transcript construction under the name $\mathsf{Hash}^\uparrow$; cryptographic reductions, probabilistic adversary models, external complexity assumptions, and host bitstring computation are not introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Hash}^\uparrow}$, maturePackageClosed)

Scope closed: The mature surface binds the inherited $\mathsf{Func}^\uparrow$ and $\mathsf{FinSet}^\uparrow$ rows, message and digest classifiers, BHist evaluation rows, transcript predicates for collision and second-preimage success, collision-freeness, resistance, irreflexivity, and the negated-boundary coverage of Definition 242.17.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Hash}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.HashUp.HashCollisionFree\_excludes\_second\_preimage\_success`

Bridge status: paperBridge

Not claimed: The chapter does not close cryptographic security reductions, probabilistic adversary models, or external complexity assumptions.

Upgrade path: No further paper theory-axis upgrade is recorded for the deterministic transcript-predicate surface; bridgeChecked remains a separate formal-axis matter.

Theorem 242.18 (Hash second-preimage success is irreflexive on the message)**.** *Let $\mathcal{H}$ be a* $\mathsf{Hash}^\uparrow$ *certificate whose message classifier $\sigma_{\mathcal{H}}$ carries the reflexivity field supplied by its naming-certificate component. For every message history x, if*

$$\mathsf{HashSecondPreimageSuccess}_{\mathcal{H}}(x, x)$$

holds, then

$$\bot.$$

Lean4 ✓ `BEDC.Derived.HashUp.HashSecondPreimageSuccess irreflexive on message`

Proof. Unfold Definition 242.1. A second-preimage transcript for the diagonal pair (x, x) gives digest histories d and d' with the two evaluation row witnesses

$$\mathsf{HashEval}_{\mathcal{H}}(x, d) \qquad \text{and} \qquad \mathsf{HashEval}_{\mathcal{H}}(x, d'),$$

the message distinction witness

$$\neg\sigma_{\mathcal{H}}(x, x),$$

and the digest comparison

$$\rho_{\mathcal{H}}(d', d).$$

The first evaluation row exhibits x as a carried message of $\mathcal{H}$. Since the message classifier is supplied by a naming certificate, the reflexivity field from Definition 9.7 gives

$$\sigma_{\mathcal{H}}(x, x).$$

This contradicts the displayed witness $\neg\sigma_{\mathcal{H}}(x, x)$. Hence no diagonal second-preimage-success transcript can exist, and the assumption implies $\perp$. $\square$

Chapter 243

A Concrete Naming Certificate for $\mathsf{PublicKey}^{\uparrow}$

The public-key-cryptosystem interface $\mathsf{PublicKey}^{\uparrow}$ packages a key-generation, encryption, and decryption triple together with security reductions to a hardness assumption (factoring, discrete logarithm, lattice). It depends on $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168).

243.1 Carrier definition

243.2 The certificate

Definition 243.1 (PublicKey decrypt-encrypt transcript interface)**.** *Let $\mathcal{P}$ be a $\mathsf{PublicKey}^{\uparrow}$ certificate over the group-side naming certificate of chapter 41 and the number-field plaintext certificate of chapter 168. Write $\mathsf{Msg}_{\mathcal{P}}(m)$ for its plaintext carrier and $\mu_{\mathcal{P}}(m, m')$ for its plaintext classifier. The plaintext certificate is a carrier naming certificate in the sense of Definition 9.7; in the concrete rational number-field surface it is supplied by Definition 168.5.*

Write $\mathsf{Pub}_{\mathcal{P}}(pk)$, $\mathsf{Sec}_{\mathcal{P}}(sk)$, and $\mathsf{Ciph}_{\mathcal{P}}(c)$ for the public-key, secret-key, and ciphertext carrier rows. The group-side rows named by Definition 41.55 type the key-generation and encryption witnesses. Write

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk)$$

for the row witness that pk and sk are a generated public-key pair, write

$$\mathsf{PKEncrypt}_{\mathcal{P}}(pk, m, c)$$

for the row witness that c is the encryption transcript of plaintext m under public key pk, and write

$$\mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d)$$

for the row witness that secret key sk decrypts ciphertext c to plaintext endpoint d.

A certified encryption transcript is the predicate

$$\mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c) \iff \mathsf{Pub}_{\mathcal{P}}(pk) \wedge \mathsf{Msg}_{\mathcal{P}}(m) \wedge \mathsf{Ciph}_{\mathcal{P}}(c) \wedge \mathsf{PKEncrypt}_{\mathcal{P}}(pk, m, c).$$

The decrypt-encrypt exactness row of $\mathcal{P}$ is

$$\mathsf{PKDecryptEncryptExact}_{\mathcal{P}} \iff \forall pk, sk, m, c : \mathsf{BHist}.\ \mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \wedge \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c) \implies \exists d : \mathsf{BHist}.$$

Lean4 (definition) `BEDC.Derived.PublicKeyUp.PKCertifiedEnc`
Lean4 (definition) `BEDC.Derived.PublicKeyUp.PKDecryptEncryptExact`

Theorem 243.2 (PublicKey decrypt-encrypt correctness)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1, and assume* $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$*. For histories pk, sk, m, and c, if*

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \qquad \textit{and} \qquad \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c),$$

then decrypting c with sk returns a carried plaintext endpoint in the message-classifier class of m:

$$\exists d : \mathsf{BHist}.\ \mathsf{Msg}_{\mathcal{P}}(d) \wedge \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d) \wedge \mu_{\mathcal{P}}(d, m).$$

Lean4 ✓ `BEDC.Derived.PublicKeyUp.PublicKeyDecryptEncrypt correctness`

Proof. Unfold Definition 243.1 only as far as the certified-encryption predicate and the decrypt-encrypt exactness row. The certified-encryption hypothesis gives the carried plaintext fact $\mathsf{Msg}_{\mathcal{P}}(m)$ together with the encryption transcript under pk.

Apply $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$ to the generated keypair row and the certified-encryption transcript. This gives a history d with

$$\mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d) \qquad \text{and} \qquad \mu_{\mathcal{P}}(d, m).$$

The plaintext classifier is supplied by a carrier naming certificate. Its symmetry field reverses $\mu_{\mathcal{P}}(d, m)$ to $\mu_{\mathcal{P}}(m, d)$, and its carrier-transport field carries $\mathsf{Msg}_{\mathcal{P}}(m)$ along that comparison to obtain $\mathsf{Msg}_{\mathcal{P}}(d)$.

Using the same witness d, the carried plaintext fact, the decryption row, and the classifier comparison prove the displayed existential statement. □

Lean4 ✓ `BEDC.Derived.PublicKeyUp.PublicKey decrypt encrypt correctness`

Definition 243.3 (PublicKey decryption output determinacy row)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1. The decrypt-output determinacy row of $\mathcal{P}$ is the predicate*

$$\mathsf{PKDecryptOutputDet}_{\mathcal{P}} \iff \forall pk, sk, c, d_1, d_2 : \mathsf{BHist}.\ \mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \wedge \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d_1) \wedge \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c$$

It records that decryption for a generated secret key and a fixed ciphertext has a plaintext endpoint determined up to the plaintext classifier of the certificate.

Lean4 (definition) `BEDC.Derived.PublicKeyUp.PKDecryptOutputDetRow`

Theorem 243.4 (PublicKey decryption output determinacy)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1, and assume* $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$*. For histories pk, sk, c, d_1, and d_2, if*

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \qquad \textit{and} \qquad \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d_1) \qquad \textit{and} \qquad \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d_2),$$

then the two decryption endpoints are plaintext-classifier equal:

$$\mu_{\mathcal{P}}(d_1, d_2).$$

Proof. By Definition 243.3, the row $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$ is the universal BEDC-history statement that any two decryption endpoints for the same generated keypair row and ciphertext are related by $\mu_{\mathcal{P}}$. Instantiate that universal statement at the displayed histories pk, sk, c, d_1, and d_2. The three hypotheses are exactly its antecedent, so the instantiated implication gives $\mu_{\mathcal{P}}(d_1, d_2)$. □

Theorem 243.5 (PublicKey certified encryption arbitrary decryption)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1. Assume* $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$ *and* $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$*. For histories pk, sk, m, c, and d, if*

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \quad \textit{and} \quad \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c) \quad \textit{and} \quad \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d),$$

then the displayed decryption endpoint is carried by the plaintext carrier and lies in the message-classifier class of m:

$$\mathsf{Msg}_{\mathcal{P}}(d) \wedge \mu_{\mathcal{P}}(d, m).$$

Proof. Apply Definition 243.2 to $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$, the generated keypair row, and the certified encryption transcript. This gives a history $e : \mathsf{BHist}$ with

$$\mathsf{Msg}_{\mathcal{P}}(e) \wedge \mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, e) \wedge \mu_{\mathcal{P}}(e, m).$$

Apply Definition 243.4 to $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$, the same generated keypair row, the displayed decryption row for d, and the decryption row for e. This yields

$$\mu_{\mathcal{P}}(d, e).$$

The plaintext classifier of $\mathcal{P}$ is supplied by a carrier naming certificate in the sense of Definition 9.7; in the concrete rational number-field surface this is the certificate cited in Definition 168.5. Its transitivity field, equivalently Definition 9.8, composes $\mu_{\mathcal{P}}(d, e)$ with $\mu_{\mathcal{P}}(e, m)$ and gives

$$\mu_{\mathcal{P}}(d, m).$$

It remains only to record carrier membership for the arbitrary endpoint. Unfolding $\mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c)$ through Definition 243.1 gives $\mathsf{Msg}_{\mathcal{P}}(m)$. The classifier symmetry field from the same carrier naming certificate reverses $\mu_{\mathcal{P}}(d, m)$ to $\mu_{\mathcal{P}}(m, d)$, and its carrier-transport field carries $\mathsf{Msg}_{\mathcal{P}}(m)$ along that comparison to obtain $\mathsf{Msg}_{\mathcal{P}}(d)$. Pairing this carrier fact with $\mu_{\mathcal{P}}(d, m)$ proves the claim. □

Lean4 ✓ `BEDC.Derived.PublicKeyUp.PublicKeyCertifiedEncryption arbitrary decryption`

Theorem 243.6 (PublicKey certified ciphertext plaintext uniqueness)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1, and assume* $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$ *and* $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$*. For histories pk, sk, m, n, and c, if*

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk) \quad \textit{and} \quad \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c) \quad \textit{and} \quad \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, n, c),$$

then the two certified plaintext endpoints are classifier-equal:

$$\mu_{\mathcal{P}}(m, n).$$

Proof. Apply Definition 243.2 to $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$, the generated keypair row, and the first certified-encryption hypothesis. This gives a history $d : \mathsf{BHist}$ with

$$\mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, d) \wedge \mu_{\mathcal{P}}(d, m).$$

Apply the same theorem to the second certified-encryption hypothesis to obtain $e : \mathsf{BHist}$ with

$$\mathsf{PKDecrypt}_{\mathcal{P}}(sk, c, e) \wedge \mu_{\mathcal{P}}(e, n).$$

Apply Definition 243.4 to $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$, the generated keypair row, and the two decrypt rows. This yields

$$\mu_{\mathcal{P}}(d, e).$$

By the symmetry field of Definition 9.7, reverse $\mu_{\mathcal{P}}(d, m)$ to get $\mu_{\mathcal{P}}(m, d)$.

Compose $\mu_{\mathcal{P}}(m, d)$ with $\mu_{\mathcal{P}}(d, e)$ using Definition 9.8 to obtain

$$\mu_{\mathcal{P}}(m, e).$$

Then compose $\mu_{\mathcal{P}}(m, e)$ with $\mu_{\mathcal{P}}(e, n)$, again by Definition 9.8, to conclude

$$\mu_{\mathcal{P}}(m, n).$$

□

Lean4 ✓ `BEDC.Derived.PublicKeyUp.PublicKeyCertifiedCiphertext plaintext uniqueness`

Theorem 243.7 (PublicKey shared-public-key decryption consistency)**.** *Let $\mathcal{P}$ be a* $\mathsf{PublicKey}^{\uparrow}$ *certificate with transcript rows as in Definition 243.1, and assume* $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$ *and* $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$*. For histories pk, sk_1, sk_2, m, c, d_1, and d_2, if*

$$\mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk_1) \quad \textit{and} \quad \mathsf{PKKeyGen}_{\mathcal{P}}(pk, sk_2) \quad \textit{and} \quad \mathsf{PKCertifiedEnc}_{\mathcal{P}}(pk, m, c),$$

and if

$$\mathsf{PKDecrypt}_{\mathcal{P}}(sk_1, c, d_1) \quad \textit{and} \quad \mathsf{PKDecrypt}_{\mathcal{P}}(sk_2, c, d_2),$$

then the two decryption endpoints are in the same plaintext classifier class:

$$\mu_{\mathcal{P}}(d_1, d_2).$$

Lean4 ✓ `BEDC.Derived.PublicKeyUp.PublicKeySharedPublicKey decryption consistency`

Proof. Apply Definition 243.5 to $\mathsf{PKDecryptEncryptExact}_{\mathcal{P}}$, $\mathsf{PKDecryptOutputDet}_{\mathcal{P}}$, the first generated keypair row, the certified encryption transcript, and the displayed decryption row for d_1. This gives

$$\mathsf{Msg}_{\mathcal{P}}(d_1) \wedge \mu_{\mathcal{P}}(d_1, m).$$

Apply the same theorem to the second generated keypair row, the same certified encryption transcript, and the displayed decryption row for d_2. This gives

$$\mathsf{Msg}_{\mathcal{P}}(d_2) \wedge \mu_{\mathcal{P}}(d_2, m).$$

The plaintext classifier of $\mathcal{P}$ is supplied by the carrier naming certificate recorded in Definition 243.1, hence by Definition 9.7. Use its symmetry field on $\mu_{\mathcal{P}}(d_2, m)$ to obtain

$$\mu_{\mathcal{P}}(m, d_2).$$

Classifier transitivity, equivalently Definition 9.8, composes $\mu_{\mathcal{P}}(d_1, m)$ with $\mu_{\mathcal{P}}(m, d_2)$ and yields

$$\mu_{\mathcal{P}}(d_1, d_2).$$

□

Closure status for $\mathsf{NameCert}_{\mathsf{PublicKey}^{\uparrow}}$.

Constructive story: A $\mathsf{PublicKey}^{\uparrow}$ packet is generated from finite BHist rows for public keys, secret keys, plaintexts, ciphertexts, encryption transcripts, decryption transcripts, and the plaintext classifier inherited from the number-field source. Correctness is read bottom-up: key generation and certified encryption expose displayed rows, Cont routes the decryption endpoint, and the result is compared by the carried classifier rather than by host message equality. Componentwise hsame transports key, ciphertext, plaintext, and transcript rows, while Pkg records the group and number-field dependencies. The security-facing surface remains a finite transcript certificate, not a cryptographic hardness theorem.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PublicKey}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the decrypt-encrypt transcript interface, decrypt-encrypt correctness, and classifier-facing stability results for $\mathsf{PublicKey}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PublicKey}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim semantic security, hardness reductions, randomness soundness, host plaintext equality, or a concrete encryption implementation.

Upgrade path: Obligation closure requires Lean encodings of the transcript carrier, decrypt-encrypt exactness row, and classifier transport for decrypted endpoints.

Chapter 244

A Concrete Naming Certificate for $\mathsf{ZeroKnowledge}^{\uparrow}$

The zero-knowledge-proof interface $\mathsf{ZeroKnowledge}^{\uparrow}$ packages an interactive prover-verifier protocol that is complete, sound, and simulation-paradigm zero-knowledge. It depends on $\mathsf{NameCert}_{\mathsf{Hash}^{\uparrow}}$ (chapter 242) and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

244.1 Carrier definition

A $\mathsf{ZeroKnowledge}^{\uparrow}$ carrier is a finite BHist packet. It displays a prover row P, a verifier row V, a challenge transcript row c, a response transcript row r, a hash commitment row k, a computable verifier row q, a simulator transcript row s, and an evidence ledger row ℓ. The hash row is sourced from $\mathsf{NameCert}_{\mathsf{Hash}^{\uparrow}}$ and the computable verifier row is sourced from $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ through the packet provenance Pkg; neither dependency is read through host bitstrings, probability spaces, or external machines.

The classifier compares two accepted packets only through displayed hsame rows: prover with prover, verifier with verifier, challenge transcript with challenge transcript, response transcript with response transcript, commitment with commitment, computable-verifier row with computable-verifier row, simulator transcript with simulator transcript, and ledger with ledger. The continuation ledger Cont records the transcript routes from prover and verifier to challenge, from challenge and prover to response, from response and hash source to commitment, from challenge and computable verifier to acceptance, from simulator and verifier to simulated transcript, and from the visible transcript rows to the evidence ledger.

244.2 The certificate

Theorem 244.1 (ZeroKnowledgeUp carrier obligation)**.** *For a* $\mathsf{ZeroKnowledge}^{\uparrow}$ *packet with displayed rows* P*,* V*,* c*,* r*,* k*,* q*,* s*, and* ℓ*, the carrier obligation is exactly the finite* BHist *surface consisting of the prover row, verifier row, challenge transcript row, response transcript row, hash commitment row, computable verifier row, simulator transcript row, the* Cont *transcript routes among those rows, and the* Pkg *provenance rows naming the consumed* $\mathsf{Hash}^{\uparrow}$ *and* $\mathsf{Computable}^{\uparrow}$ *certificates. No cryptographic hardness predicate, negligible bound, host randomness source, or external protocol machine is part of this carrier.*

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeCarrier obligation`

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeFinitePacket carrier obligation`

Proof. Project the packet to its displayed histories. The prover, verifier, challenge, response, commitment, computable-verifier, simulator, and evidence rows are the only carrier coordinates.

Next project the continuation evidence. Each visible read is one of the listed Cont routes, and each dependency read is one of the two Pkg provenance rows. Repacking those projections gives the same finite carrier surface, so no unlisted host object is available to the carrier. □

Theorem 244.2 (ZeroKnowledgeUp classifier obligation)**.** *Two accepted* ZeroKnowledge$^{\uparrow}$ *packets classify together only when their prover rows, verifier rows, challenge transcript rows, response transcript rows, hash commitment rows, computable verifier rows, simulator transcript rows, continuation ledgers, and package provenance rows are related by the displayed componentwise* hsame *comparisons. The classifier does not compare hidden witnesses, probability distributions, bitstring encodings, or machine implementations outside the accepted* BHist *packet.*

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeCarrier classifier obligation`

Proof. Read the classifier by projection to the accepted packet coordinates. Each coordinate has a named hsame comparison row, and the dependency rows are compared through the same Pkg provenance that supplied Hash$^{\uparrow}$ and Computable$^{\uparrow}$.

For reflexivity, symmetry, and transitivity, apply the corresponding hsame operation componentwise to the displayed rows. The continuation and provenance rows are then repacked with those transported coordinates, giving a classifier on accepted packets and nothing beyond them. □

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgePacket classifier transport`

Theorem 244.3 (ZeroKnowledgeUp completeness ledger obligation)**.** *The completeness ledger of a* ZeroKnowledge$^{\uparrow}$ *packet is a BEDC obligation over the displayed prover row P, verifier row V, challenge row c, response row r, computable verifier row q, transcript continuation rows, and provenance rows for* Hash$^{\uparrow}$ *and* Computable$^{\uparrow}$*. It states only that the accepted transcript route records a verifier-acceptance row in the packet ledger; it does not assert a probability of acceptance or a completeness error bound.*

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeFiniteCarrier completeness ledger obligation`

Proof. Project the completeness evidence to the transcript route from prover and verifier into challenge, then from challenge and prover into response. The computable verifier row reads that response through the displayed Cont evidence.

The verifier-acceptance row is then packed into the ledger ℓ together with the dependency provenance. Since every object used in this packing is one of the carrier rows of Definition 244.1, the completeness ledger is a finite BEDC row statement rather than a probabilistic claim. □

Theorem 244.4 (ZeroKnowledgeUp soundness ledger obligation)**.** *The soundness ledger of a* ZeroKnowledge$^{\uparrow}$ *packet is a finite BEDC obligation over challenge rows, response rows, hash commitment rows, computable verifier rows,* hsame *comparisons,* Cont *transcript routes, and* Pkg *provenance for* Hash$^{\uparrow}$ *and* Computable$^{\uparrow}$*. It records only the visible rows needed to compare an accepting transcript with the commitment and verifier rows; it does not claim cryptographic hardness, extractor existence, or a negligible cheating bound.*

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeCarrier soundness ledger obligation`

Proof. First project the accepting transcript to its challenge, response, commitment, and computable-verifier rows. The hash dependency is read through the carried $\mathsf{Hash}^{\uparrow}$ provenance, and the verifier computation is read through the carried $\mathsf{Computable}^{\uparrow}$ provenance.

The ledger comparison is then obtained by transporting those rows through their displayed hsame comparisons and repacking them with the transcript Cont routes. This proves only that the packet exposes the finite soundness surface claimed in the statement. □

Theorem 244.5 (ZeroKnowledgeUp simulation ledger obligation)**.** *The simulation ledger of a* $\mathsf{ZeroKnowledge}^{\uparrow}$ *packet is a finite BEDC obligation over the simulator transcript row s, verifier row V, challenge row c, response row r, commitment row k, computable verifier row q, componentwise* hsame *comparisons, transcript* Cont *routes, and* Pkg *provenance for* $\mathsf{Hash}^{\uparrow}$ *and* $\mathsf{Computable}^{\uparrow}$*. It states that the simulated transcript row is compared to the displayed interaction transcript by packet rows alone; it does not assert distributional indistinguishability, zero-knowledge error bounds, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeCarrier simulation ledger obligation`
Lean4 ✓ `BEDC.Derived.ZeroKnowledgeUp.ZeroKnowledgeCarrier simulation transcript boundary`

Proof. Project the simulator evidence to the simulator transcript row and the verifier-facing transcript rows. The comparison with the interaction transcript is a row-by-row hsame comparison between the displayed challenge, response, commitment, and verifier-computation coordinates.

Repack the simulator route, the verifier route, and the dependency provenance into the ledger ℓ. Because the proof uses only accepted carrier rows and their Cont routes, the result is a BEDC simulation surface and not a claim about external distributions. □

Definition 244.6 (ZeroKnowledgeUp public finite-transcript surface)**.** *For a* $\mathsf{ZeroKnowledge}^{\uparrow}$ *packet, the public finite-transcript surface is the following finite* BHist *package: the prover row P, verifier row V, challenge transcript row c, response transcript row r, hash commitment row k, computable verifier row q, simulator transcript row s, evidence ledger row ℓ, the componentwise* hsame *comparisons on those rows, the* Cont *routes from prover and verifier to challenge, from challenge and prover to response, from response and the* $\mathsf{Hash}^{\uparrow}$ *source to commitment, from challenge and the* $\mathsf{Computable}^{\uparrow}$ *source to verifier acceptance, from simulator and verifier to simulated transcript, and from the visible transcript rows to ℓ, together with the* Pkg *provenance rows naming the consumed* $\mathsf{NameCert}_{\mathsf{Hash}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *certificates.*

Theorem 244.7 (ZeroKnowledgeUp public finite-transcript surface)**.** *Let Z be a* $\mathsf{ZeroKnowledge}^{\uparrow}$ *packet satisfying the carrier, classifier, completeness-ledger, soundness-ledger, and simulation-ledger obligations of Definition 244.1, Definition 244.2, Definition 244.3, Definition 244.4, and Definition 244.5. Then the public* $\mathsf{NameCert}_{\mathsf{ZeroKnowledge}^{\uparrow}}$ *surface of Z is exactly the finite-transcript surface of Definition 244.6. In particular, every public consumer read is one of the displayed transcript, classifier, continuation, ledger, or provenance rows, and the packet exports no hidden witness, probability distribution, hardness predicate, extractor, negligible bound, or standard bridge.*

Proof. Project the public certificate to its carrier field. By Definition 244.1, the only carrier coordinates are the rows P, V, c, r, k, q, s, and ℓ, together with the named Cont transcript routes and the two Pkg provenance rows for $\mathsf{Hash}^{\uparrow}$ and $\mathsf{Computable}^{\uparrow}$. This gives the row inventory of Definition 244.6. The commitment coordinate k is read only through the consumed $\mathsf{NameCert}_{\mathsf{Hash}^{\uparrow}}$ row, whose local public use here is the finite hash-evaluation transcript boundary of Definition 242.5; the verifier coordinate q is read only through the consumed $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ row, whose local public use here is the bounded-simulation ledger boundary of Definition 199.6.

Project next to the classifier field. By Definition 244.2, accepted packets classify only by componentwise hsame comparisons on the displayed prover, verifier, challenge, response, commitment, computable-verifier, simulator, continuation-ledger, and provenance rows. Thus a consumer cannot distinguish or identify packets through a witness value, a distribution law, a machine implementation, or any object not carried by those comparisons.

The three ledger obligations exhaust the remaining public reads. By Definition 244.3, completeness contributes only the finite accepted-transcript route through P, V, c, r, q, the transcript continuation rows, and the dependency provenance; it contributes no acceptance probability or error bound. By Definition 244.4, soundness contributes only the visible comparison between accepting transcript rows, commitment rows, verifier rows, hsame transport, Cont routes, and Pkg provenance; it contributes no cryptographic hardness predicate, extractor, or negligible cheating bound. By Definition 244.5, simulation contributes only the simulator transcript row s, the verifier-facing transcript rows, their componentwise hsame comparisons, and the same continuation and provenance rows; it contributes no distributional indistinguishability claim, zero-knowledge error bound, or standard bridge.

Combining the carrier projection, classifier projection, and the three ledger projections gives every row listed in Definition 244.6, so the finite-transcript surface is public. Conversely, the same five obligations leave no public field outside those rows: each public read is either a carrier coordinate, a componentwise classifier comparison, a transcript continuation route, one of the completeness, soundness, or simulation ledger rows, or one of the two dependency provenance rows. Therefore the public $\mathsf{NameCert}_{\mathsf{ZeroKnowledge}^{\uparrow}}$ surface is exactly the displayed finite BHist/Cont/Pkg transcript surface and exports none of the excluded host-level data. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZeroKnowledge}^{\uparrow}}$.
