Constructive story: A $\mathsf{ZeroKnowledge}^{\uparrow}$ packet is generated from finite BHist rows for prover, verifier, challenge, response, commitment, computable-verifier, simulator transcript, and evidence ledger data. Completeness, soundness, and simulation appear only as public transcript ledgers: each accepted read is routed by Cont through displayed transcript rows, not through probability spaces or external machines. The classifier is componentwise hsame on prover, verifier, transcript, commitment, simulator, and ledger rows, while Pkg records the $\mathsf{Hash}^{\uparrow}$ and $\mathsf{Computable}^{\uparrow}$ sources. The resulting object is a finite public transcript surface with explicit refusal of hidden cryptographic semantics.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ZeroKnowledge}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the finite transcript carrier, classifier projection, completeness, soundness, simulation ledger obligations, and public finite-transcript surface for $\mathsf{ZeroKnowledge}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ZeroKnowledge}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim negligible bounds, distributional indistinguishability, extractor existence, host randomness, or a standard protocol bridge.

Upgrade path: Obligation closure requires Lean encodings of the finite transcript carrier, componentwise classifier, and the three public ledger obligations.

Chapter 245

A Concrete Naming Certificate for $\mathsf{CharacterTheory}^{\uparrow}$

The character-theory interface $\mathsf{CharacterTheory}^{\uparrow}$ packages, for a finite group, the trace functions of its irreducible representations together with the orthogonality relations and class-function basis. It depends on $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47).

245.1 Carrier definition

Definition 245.1 (CharacterTheoryUp root BHist surface)**.** *The root* $\mathsf{CharacterTheory}^{\uparrow}$ *surface is a finite* BHist *packet*

$$\mathcal{X}_{\mathsf{CharacterTheory}^{\uparrow}} := (G, V, \rho, \tau, \Omega, \Pi)$$

whose rows have the following meanings:

1. *G is the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *source row for the finite group endpoint.*
2. *V is the consumed* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *source row for the representation space endpoint.*
3. *ρ is the displayed representation-action row, read as a finite* Cont *ledger from the group row and vector-space row to an endomorphism row of V.*
4. *τ is the trace row of the displayed action endpoint, carried as a* BHist *readback row and not as a host matrix trace.*
5. *Ω is the orthogonality and class-function ledger, consisting only of the finite rows that record class-function basis reads, trace-pairing reads, and the* hsame *comparisons used to transport those reads.*
6. *$\Pi : \mathsf{Pkg}$ is the provenance row tying G, V, ρ, τ, and Ω to the same accepted package.*

No row of $\mathcal{X}_{\mathsf{CharacterTheory}^{\uparrow}}$ is a quotient of conjugacy classes, a complex inner-product space, or an ambient trace operator outside this finite BHist *packet.*

Lean4 (definition) `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface`

Theorem 245.2 (CharacterTheoryUp root carrier obligation)**.** *An accepted root packet $\mathcal{X}_{\mathsf{CharacterTheory}^{\uparrow}}$ exposes only the* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row G, the* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *row V, the representation-action row ρ, the trace row τ, and the provenance row $\Pi : \mathsf{Pkg}$ as carrier-facing data. It exposes no host group element set, no host vector space, no matrix algebra, and no detached trace carrier beyond these displayed rows.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootCarrier obligation`
Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface root carrier obligation`

Proof. Unpack the packet of Definition 245.1. Its carrier-facing coordinates are exactly G, V, ρ, τ, and Π; the orthogonality ledger Ω is a downstream readback ledger rather than a new carrier coordinate.

For each accepted carrier read, project to the corresponding coordinate of the finite packet. The group source is G, the vector source is V, the action is ρ, the trace readback is τ, and the provenance is Π.

Conversely, repack those five rows into the displayed tuple and leave Ω available only as ledger data. Since the definition lists no other constructor for accepted root packets, there is no additional host carrier or trace object to expose. □

Theorem 245.3 (CharacterTheoryUp root classifier obligation)**.** *If two accepted root packets have* hsame*-transported group source rows,* hsame*-transported vector-space source rows, and* hsame*-transported trace rows, then they determine the same* $\mathsf{CharacterTheory}^{\uparrow}$ *character classifier. The classifier transport uses only those source and trace transports together with the representation-action row of Definition 245.1.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface root classifier obligation`

Proof. Project the two accepted packets to their G, V, ρ, and τ rows. The displayed hsame transport on G identifies the group source endpoints, and the displayed hsame transport on V identifies the vector-space endpoints that carry the representation row.

Transport the action row ρ along the two source comparisons. The trace row τ is then transported along the given trace comparison, so the character readback obtained from the transported action has the same BHist classifier endpoint as the original readback.

Repack the transported source rows, action row, trace row, ledger row, and provenance row as an accepted packet. The character classifier reads only this transported trace endpoint, so the classifier is preserved. □

Theorem 245.4 (CharacterTheoryUp root ledger obligation)**.** *Every downstream orthogonality read and every class-function-basis read of an accepted* $\mathsf{CharacterTheory}^{\uparrow}$ *root packet factors through the finite* Cont *and* Pkg *ledger rows of* Ω *and* Π*. Such reads introduce no host trace, quotient class object, or complex inner product beyond the rows displayed in Definition 245.1.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface root ledger obligation`

Proof. Unpack the ledger coordinate Ω. Its entries are finite rows for trace-pairing reads, class-function basis reads, and the hsame comparisons that transport those reads across accepted source endpoints.

Any downstream orthogonality query first projects to the trace row τ and then follows a finite Cont row inside Ω. Any downstream class-function-basis query projects to the same packet and follows the basis read rows recorded in Ω.

The provenance row $\Pi : \mathsf{Pkg}$ ties those ledger entries back to the same accepted group source, vector-space source, action, and trace rows. Repacking the query through Ω and Π leaves no remaining coordinate from which a host trace, quotient class object, or complex inner product could be read. □

245.2 The certificate

Theorem 245.5 (CharacterTheoryUp source compatibility obligation)**.** *Let* $\mathcal{X}_{\mathsf{CharacterTheory}^{\uparrow}} = (G, V, \rho, \tau, \Omega, \Pi)$ *be an accepted packet of Definition 245.1. If the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row* G *and consumed* $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ *row* V *move along displayed* hsame *rows, and if the representation-action row* ρ *is transported by the finite* Cont *ledger recorded with the packet, then the resulting source-compatible trace row and its provenance remain in the same finite* BHist *and* Pkg *packet. No host trace operator, quotient class object, or detached carrier is introduced by this transport.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface source compatibility obligation`

Proof. Project the six coordinates G, V, ρ, τ, Ω, and Π from Definition 245.1. The displayed hsame rows supply the group and vector-space source comparisons, and the finite Cont ledger supplies the action comparison for ρ.

Apply Definition 245.3 to the transported source and action data. The classifier comparison is therefore read through the transported trace endpoint rather than through an ambient trace object.

Finally repack the transported source rows, action row, trace row, and ledger entries with the same provenance coordinate $\Pi : \mathsf{Pkg}$. Since each coordinate is projected from and returned to the same finite BHist packet, no host trace or quotient class object is available. □

Theorem 245.6 (CharacterTheoryUp trace transport stability)**.** *For an accepted packet* $\mathcal{X}_{\mathsf{CharacterTheory}^{\uparrow}} = (G, V, \rho, \tau, \Omega, \Pi)$*, every orthogonality read and every class-function-basis read recorded in* Ω *transports along the source-compatible trace comparison of Definition 245.5. Each transported read factors through finite* Cont*,* hsame*, and* Pkg *rows of the displayed* BHist *packet.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface trace transport stability`

Proof. Apply Definition 245.4 to project the orthogonality and class-function-basis reads from Ω. The theorem confines those reads to finite Cont rows, the relevant hsame comparisons, and the provenance row $\Pi : \mathsf{Pkg}$.

Use Definition 245.5 to transport the trace endpoint supplied by the group and vector-space source comparisons. The ledger reads then follow the transported trace row inside the same finite packet.

Repack the transported read rows with Ω and Π. Because the reads have no endpoint outside the displayed BHist coordinates, stability is exactly preservation of those finite ledger rows. □

Theorem 245.7 (CharacterTheoryUp NameCert obligation surface)**.** *The root packet definition of Definition 245.1, together with Definition 245.2, Definition 245.3, Definition 245.4, Definition 245.5, and Definition 245.6, supplies the carrier, classifier, source-compatibility, stability, ledger, and no-host-boundary fields required of the* $\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$ *obligation surface.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface carrier obligation`

Proof. Enumerate the six packet fields G, V, ρ, τ, Ω, and $\Pi : \mathsf{Pkg}$ from Definition 245.1. The carrier face is Definition 245.2, and the classifier face is Definition 245.3.

The source-compatibility field is Definition 245.5. The stability field is Definition 245.6, and the ledger field is Definition 245.4.

The remaining no-host-boundary field follows by finite constructor projection and repacking. Every field just listed reads from the displayed BHist, Cont, hsame, and Pkg rows, so the

$\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$ surface receives no quotient class carrier, host trace, or external representation object. □

Theorem 245.8 (CharacterTheoryUp scoped source route)**.** *Every accepted* $\mathsf{CharacterTheory}^{\uparrow}$ *packet factors through exactly the finite source rows displayed in this chapter: the group-action carrier row, trace readback row, class-function classifier row, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$ *row. The route exports no external character table, host trace equality, quotient conjugacy-class enumeration, or ambient representation category outside those rows.*

Lean4 ✓ `BEDC.Derived.CharacterTheoryUp.CharacterTheoryRootBHistSurface scoped source route`

Proof. Project the accepted root carrier of Definition 245.1. The group source, vector-space source, representation action, trace readback, orthogonality and class-function ledger, and provenance rows are the only carrier coordinates available.

Use the root carrier, classifier, and ledger obligations, Definition 245.2, Definition 245.3, and Definition 245.4. They force carrier reads, classifier comparison, and ledger reads to pass through the displayed finite rows rather than through host trace equality or an external character table.

Finally apply source compatibility, trace transport, and the NameCert obligation surface, Definition 245.5, Definition 245.6, and Definition 245.7. These results repack all transported reads through hsame, Cont, Pkg, and the local naming row, leaving no exported quotient conjugacy-class enumeration or ambient representation category. □

Theorem 245.9 (CharacterTheoryUp scoped source induction)**.** *The root carrier, classifier, ledger, source compatibility, trace transport, NameCert obligation surface, and scoped source route jointly bind every* $\mathsf{CharacterTheory}^{\uparrow}$ *read to the displayed* $\mathsf{Group}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$ *rows. Induction over accepted reads therefore has no step that leaves the group source row, vector-space source row, representation-action row, trace readback row, class-function ledger, componentwise transport, replay, provenance, and local naming surface.*

Proof. Start with the root carrier of Definition 245.1. Its rows display the group source, vector-space source, representation action, trace readback, class-function ledger, and provenance surface.

Use the carrier, classifier, and ledger obligations, Definition 245.2, Definition 245.3, and Definition 245.4. These bind every carrier read, classifier comparison, and ledger read to the displayed source rows and their finite transport data.

Finally apply source compatibility, trace transport stability, the NameCert obligation surface, and the scoped source route. They close the induction step under hsame, Cont, Pkg, and local naming, so no read can escape to a host trace operator, quotient conjugacy-class enumeration, or external representation category. □

Closure status for $\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CharacterTheory}^{\uparrow}$ packet is generated from finite BHist rows for a representation source, class-function or trace readbacks, root or character ledgers, source-compatibility rows, and the local naming row. The trace-facing data are displayed histories transported by hsame, so equality of characters is not imported as host class-function equality. The Cont rows replay how representation rows feed the trace and root ledgers, and Pkg records the representation-theoretic dependencies that the packet consumes. The public surface is therefore the finite character ledger and its stability obligations, with quotient classes and ambient representation objects left outside.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CharacterTheory}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 245.9 supplies the bridge route through $\mathsf{Group}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, componentwise hsame, displayed Cont, Pkg, and local NameCert rows while keeping trace, class-function, and representation reads inside the finite CharacterTheory packet.

Formal verification: FormalStatus(NameCert$_{\mathsf{CharacterTheory}^{\uparrow}}$, unformalized)
Bridge status: none
Origin: human
Not claimed: It does not claim full character-table computation, orthogonality relations, quotient conjugacy classes, host trace equality, or external representation categories.
Upgrade path: The paper closure is complete; the remaining work is Lean verification and bridge evidence for the displayed finite character-theory rows.

Chapter 246

A Concrete Naming Certificate for $\mathsf{RepresentationRing}^{\uparrow}$

The representation-ring interface $\mathsf{RepresentationRing}^{\uparrow}$ packages the Grothendieck ring of finite-dimensional representations of a group under direct sum and tensor product. It depends on $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ (chapter 41) and $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ (chapter 43).

246.1 Carrier definition

Definition 246.1 (RepresentationRingUp BHist representation packet)**.** *A* $\mathsf{RepresentationRing}^{\uparrow}$ *representation packet is a finite* BHist *tuple*

$$\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda).$$

The row G is the consumed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *packet, and R is the consumed* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *packet. The row V is the finite list of representation endpoints carried as* BHist *rows: each endpoint has its group action source read through G and its additive and multiplicative target rows read through R. The row S records the displayed direct-sum faces, and T records the displayed tensor-product faces. Both are finite* Cont *ledgers whose endpoints are members of V.*

The row P is the provenance packet listing the Pkg *rows consumed from G and R and the package rows attached to S and T. The row ρ is the Grothendieck classifier row naming formal direct-sum balance among the displayed representation endpoints. The finite ledger λ is the* Cont *list containing exactly the consumed GroupUp rows, consumed RingUp rows, representation rows, direct-sum rows, tensor rows, classifier row, and provenance rows exposed by the public packet.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingTasteGate single carrier alignment`

Definition 246.2 (RepresentationRingUp Grothendieck ledger classifier)**.** *For two representation packets*

$$\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda) \qquad \text{and} \qquad \mathcal{K}' = (G', R', V', S', T', P', \rho', \lambda'),$$

the Grothendieck ledger classifier $\mathcal{K} \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}'$ *is the finite componentwise transport datum consisting of:*

1. *an* hsame *transport row between the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *packets G and G';*
2. *an* hsame *transport row between the consumed* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *packets R and R';*

3. *an entrywise* hsame *transport row between the displayed representation endpoint lists V and V';*
4. *entrywise* hsame *transport rows between the direct-sum ledgers S and S' and between the tensor-product ledgers T and T';*
5. *an* hsame *transport row between the provenance packets P and P';*
6. *an* hsame *transport row between the Grothendieck classifier rows ρ and ρ';*
7. *a finite* Cont *ledger comparison between λ and λ', entry by entry.*

Thus equality in the public representation-ring carrier is not host equality of representation categories. It is the displayed hsame *transport of the consumed GroupUp packet, consumed RingUp packet, representation rows, direct-sum rows, tensor rows, provenance, and finite continuation ledger.*

Lean4 (definition) `BEDC.Derived.RepresentationRingUp.RepresentationRingGrothendieckClassifier`

Theorem 246.3 (RepresentationRingUp Grothendieck classifier reflexivity)**.** *Every representation packet $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ satisfies $\mathcal{K} \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}$. The row is the componentwise reflexive* hsame *datum on G, R, V, S, T, P, ρ, together with the identical finite* Cont *ledger comparison on λ.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket semantic name certificate`

Proof. Apply the classifier definition in Definition 246.2 to the pair $(\mathcal{K}, \mathcal{K})$. For the consumed GroupUp and RingUp packets use the reflexive hsame rows on G and R.

For the displayed representation endpoints, direct-sum rows, tensor rows, provenance packet, and Grothendieck classifier row, choose the entrywise reflexive hsame rows on V, S, T, P, ρ. These are exactly the component slots required by the displayed classifier list.

For the ledger slot choose the identity comparison of the finite Cont ledger λ with itself. Repacking these component rows gives $\mathcal{K} \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}$. □

Theorem 246.4 (RepresentationRingUp Grothendieck classifier symmetry)**.** *For representation packets $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ and $\mathcal{K}' = (G', R', V', S', T', P', \rho', \lambda')$, a classifier row $\mathcal{K} \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}'$ determines a classifier row $\mathcal{K}' \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}$ by reversing each displayed* hsame *row and reversing the finite* Cont *ledger comparison.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket grothendieck classifier symmetric`

Proof. Unpack the classifier row using Definition 246.2. It consists of component transports from G to G', from R to R', entrywise from V to V', from S to S', from T to T', from P to P', and from ρ to ρ', together with the finite ledger comparison from λ to λ'.

Reverse the two dependency rows by symmetry of hsame, giving rows from G' to G and from R' to R. Reverse the entrywise rows on the endpoint list, direct-sum ledger, tensor ledger, provenance packet, and classifier row in the same componentwise manner.

Reverse the finite Cont ledger comparison so that each entry of λ' is matched with the corresponding entry of λ. The reversed component family is precisely the classifier datum from $\mathcal{K}'$ to $\mathcal{K}$. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingGrothendieckClassifier symmetric`

Theorem 246.5 (RepresentationRingUp Grothendieck classifier transitivity)**.** *For representation packets* $\mathcal{K}_0 = (G_0, R_0, V_0, S_0, T_0, P_0, \rho_0, \lambda_0)$*,* $\mathcal{K}_1 = (G_1, R_1, V_1, S_1, T_1, P_1, \rho_1, \lambda_1)$*, and* $\mathcal{K}_2 = (G_2, R_2, V_2, S_2, T_2, P_2, \rho_2, \lambda_2)$*, classifier rows* $\mathcal{K}_0 \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}_1$ *and* $\mathcal{K}_1 \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}_2$ *compose to a classifier row* $\mathcal{K}_0 \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}_2$*. The composite is componentwise* hsame *transitivity on* G, R, V, S, T, P, ρ*, together with composition of the finite* Cont *ledger comparisons from* λ_0 *through* λ_1 *to* λ_2*.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket grothendieck classifier transitive`

Proof. Unpack both classifier rows by Definition 246.2. The first row supplies component transports from the subscript 0 packet to the subscript 1 packet, and the second supplies the corresponding component transports from the subscript 1 packet to the subscript 2 packet.

Compose the consumed GroupUp and RingUp rows by transitivity of hsame, obtaining rows from G_0 to G_2 and from R_0 to R_2. Compose the endpoint-list rows entry by entry, and do the same for the direct-sum ledger, tensor ledger, provenance packet, and Grothendieck classifier row.

For the continuation ledger, concatenate the comparison from λ_0 to λ_1 with the comparison from λ_1 to λ_2, and then read it as the finite entrywise comparison from λ_0 to λ_2. Repacking the composed components gives the required classifier row from $\mathcal{K}_0$ to $\mathcal{K}_2$. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingGrothendieckClassifier transitive`

246.2 The certificate

Theorem 246.6 (RepresentationRingUp carrier BHist boundary)**.** *Every public endpoint of a* $\mathsf{RepresentationRing}^{\uparrow}$ *carrier packet of Definition 246.1 is one of the displayed* BHist *rows in* $G, R, V, S, T, P, \rho, \lambda$*. In particular, every representation endpoint is scoped through the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *certificates, and no additional group carrier, ring carrier, module carrier, or host representation object is exported at the boundary.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket carrier boundary`

Proof. Project an accepted packet to the tuple $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$. The carrier definition lists all public rows in that tuple, so a public endpoint can only be the consumed GroupUp row, the consumed RingUp row, a representation endpoint from V, a direct-sum row from S, a tensor row from T, a provenance row from P, the Grothendieck classifier row ρ, or an entry of the finite ledger λ.

For a representation endpoint in V, the same projection reads its action source through G and its target algebra rows through R. The direct-sum and tensor rows are ledger faces whose endpoints are members of V, so they also remain scoped by those two consumed certificates.

Conversely, any row from the displayed tuple repacks into the public carrier surface by the constructor pattern of Definition 246.1. No external representation object is needed, because the boundary is exactly the finite BHist packet. □

Theorem 246.7 (RepresentationRingUp direct-sum tensor ledger stability)**.** *If two packets of Definition 246.1 are related by the classifier of Definition 246.2, then the direct-sum faces and tensor-product faces of the first packet transport to the corresponding faces of the second packet through* hsame *and the finite* Cont *ledger comparison. The transported packet preserves the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *sources and the Grothendieck classifier row.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket direct sum tensor ledger stability`

Proof. Unpack the classifier between $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ and $\mathcal{K}' = (G', R', V', S', T', P', \rho', \lambda')$. It supplies transported GroupUp and RingUp dependency rows, entrywise endpoint transport between V and V', entrywise ledger transport between S and S' and between T and T', provenance transport, classifier-row transport, and a finite comparison between λ and λ'.

Read a direct-sum face from S. Its endpoints are displayed members of V, so the endpoint comparison in the classifier carries them to the matching members of V'. The ledger comparison then carries the Cont row witnessing the direct-sum face to the corresponding entry of S'.

The tensor-product case is identical except that the ledger entry is read from T. The transported endpoints still read their action source through G' and their target rows through R', because the classifier transported the consumed GroupUp and RingUp packets at the same time.

Finally transport ρ to ρ' and P to P'. Repacking these rows gives a representation-ring packet with stable direct-sum and tensor faces over the transported finite ledger. □

Theorem 246.8 (RepresentationRingUp NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *obligation surface is the package consisting of the carrier packet of Definition 246.1, the Grothendieck ledger classifier of Definition 246.2, the carrier boundary of Definition 246.6, the direct-sum and tensor stability row of Definition 246.7, exactness of the finite* Cont *and* Pkg *ledger rows, and the consumer boundary used by* $\mathsf{InducedRep}^{\uparrow}$ *through* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$*. The consumer may read the consumed GroupUp packet, consumed RingUp packet, representation endpoints, direct-sum faces, tensor faces, Grothendieck classifier row, provenance rows, and finite ledger rows, but it receives no additional induction functor, restriction functor, character row, or host-level representation category.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket namecert obligation surface`

Proof. Start with the carrier and classifier definitions. The carrier supplies the finite row family, while the classifier specifies componentwise hsame transport for each dependency, endpoint list, operation face, provenance packet, classifier row, and ledger entry.

Apply the carrier boundary theorem to identify the public endpoints. This shows that every exported representation-ring row is already one of the displayed BHist rows and that the representation endpoints remain scoped by the consumed GroupUp and RingUp certificates.

Next apply the direct-sum and tensor stability theorem. It transports the two operation faces through the same endpoint comparisons and the same finite Cont ledger comparison, so the Grothendieck classifier row remains attached to the transported packet.

Exactness follows by inspecting the displayed rows. The only provenance rows are the Pkg rows in P, and the only continuation rows are the entries of λ together with the displayed direct-sum and tensor faces. Thus every public row is accounted for by projection from the packet.

For the downstream boundary, an $\mathsf{InducedRep}^{\uparrow}$ consumer reads precisely this public surface: representation endpoints together with direct-sum, tensor, classifier, provenance, and dependency rows. Induction, restriction, Frobenius reciprocity, and character-theoretic data are not fields of $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ and must be supplied by their own certificates. □

Theorem 246.9 (RepresentationRingUp classifier ledger exhaustion)**.** *Every accepted Grothendieck ledger classifier row for* $\mathsf{RepresentationRing}^{\uparrow}$ *is exhausted by the finite rows displayed in Definition 246.2. Concretely, for packets*

$$\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda) \qquad \textit{and} \qquad \mathcal{K}' = (G', R', V', S', T', P', \rho', \lambda'),$$

an accepted classifier between them consists only of BHist *direct-sum rows from* S *and* S'*, tensor-product rows from* T *and* T'*, provenance rows from* P *and* P'*,* hsame *transport rows for the consumed packets, endpoints, operation ledgers, provenance packets, and classifier rows, and the finite* Cont *comparison between* λ *and* λ'*. There is no further classifier row outside that displayed ledger.*

Proof. Project the accepted classifier to the seven entries listed in Definition 246.2. Each entry is either an hsame transport row or a finite Cont comparison row, and the operation entries are exactly the displayed direct-sum and tensor-product ledgers.

The carrier boundary theorem identifies every public representation-ring endpoint as one of the rows of Definition 246.1. Hence any classifier row with public effect must land on one of G, R, V, S, T, P, ρ, or λ.

Apply the obligation-surface theorem to the accepted NameCert packet. It permits no additional host representation category, quotient object, character row, or functorial equality row. The seven displayed classifier entries therefore exhaust the accepted Grothendieck ledger classifier. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket classifier ledger exhaustion`

Theorem 246.10 (RepresentationRingUp tensor-product descent)**.** *Let* $\mathcal{K}$ *and* $\mathcal{K}'$ *be packets of Definition 246.1 related by the classifier of Definition 246.2. If a tensor-product representation packet is read from two endpoints of* V *together with a tensor ledger row of* T*, then the transported endpoints in* V' *and the corresponding tensor ledger row of* T' *form a tensor-product representation packet related to the first one by the same classifier. Thus tensor products descend along the finite representation-ring classifier relation.*

Proof. Unpack the classifier between $\mathcal{K}$ and $\mathcal{K}'$. It supplies entrywise hsame transport for the representation endpoints and entrywise transport between the tensor ledgers T and T'.

Read the chosen tensor-product packet from its two endpoint rows in V and its tensor ledger row in T. The endpoint transports carry those two rows to the matching endpoint rows in V', and the tensor-ledger transport carries the operation row to the corresponding member of T'.

Apply the direct-sum tensor ledger stability theorem to preserve the consumed GroupUp and RingUp sources, the provenance row, the Grothendieck classifier row, and the finite Cont ledger comparison. Repacking the transported rows gives the tensor-product packet over $\mathcal{K}'$, related by the same displayed classifier data. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket tensor product descent`

Theorem 246.11 (RepresentationRingUp induced consumer boundary)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *consumes exactly the finite boundary rows consisting of the group source row, the subgroup boundary row supplied by its own group-side certificate, the representation packet of Definition 246.1, the induction ledger rows supplied by the consumer certificate, and the Grothendieck classifier rows of Definition 246.2. It does not receive a host quotient of representation categories, an external representation-equality oracle, or any equality relation beyond the displayed* hsame *and* Cont *rows.*

Proof. Start from the public representation-ring packet. Its exposed rows are the consumed GroupUp and RingUp sources, representation endpoints, direct-sum and tensor ledgers, provenance rows, classifier row, and continuation ledger.

An $\mathsf{InducedRep}^{\uparrow}$ consumer adds its own subgroup boundary and induction ledger, both as finite certificate rows. The representation-ring side contributes only the representation packet and the Grothendieck classifier needed to transport that packet across accepted classifier-related inputs.

The obligation-surface theorem excludes any additional induction functor, restriction functor, character row, or host representation category from $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$. The carrier boundary and classifier exhaustion results then leave exactly the named rows, with equality mediated only by hsame and finite Cont comparison. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket induced consumer boundary`

Theorem 246.12 (RepresentationRingUp InducedRep consumer boundary)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *may read only the finite* BHist *rows displayed in the carrier packet* $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ *of Definition 246.1: the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row* G*, the consumed* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *row* R*, the representation endpoint list* V*, the direct-sum ledger* S*, the tensor-product ledger* T*, the* Pkg *provenance packet* P*, the Grothendieck classifier row* ρ*, and the finite* Cont *ledger* λ*. Any induction, restriction, Frobenius, subgroup-inclusion, or character-theoretic row required by* $\mathsf{InducedRep}^{\uparrow}$ *lies outside this RepresentationRingUp boundary unless it is separately supplied by the* $\mathsf{InducedRep}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket consumer boundary`

Proof. Project the consumer request to the carrier packet $\mathcal{K}$. The carrier definition lists exactly the rows $G, R, V, S, T, P, \rho, \lambda$, and each representation endpoint in V reads its action source through G and its algebra target through R.

The operation rows are also already named. A direct-sum request lands in the finite Cont ledger S, a tensor-product request lands in the finite Cont ledger T, and every public continuation read is an entry of λ. Provenance is read through the displayed Pkg packet P.

Repack these projections as the representation-ring part of an $\mathsf{InducedRep}^{\uparrow}$ input. The repacking gives a concrete BEDC source boundary: the downstream packet receives the rows named above and no host representation category, induction functor, restriction functor, Frobenius adjunction, or character row from $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$. □

Theorem 246.13 (RepresentationRingUp classifier exactness)**.** *For packets* $\mathcal{K}$ *and* $\mathcal{K}'$ *of Definition 246.1, the Grothendieck ledger classifier* $\mathcal{K} \sim^{\mathrm{gr}}_{\mathsf{RepresentationRing}^{\uparrow}} \mathcal{K}'$ *of Definition 246.2 is exact for the public carrier: its projections are precisely the* hsame *rows for the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *packets, the entrywise representation rows, the direct-sum and tensor* Cont *ledgers, the* Pkg *provenance packet, the Grothendieck row* ρ*, and the finite ledger comparison for* λ*. Conversely, those displayed projections repack into the classifier without using host equality of representation categories.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket classifier exactness`

Proof. Unpack the classifier between $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ and $\mathcal{K}' = (G', R', V', S', T', P', \rho', \lambda')$. Its fields are the two dependency comparisons, endpoint-list comparison, operation-ledger comparisons, provenance comparison, Grothendieck-row comparison, and finite ledger comparison.

Each field is a projection of a public row of the carrier packet. The GroupUp and RingUp comparisons account for the dependency rows; the endpoint and operation comparisons account for V, S, T; the provenance comparison accounts for P; the Grothendieck comparison accounts for ρ; and the finite ledger comparison accounts for λ.

For the converse direction, begin with exactly those displayed projections. Place them in the same ordered slots required by Definition 246.2. This constructs the classifier row by repacking finite BEDC data, so no source-level equivalence of representation categories is invoked. □

Theorem 246.14 (RepresentationRingUp operation ledger coverage)**.** *Every public operation row of a* $\mathsf{RepresentationRing}^{\uparrow}$ *carrier packet is covered by the finite ledgers S, T, and λ of Definition 246.1. Direct-sum operations are exactly the rows of S, tensor-product operations are exactly the rows of T, their endpoints are members of the representation endpoint list V, and their dependency and provenance reads factor through the consumed* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$ *row G, the consumed* $\mathsf{NameCert}_{\mathsf{Ring}^{\uparrow}}$ *row R, and the* Pkg *packet P.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket operation ledger coverage`

Proof. Project a public operation row from the packet $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$. The carrier definition has only two operation ledgers: S for direct sums and T for tensor products. Thus the row is read from one of those finite Cont ledgers.

In the direct-sum case, the endpoints of the selected row are displayed members of V. Their group-action source is obtained by projecting G, and their additive target rows are obtained by projecting R. The relevant continuation entry is also listed in λ, and its package provenance is listed in P.

The tensor-product case is parallel. The selected row lies in T, its endpoints are members of V, its dependency rows are again G and R, and its public continuation and package reads are entries of λ and P. Repacking these projections covers every operation row and leaves no unlisted operation at the boundary. □

Theorem 246.15 (RepresentationRingUp finite BHist source exhaustion)**.** *The finite* BHist *source of a* $\mathsf{RepresentationRing}^{\uparrow}$ *public packet is exhausted by the displayed tuple $G, R, V, S, T, P, \rho, \lambda$. Every public carrier, classifier, operation, ledger, provenance, and downstream-consumer row is a projection of that tuple or a row named by one of its finite* Cont *ledgers. No ambient group object, ambient ring object, module category, character table, or representation category is a separate source row of the public certificate.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket finite source exhaustion`

Proof. Inspect the carrier packet. Its dependency sources are exactly G and R, its representation endpoints are exactly the finite list V, and its operation sources are exactly the finite ledgers S and T. The classifier source is the row ρ, provenance is the packet P, and public continuation data is the ledger λ.

Now consider any public read. A carrier read is one of those fields. A classifier read is a projection of Definition 246.2. An operation read is covered by Definition 246.14. A consumer read for $\mathsf{InducedRep}^{\uparrow}$ is covered by Definition 246.12.

These cases exhaust the finite packet. Repacking the selected projections returns a row of the same BHist source, and there is no remaining slot where an ambient host object or representation category could enter as a public source. □

Theorem 246.16 (RepresentationRingUp public NameCert surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *surface consists exactly of the* BHist *carrier packet of Definition 246.1, the Grothendieck ledger classifier of Definition 246.2, the consumer boundary of Definition 246.12, the classifier exactness of Definition 246.13, the operation-ledger coverage of Definition 246.14, and the finite source exhaustion of Definition 246.15. This surface exports the GroupUp and RingUp dependency rows, finite representation endpoint rows, finite* Cont *ledgers,* Pkg *provenance, and the Grothendieck classifier row, and it exports nothing outside those rows.*

Proof. Begin with the carrier packet and classifier. They provide the finite BEDC rows $G, R, V, S, T, P, \rho, \lambda$ and the componentwise comparisons between two such packets. The classifier exactness theorem shows that these comparisons are precisely the public classifier fields.

Next use the operation-ledger coverage theorem. It accounts for all direct sum and tensor product rows through S, T, λ, and P, with endpoints in V and dependencies through G and R.

The consumer boundary theorem supplies the downstream side: an $\mathsf{InducedRep}^{\uparrow}$ packet may consume the same finite surface but receives no induction, restriction, Frobenius, subgroup-inclusion, or character data from the representation-ring certificate.

Finally apply finite source exhaustion. Every public row named by the certificate is already a projection of the displayed BHist packet or of one of its finite Cont ledgers. Repacking those projections gives the public $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ surface. □

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket public namecert surface`

Definition 246.17 (RepresentationRingUp obligation row inventory)**.** *The* $\mathsf{RepresentationRing}^{\uparrow}$ *obligation row inventory is the finite list of public rows that a* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *packet must expose:*

1. *the carrier packet row of Definition 246.1, including the GroupUp packet, RingUp packet, finite representation endpoints, direct-sum ledger, tensor-product ledger, provenance packet, and finite* Cont *ledger;*
2. *the Grothendieck classifier row of Definition 246.2;*
3. *the direct-sum ledger row, consisting of source endpoint rows, target endpoint rows, and the finite* Cont *records witnessing the displayed direct sum construction;*
4. *the tensor-product ledger row, consisting of source endpoint rows, target endpoint rows, and the finite* Cont *records witnessing the displayed tensor construction;*
5. *the provenance packet row, namely the* Pkg *row that records that each operation endpoint is read from the displayed GroupUp and RingUp dependencies;*
6. *the finite* Cont *ledger row for all carrier, classifier, direct-sum, tensor-product, and provenance continuations in the public packet;*
7. *the consumer readback rows exposed to* $\mathsf{InducedRep}^{\uparrow}$ *and no other downstream consumer.*

Lean4 (definition) `BEDC.Derived.RepresentationRingUp.RepresentationRingObligationRowInventory`

Theorem 246.18 (RepresentationRingUp obligation inventory soundness)**.** *Every row listed in Definition 246.17 is supplied by the displayed* $\mathsf{RepresentationRing}^{\uparrow}$ *public packet: carrier rows come from Definition 246.6, classifier rows from Definition 246.13, semantic certificate rows from Definition 246.8, direct-sum and tensor rows from Definition 246.14, provenance and finite* Cont *rows from Definition 246.15, and consumer readback rows from Definition 246.12.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket obligation inventory sound`

Proof. Start with the carrier packet. The carrier boundary theorem projects the finite GroupUp packet, RingUp packet, representation endpoint rows, operation ledgers, provenance packet, and finite Cont records from the displayed BHist representation packet.

Next read the classifier and semantic certificate rows. Classifier exactness identifies the Grothendieck classifier with the finite ledger comparison, and the obligation-surface theorem places that classifier inside the public $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ surface.

The operation rows are covered by the operation-ledger theorem. It handles the direct-sum ledger and tensor-product ledger by reading their source endpoints, target endpoints, provenance packet, and finite Cont records from the same packet.

Finally apply finite source exhaustion and the consumer boundary theorem. Finite source exhaustion supplies the remaining provenance and Cont rows, and the consumer boundary theorem supplies exactly the $\mathsf{InducedRep}^{\uparrow}$ readback rows named by the inventory. □

Theorem 246.19 (RepresentationRingUp obligation inventory exhaustion)**.** *Every public* $\mathsf{RepresentationRing}^{\uparrow}$ *obligation projects to one of the rows in Definition 246.17. In particular, the public surface never reads a host representation category, an ambient Grothendieck quotient, character theory, induction-restriction calculus, or any operation not displayed by the finite carrier packet.*

Lean4 ✓ `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket obligation inventory exhaustive`

Proof. Let a public $\mathsf{RepresentationRing}^{\uparrow}$ obligation be given. By the public NameCert surface theorem, it is a carrier, classifier, operation, provenance, finite Cont, or consumer row of the displayed packet.

Carrier obligations project to the carrier packet row. Classifier obligations project to the Grothendieck classifier row. Operation obligations are either direct-sum rows or tensor-product rows, hence project to the corresponding ledger row.

Provenance and finite-continuation obligations project to the provenance packet row or to the finite Cont ledger row. Consumer obligations project to the $\mathsf{InducedRep}^{\uparrow}$ readback row and receive no additional downstream surface.

These cases exhaust the public packet by finite source exhaustion. Since the exhaustion theorem has no branch for a host representation category, Grothendieck quotient object, character row, or induction-restriction calculus, none of those structures is read by a public $\mathsf{RepresentationRing}^{\uparrow}$ obligation. □

Closure status for $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$**.**

Constructive story: A representation ring is generated as a finite packet $\mathcal{K} = (G, R, V, S, T, P, \rho, \lambda)$ whose G row consumes $\mathsf{Group}^{\uparrow}$, whose R row consumes $\mathsf{Ring}^{\uparrow}$, whose V row lists representation endpoints, and whose S and T ledgers display direct-sum and tensor-product faces. The carrier accepts exactly the consumed group and ring packets, the finite representation endpoint list, the operation ledgers, the provenance packet, the Grothendieck classifier row, and the finite Cont ledger; it excludes a host representation category, module category, character table, induction or restriction functor, and ambient Grothendieck quotient object. Two packets classify together when every displayed component is transported

by hsame and the continuation ledger is compared entry by entry, so Grothendieck equality is a finite ledger balance among direct-sum rows rather than an external quotient. The source specification is the packet of dependency rows and representation endpoints, the pattern records direct-sum and tensor ledger coverage, classifier exactness, consumer boundary, and finite source exhaustion, and the ledger keeps operation endpoints, provenance, classifier rows, and continuation entries visible. The five naming-certificate obligations are discharged by the reflexive packet classifier for inhabitance and reflexivity, componentwise reversal for symmetry, componentwise composition for transitivity, and direct-sum/tensor ledger stability for closure under classifier transport. A history h lies in the signature gap of a $\mathsf{RepresentationRing}^{\uparrow}$ token p when the source domain accepts the finite packet, the signature relation pairs it with an answer packet and evidence ledger, and token introduction names that answer as p; concretely, the consumed group and ring rows, representation endpoints, operation ledgers, Grothendieck balance row, and provenance of h are the packet encoded by p. The chapter registers this finite Grothendieck-ledger construction under $\mathsf{RepresentationRing}^{\uparrow}$; it exports the rows needed by induced-representation consumers without adding character theory, induction-restriction calculus, a standard bridge, or a host representation-ring primitive.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature scope is the displayed GroupUp packet, RingUp packet, representation endpoints, direct-sum and tensor ledgers, Grothendieck classifier, public NameCert surface, finite BHist source exhaustion, consumer obligations, induced-representation readback rows, and obligation inventory soundness and exhaustion.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RepresentationRingUp.RepresentationRingBHistRepresentationPacket\_public\_namecert\_sur`

Bridge status: none

Not claimed: Full representation theory, character theory, induction-restriction calculus, and standard bridge data are not claimed by this chapter.

Upgrade path: No further paper theory-axis upgrade is recorded for this chapter; bridgeChecked remains a separate formal-axis target.

Chapter 247

A Concrete Naming Certificate for $\mathsf{InducedRep}^{\uparrow}$

The induced-representation interface $\mathsf{InducedRep}^{\uparrow}$ records a finite induction–restriction packet with consumed $\mathsf{Subgroup}^{\uparrow}$ and $\mathsf{RepresentationRing}^{\uparrow}$ certificate rows, Frobenius rows, classifier rows, continuation ledgers, and package provenance. The induction-restriction packet consumes the subgroup carrier of chapter 80 and the character-ledger surface of chapter 246 before the local Frobenius rows are named.

247.1 Carrier definition

Definition 247.1 (InducedRepUp BHist carrier packet)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda).$$

The row S is the consumed $\mathsf{NameCert}_{\mathsf{Subgroup}^{\uparrow}}$ *packet naming the subgroup inclusion. The row R is the consumed* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *packet naming the source and target representation-ring rows. The rows i and r are the displayed induction and restriction endpoints, each scoped by S for the subgroup inclusion and by R for the representation-ring source and target rows. The row F is the finite Frobenius reciprocity ledger whose entries compare the displayed induction and restriction endpoints without exporting a host adjunction.*

The rows η and ϵ are the Frobenius unit and counit rows in the same finite ledger. The row ρ is the Pkg *provenance packet recording exactly the consumed package rows from S and R together with the package rows attached to i, r, F, η, and ϵ. The finite row λ is the* Cont *ledger containing exactly the consumed SubgroupUp rows, consumed RepresentationRingUp rows, induction and restriction endpoint rows, Frobenius rows, provenance rows, and public continuation rows exposed by the packet.*

Definition 247.2 (InducedRepUp induction–restriction packet)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *induction–restriction packet is a finite* BHist *packet*

$$\mathcal{P}_{\mathsf{InducedRep}^{\uparrow}} = (S_{\leq}, R_{\mathrm{rep}}, I_{\uparrow}, R_{\downarrow}, \Phi, H_{\leq}, H_{\mathrm{rep}}, H_{\uparrow}, H_{\downarrow}, C_{\mathrm{src}}, C_{\mathrm{fr}}, \Pi).$$

The row $S_{\leq}$ is the consumed subgroup-inclusion row supplied by $\mathsf{NameCert}_{\mathsf{Subgroup}^{\uparrow}}$*. The row R_{rep} is the consumed representation-ring row supplied by* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$*. The rows $I_{\uparrow}$ and $R_{\downarrow}$ are the displayed induction and restriction rows over that same subgroup source and representation-ring source.*

The row Φ is the finite Frobenius comparison row. It compares the displayed $I_\uparrow$ and $R_\downarrow$ rows as BEDC data and does not export a host adjunction. The classifier rows $H_\leq, H_{\mathrm{rep}}, H_\uparrow, H_\downarrow$ are the corresponding hsame *rows for subgroup inclusion, representation-ring transport, induction transport, and restriction transport. The ledgers C_{src} and C_{fr} are finite* Cont *ledgers for the source-certificate rows and the Frobenius comparison rows. The row Π is the* Pkg *provenance row recording exactly the consumed* $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ *package, the consumed* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^\uparrow}$ *package, and the displayed induction, restriction, classifier, Frobenius, and continuation rows.*

Definition 247.3 (InducedRepUp restriction-induction classifier)**.** *For two carrier packets*

$$\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda) \qquad \text{and} \qquad \mathcal{I}' = (S', R', i', r', F', \eta', \epsilon', \rho', \lambda'),$$

the restriction-induction classifier $\mathcal{I} \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^\uparrow} \mathcal{I}'$ is the finite componentwise transport datum consisting of:

1. *an* hsame *transport row between the consumed* $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ *packets S and S';*
2. *an* hsame *transport row between the consumed* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^\uparrow}$ *packets R and R';*
3. *entrywise* hsame *transport of the subgroup-inclusion rows read from S and the representation-ring rows read from R;*
4. hsame *transport rows between the induction endpoints i and i' and between the restriction endpoints r and r';*
5. *entrywise* hsame *transport of the Frobenius ledger rows F, η, ϵ to F', η', ϵ';*
6. *an* hsame *transport row between the provenance packets ρ and ρ';*
7. *a finite* Cont *ledger comparison between λ and λ', entry by entry.*

This classifier transports only displayed BEDC rows: subgroup inclusion rows, representation-ring rows, induction and restriction endpoints, Frobenius unit and counit rows, provenance, and continuation entries. It explicitly does not require equality of host induction functors, host restriction functors, representation categories, or adjunction data outside the finite packet.

247.2 The certificate

Theorem 247.4 (InducedRepUp subgroup source boundary)**.** *For every* $\mathsf{InducedRep}^\uparrow$ *packet of Definition 247.2, the subgroup source visible to downstream consumers is exactly the finite* BHist *row $S_\leq$ consumed from* $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$*, together with its* hsame *classifier row $H_\leq$, its* Cont *entries inside C_{src}, and its* Pkg *provenance inside Π. No additional subgroup object, ambient group, inclusion witness, or host restriction datum is part of the public source boundary.*

Lean4 ✓ `BEDC.Derived.InducedRepUp.InducedRepSubgroupSource boundary`

Proof. The traditional target is the subgroup inclusion along which induction and restriction are displayed. The BEDC source is not an ambient group object but the consumed $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ row $S_\leq$ in the packet.

Project the carrier. The only subgroup-source row in $\mathcal{P}_{\mathsf{InducedRep}^\uparrow}$ is $S_\leq$, and the matching classifier entry is $H_\leq$. Stability is therefore componentwise hsame transport through $H_\leq$ together with the source continuation entries recorded in C_{src}.

The ledger and exactness clauses are read from Π and C_{src}. Every exported subgroup-source entry occurs in those rows, and every such entry is named by the packet. Since no StandardBridge row is carried, the standard bridge is absent at this boundary. □

Theorem 247.5 (InducedRepUp representation-ring action boundary)**.** *For every* $\mathsf{InducedRep}^{\uparrow}$ *packet of Definition 247.2, the representation-ring action visible at the induction and restriction interface is exactly the finite* BHist *row* R_{rep} *consumed from* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$*, the displayed rows* $I_{\uparrow}$ *and* $R_{\downarrow}$*, the* hsame *classifier rows* $H_{\mathrm{rep}}, H_{\uparrow}, H_{\downarrow}$*, the continuation rows in* C_{src} *and* C_{fr}*, and the* Pkg *provenance row* Π*.*

Proof. The traditional target is an action of representation rings on induction and restriction. The BEDC source is the consumed $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ row R_{rep}, and the carrier exposes only the two displayed action endpoints $I_{\uparrow}$ and $R_{\downarrow}$.

Classifier stability is componentwise. The row H_{rep} transports the representation-ring source, while $H_{\uparrow}$ and $H_{\downarrow}$ transport the displayed induction and restriction rows. The Cont ledgers record the public continuation entries attached to those rows and to the Frobenius comparison.

Exactness is obtained by checking the provenance row Π. Any action row available to a consumer must be one of $R_{\mathrm{rep}}, I_{\uparrow}, R_{\downarrow}$ or a continuation entry named by the displayed ledgers. No host representation category, functor equality, or standard bridge is exported. □

Theorem 247.6 (InducedRepUp Frobenius reciprocity classifier)**.** *The Frobenius reciprocity data of an* $\mathsf{InducedRep}^{\uparrow}$ *packet is classified by the finite comparison row* Φ*, the endpoint classifier rows* $H_{\uparrow}$ *and* $H_{\downarrow}$*, the source classifier rows* $H_{\leq}$ *and* H_{rep}*, the* Cont *ledger* C_{fr}*, and the* Pkg *provenance row* Π*. Thus* hsame *equivalence of Frobenius rows is a BEDC comparison between displayed induction and restriction rows, not equality of a host adjunction.*

Proof. The traditional target is Frobenius reciprocity for induction and restriction. The BEDC carrier names this target by the row Φ, whose endpoints are the displayed rows $I_{\uparrow}$ and $R_{\downarrow}$ over the source rows $S_{\leq}$ and R_{rep}.

The classifier is the tuple of hsame rows. Source transport uses $H_{\leq}$ and H_{rep}; endpoint transport uses $H_{\uparrow}$ and $H_{\downarrow}$. Stability of the Frobenius comparison is the finite Cont transport recorded in C_{fr}.

The ledger clause is exactly the combination of C_{fr} and Π. Exactness follows because every Frobenius entry consumed by the public interface is named by Φ or by that ledger. The packet carries no $\mathsf{StandardBridge}$ row, so the standard bridge is absent and the classifier remains inside BHist. □

Theorem 247.7 (InducedRepUp public obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$ *obligation surface consists of the* BHist *packet of Definition 247.2, the consumed* $\mathsf{NameCert}_{\mathsf{Subgroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *rows, the displayed induction and restriction rows, the Frobenius comparison row, all listed* hsame *classifier rows, the* Cont *ledgers* C_{src} *and* C_{fr}*, and the* Pkg *provenance row* Π*. No obligation outside those displayed rows is public.*

Proof. The traditional target is the public certificate for an induced representation interface. The BEDC source is the pair of consumed certificates $\mathsf{NameCert}_{\mathsf{Subgroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$, read through $S_{\leq}$ and R_{rep}.

The carrier is the finite packet $\mathcal{P}_{\mathsf{InducedRep}^{\uparrow}}$. Its classifier rows are $H_{\leq}, H_{\mathrm{rep}}, H_{\uparrow}, H_{\downarrow}$, and stability is the corresponding componentwise hsame transport together with the two finite Cont ledgers.

The ledger and exactness conditions are public precisely because they are recorded in C_{src}, C_{fr}, and Π. Every row in the surface is a projection of the packet, and every projection repacks into the same surface. With no $\mathsf{StandardBridge}$ row present, the standard bridge is absent. □

Theorem 247.8 (InducedRepUp consumer boundary)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *consumer may inspect exactly the source rows* $S_{\leq}$ *and* R_{rep}*, the displayed induction and restriction rows* $I_{\uparrow}$ *and* $R_{\downarrow}$*, the Frobenius row* Φ*, the* hsame *classifier rows* $H_{\leq}, H_{\mathrm{rep}}, H_{\uparrow}, H_{\downarrow}$*, the* Cont *ledgers* C_{src} *and* C_{fr}*, and the*

Pkg *row* Π. *Any use of* $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ *or* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^\uparrow}$ *by that consumer factors through those rows.*

Proof. The traditional target is a downstream use of induction, restriction, and Frobenius reciprocity. The BEDC source data are the two consumed certificates, and the carrier presents them only through $S_\leq$ and R_{rep}.

For classifier stability, the consumer must use the displayed hsame rows. Subgroup and representation-ring requests pass through $H_\leq$ and H_{rep}; induction and restriction requests pass through $H_\uparrow$ and $H_\downarrow$; Frobenius requests pass through Φ and C_{fr}.

The ledger is finite and explicit: C_{src}, C_{fr}, and Π list exactly what the consumer may read. Exactness is the converse projection from those listed rows back to the carrier. No host carrier, external representation category, adjunction object, or standard bridge is available beyond that boundary. □

Theorem 247.9 (InducedRepUp Frobenius ledger boundary)**.** *Every Frobenius row exported by an* $\mathsf{InducedRep}^\uparrow$ *carrier of Definition 247.1 is one of the displayed finite rows* $F, \eta, \epsilon, \lambda$*. Its endpoints are the displayed induction row* i *and restriction row* r*, scoped through the consumed* $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^\uparrow}$ *packets. No host adjunction, host functor equality, naturality square, or external representation category is exported at the Frobenius boundary.*

Lean4 ✓ `BEDC.Derived.InducedRepUp.InducedRepFrobeniusLedger boundary`

Proof. Project an accepted packet to $\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda)$. The carrier definition lists the Frobenius part as the finite ledger F together with the unit row η, the counit row ϵ, and the public continuation entries in λ.

The displayed endpoints of those rows are i and r. Their subgroup source is read through S, and their representation-ring source and target rows are read through R. The source certificates are precisely the SubgroupUp and RepresentationRingUp NameCert rows cited in the packet.

Exactness is the reverse projection. A row outside $F, \eta, \epsilon, \lambda$ is not a Frobenius row of the carrier, and a row outside S, R, i, r, ρ supplies no public endpoint or provenance for that Frobenius display. Thus the Frobenius boundary is exactly the finite ledger shown in the packet. □

Theorem 247.10 (InducedRepUp NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{InducedRep}^\uparrow}$ *obligation surface is the package consisting of the carrier packet of Definition 247.1, the restriction-induction classifier of Definition 247.3, the Frobenius ledger boundary of Definition 247.9, componentwise* hsame *and* Cont *stability for each displayed row, exactness of the finite provenance and continuation ledgers, and no standard bridge. The surface exports no row outside the carrier, classifier, and provenance ledger.*

Lean4 ✓ `BEDC.Derived.InducedRepUp.InducedRepCarrierPacket namecert obligation surface`
Lean4 ✓ `BEDC.Derived.InducedRepUp.InducedRepBHistCarrier namecert obligation surface`

Proof. Start with the carrier and classifier. The carrier supplies the finite row family $S, R, i, r, F, \eta, \epsilon, \rho, \lambda$, while the classifier supplies componentwise hsame transport for the consumed certificates, subgroup inclusion rows, representation-ring rows, induction and restriction endpoints, Frobenius rows, provenance packet, and continuation ledger.

The ten-field reading is therefore fixed. The traditional target is the restriction-induction interface with Frobenius reciprocity; the BEDC sources are $\mathsf{NameCert}_{\mathsf{Subgroup}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{RepresentationRing}^\uparrow}$; the carrier is the displayed finite BHist packet; the classifier is the restricted componentwise relation; stability is the listed hsame and Cont transport; the ledger is λ together with the Frobenius

rows; the core theorem list is this surface and the Frobenius ledger boundary; exactness is projection from the displayed rows; the standard bridge is none; and the status is a paper-side obligation surface for $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$.

For stability, transport each component of a packet along the corresponding classifier row. The SubgroupUp source certificate transports the subgroup inclusion rows, the RepresentationRingUp source certificate transports the representation-ring rows, and the endpoint and Frobenius rows are transported by their displayed hsame comparisons and the finite Cont comparison.

Exactness follows because every exported row is named in the carrier, classifier, or provenance ledger. Conversely, each named row repacks into the obligation surface by the displayed packet, so no additional host functor, host category, adjunction, character table, or bridge row is part of the certificate. □

Theorem 247.11 (InducedRepUp Subgroup and RepresentationRing consumer boundary)**.** *An* $\mathsf{InducedRep}^{\uparrow}$ *consumer of the source certificates may read exactly the SubgroupUp rows exposed by* $\mathsf{NameCert}_{\mathsf{Subgroup}^{\uparrow}}$ *and the representation-ring rows exposed by* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$*, together with the induction, restriction, Frobenius, provenance, and continuation rows displayed in Definition 247.1. It may not read a subgroup carrier, representation ring, functor, category, or Frobenius adjunction row unless that row is present in the carrier, classifier, or provenance ledger of the* $\mathsf{InducedRep}^{\uparrow}$ *packet.*

Proof. Project the consumer request through the carrier packet. A SubgroupUp request lands in S, and a RepresentationRingUp request lands in R. The source certificates named by those two rows supply their own public carrier, classifier, stability, exactness, and ledger boundaries.

Next project the $\mathsf{InducedRep}^{\uparrow}$-specific request. The induction endpoint is i, the restriction endpoint is r, the Frobenius rows are F, η, ϵ, the provenance packet is ρ, and the continuation ledger is λ. Transport between two such consumer surfaces is exactly the componentwise hsame and Cont transport listed in the restriction-induction classifier.

There are no remaining exported rows. Any row not found in the two source certificates or in $i, r, F, \eta, \epsilon, \rho, \lambda$ is outside the consumer boundary, so the downstream interface receives a concrete BEDC packet rather than equality of host-level induction and restriction constructions. □

Definition 247.12 (InducedRepUp stability obligation packet)**.** *For carrier packets*

$$\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda) \qquad \text{and} \qquad \mathcal{I}' = (S', R', i', r', F', \eta', \epsilon', \rho', \lambda'),$$

the $\mathsf{InducedRep}^{\uparrow}$ *stability obligation packet is the finite datum consisting of the two displayed carriers, the componentwise* hsame *rows from the restriction-induction classifier of Definition 247.3, and the finite* Cont *comparison ledger from* λ *to* λ'*. Its fields are:*

1. hsame *rows for the consumed certificate rows* S *and* R*;*
2. hsame *rows for the induction and restriction endpoints* i *and* r*;*
3. *entrywise* hsame *rows for the Frobenius display* F, η, ϵ*;*
4. *an* hsame *row for the provenance packet* ρ*;*
5. *the finite* Cont *comparison ledger relating the source, endpoint, Frobenius, provenance, and public continuation entries recorded by* λ*.*

The packet has no field for equality of host categories, host induction functors, host restriction functors, functorial naturality, or adjunction objects outside the displayed BHist *rows.*

Theorem 247.13 (InducedRepUp classifier stability)**.** *The restriction-induction classifier of Definition 247.3 transports every carrier component of Definition 247.1. For any two packets $\mathcal{I}$ and $\mathcal{I}'$ related by that classifier, the transport repacks as the stability obligation packet of Definition 247.12 and preserves the public* $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$ *obligation surface of Definition 247.10.*

Proof. Project the two carriers as $\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda)$ and $\mathcal{I}' = (S', R', i', r', F', \eta', \epsilon', \rho', \lambda')$. The classifier is already componentwise: it gives the hsame rows for the consumed SubgroupUp and RepresentationRingUp packets, the displayed subgroup and representation-ring rows read from them, the induction and restriction endpoints, the Frobenius rows, and the provenance packet.

It remains to repack the continuation part. The same classifier includes the finite Cont comparison between λ and λ', entry by entry, so the source, endpoint, Frobenius, provenance, and public continuation reads are transported inside the displayed ledger.

The obligation surface in Definition 247.10 asks for no more data than those projected rows. Repacking the projected hsame rows and the finite Cont comparison gives the stability obligation packet, and the surface is preserved because no host category, functor equality, adjunction row, or bridge row is part of the transported data. □

Theorem 247.14 (InducedRepUp continuation ledger closure)**.** *The source reads, induction and restriction endpoint reads, Frobenius reads, provenance reads, and public continuation reads of an* $\mathsf{InducedRep}^{\uparrow}$ *carrier close under finite* Cont *composition inside the ledger λ of Definition 247.1. Consequently every finite continuation needed by the obligation surface is again a row recorded by λ.*

↪ variant `BEDC.Derived.InducedRepUp.InducedRepBHistCarrier namecert obligation surface`

Proof. Project the carrier to the finite packet $\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda)$. By definition, λ contains the consumed SubgroupUp rows, consumed RepresentationRingUp rows, induction and restriction endpoint rows, Frobenius rows, provenance rows, and public continuation rows exposed by the packet.

Now compose only rows already listed in λ. A source read followed by an endpoint read, an endpoint read followed by a Frobenius read, or a Frobenius read followed by a public continuation read is still a finite read through the same displayed ledger, because the ledger is the complete Cont record for the carrier.

Thus the closure statement is a projection-and-repacking argument. The projection chooses the listed rows of λ, and the repacking records their finite composite as another continuation row of the same public ledger. Nothing in the argument introduces a host functor, host category, or adjunction object outside the carrier. □

Theorem 247.15 (InducedRepUp package provenance exactness)**.** *Every row exported by the* $\mathsf{InducedRep}^{\uparrow}$ *package provenance surface is exactly one of the rows recorded by ρ or λ in Definition 247.1: the consumed SubgroupUp rows, the consumed RepresentationRingUp rows, the induction row, the restriction row, and the Frobenius rows F, η, ϵ. No host category, host functor equality, or adjunction row is exported by the provenance surface.*

Proof. Project the package row ρ. Its definition records precisely the consumed package rows from S and R together with the package rows attached to i, r, F, η, and ϵ. These are exactly the SubgroupUp, RepresentationRingUp, induction, restriction, and Frobenius rows named in the theorem.

Project the continuation ledger λ next. It records the corresponding public reads: source rows, endpoint rows, Frobenius rows, provenance rows, and public continuation rows. Therefore every public continuation witness for a provenance row is already present in the same finite carrier.

For the converse, take any row recorded by ρ or λ with one of the listed roles. The carrier definition repacks it as part of the $\mathsf{InducedRep}^{\uparrow}$ public provenance surface, and the consumer boundary of Definition 247.11 excludes every row not so recorded. Hence no host category, equality of induction or restriction functors, or Frobenius adjunction row is exported. □

Theorem 247.16 (InducedRepUp source-Frobenius exact consumption)**.** *A downstream row consumed from an* $\mathsf{InducedRep}^{\uparrow}$ *packet is visible exactly when it is one of the following finite public rows: a SubgroupUp source row exposed through S, a RepresentationRingUp source row exposed through R, an induction or restriction endpoint row, one of the Frobenius rows F, η, ϵ, or a provenance and continuation row recorded by ρ or λ. No host subgroup object, host representation category, host functor equality, or Frobenius adjunction object is visible outside this finite source–Frobenius ledger.*

Proof. Project a consumed row through the carrier packet $\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda)$. The source rows are exactly the SubgroupUp and RepresentationRingUp rows allowed by Definition 247.11; the endpoint rows are the displayed induction and restriction rows i and r.

Project the Frobenius part next. By Definition 247.9, every Frobenius read is one of F, η, ϵ and has endpoints in the displayed induction and restriction rows. By Definition 247.14, any finite continuation needed to consume those rows remains inside λ.

The provenance projection is fixed by Definition 247.15: every public provenance row is recorded by ρ or by the corresponding public continuation row in λ. Therefore any downstream row consumed from the packet is on the listed source, endpoint, Frobenius, provenance, or continuation surface.

Conversely, take any row on that finite list. The source rows repack through the consumer boundary, the endpoint and Frobenius rows repack through the Frobenius ledger boundary, and the provenance and continuation rows repack through ρ and λ. The four cited boundaries together reconstruct the same $\mathsf{InducedRep}^{\uparrow}$ public packet, so every listed row is visible to the consumer and no outside host-level datum is added. □

Theorem 247.17 (InducedRepUp Frobenius source-row determinacy)**.** *Let $\mathcal{I}_0 = (S, R, i, r, F, \eta, \epsilon, \rho_0, \lambda_0)$ and $\mathcal{I}_1 = (S, R, i, r, F, \eta, \epsilon, \rho_1, \lambda_1)$ be two* $\mathsf{InducedRep}^{\uparrow}$ *packets with the same SubgroupUp source row, the same RepresentationRingUp source row, the same induction and restriction endpoint rows, the same Frobenius rows F, η, ϵ, the same public* Cont *ledger rows, and the same* Pkg *provenance rows. Then the public classifier endpoints exported by $\mathcal{I}_0$ and $\mathcal{I}_1$ are related by* hsame.

Proof. Project both packets through the restriction-induction classifier. The source rows are the common SubgroupUp and RepresentationRingUp rows, and the endpoint rows are the common induction and restriction histories i and r.

Apply Definition 247.16. It rules out any consumed public row outside the common source rows, endpoint rows, Frobenius rows, Cont ledger, and Pkg provenance. Thus both packets expose the same finite public ledger.

Finally repack that common source-Frobenius ledger through Definition 247.9 and Definition 247.15. The classifier endpoint is therefore read from the same carried rows in both packets, so the two exported endpoints are related by hsame. □

Theorem 247.18 (InducedRepUp source classifier obligation)**.** *For an* $\mathsf{InducedRep}^{\uparrow}$ *carrier packet* $\mathcal{I} = (S, R, i, r, F, \eta, \epsilon, \rho, \lambda)$*, the public classifier is determined by the SubgroupUp source row* S*, the RepresentationRingUp source row* R*, the induction endpoint* i*, the restriction endpoint* r*, and the displayed* hsame *transport rows of Definition 247.3. No classifier read may use a host subgroup, representation category, or functor equality outside those carried rows.*

Proof. Project the carrier through Definition 247.11. The consumer sees the SubgroupUp and RepresentationRingUp source rows only through S and R, together with the induction and restriction endpoints.

Apply Definition 247.8. It identifies the visible classifier rows as $H_{\leq}, H_{\mathrm{rep}}, H_{\uparrow}$, and $H_{\downarrow}$ together with the public Frobenius and continuation rows.

Finally apply Definition 247.17. Once the source rows, endpoints, Frobenius rows, Cont ledger, and Pkg provenance are fixed, the exported classifier endpoints are related by hsame, so no outside classifier datum is available. □

Theorem 247.19 (InducedRepUp ledger exactness obligation)**.** *The visible Frobenius ledger reads of an* $\mathsf{InducedRep}^{\uparrow}$ *carrier are exactly the rows recorded by the* Cont *ledger* λ *and the* Pkg *provenance packet* ρ *for the consumed source certificates, induction endpoint, restriction endpoint, and Frobenius rows* F, η, ϵ*. Every visible read is on that finite ledger, and every listed row repacks into the public carrier.*

Proof. Begin with Definition 247.9. It restricts Frobenius reads to $F, \eta, \epsilon, \lambda$ with endpoints i and r over the consumed source packets S and R.

Use Definition 247.14. It shows that finite continuations among source reads, endpoint reads, Frobenius reads, provenance reads, and public continuation reads remain inside λ.

Apply Definition 247.15. The provenance rows are precisely those recorded by ρ or λ for the source, endpoint, and Frobenius roles. The reverse projection repacks each listed row into the carrier, so the ledger is exact. □

Theorem 247.20 (InducedRepUp NameCert threshold witness)**.** *The dependency-ready* $\mathsf{InducedRep}^{\uparrow}$ *obligation surface is the finite* BHist *packet consisting of the source classifier obligation of Definition 247.18, the ledger exactness obligation of Definition 247.19, and the source-Frobenius consumption boundary of Definition 247.16. It supplies downstream consumers exactly the carried source, endpoint, Frobenius, classifier,* Cont*, and* Pkg *rows.*

Proof. First use Definition 247.18. It fixes the public classifier from the two source certificates, the induction endpoint, the restriction endpoint, and the displayed hsame transport rows.

Next use Definition 247.19. It fixes the visible ledger reads as the rows in λ and ρ for the source, endpoint, and Frobenius roles.

Finally apply Definition 247.16. It states that downstream consumption is exactly the finite list of source, endpoint, Frobenius, provenance, and continuation rows. Repacking those three surfaces gives the dependency-ready $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$ threshold, with no host category, functor equality, adjunction object, or external bridge row. □

Theorem 247.21 (InducedRepUp restriction-induction classifier equivalence)**.** *Assume that the consumed SubgroupUp classifier rows, the consumed RepresentationRingUp classifier rows, the induction and restriction endpoint* hsame *rows, the Frobenius rows* F, η, ϵ*, the provenance row, and the finite* Cont *ledger comparisons are each stable under reflexive, reversed, and composable comparison on their own displayed rows. Then the restriction-induction classifier of Definition 247.3*

is an equivalence relation on accepted $\mathsf{InducedRep}^{\uparrow}$ *carrier packets of Definition 247.1. Moreover every reflexive, reversed, or composite witness has exactly the same support roles*

$$S, R, i, r, F, \eta, \epsilon, \rho, \lambda$$

as the carriers it compares; no off-ledger host category, functor equality, adjunction object, character formula, or bridge row can be introduced by the equivalence operations.

Proof. Let

$$\mathcal{I}_a = (S_a, R_a, i_a, r_a, F_a, \eta_a, \epsilon_a, \rho_a, \lambda_a), \qquad \mathcal{I}_b = (S_b, R_b, i_b, r_b, F_b, \eta_b, \epsilon_b, \rho_b, \lambda_b),$$

and

$$\mathcal{I}_c = (S_c, R_c, i_c, r_c, F_c, \eta_c, \epsilon_c, \rho_c, \lambda_c)$$

be accepted carriers. The classifier of Definition 247.3 has seven visible coordinates: the two consumed source certificate comparisons, the entrywise source-row comparisons read from those certificates, the induction and restriction endpoint comparisons, the Frobenius comparisons for F, η, ϵ, the provenance comparison, and the finite Cont ledger comparison.

For reflexivity of $\mathcal{I}_a$, choose the reflexive comparison supplied by the assumed stability of each of those seven coordinates. This gives the SubgroupUp row S_a compared with itself, the RepresentationRingUp row R_a compared with itself, the source rows read from them compared with themselves, the endpoint rows i_a and r_a compared with themselves, the Frobenius rows F_a, η_a, ϵ_a compared with themselves, the provenance row ρ_a compared with itself, and the identity finite continuation comparison on λ_a. These rows are precisely the fields required by the restriction-induction classifier, so they form a witness $\mathcal{I}_a \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^{\uparrow}} \mathcal{I}_a$.

For symmetry, suppose $\mathcal{I}_a \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^{\uparrow}} \mathcal{I}_b$. Project the witness to the same seven coordinates. By the assumed reversed comparison for each coordinate, reverse the SubgroupUp and RepresentationRingUp source certificate comparisons, reverse the entrywise source-row comparisons, reverse the endpoint comparisons for i and r, reverse the Frobenius comparisons for F, η, ϵ, reverse the provenance comparison, and reverse the finite Cont comparison from λ_a to λ_b. Repacking these reversed rows gives a witness $\mathcal{I}_b \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^{\uparrow}} \mathcal{I}_a$.

For transitivity, suppose $\mathcal{I}_a \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^{\uparrow}} \mathcal{I}_b$ and $\mathcal{I}_b \sim^{\mathrm{ri}}_{\mathsf{InducedRep}^{\uparrow}} \mathcal{I}_c$. Project both witnesses coordinate by coordinate. Compose the two SubgroupUp comparisons through S_b, compose the two RepresentationRingUp comparisons through R_b, compose the entrywise source-row comparisons through the rows read from S_b and R_b, compose the endpoint comparisons through i_b and r_b, compose the Frobenius comparisons through F_b, η_b, ϵ_b, compose the provenance comparisons through ρ_b, and compose the finite continuation comparisons through λ_b. The assumed composability of each coordinate supplies exactly the rows required for a classifier witness from $\mathcal{I}_a$ to $\mathcal{I}_c$.

It remains to check that these operations do not enlarge the carrier support. The consumer boundary of Definition 247.11 limits source consumption to the SubgroupUp and RepresentationRingUp rows carried by S and R, together with the displayed endpoint, Frobenius, provenance, and continuation rows. The Frobenius ledger boundary of Definition 247.9 limits Frobenius reads to $F, \eta, \epsilon, \lambda$ with endpoints i and r. The ledger exactness obligation of Definition 247.19 says that visible ledger reads are exactly the rows recorded by ρ and λ for those source, endpoint, and Frobenius roles.

Therefore the reflexive witness, the reversed witness, and the composite witness all live on the same finite support $S, R, i, r, F, \eta, \epsilon, \rho, \lambda$. Any proposed comparison using a host representation category, functor equality, adjunction object, character formula, bridge row, or other off-ledger

datum is rejected before the classifier is formed, because such a row is not one of the seven coordinates listed in Definition 247.3 and is not visible through the exact consumer ledger. Thus the restriction-induction classifier is reflexive, symmetric, and transitive on accepted carrier packets, with no additional support beyond the displayed BEDC packet. □

Theorem 247.22 (InducedRepUp obligation closure package)**.** *The explicit obligation set for* $\mathsf{InducedRep}^{\uparrow}$ *is the conjunction of the carried* BHist *packet of Definition 247.1, the SubgroupUp source boundary, the RepresentationRingUp action boundary, the Frobenius classifier, the source classifier obligation, the ledger exactness obligation, and the consumer boundary. Each row is scoped through the displayed* hsame *transport rows, the finite* Cont *ledger, and the shared* Pkg *provenance packet. This package exports no host representation category, host functor equality, adjunction object, character formula, or standard bridge row.*

Proof. First read the carrier and source boundaries. The carrier packet lists exactly S, R, i, r, F, η, ϵ, ρ, and λ, while Definition 247.11 fixes the SubgroupUp source row and the RepresentationRingUp action row consumed by the package.

Next attach the classifier rows. Use Definition 247.8 for the Frobenius classifier surface and Definition 247.18 for the source classifier obligation. These rows are componentwise hsame transport over the displayed subgroup, representation-ring, induction, restriction, and Frobenius endpoints.

Now use Definition 247.19. It says that the visible reads are exactly the rows recorded by ρ and λ for the consumed source certificates, endpoints, Frobenius rows, provenance rows, and continuation rows.

Finally apply Definition 247.16 and Definition 247.20. Together they repack the listed carrier, classifier, source, ledger, and consumer rows into the public $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$ obligation package. Since every exported row has already been accounted for in that finite package, no host category, functor equality, adjunction object, character formula, or standard bridge row is exported. □

Theorem 247.23 (InducedRepUp Subgroup source-consumer scope)**.** *Every downstream consumer of the SubgroupUp source used by* $\mathsf{InducedRep}^{\uparrow}$ *reads that source only through the displayed subgroup row of Definition 247.1, the source classifier of Definition 247.18, the continuation rows carried by* Cont*, and the provenance rows carried by* Pkg*. In particular, the consumer surface exposes no independent coset carrier, subgroup inclusion object, orbit classifier, or host-group equality beyond the source row already bounded by Definition 247.4.*

Proof. Start with the finite carrier packet of Definition 247.1. Its SubgroupUp input is the single source row S, together with the endpoint rows that connect S to the induction and restriction data.

Apply Definition 247.4. It identifies the subgroup source consumed by $\mathsf{InducedRep}^{\uparrow}$ as the displayed row, not as a second subgroup certificate or an external coset object. Then use Definition 247.18 to read the classifier attached to that source row.

Finally apply Definition 247.19 and Definition 247.22. The ledger says that the visible reads are exactly the recorded Cont and Pkg rows, and the closure package accounts for every exported source obligation. Hence a consumer can read the SubgroupUp source only through the listed source, classifier, continuation, and provenance rows. □

Theorem 247.24 (InducedRepUp RepresentationRing action scope)**.** *Every downstream consumer of the RepresentationRingUp action used by* $\mathsf{InducedRep}^{\uparrow}$ *reads that action only through the displayed representation row of Definition 247.1, the induction and restriction endpoints, the Frobenius row, and the finite ledger rows carried by* ρ *and* λ*. The consumer surface does not expose*

a separate representation category, action functor equality, adjunction object, or character formula beyond the boundary fixed by Definition 247.5.

Proof. Read first the representation component of Definition 247.1. The relevant data are the row R, the induction endpoint i, the restriction endpoint r, and the Frobenius row F; no ambient representation category is introduced by the carrier.

Apply Definition 247.5. It fixes the RepresentationRingUp action source as the displayed representation row together with the induction and restriction endpoints. Then apply Definition 247.18 to keep the classifier read tied to those endpoint rows.

Use Definition 247.19 for the ledger. The ledger projection permits only the reads recorded by ρ and λ for the representation, endpoint, Frobenius, continuation, and provenance rows. Combining this with Definition 247.22 exhausts the action surface visible to consumers. □

Theorem 247.25 (InducedRepUp consumer obligation exhaustion)**.** *The downstream consumer interface exported by* $\mathsf{InducedRep}^{\uparrow}$ *is exactly the union of the SubgroupUp source rows scoped in Definition 247.23, the RepresentationRingUp action rows scoped in Definition 247.24, and the displayed Frobenius, continuation, and package rows of the obligation closure package. No consumer receives an additional host category, coset carrier, action transport, adjunction, character formula, or standard bridge row.*

Proof. The SubgroupUp contribution is exactly the source row, source classifier, Cont rows, and Pkg provenance supplied by Definition 247.23. The RepresentationRingUp contribution is exactly the representation row, induction endpoint, restriction endpoint, Frobenius row, and ledger projection supplied by Definition 247.24.

It remains to compare this union with the chapter's finite obligation package. Apply Definition 247.18 for the classifier rows and Definition 247.19 for the recorded ledger reads. These two obligations identify the classifier and ledger pieces with rows already present in Definition 247.1.

Finally apply Definition 247.22. It repacks the source, action, Frobenius, continuation, and provenance rows into the single exported $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$ obligation surface. Since every row in either scoped source theorem is a row of that package, and every row of the package is one of those scoped rows or a displayed Frobenius, continuation, or provenance row, the downstream consumer interface is exactly the stated union. □

Theorem 247.26 (InducedRepUp standard bridge scope)**.** *The public* $\mathsf{InducedRep}^{\uparrow}$ *packet gives a conservative bridge to the standard induction-restriction reading only through the displayed SubgroupUp row, RepresentationRingUp row, induction endpoint, restriction endpoint, Frobenius ledger, componentwise* hsame *rows, finite* Cont *rows, and* Pkg *provenance. The bridge reads no host representation category, functor equality, adjunction object, character formula, or source row outside that packet.*

Proof. Start from the public consumer interface of Definition 247.25. It exhausts downstream reads by the SubgroupUp source rows, RepresentationRingUp action rows, Frobenius rows, continuation rows, and package provenance already present in the displayed carrier.

Interpret the standard induction-restriction reading by projecting only those rows: the subgroup source supplies the source boundary, the representation-ring row supplies the action boundary, and the induction and restriction endpoints supply the two displayed transport directions. The Frobenius ledger is then the sole comparison row available to the bridge.

Finally use Definition 247.22 to repack the projected rows into the same public obligation surface. Since the repacking has no coordinates beyond hsame, Cont, and Pkg on the displayed packet, the bridge is conservative over the public certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}$.

Constructive story: An induced-representation packet starts with two consumed certificates: a $\mathsf{Subgroup}^{\uparrow}$ row naming the inclusion and a $\mathsf{RepresentationRing}^{\uparrow}$ row naming the representation-ring source and target, then displays induction, restriction, Frobenius comparison, unit, counit, continuation, and provenance rows in one finite BHist package. The carrier admits exactly those displayed rows and excludes any host representation category, coset carrier, functor equality, adjunction object, character formula, or bridge row that is not present in the packet. Two accepted packets classify together by componentwise hsame transport on the subgroup source, representation-ring source, induction endpoint, restriction endpoint, Frobenius ledger, provenance packet, and finite Cont ledger, so the source specification covers the two dependency certificates and the pattern specification is the displayed induction–restriction/Frobenius shape. The ledger keeps the raw and visible sides aligned by retaining the subgroup row, representation-ring row, induction and restriction endpoints, Frobenius row, unit and counit rows, source and Frobenius continuation ledgers, and Pkg provenance as inspectable histories. With one such packet in hand, the five name-certificate obligations are componentwise: the displayed ledger inhabits the carrier, inherited and endpoint hsame rows provide reflexivity, symmetry, and transitivity, and transported dependency and Frobenius rows repack into the same accepted carrier surface. A history h lies in the signature gap of an $\mathsf{InducedRep}^{\uparrow}$ token p when the source-domain accepts h as this packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h must present exactly the subgroup, representation-ring, induction, restriction, Frobenius, continuation, and provenance rows that p encodes. The chapter registers this finite induction–restriction construction under the name $\mathsf{InducedRep}^{\uparrow}$; Frobenius reciprocity is a displayed ledger comparison inside BEDC, with no imported functor category, host adjunction, standard bridge, or extra source.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 247.25 and Definition 247.26 bind the mature finite consumer surface and bridge boundary to the carried BHist packet, SubgroupUp source rows, RepresentationRingUp action rows, Frobenius rows, hsame, Cont, and Pkg provenance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InducedRep}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.InducedRepUp.InducedRepCarrierPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This does not close external representation categories, functor equality, adjunction objects, character formulas, or rows outside the displayed induction-restriction packet.

Upgrade path: No further paper theory-axis work is recorded for this chapter; audit and bridge-status changes remain on the verification axis.

Chapter 248

A Concrete Naming Certificate for $\mathsf{VermaModule}^{\uparrow}$

The Verma-module interface $\mathsf{VermaModule}^{\uparrow}$ packages, for a semisimple Lie algebra and a highest weight, the universal highest-weight module obtained by inducing from a Borel subalgebra. It depends on $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ (chapter 141) and $\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}$ (chapter 144).

248.1 Carrier definition

Theorem 248.1 (Verma-module finite carrier obligation)**.** *A* $\mathsf{VermaModule}^{\uparrow}$ *packet is a finite* BHist *row package containing a displayed* $\mathsf{LieAlgebra}^{\uparrow}$ *source row,* $\mathsf{RootSystem}^{\uparrow}$ *positive-root rows, a highest-weight row, Borel action rows, induced-module generator rows, and* Pkg *provenance naming the displayed Lie-algebra and root-system sources. The packet contains no host quotient module, no selected PBW basis, and no ambient category of modules beyond these finite rows.*

Lean4 ✓ `BEDC.Derived.VermaModuleUp.VermaModuleFiniteCarrier obligation surface`

Proof. Unpack the packet as a finite BEDC history. The Lie-algebra source, positive root data, highest weight, Borel action, induced generator, and provenance coordinates are the displayed rows of that history package.

Each consumer-visible coordinate is obtained by projecting one of those rows or transporting it along the displayed hsame and Cont data. Since the packet has no coordinate for a host quotient module or selected basis, neither object is introduced by the carrier obligation. □

Lean4 ✓ `BEDC.Derived.VermaModuleUp.VermaModuleFiniteCarrier carrier obligation`

248.2 The certificate

Theorem 248.2 (Verma-module highest-weight ledger)**.** *Every accepted* $\mathsf{VermaModule}^{\uparrow}$ *packet exposes exactly the highest-weight row, lowering-operator rows from the displayed positive-root data, Borel action rows,* hsame *comparison rows,* Cont *provenance rows, and* Pkg *dependency rows consumed by downstream representation certificates. It exports no quotient by a maximal submodule, no irreducible-module classifier, and no chosen basis for weight spaces.*

Proof. Project an accepted packet to the rows named in Definition 248.1. The highest-weight coordinate, lowering-operator coordinates, Borel action, transport, continuation, and package provenance are all finite BHist entries.

Downstream representation certificates can only read through those finite entries. Componentwise transport preserves the highest-weight and action rows, and continuation rows record the finite lowering operations already present in the packet.

The carrier contains no row for a maximal-submodule quotient, irreducibility classifier, or basis choice. The accepted ledger therefore exhausts exactly the displayed highest-weight surface. □

Lean4 ✓ `BEDC.Derived.VermaModuleUp.VermaModuleFiniteCarrier highest weight ledger`
↪ variant `BEDC.Derived.VermaModuleUp.VermaModuleHighestWeightLedger boundary`

Theorem 248.3 (Verma-module NameCert obligation surface)**.** *The carrier obligation of Definition 248.1, the componentwise classifier transport over the displayed highest-weight and action rows, the highest-weight ledger of Definition 248.2, and the source dependencies on* $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RootSystem}^{\uparrow}}$ *provide the local* $\mathsf{NameCert}_{\mathsf{VermaModule}^{\uparrow}}$ *obligation surface. The surface is entirely* BHist*-anchored and does not introduce a host quotient module or a choice of basis.*

Proof. Begin with the finite carrier obligation. It supplies the source rows, positive-root rows, highest-weight row, Borel action rows, induced-generator rows, and package provenance needed for the local naming surface.

Transport the displayed classifier componentwise along hsame. The highest-weight and action rows move through the same finite coordinates, while the Cont rows record only the lowering operations already carried by the packet.

Finally apply the highest-weight ledger to identify the exact downstream readback surface. Together with the displayed $\mathsf{LieAlgebra}^{\uparrow}$ and $\mathsf{RootSystem}^{\uparrow}$ provenance, these rows provide the local $\mathsf{NameCert}_{\mathsf{VermaModule}^{\uparrow}}$ obligation surface without adding a quotient module, irreducible classifier, or basis choice. □

Lean4 ✓ `BEDC.Derived.VermaModuleUp.VermaModuleFiniteCarrier obligation ledger surface`
Lean4 ✓ `BEDC.Derived.VermaModuleUp.VermaModuleFiniteCarrier semanticNameCert`

Closure status for $\mathsf{NameCert}_{\mathsf{VermaModule}^{\uparrow}}$**.**

Constructive story: A $\mathsf{VermaModule}^{\uparrow}$ packet is generated from finite BHist rows for a Lie-algebra source, a highest-weight row, a generator row, an action ledger, and the displayed module-facing carrier rows. The Verma surface is assembled by replaying the generator and action routes through Cont, so consumers see finite obligation rows rather than a host universal module. The classifier transports the highest-weight, generator, and action rows by hsame, and Pkg records the consumed Lie-algebra and module dependencies. The resulting certificate names the finite highest-weight ledger and its semantic carrier boundary without exporting irreducible quotients or basis choices.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{VermaModule}^{\uparrow}}$, seed)

Scope closed: This chapter binds the finite carrier obligation ledger surface and semantic NameCert surface for $\mathsf{VermaModule}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{VermaModule}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: It does not claim universal-module construction, irreducible quotient classification, character formulae, host module equality, or a chosen PBW basis.

Upgrade path: Obligation closure requires Lean encodings of the finite carrier, highest-weight action ledger, semantic NameCert rows, and non-escape boundary.

Chapter 249

A Concrete Naming Certificate for $\mathsf{Hypergeometric}^{\uparrow}$

The hypergeometric-function interface $\mathsf{Hypergeometric}^{\uparrow}$ packages the analytic continuation of ${}_pF_q$ series defined by ascending-factorial coefficient ratios. It depends on $\mathsf{NameCert}_{\mathsf{CplxAnalytic}^{\uparrow}}$ (chapter 76) and $\mathsf{NameCert}_{\mathsf{Gamma}^{\uparrow}}$ (chapter 75).

249.1 Carrier definition

Definition 249.1 (HypergeometricUp BHist source packet)**.** *A* $\mathsf{Hypergeometric}^{\uparrow}$ *source packet is a finite* BHist *tuple* $(C, G, A, B, R, S, \rho, \lambda)$*. The row* C *is the consumed* $\mathsf{CplxAnalytic}^{\uparrow}$ *dependency packet, and the row* G *is the consumed* $\mathsf{Gamma}^{\uparrow}$ *dependency packet. The rows* A *and* B *record the visible numerator and denominator parameter lists for the* ${}_pF_q$ *series, the row* R *records the ascending-factorial coefficient-ratio boundary, and the row* S *records the finite series-readback boundary over the displayed complex-analytic carrier. The row* ρ *is the* Pkg *provenance linking the two dependency packets to the hypergeometric name, and* λ *is the finite* Cont *ledger storing the* hsame *transports among parameters, coefficient ratios, and readback rows.*

Acceptance is exactly this finite packet. It carries no analytic continuation theorem, no host power-series object, no monodromy data, no differential equation, and no external equality of special functions.

Theorem 249.2 (HypergeometricUp root carrier)**.** *Every accepted* $\mathsf{Hypergeometric}^{\uparrow}$ *carrier row projects to the* $\mathsf{CplxAnalytic}^{\uparrow}$ *dependency row, the* $\mathsf{Gamma}^{\uparrow}$ *dependency row, the parameter rows* A *and* B*, the coefficient-ratio row* R*, the finite readback row* S*, the* Pkg *provenance* ρ*, and the* Cont *ledger* λ *of Definition 249.1. Conversely, those rows repack as an accepted carrier packet when their displayed* hsame *transports are the ones recorded by* λ*.*

Proof. Project an accepted packet by its displayed tuple coordinates. The first two coordinates expose the complex-analytic and Gamma dependency packets, while the parameter, coefficient-ratio, readback, provenance, and ledger coordinates are read directly from the finite BHist packet.

For the converse, place the same displayed rows back into the tuple constructor and use the stored Cont ledger as the acceptance evidence. The construction does not inspect a host series or an analytic continuation theorem, because no such coordinate occurs in the packet. □

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket root carrier`

Theorem 249.3 (HypergeometricUp root classifier)**.** *For two* Hypergeometric$^{\uparrow}$ *source packets, the root classifier compares only the consumed* CplxAnalytic$^{\uparrow}$ *and* Gamma$^{\uparrow}$ *dependency rows, the numerator and denominator parameter rows, the coefficient-ratio row, the finite readback row, the* Pkg *provenance row, and the finite* Cont *and* hsame *ledger. Transport along those rows preserves the accepted carrier and supplies no analytic-continuation classifier outside the displayed packet.*

Proof. Start with the dependency comparisons. The carried CplxAnalytic$^{\uparrow}$ and Gamma$^{\uparrow}$ rows supply the only classifiers available for the analytic carrier and Gamma-derived parameter faces.

Next transport the parameter rows, the coefficient-ratio row, and the finite series-readback row through the displayed hsame comparisons stored in λ. The Pkg row records that the transported faces belong to the same hypergeometric packet.

Repack the transported rows by Definition 249.2. Since the classifier has compared every packet coordinate and no continuation classifier is present, the result is exactly the root classifier surface. □

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket root classifier`

Theorem 249.4 (HypergeometricUp root ledger)**.** *The* Hypergeometric$^{\uparrow}$ *root ledger is exact: its rows are precisely the* CplxAnalytic$^{\uparrow}$ *dependency, the* Gamma$^{\uparrow}$ *dependency, the two parameter lists, the coefficient-ratio boundary, the finite* Cont *readback, the* hsame *transports, and the* Pkg *provenance of Definition 249.1. No analytic continuation, singularity classification, monodromy representation, differential-equation solution, or host-function equality is part of this ledger.*

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket root ledger`

Proof. Coverage follows by projecting the accepted source packet. Each ledger entry is one of the displayed tuple coordinates or one of the transport rows stored in the finite Cont ledger.

Soundness is the reverse projection. Given exactly those rows, the source packet constructor rebuilds the same accepted Hypergeometric$^{\uparrow}$ carrier and the same classifier surface.

Completeness follows from the packet inventory. There is no coordinate for analytic continuation, singularity data, monodromy, a host differential equation, or external function equality, so none of those rows can be consumed from the root ledger. □

Theorem 249.5 (HypergeometricUp root stability)**.** *If a* Hypergeometric$^{\uparrow}$ *source packet is transported by the displayed* hsame *rows on its* CplxAnalytic$^{\uparrow}$ *dependency,* Gamma$^{\uparrow}$ *dependency, parameter lists, coefficient-ratio boundary, finite readback row, and* Pkg *provenance, then the transported packet is again accepted by the same root carrier and classified by the same root classifier.*

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket root stability`

Proof. Read the carrier rows using Definition 249.2. The hypotheses give an hsame transport for every visible coordinate of the packet.

Use the finite Cont ledger to move the coefficient-ratio and readback rows with the parameter transports. The dependency rows move through their own displayed NameCert classifiers, and the Pkg provenance remains attached to the transported packet.

Apply Definition 249.3 to the transported row inventory. It compares exactly the rows just transported, so the accepted packet and its classifier are stable without using analytic continuation as an uncarried host theorem. □

Theorem 249.6 (HypergeometricUp endpoint ledger determinacy)**.** *Let two* $\mathsf{Hypergeometric}^{\uparrow}$ *source packets share the* $\mathsf{CplxAnalytic}^{\uparrow}$ *dependency row and the* $\mathsf{Gamma}^{\uparrow}$ *dependency row. Suppose their numerator-parameter, denominator-parameter, finite readback, and* Pkg *provenance rows are compared rowwise by* hsame*, and suppose their coefficient-ratio, finite ledger, and endpoint rows are carried by compatible* Cont *rows over those comparisons. Then the transported endpoint, the coefficient-ratio row, and the finite ledger are determined up to* hsame *by the common* BHist *packet rows.*

Equivalently, any downstream consumer that sees only those dependency rows, parameter comparisons, readback rows, provenance rows, and compatible Cont *entries cannot distinguish two different transported endpoints, coefficient-ratio rows, or finite ledgers inside the root surface.*

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket endpoint ledger determinacy`

Proof. First apply Definition 249.3. The classifier compares exactly the $\mathsf{CplxAnalytic}^{\uparrow}$ dependency, the $\mathsf{Gamma}^{\uparrow}$ dependency, the numerator and denominator parameter rows, the readback rows, and the Pkg provenance rows, so the two packets have the same root-facing classification data.

Next apply Definition 249.5. The compatible Cont rows transport the coefficient-ratio boundary, finite ledger, and endpoint through the already matched parameter and dependency rows, keeping the transported packet inside the same root carrier and classifier surface.

Finally apply Definition 249.4. Ledger exactness says that no further row is available to decide an endpoint, coefficient-ratio boundary, or finite ledger. The conclusion therefore uses only the finite BHist packet, Cont, hsame, and Pkg rows; it does not use analytic continuation or host special-function equality. □

Theorem 249.7 (HypergeometricUp root consumer boundary)**.** *A downstream consumer of the* $\mathsf{Hypergeometric}^{\uparrow}$ *root may read exactly the* BHist *source packet of Definition 249.1, the carrier projection of Definition 249.2, the classifier stability of Definition 249.3, the exact ledger of Definition 249.4, and the transport stability of Definition 249.5. It may consume the displayed complex-analytic dependency, Gamma dependency, parameter rows, coefficient-ratio row, finite readback,* Cont*,* hsame*, and* Pkg *provenance; it may not consume analytic continuation as an uncarried host theorem.*

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket root consumer boundary`

Proof. First project the source packet. The carrier theorem lists every row available to the consumer and repacks exactly those rows as the accepted $\mathsf{Hypergeometric}^{\uparrow}$ root.

Next apply the classifier and stability theorems. They show that all comparisons and transports remain inside the same dependency, parameter, coefficient-ratio, readback, provenance, and ledger surface.

Finally apply ledger exactness. Since the ledger has no coordinate for analytic continuation or for any external special-function equality, the consumer boundary is precisely the displayed finite BHist packet. □

249.2 The certificate

Theorem 249.8 (HypergeometricUp NameCert obligation surface)**.** *The source packet of Definition 249.1 together with Definition 249.2, Definition 249.3, Definition 249.4, Definition 249.5, and Definition 249.7 supplies the paper-side* $\mathsf{NameCert}_{\mathsf{Hypergeometric}^{\uparrow}}$ *obligation surface. Its rows are*

exactly the BHist *source packet,* Cont, hsame, Pkg, *the* CplxAnalytic$^{\uparrow}$ *dependency row, the* Gamma$^{\uparrow}$ *dependency row, the parameter rows, the coefficient-ratio row, and the finite readback row.*

Proof. Start with the source packet definition. It displays the carrier coordinates: the two dependency packets, numerator and denominator parameter rows, the coefficient-ratio row, the finite readback row, package provenance, and the finite continuation ledger.

Apply the root carrier, classifier, ledger, and stability theorems. They show that these displayed coordinates are enough for habitation, rowwise classification, ledger exactness, and transport stability of the Hypergeometric$^{\uparrow}$ packet.

Finally use the root consumer-boundary theorem. It states that downstream reads factor through the same displayed rows, so the five local theorems assemble the paper-side NameCert$_{\text{Hypergeometric}^{\uparrow}}$ obligation surface without adding an analytic-continuation row. □

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket namecert obligation surface`

Theorem 249.9 (HypergeometricUp signature-gap boundary)**.** *Any* Hypergeometric$^{\uparrow}$ *token gap may expose only the rows of Definition 249.8: the finite* BHist *packet,* Cont, hsame, Pkg, *the* CplxAnalytic$^{\uparrow}$ *and* Gamma$^{\uparrow}$ *dependency rows, parameter rows, the coefficient-ratio row, and the finite readback row. It never exposes analytic continuation, monodromy, singularity classification, host differential equations, or host special-function equality.*

Proof. Use the NameCert obligation surface to enumerate the only rows accepted and transported by the certificate. The carrier and classifier theorems keep token gap reads inside those finite packet coordinates.

The ledger and stability theorems exclude additional coordinates from the transport surface. In particular, analytic continuation, monodromy, singularity classification, host differential equations, and host special-function equality are not fields of the packet and cannot be recovered by hsame or Cont.

The consumer-boundary theorem gives the downstream direction. Any exposed token gap row must be consumed through the finite packet surface already listed, so the signature gap has exactly that boundary. □

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket signature gap boundary`

Theorem 249.10 (HypergeometricUp public certificate handoff)**.** *The public* NameCert$_{\text{Hypergeometric}^{\uparrow}}$ *handoff consists exactly of the finite* BHist *source packet of Definition 249.1,* Cont, hsame, Pkg, *the* CplxAnalytic$^{\uparrow}$ *dependency row, the* Gamma$^{\uparrow}$ *dependency row, the parameter rows, the coefficient-ratio row, the finite readback row, and the signature-gap exclusion of Definition 249.9. It exports no analytic continuation, monodromy, singularity classification, host differential equation, or host special-function equality.*

Lean4 ✓ `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket public certificate handoff`

Proof. First apply Definition 249.8. It packages the finite source packet with exactly the continuation, transport, provenance, dependency, parameter, coefficient-ratio, and readback rows required by the public name certificate.

Next apply Definition 249.9. The same finite rows are the only rows visible through a token gap, and the excluded analytic objects have no coordinate in the accepted packet.

Combining the obligation surface with the gap boundary gives the consumer handoff. A downstream chapter may cite this theorem to receive the displayed finite BHist packet and the stated exclusions without importing any host analytic continuation or special-function equality. □

Theorem 249.11 (HypergeometricUp finite consumer completeness)**.** *Every downstream finite consumer of the public* Hypergeometric$^{\uparrow}$ *handoff factors through exactly the finite* BHist *source packet, the* CplxAnalytic$^{\uparrow}$ *and* Gamma$^{\uparrow}$ *dependency rows, the parameter rows, the coefficient-ratio row, the finite readback row, the signature-gap boundary, componentwise* hsame *transport, finite* Cont *routes,* Pkg *provenance, and the local* NameCert *surface displayed in this chapter. The factorization exposes no analytic continuation, monodromy, singularity classification, host differential equation, asymptotic package, or host special-function equality.*

Proof. Begin with the certificate surface. By Definition 249.8, the accepted packet contains only the finite source packet, the two dependency rows, parameter rows, coefficient-ratio row, readback row, continuation ledger, transport rows, package provenance, and local name-certificate data.

Next apply Definition 249.9. A token-gap read can expose only those same finite coordinates, so a finite consumer has no separate channel for analytic continuation, monodromy, singularity classification, host differential equations, or host special-function equality.

Finally use Definition 249.10. The public handoff is the consumer-facing form of the same packet. Therefore every finite downstream consumer factors through that displayed surface, and the listed exclusions remain outside the consumer boundary. □

Closure status for NameCert$_{\text{Hypergeometric}^{\uparrow}}$.

Constructive story: A hypergeometric packet is assembled from the finite BHist source packet, the CplxAnalytic$^{\uparrow}$ and Gamma$^{\uparrow}$ dependency rows, the parameter rows, the coefficient-ratio row, the finite readback row, and the displayed NameCert obligation surface. The carrier accepts only these rows together with Cont, hsame, and Pkg provenance, so downstream consumers receive the public certificate handoff while analytic continuation, differential-equation semantics, asymptotics, and standard special-function bridges remain outside the displayed packet.

Theory closure: TheoryGate(NameCert$_{\text{Hypergeometric}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridge boundary is the displayed finite hypergeometric source, signature-gap, ledger, hsame, Cont, Pkg, and NameCert surface.

Formal verification: FormalStatus(NameCert$_{\text{Hypergeometric}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.HypergeometricUp.HypergeometricBHistSourcePacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close analytic continuation, differential equations, asymptotics, standard hypergeometric identities, or standard bridge rows.

Upgrade path: No further paper theory-axis grade remains; standard analytic identities and bridge checking stay outside this closure block.

Chapter 250

A Concrete Naming Certificate for $\mathsf{Bessel}^{\uparrow}$

The Bessel-function interface $\mathsf{Bessel}^{\uparrow}$ packages the holomorphic solutions to Bessel's ODE $x^2y'' + xy' + (x^2 - n^2)y = 0$, with their integral representations and recurrence laws. It depends on $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ (chapter 193) and $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ (chapter 68).

250.1 Carrier definition

Definition 250.1 (BesselUp BHist carrier packet)**.** *The* $\mathsf{Bessel}^{\uparrow}$ *carrier is the* BHist *packet*

$$\mathcal{B} = (O, H, \nu, \sigma, \tau, \rho, \kappa, \pi)$$

where O is an $\mathsf{Ode}^{\uparrow}$ *source row for the displayed Bessel differential equation, H is a* $\mathsf{Holomorphic}^{\uparrow}$ *source row for the corresponding disk-local solution histories, ν is the order and index row, σ and τ are the solution endpoint rows, ρ is the finite recurrence ledger, κ is the family of* hsame *transport rows connecting the ODE, holomorphic, order, and endpoint entries, and π is the shared* Pkg *provenance row. A* $\mathsf{Bessel}^{\uparrow}$ *consumer reads solution data only through this packet.*

250.2 The certificate

Theorem 250.2 (BesselUp root ODE source obligation)**.** *Every accepted* $\mathsf{Bessel}^{\uparrow}$ *root packet projects an* $\mathsf{Ode}^{\uparrow}$ *source row for the Bessel equation, its order and index row, the solution endpoint rows, the ODE-side endpoint classifier, and the* Pkg *provenance recorded in Definition 250.1. The root packet exports no host analytic solution operator and no equality of ordinary functions.*

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket root ode source obligation`

Proof. Project the carrier packet of Definition 250.1 to its O, ν, σ, τ, κ, and π coordinates. These are exactly the ODE source, order data, endpoint data, transport rows, and provenance rows named in the statement.

Repack the projected rows through the $\mathsf{Ode}^{\uparrow}$ naming surface. Since the carrier stores endpoint comparison as hsame rows and package provenance as Pkg data, the projection never requires a host solution operator or function equality. □

Theorem 250.3 (BesselUp holomorphic consumer boundary)**.** *Every holomorphic read accepted by the* $\mathsf{Bessel}^{\uparrow}$ *root packet is determined by the* $\mathsf{Holomorphic}^{\uparrow}$ *source row, the solution endpoint rows, the order/index row, the* hsame *transport packet, and the shared* Pkg *provenance of Definition 250.1. It does not add a separate complex-analysis carrier or a standard holomorphic function bridge.*

Proof. Read the H coordinate of the carrier packet together with the endpoint rows, order/index row, transport packet, and provenance. These are the only rows exposed to the holomorphic consumer side.

Transport the endpoint histories along the componentwise hsame rows in κ. Repacking those rows through the $\mathsf{Holomorphic}^{\uparrow}$ naming surface gives the same holomorphic consumer boundary, while the packet contains no field for a separate carrier or standard bridge. □

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket holomorphic consumer boundary`

Theorem 250.4 (BesselUp recurrence ledger exactness)**.** *The recurrence ledger* ρ *in a* $\mathsf{Bessel}^{\uparrow}$ *carrier packet exhausts the accepted recurrence reads for the carried order/index row and solution endpoint rows. Each recurrence read is a finite* Cont *route transported by the packet's* hsame *rows and justified by the same* Pkg *provenance; conversely each ledger entry repacks as one accepted recurrence read.*

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket recurrence ledger exactness`

Proof. Project the recurrence ledger ρ from Definition 250.1. Each entry has source endpoints, target endpoints, order/index data, and a displayed finite Cont route.

Use the hsame packet κ to transport the endpoints and order row inside the shared BHist carrier. The Pkg row π records that the transported route belongs to the same Bessel packet.

For the converse direction, start from any accepted recurrence read. Its fields are exactly a source endpoint row, target endpoint row, order/index row, finite continuation route, transport row, and provenance row, so it repackages as an entry of ρ. □

Theorem 250.5 (BesselUp name-certificate obligation surface)**.** *The* $\mathsf{Bessel}^{\uparrow}$ *root naming obligation surface consists exactly of the carrier packet of Definition 250.1, the* $\mathsf{Ode}^{\uparrow}$ *source obligation of Definition 250.2, the* $\mathsf{Holomorphic}^{\uparrow}$ *consumer boundary of Definition 250.3, and the recurrence ledger exactness of Definition 250.4. This surface contains no host analytic primitive, no standard Bessel model, and no function-space quotient row.*

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket namecert obligation surface`

Proof. Assemble the packet by projection from Definition 250.1. The ODE source, holomorphic source, order/index row, endpoints, recurrence ledger, transport rows, and provenance are all coordinates of the same BHist carrier.

Apply Definition 250.2 to identify the ODE source side and Definition 250.3 to identify the holomorphic consumer side. Both projections use the same transport packet and provenance row.

Finally apply Definition 250.4. The finite recurrence ledger covers exactly the accepted recurrence reads, so repacking the three projections gives the whole name-certificate obligation surface without adding analytic primitives or quotient data. □

Theorem 250.6 (BesselUp carrier, equation, and order obligation)**.** *An accepted* $\mathsf{Bessel}^{\uparrow}$ *name-certificate packet binds the Bessel ODE source row* O*, the order and index row* ν*, the two solution endpoint rows, the ODE-side endpoint classifier, the* hsame *transport packet, and the shared* Pkg *provenance to one* BHist *carrier packet* $\mathcal{B}$ *of Definition 250.1. No consumer can read the equation*

row or the order row through a second carrier, a host analytic solution operator, or an equality of ordinary functions.

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket carrier equation order obligation`

Proof. Project the accepted root packet through Definition 250.5. Its carrier coordinate is the packet $\mathcal{B}$ of Definition 250.1, whose O, ν, endpoint, transport, and provenance coordinates are the displayed ODE source, order and index, endpoint, hsame, and Pkg rows.

Apply Definition 250.2. This projection already identifies the ODE row, the order and index row, the endpoint classifiers, and the provenance as rows of the same root packet. Since the obligation surface has no field for a second carrier, host solution operator, or ordinary-function equality, those data are not exported. □

Theorem 250.7 (BesselUp recurrence Cont ledger obligation)**.** *Every recurrence read accepted by a* Bessel$^{\uparrow}$ *name-certificate packet is exactly one of the finite* Cont *ledger rows already exposed by Definition 250.4, transported along the packet's* hsame *rows and justified by the same* Pkg *provenance. Conversely, each such finite ledger row repacks as an accepted recurrence read for the same order and endpoint rows.*

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket recurrence cont ledger obligation`

Proof. Start from an accepted recurrence read of the name-certificate packet. Apply Definition 250.5 to place the read inside the carrier packet, with the same order row, endpoint rows, transport packet, and provenance as the root surface.

Now apply Definition 250.4. It says that the recurrence ledger ρ exhausts accepted recurrence reads and that each read is a finite Cont route transported by the packet's hsame rows. The reverse direction in the same theorem repacks each finite ledger entry as an accepted recurrence read, so the exposed ledger is exact. □

Theorem 250.8 (BesselUp asymptotic ledger scope)**.** *Any holomorphic or asymptotic consumer read of a* Bessel$^{\uparrow}$ *packet is scoped to the displayed Bessel ODE source row, the* Holomorphic$^{\uparrow}$ *source row, the order and index row, the solution endpoint rows, the recurrence ledger, the* hsame *transport packet, and the shared* Pkg *provenance. The read exposes no standard analytic primitive, no host Bessel function model, no function-space quotient, and no separate asymptotic carrier.*

Lean4 ✓ `BEDC.Derived.BesselUp.BesselRootPacket asymptotic ledger scope`

Proof. For holomorphic reads, apply Definition 250.3. It restricts the consumer surface to the Holomorphic$^{\uparrow}$ source row, endpoint rows, order and index row, transport packet, and provenance of the shared carrier.

For recurrence and endpoint movement, apply Definition 250.4. The only routes available to the consumer are the finite recurrence Cont rows transported by the same hsame packet and justified by the same provenance.

Finally compose these two projections with Definition 250.5. The resulting surface is the ODE row, HolomorphicUp row, order row, endpoints, recurrence ledger, transport packet, and Pkg row of one BHist carrier. Because the root surface excludes host analytic primitives, standard Bessel models, function-space quotients, and separate carriers, the asymptotic read has no additional row to expose. □

Theorem 250.9 (BesselUp public certificate export)**.** *The public* $\mathsf{Bessel}^{\uparrow}$ *certificate is exactly the finite packet assembled from the Bessel ODE source row, the* $\mathsf{Holomorphic}^{\uparrow}$ *source row, the order and index rows, the solution endpoint rows, the recurrence ledger, the asymptotic ledger scope, componentwise* hsame *transport, finite* Cont *routes, and the* Pkg *provenance already fixed in this chapter. It exports analytic existence, analytic uniqueness, host Bessel functions, asymptotic expansions as functions, and a standard bridge nowhere in the public packet.*

Proof. Start with the ODE and holomorphic source boundary. Apply Definition 250.2 to fix the displayed Bessel ODE row and Definition 250.3 to bind every holomorphic consumer read to the same source row, endpoint rows, order and index rows, transport packet, and provenance.

Next project the recurrence data. By Definition 250.4, each recurrence read is one of the finite ledger entries transported by the packet's componentwise hsame rows and justified by the same Pkg provenance.

Finally combine those rows with Definition 250.5 and Definition 250.8. The first theorem supplies the carrier, classifier, transport, and name-certificate obligations; the second restricts holomorphic and asymptotic-facing reads to the displayed finite packet. No coordinate remains for analytic existence, uniqueness, host Bessel functions, functional asymptotic expansions, or a standard bridge. □

Theorem 250.10 (BesselUp standard root bridge boundary)**.** *The public root packet exported by Definition 250.9 is exactly the bridge-facing surface for* $\mathsf{Bessel}^{\uparrow}$*. Its visible rows are the* $\mathsf{Ode}^{\uparrow}$ *source row, the* $\mathsf{Holomorphic}^{\uparrow}$ *source row, the order and index histories, the solution endpoints, the recurrence ledgers, componentwise* hsame *transport, finite* Cont *routes, the shared* Pkg *provenance, and the local* NameCert *rows. No bridge-facing coordinate is available for analytic existence, asymptotic expansions as functions, host Bessel functions, or a standard analytic model.*

Proof. First take the public packet of Definition 250.9. It already identifies the ODE, holomorphic, order, endpoint, recurrence, transport, continuation, and provenance rows that a public consumer may receive.

Next compose the packet with the root and recurrence boundaries. The ODE source is fixed by Definition 250.2, the holomorphic reads by Definition 250.3, and the recurrence reads by Definition 250.4. The name-certificate obligations of Definition 250.5 place these rows under the same local NameCert and Pkg surface.

Finally use coordinate exhaustion. The carrier packet has coordinates only for the displayed ODE row, holomorphic row, order and index histories, endpoints, recurrence ledgers, hsame, Cont, Pkg, and local NameCert data. Since analytic existence, asymptotic functions, host Bessel functions, and a standard analytic model are not coordinates of that packet, the public export is precisely the bridge-facing boundary and nothing larger. □

Closure status for $\mathsf{NameCert}_{\mathsf{Bessel}^{\uparrow}}$**.**

Constructive story: A Bessel packet is generated by placing an $\mathsf{Ode}^{\uparrow}$ row for the displayed Bessel differential equation beside a $\mathsf{Holomorphic}^{\uparrow}$ row for the disk-local solution histories, then adding order and index histories, solution endpoints, recurrence entries, transport rows, and package provenance. The carrier accepts only this finite packet $(O, H, \nu, \sigma, \tau, \rho, \kappa, \pi)$; a host analytic solution operator, ordinary-function equality, function-space quotient, or standard Bessel model is not part of the surface. Two accepted packets classify together by componentwise hsame transport of the ODE source, holomorphic source, order and index rows, solution endpoints, recurrence ledgers, and provenance, with finite Cont routes carrying each recurrence readback. The source specification is the paired ODE and holomorphic certificate boundary, the pattern specification is the Bessel-equation solution surface with its recurrence laws, and the ledger keeps the order/index row, solution endpoints, recurrence routes, endpoint classifiers, and shared Pkg row visible. The five name-certificate obligations are witnessed by an accepted root packet, by the equivalence laws of the component classifiers, and by recurrence-ledger exactness, which says every transported recurrence read repacks as one of the same finite ledger entries. A packet history

h lies in the signature gap of a Bessel$^{\uparrow}$ token p when the source-domain accepts its ODE and holomorphic rows, the signature relation pairs it with an answer Bessel packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the order, solution endpoints, and recurrence ledger are precisely the rows encoded by p. The chapter registers this ODE-and-recurrence packet under the name Bessel$^{\uparrow}$; it introduces no analytic existence or uniqueness theorem, no asymptotic expansion package, no host Bessel function, and no standard bridge.

Theory closure: TheoryGate(NameCert$_{\text{Bessel}\uparrow}$, maturePackageClosed)

Scope closed: The obligation scope binds the Bessel ODE row, Holomorphic$^{\uparrow}$ source row, order and index rows, solution endpoints, recurrence ledger, componentwise hsame transport, finite Cont routes, and Pkg provenance of the root packet.

Formal verification: FormalStatus(NameCert$_{\text{Bessel}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.BesselUp.BesselRootPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not claim analytic existence or uniqueness, asymptotic expansions, host Bessel functions, function-space quotients, or a standard bridge.

Upgrade path: No further paper-side theory-axis upgrade remains for the displayed ODE, holomorphic, recurrence-ledger, classifier, provenance, and bridge consumer surface.

Chapter 251

A Concrete Naming Certificate for $\mathsf{ThetaFunction}^{\uparrow}$

The theta-function interface $\mathsf{ThetaFunction}^{\uparrow}$ packages the holomorphic functions $\theta(z, \tau)$ on $\mathbb{C} \times \mathbb{H}$ satisfying the heat equation and the lattice-quasiperiodicity laws. It depends on $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ (chapter 68) and $\mathsf{NameCert}_{\mathsf{EllipticCurve}^{\uparrow}}$ (chapter 175).

251.1 Carrier definition

Definition 251.1 (ThetaFunction carrier source)**.** *A* $\mathsf{ThetaFunction}^{\uparrow}$ *carrier source is a finite* BHist *packet* $\Theta = (E, H, Q, \Pi, C)$ *whose rows consist of an* $\mathsf{EllipticCurve}^{\uparrow}$ *period ledger* E*, a* $\mathsf{Holomorphic}^{\uparrow}$ *local-function row* H *on the displayed* (z, τ) *chart, a finite* q*-expansion coefficient window* Q *compatible with the* $\mathsf{CplxSer}^{\uparrow}$ *coefficient ledger,* Pkg *provenance* Π *for the elliptic-curve, holomorphic, and complex-series dependencies, and finite* Cont *readback rows* C *tying the period, chart, and coefficient observations to the same packet.*

Lean4 (definition) `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrier`

Definition 251.2 (ThetaFunction classifier)**.** *Two carrier sources* $\Theta = (E, H, Q, \Pi, C)$ *and* $\Theta' = (E', H', Q', \Pi', C')$ *are classified by the* $\mathsf{ThetaFunction}^{\uparrow}$ *source classifier when the* $\mathsf{EllipticCurve}^{\uparrow}$ *period rows are transported by the same* hsame*-stable period comparison, the finite coefficient windows* Q *and* Q' *agree under the displayed* $\mathsf{CplxSer}^{\uparrow}$ *coefficient-window classifier, the* $\mathsf{Holomorphic}^{\uparrow}$ *chart rows* H *and* H' *agree on the same local-function source, and the* Pkg *and* Cont *provenance rows are componentwise the displayed rows for those transports.*

Lean4 (definition) `BEDC.Derived.ThetaFunctionUp.ThetaFunctionSourceClassifier`
Lean4 (definition) `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource classifier`

251.2 The certificate

Theorem 251.3 (ThetaFunction hsame stability)**.** *The classifier of Definition 251.2 is stable under rowwise* hsame *transport of the period ledger, coefficient window, holomorphic chart row,* Pkg *provenance, and* Cont *readback rows.*

Proof. Unpack the classifier into its displayed coordinates. The period coordinate is transported by the $\mathsf{EllipticCurve}^{\uparrow}$ period row, the chart coordinate by the $\mathsf{Holomorphic}^{\uparrow}$ local-function row, and the coefficient coordinate by the $\mathsf{CplxSer}^{\uparrow}$ window row.

Transport each coordinate along the given hsame witness and keep the same Cont readback route and Pkg provenance. Repacking these transported rows gives a classifier witness for the target packet, with no appeal to host function equality or analytic continuation. □

Lean4 ✓ `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrier hsame stability`

Theorem 251.4 (ThetaFunction ledger exactness)**.** *Every accepted* ThetaFunction$^{\uparrow}$ *carrier source exposes exactly the* EllipticCurve$^{\uparrow}$ *period rows, finite q-expansion coefficient rows,* Holomorphic$^{\uparrow}$ *chart rows,* Pkg *provenance, and* Cont *readback rows of Definition 251.1. It exposes no analytic continuation datum, completed modular form, host holomorphic-function equality, or infinite coefficient object.*

Lean4 ✓ `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource ledger exactness`

Proof. Project an accepted carrier source to the five components in Definition 251.1. These projections are the period ledger, holomorphic chart, coefficient window, provenance, and finite readback rows.

Conversely, any ledger read admitted by the carrier must enter through one of those five coordinates. The EllipticCurve$^{\uparrow}$, Holomorphic$^{\uparrow}$, and CplxSer$^{\uparrow}$ dependency anchors account for the mathematical rows, while Pkg and Cont account for provenance and finite readback.

There is no constructor field for analytic continuation, completed modular forms, host equality of functions, or an infinite coefficient object. Therefore none of those objects is exported by the ledger. □

Theorem 251.5 (ThetaFunction NameCert boundary)**.** *The carrier source of Definition 251.1, the classifier of Definition 251.2, the stability theorem Definition 251.3, and the ledger exactness theorem Definition 251.4 assemble the* ThetaFunction$^{\uparrow}$ NameCert *boundary over* BHist, hsame, Cont, *and* Pkg. *The boundary consumes only the displayed* EllipticCurve$^{\uparrow}$, Holomorphic$^{\uparrow}$, *and* CplxSer$^{\uparrow}$ *source rows and supplies exactly the finite period, chart, and coefficient observation surface.*

Lean4 ✓ `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource namecert boundary`

Proof. The carrier definition supplies the source object for the certificate. The classifier definition supplies the comparison relation, and Definition 251.3 gives transport of accepted rows along the componentwise hsame comparisons.

The exact ledger is supplied by Definition 251.4. Its projections are precisely the period, chart, coefficient, provenance, and readback rows required by the displayed NameCert surface.

Combining these rows gives the advertised boundary: a finite BHist packet with dependency provenance through Pkg, readback through Cont, and no additional analytic-continuation or completed-modular-form field. □

Theorem 251.6 (ThetaFunction modular-shift ledger)**.** *Let* Θ *be a* ThetaFunction$^{\uparrow}$ *packet whose* CplxSer$^{\uparrow}$ *source row is transported by a certified integer or unary period-shift row. The transported packet preserves the displayed q-expansion carrier, classifier, and ledger rows through the same* hsame *comparisons,* Cont *provenance, and* Pkg *entries. The shift is recorded as a finite package-ledger row rather than as an external modular-group action.*

Lean4 ✓ `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource modular shift ledger`

Proof. Inspect the carrier packet of Definition 251.1. The period row, holomorphic chart row, coefficient window, provenance row, and readback row are the only available coordinates.

Use the $\mathsf{CplxSer}^{\uparrow}$ pointwise append and transport rows on each finite coefficient window touched by the certified shift. The $\mathsf{Holomorphic}^{\uparrow}$ source row supplies stability for the analytic carrier coordinate, while the $\mathsf{EllipticCurve}^{\uparrow}$ period ledger supplies the displayed period source.

Repack the transported coefficient, period, chart, continuation, and package rows. Since the shift appears only as a Pkg ledger entry, the resulting packet preserves the carrier, classifier, and ledger without exporting a modular-group action. □

Theorem 251.7 (ThetaFunction period-lattice scope)**.** *Every consumer-visible period-lattice readback of a* $\mathsf{ThetaFunction}^{\uparrow}$ *packet factors through the* $\mathsf{CplxSer}^{\uparrow}$ *coefficient stream, the* $\mathsf{EllipticCurve}^{\uparrow}$ *period source, the* $\mathsf{Holomorphic}^{\uparrow}$ *carrier row, displayed* hsame *comparisons, the* Cont *route, and the* Pkg *ledger of Definition 251.1. The packet exports no analytic continuation object, quotient torus, host lattice object, or completed infinite coefficient stream.*

Lean4 ✓ `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource period lattice scope`

Proof. Begin with the carrier source, classifier, hsame stability, and ledger exactness rows. These rows already identify the finite period ledger, local holomorphic chart, coefficient window, provenance, and readback coordinates.

For a period-lattice readback, first project the $\mathsf{EllipticCurve}^{\uparrow}$ period source and the $\mathsf{CplxSer}^{\uparrow}$ coefficient stream rows. Then transport the chart and coefficient windows along the displayed hsame comparisons and follow the recorded Cont route.

The NameCert boundary of Definition 251.5 exhausts the consumer-visible surface. Since the boundary has no constructor field for analytic continuation, quotient tori, host lattices, or completed coefficient streams, none of those objects is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{ThetaFunction}^{\uparrow}}$.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ThetaFunction}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The seed scope names the displayed $\mathsf{EllipticCurve}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{CplxSer}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows of the theta-function packet.

Constructive story: A theta-function packet records finite period, holomorphic chart, coefficient-window, continuation, and package rows as its visible certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ThetaFunction}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ThetaFunctionUp.ThetaFunctionCarrierSource\_namecert\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not close analytic continuation, quotient tori, completed modular forms, host lattice objects, or standard bridges.

Upgrade path: Bridge closure requires a standard bridge boundary for the displayed theta-function public packet.

Theorem 251.8 (ThetaFunction coefficient-prefix restriction carrier)**.** *Let* $\Theta = (E, H, Q, \Pi, C)$ *be an accepted* $\mathsf{ThetaFunction}^{\uparrow}$ *carrier source of Definition 251.1. Let* $Q_{\preceq n}$ *be a displayed finite prefix window of the same q-expansion coefficient ledger. Suppose the* $\mathsf{CplxSer}^{\uparrow}$ *coefficient-window classifier accepts* $Q_{\preceq n}$ *under the same coefficient source that accepts* Q*, and suppose the displayed prefix readback is one of the finite coefficient observations already routed by the* Cont *rows in* C*. Then*

$$\Theta_{\preceq n} = (E, H, Q_{\preceq n}, \Pi, C)$$

is again an accepted $\mathsf{ThetaFunction}^{\uparrow}$ *carrier source. The replacement keeps the period ledger, holomorphic chart row, package provenance, and continuation rows fixed, and changes only the finite coefficient-window coordinate from* Q *to the classified prefix* $Q_{\preceq n}$*.*

Proof. Invert the accepted carrier source by Definition 251.1. Its exposed rows are exactly the period ledger E, the holomorphic local-function row H, the finite coefficient window Q, the package provenance Π, and the finite readback rows C tying the period, chart, and coefficient observations to the same packet.

The prefix hypothesis supplies a finite coefficient row $Q_{\preceq n}$ over the same displayed $\mathsf{CplxSer}^{\uparrow}$ coefficient ledger. Since it is accepted by the same coefficient-window classifier as Q, replacing the coefficient coordinate does not introduce a different coefficient source, a completed series, or an unrecorded equality of analytic functions. The coefficient row remains a finite window row in the exact sense required by the carrier definition.

The period coordinate E and the chart coordinate H are not altered. The package row Π is also unchanged, because the dependency provenance still names the same elliptic-curve, holomorphic, and complex-series sources. The continuation row C remains valid by the displayed prefix-readback assumption: its period and chart components are identical, and its coefficient component already routes the prefix observation $Q_{\preceq n}$ as a finite readback under the same packet.

Repacking the five displayed coordinates gives $(E, H, Q_{\preceq n}, \Pi, C)$, which satisfies the carrier clauses of Definition 251.1. Finally, Definition 251.4 shows that this operation has no hidden effect on the public ledger: the result still exposes only the elliptic-curve period rows, the holomorphic chart row, the finite coefficient window, Pkg provenance, and Cont readbacks, with no analytic continuation datum, completed modular form, host holomorphic-function equality, or infinite coefficient object. □

Chapter 252

A Concrete Naming Certificate for $\mathsf{ModularForm}^{\uparrow}$

The modular-form interface $\mathsf{ModularForm}^{\uparrow}$ packages a holomorphic function on the upper half plane invariant under a congruence subgroup of $SL_2(\mathbb{Z})$ up to a fixed weight factor. It depends on $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ (chapter 68) and $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ (chapter 104).

252.1 Carrier definition

Definition 252.1 (Modular-form q-expansion carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ *source row and a* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *source row for the same displayed weight and congruence-subgroup context. A* $\mathsf{ModularForm}^{\uparrow}$ *carrier row is the finite* BHist *ledger consisting of the holomorphic source answer row, the automorphic transformation answer row, a finite q-expansion coefficient observation row, and the* Cont *witnesses that place the coefficient observations under both sources.*

The carrier records finite q-expansion and transformation data only. It does not assert analytic continuation, dimension formulas, Hecke operators, cusp expansions at every cusp, or a host space of modular forms.

Lean4 (definition) `BEDC.Derived.ModularFormUp.ModularFormQExpansionCarrier`

Definition 252.2 (Modular-form congruence classifier)**.** *Two rows of Definition 252.1 are classified as the same* $\mathsf{ModularForm}^{\uparrow}$ *observation exactly when their holomorphic source rows are transported by* $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$*, their automorphic transformation rows are transported by* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$*, and their visible finite q-expansion coefficient packages are matched by* hsame*,* Cont*, and* Pkg*.*

The classifier is generated by source transport, finite coefficient package transport, and congruence-subgroup transformation transport. It contains no generator for analytic continuation, dimension counting, or Hecke stability.

252.2 The certificate

Theorem 252.3 (Modular-form holomorphic source scope)**.** *Every* $\mathsf{ModularForm}^{\uparrow}$ *carrier row contains one* $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ *source row, one* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *transformation source row, and finite q-expansion coefficient answer histories attached to those sources by* Cont *and* Pkg *witnesses.*

Lean4 ✓ `BEDC.Derived.ModularFormUp.ModularFormQExpansionCarrier holomorphic source scope`

Proof. Invert Definition 252.1. The holomorphic source and automorphic source are explicit fields, while the coefficient data are finite answer rows recorded under those fields.

The classifier of Definition 252.2 can change representatives only through the two source certificates and the displayed finite coefficient package witnesses. Thus the source scope is exactly the holomorphic row, the automorphic row, and the finite q-expansion ledger. □

Theorem 252.4 (Modular-form automorphic transport stability)**.** *If two* $\mathsf{ModularForm}^{\uparrow}$ *rows are classified by Definition 252.2, then transporting the automorphic transformation row through* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *and transporting any visible q-expansion coefficient row through* hsame*,* Cont*, or* Pkg *preserves the classified carrier row.*

Lean4 ✓ `BEDC.Derived.ModularFormUp.ModularFormAutomorphicTransport stability`

Proof. Transport the automorphic source first. The $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ classifier supplies the new transformation answer row, and the carrier retains the same displayed weight and congruence-subgroup context.

For the coefficient row, use the stored hsame endpoint comparison and the Pkg package comparison, with Cont placing the transported coefficient back under the holomorphic and automorphic source rows. Since the coefficient list is finite, concatenating these transports yields a classifier witness for the whole row. □

Theorem 252.5 (Modular-form NameCert obligation surface)**.** *The* $\mathsf{ModularForm}^{\uparrow}$ *chapter exports a NameCert obligation surface consisting of the finite q-expansion carrier, the congruence classifier, the holomorphic and automorphic source rows, and ledger exactness for the displayed coefficient and transformation observations.*

Lean4 ✓ `BEDC.Derived.ModularFormUp.ModularFormQExpansionCarrier semantic name certificate`

Proof. Assemble the surface from a carried row and a classifier witness. The carried row supplies the holomorphic source, the automorphic source, and the finite q-expansion observations; the classifier supplies only source transport, coefficient transport, and transformation transport.

Ledger exactness follows by inverting those constructors. Every accepted field is a source row, a coefficient answer, a transformation answer, or a named hsame, Cont, or Pkg witness. Therefore the obligation surface stays within finite BEDC data and makes no analytic-continuation, dimension-formula, or Hecke-theoretic claim. □

Lean4 ✓ `BEDC.Derived.ModularFormUp.ModularFormQExpansionCarrier namecert obligation surface`

Closure status for $\mathsf{NameCert}_{\mathsf{ModularForm}^{\uparrow}}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ModularForm}^{\uparrow}}$, publicClosed)

Scope closed: The obligation surface records the finite q-expansion carrier of Definition 252.1, the congruence classifier of Definition 252.2, the $\mathsf{Holomorphic}^{\uparrow}$ and $\mathsf{Automorphic}^{\uparrow}$ source rows, and the BHist, hsame, Cont, and Pkg rows exposed by Definition 252.5.

Constructive story: A modular-form packet consumes one $\mathsf{Holomorphic}^{\uparrow}$ source row and one $\mathsf{Automorphic}^{\uparrow}$ source row over the same displayed weight and congruence-subgroup context, then attaches a finite q-expansion coefficient ledger through Cont, Pkg, and hsame rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ModularForm}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ModularFormUp.ModularFormAutomorphicTransport\_stability`

Bridge status: none

Not claimed: This obligation boundary does not close analytic continuation, dimension formulas, Hecke operators, all-cusp expansions, or a host modular-form space.

Upgrade path: The next paper-grade step is a bridge boundary for the public q-expansion and automorphic-source package.

Theorem 252.6 (Modular-form empty coefficient classifier)**.** *Let R and R' be two* $\mathsf{ModularForm}^{\uparrow}$ *carrier rows of Definition 252.1 over the same displayed weight and congruence-subgroup context. Suppose that both rows use the same* $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ *source row H, the same* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *source row A, and the visible q-expansion coefficient observation row is* e *in both carriers. Then R and R' are classified as the same* $\mathsf{ModularForm}^{\uparrow}$ *observation by the modular-form congruence classifier of Definition 252.2.*

Lean4 ✓ `BEDC.Derived.ModularFormUp.ModularFormQExpansionCarrier empty coefficient classifier`

Proof. Unpack the two carrier rows by Definition 252.1. Their source part is the common pair (H, A), so the holomorphic source component is transported by the reflexive classifier row of $\mathsf{NameCert}_{\mathsf{Holomorphic}^{\uparrow}}$ and the automorphic component is transported by the reflexive classifier row of $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$. The displayed weight and congruence-subgroup context is also common, so no context replacement is required.

It remains only to compare the finite q-expansion coefficient ledger. Both visible coefficient rows are e. The empty history supplies the endpoint comparison $\mathsf{ehsamee}$, and the right-unit continuation rows place the empty coefficient observation under the already shared holomorphic and automorphic source rows:

$$\mathsf{Cont}(H, \mathsf{e}, H) \qquad \text{and} \qquad \mathsf{Cont}(A, \mathsf{e}, A).$$

The finite coefficient package therefore has no nonempty coefficient entry to match. Its package comparison is the empty package comparison, with the displayed hsame and Cont witnesses as its whole ledger.

The generators listed in Definition 252.2 are exactly source transport, finite coefficient package transport, and congruence-subgroup transformation transport. Applying the two reflexive source transports, the empty coefficient package comparison, and the shared automorphic transformation context gives a classifier witness from R to R'. Since no generator for analytic continuation, dimension counting, Hecke stability, or all-cusp data participates in that classifier, the conclusion is confined to the two empty-coefficient carrier rows. □

Chapter 253

A Concrete Naming Certificate for $\mathsf{ClebschGordan}^{\uparrow}$

The Clebsch-Gordan interface $\mathsf{ClebschGordan}^{\uparrow}$ packages, for a pair of irreducible representations of a compact Lie group, the decomposition of their tensor product into irreducibles together with the explicit coupling coefficients. It depends on $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140) and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87).

253.1 Carrier definition

253.2 The certificate

Definition 253.1 (ClebschGordanUp BHist coupling packet)**.** *A* $\mathsf{ClebschGordan}^{\uparrow}$ *coupling packet is a finite* BHist *tuple*

$$\mathcal{C} = (G, T, R, V_1, V_2, \tau, D, \Gamma, \theta, P, \lambda).$$

The rows G, T, and R are consumed certificates $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$. *The rows V_1 and V_2 are the two irreducible source-representation histories, each read through G and R. The row τ is the tensor-product endpoint history for $V_1 \otimes V_2$ read through T.*

The finite decomposition ledger D lists irreducible output histories W_j with multiplicity histories m_j and representation-ring summand rows in R. The coefficient ledger Γ lists the displayed coupling-coefficient histories $\gamma^{j,q}_{a,b}$ that relate source basis histories for V_1 and V_2 to output basis histories for each W_j and multiplicity slot q. The row θ is the componentwise hsame *transport datum for $G, T, R, V_1, V_2, \tau, D, \Gamma$.*

The row P is the Pkg *provenance recording exactly the consumed LieGroupUp, TensorProductUp, RepresentationRingUp, decomposition, and coefficient rows. The finite ledger λ is the* Cont *route containing only those displayed rows and their endpoint readbacks.*

Theorem 253.2 (ClebschGordanUp carrier source obligation)**.** *Every public carrier row of a* $\mathsf{ClebschGordan}^{\uparrow}$ *coupling packet is one of the displayed rows of Definition 253.1. In particular, the two irreducible source rows are read only through* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$, *and the tensor endpoint is read only through* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ *together with those two source rows.*

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket carrier source obligation`

Proof. Project an accepted packet to the tuple $\mathcal{C} = (G, T, R, V_1, V_2, \tau, D, \Gamma, \theta, P, \lambda)$. The carrier definition lists all public rows in that tuple, so no additional carrier row can be read by a downstream consumer.

The two source rows V_1 and V_2 carry their group action through G and their representation-ring membership through R. The tensor endpoint τ is then the row supplied by T on those same two source histories.

Repacking these projections gives the carrier obligation: source irreducibles, tensor endpoint, decomposition entries, coefficients, transport, provenance, and continuation are all BHist rows of the same displayed packet. □

Theorem 253.3 (ClebschGordanUp classifier transport obligation)**.** *Let $\mathcal{C}$ and $\mathcal{C}'$ be two Definition 253.1 packets. A public* $\mathsf{ClebschGordan}^{\uparrow}$ *classifier row from $\mathcal{C}$ to $\mathcal{C}'$ is the componentwise* hsame *transport of the consumed* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *rows, the two irreducible source rows, the tensor endpoint row, the finite decomposition ledger, the coefficient histories, the* Pkg *provenance row, and the finite* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket classifier transport obligation`

Proof. Unpack the transport row θ in the source packet and the corresponding row θ' in the target packet. Their displayed fields compare the three consumed certificates, the two source irreducibles, and the tensor endpoint by hsame.

The same componentwise comparison transports the decomposition ledger D: each output irreducible history, multiplicity history, and representation-ring summand row is matched with its transported target row. The coefficient ledger Γ is transported entry by entry over the same source and output histories.

Finally compare P and λ by the displayed provenance and continuation rows. These projections exhaust the public classifier, so no host equality of representations, basis vectors, or coefficient arrays is available outside the packet. □

Theorem 253.4 (ClebschGordanUp ledger exactness obligation)**.** *The exact ledger of a* $\mathsf{ClebschGordan}^{\uparrow}$ *coupling packet consists precisely of the tensor endpoint τ, the finite decomposition ledger D, the coefficient-history ledger Γ, the componentwise* hsame *transport θ, the provenance packet P, and the finite* Cont *route λ. Every accepted coupling read projects to these rows, and every family of these rows repacks as the public coupling ledger.*

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket ledger exactness obligation`

Proof. For the projection direction, take an accepted coupling read and inspect its public packet. The tensor product endpoint is the row τ, the finite list of irreducible summands and multiplicities is D, and the coupling coefficients are the histories in Γ.

The transport, provenance, and continuation fields are then the displayed rows θ, P, and λ. Because the packet definition contains no other public field, the projection cannot expose a host decomposition theorem or an unrecorded coefficient table.

For the reverse direction, start with rows of exactly these six forms over the same consumed G, T, R, V_1, V_2 source data. Insert them into the tuple of Definition 253.1. The resulting tuple is the public ledger, so exactness is projection followed by this repacking. □

Theorem 253.5 (ClebschGordanUp source NameCert boundary)**.** *The source boundary of a* $\mathsf{ClebschGordan}^{\uparrow}$ *coupling packet is exactly the triple of consumed certificates* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{RepresentationRing}^{\uparrow}}$ *together with the two irreducible source rows*

and their tensor endpoint. It does not export a separate compact-group carrier, representation category, basis convention, or ambient Hilbert-space object.

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket source namecert boundary`

Proof. Project the dependency rows G, T, R from the packet. The irreducible source histories V_1 and V_2 are scoped by G and R, while the tensor row τ is scoped by T and those same two source histories.

The decomposition ledger and coefficient histories are downstream rows over this source boundary. They refer back to G, T, R, V_1, V_2, τ through Pkg provenance and through the displayed Cont route.

Since no other source row occurs in the tuple, any consumer requesting a Clebsch-Gordan source can receive only those certificates and histories. Thus the boundary is a BEDC source boundary, not a hidden representation theory environment. □

Theorem 253.6 (ClebschGordanUp consumer readback boundary)**.** *Every downstream consumer of a* ClebschGordan$^{\uparrow}$ *coupling packet reads only the two irreducible source histories, the tensor endpoint, the finite decomposition ledger, the coefficient histories, the componentwise* hsame *transport rows, the* Pkg *provenance, and the finite* Cont *readback route of Definition 253.1. If two packets agree on those rows by the public classifier, then every such consumer has the same readback.*

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket consumer readback boundary`

Proof. Let a consumer be invariant under the displayed rows named in the statement. Project both packets to their source histories, tensor endpoint, decomposition ledger, coefficient histories, transport rows, provenance, and continuation route.

The public classifier supplies componentwise hsame comparisons for those projections. The consumer therefore sees the same source inputs, the same tensor endpoint, the same finite decomposition entries, and the same coefficient histories after transport.

By the ledger exactness obligation of Definition 253.4, there is no further public row that could affect the consumer. Repacking the transported projections gives identical readback at the consumer boundary. □

Theorem 253.7 (ClebschGordanUp coefficient slot determinacy)**.** *Let two accepted reads of coefficient histories in the coefficient ledger Γ of a* ClebschGordan$^{\uparrow}$ *coupling packet have the same transported source rows V_1 and V_2, the same tensor endpoint τ, the same output irreducible row W_j, the same multiplicity history m_j, and the same source and output basis-index histories. Then the public classifier identifies the two coefficient rows by the componentwise* hsame *transport field of the coupling packet of Definition 253.1.*

Equivalently, a displayed coefficient history accepted in Γ belongs to a unique public slot determined by $(V_1, V_2, \tau, W_j, m_j)$ together with its basis-index histories; no second public coefficient table can be read at that same slot.

Proof. Project the two accepted coefficient reads through Definition 253.1. Each read is a row of the same displayed coefficient ledger Γ, so its source rows, tensor endpoint, output row, multiplicity row, and basis-index histories are among the packet fields.

Use the classifier transport obligation of Definition 253.3. Under the shared slot hypotheses, the public classifier compares the two coefficient rows by the componentwise hsame entry assigned to Γ in the transport row θ.

It remains to exclude a second public coefficient source for that slot. Apply the ledger exactness obligation of Definition 253.4: every accepted coefficient read is projected from Γ, and the packet has no additional coefficient table. Thus the transported Γ entry is the unique public coefficient row at the displayed slot. □

Lean4 ✓ `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket coefficient slot determinacy`

Closure status for $\mathsf{NameCert}_{\mathsf{ClebschGordan}^{\uparrow}}$.

Constructive story: A coupling packet is generated by consuming a LieGroup$^{\uparrow}$ row, a TensorProduct$^{\uparrow}$ row, and a RepresentationRing$^{\uparrow}$ row, then displaying two irreducible source-representation histories, their tensor endpoint, a finite decomposition ledger, coefficient histories, transport data, provenance, and a continuation route. The carrier accepts only finite packets of the form $(G, T, R, V_1, V_2, \tau, D, \Gamma, \theta, P, \lambda)$; no representation category, Hilbert-space basis convention, host decomposition theorem, or external coefficient table is available outside those rows. Two packets classify together by componentwise hsame transport of the three consumed certificates, the two sources, the tensor endpoint, decomposition entries, coefficient slots, provenance, and finite Cont ledger. The source specification is the Lie-group, tensor-product, and representation-ring boundary with the two irreducible source rows, the pattern specification is tensor-product decomposition into irreducible outputs with multiplicities and coupling coefficients, and the ledger keeps D, Γ, θ, P, and λ visible. The five name-certificate obligations are inherited from the three dependency classifiers and from the exactness rows: an accepted packet inhabits the carrier, component transport is reflexive, symmetric, and transitive, and any transported coefficient or decomposition row repacks into the same public coupling ledger. A packet history h lies in the signature gap of a ClebschGordan$^{\uparrow}$ token p when the source-domain accepts its representation-coupling surface, the signature relation pairs it with an answer coupling packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the tensor endpoint, summand ledger, multiplicities, and coefficient slots are exactly those encoded by p. The chapter registers this finite coupling-ledger construction under the name ClebschGordan$^{\uparrow}$; it introduces no full representation-category bridge and no standard Clebsch–Gordan coefficient table.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ClebschGordan}^{\uparrow}}$, publicClosed)

Scope closed: The scoped boundary binds the carrier source, classifier transport, ledger exactness, source NameCert boundary, consumer readback boundary, and coefficient slot determinacy obligations for the BHist coupling packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ClebschGordan}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ClebschGordanUp.ClebschGordanCouplingPacket\_coefficient\_slot\_determinacy`

Bridge status: none

Not claimed: This chapter does not close a full representation-category bridge or standard Clebsch-Gordan coefficient tables.

Upgrade path: Bridged closure requires a standard coupling bridge over the displayed LieGroup$^{\uparrow}$, TensorProduct$^{\uparrow}$, RepresentationRing$^{\uparrow}$, decomposition, coefficient, transport, provenance, and finite Cont rows.

Chapter 254

A Concrete Naming Certificate for $\mathsf{Knot}^{\uparrow}$

The knot interface $\mathsf{Knot}^{\uparrow}$ packages a diagrammatic BEDC surface whose traditional reading is a closed one-dimensional source carried through an ambient deformation ledger. It depends on $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ (chapter 58) and $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$ (chapter 156); those dependencies supply the endpoint rows and deformation rows, while the knot certificate records only finite BHist, Cont, hsame, and Pkg data.

254.1 Carrier definition

Definition 254.1 (KnotUp diagram BHist carrier)**.** *A* $\mathsf{Knot}^{\uparrow}$ *diagram packet is a finite carried tuple*

$$\mathcal{K} = (\mathcal{S}, \mathcal{A}, d, r, h, e_0, e_1, \rho, \lambda)$$

whose rows are all BEDC rows. The source row $\mathcal{S}$ *is a consumed* $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ *packet, read only through its exposed source carrier, component classifier, endpoint readback, and ledger surface. The ambient row* $\mathcal{A}$ *is the target row in which the diagram lives; it is a* BHist *endpoint family classified by the same package provenance as the deformation rows and not by an external host embedding.*

The diagram row d *is a finite crossing ledger. Each crossing entry is a* BHist *face whose incident source endpoints are read from* $\mathcal{S}$ *and whose over-under comparison is a displayed* hsame *or* Cont *row. The row* r *is the Reidemeister trace: a finite* Cont *list whose entries are exactly the local crossing changes, endpoint-preserving moves, and package-provenance updates used to pass from one diagram ledger to the next. The row* h *is the consumed* $\mathsf{Homotopy}^{\uparrow}$ *deformation row, read as an ambient-deformation history compatible with the same endpoints and with the same finite trace.*

The endpoint rows e_0 *and* e_1 *expose the initial and final embedded-source interfaces as* BHist *rows over* $\mathcal{S}$ *and* $\mathcal{A}$*. The row* ρ *records the* Pkg *provenance of the source certificate, ambient target row, diagram ledger, Reidemeister trace, and HomotopyUp deformation row. The finite ledger* λ *is the* Cont *display containing precisely those source, ambient, crossing, move-trace, deformation, endpoint, classifier, provenance, and exactness rows accepted by the public* $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$ *carrier.*

Definition 254.2 (KnotUp Reidemeister ledger classifier)**.** *Two* $\mathsf{Knot}^{\uparrow}$ *diagram packets* $\mathcal{K} = (\mathcal{S}, \mathcal{A}, d, r, h, e_0, e_1, \rho, \lambda)$ *and* $\mathcal{K}' = (\mathcal{S}', \mathcal{A}', d', r', h', e'_0, e'_1, \rho', \lambda')$ *are related by the* $\mathsf{Knot}^{\uparrow}$ *Reidemeister ledger classifier when the following finite rows are supplied:*

1. *the* $\mathsf{S}^{1\uparrow}$ *source packets* $\mathcal{S}$ *and* $\mathcal{S}'$ *are transported by the* hsame *classifier of* $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$*;*

2. *the crossing ledgers d and d' are matched entrywise by* hsame *on their incident source endpoint rows and by* Cont *transport on their over-under comparison rows;*
3. *the Reidemeister traces r and r' are related by a finite* Cont *refinement whose entries are again Reidemeister trace rows, not external diagram equivalences;*
4. *the HomotopyUp deformation rows h and h' are related by the ambient-deformation classifier exposed by* $\mathsf{NameCert}_{\mathsf{Homotopy}^\uparrow}$*;*
5. *the endpoint rows e_0, e_1, e_0', e_1' and the provenance rows ρ, ρ' remain in the same* Pkg *scope, and the resulting ledgers λ, λ' list exactly the transported source, diagram, deformation, endpoint, and provenance faces.*

This classifier is componentwise on the visible BEDC rows. It does not identify packets by equality of host embeddings, by a quotient of knots, or by treating ambient isotopy as an undecomposed primitive.

254.2 The certificate

Theorem 254.3 (KnotUp SOne source boundary)**.** *For a* $\mathsf{Knot}^\uparrow$ *diagram packet $\mathcal{K}$ of Definition 254.1, the public source boundary exposed to* $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ *is exactly the* $\mathsf{S}^{1\uparrow}$ *source carrier row $\mathcal{S}$, its component classifier rows, the endpoint rows e_0 and e_1, and the package-provenance row ρ linking those endpoints to the ambient target row. No carrier clause may read an unclassified source point, an external circle object, or a host-level embedding in place of these rows.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket sone source boundary`

Proof. Project $\mathcal{K}$ to its source field $\mathcal{S}$. The source certificate is already a $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ packet, so its carrier, component classifier, endpoint readback, and ledger rows are exactly the rows available to the knot packet.

Next project the endpoint fields e_0 and e_1. By Definition 254.1, each endpoint row is a BHist interface over the source packet and ambient target row, and the provenance field ρ records that these endpoints are part of the same Pkg package.

Conversely, given precisely those source, endpoint, and provenance rows, place them in the displayed fields of $\mathcal{K}$ and leave the diagram, trace, deformation, and ledger rows to the remaining certificate clauses. This reconstructs the public source boundary without adding any host source object. □

Theorem 254.4 (KnotUp Homotopy ledger boundary)**.** *For a* $\mathsf{Knot}^\uparrow$ *diagram packet $\mathcal{K}$ of Definition 254.1, the HomotopyUp and Reidemeister rows exposed to* $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ *are exactly the crossing ledger d, the Reidemeister trace r, the HomotopyUp deformation row h, and the finite* Cont *ledger λ. If two packets are related by the classifier of Definition 254.2, these four rows are stable under the displayed* hsame *and* Cont *transports.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket homotopy ledger boundary`

Proof. First read the crossing ledger d. Its entries name only incident $\mathsf{S}^{1\uparrow}$ endpoint rows, over-under comparison rows, and finite BHist faces. Transporting the source endpoints by hsame therefore transports every crossing entry componentwise.

Now read the Reidemeister trace r and the deformation row h. The trace is a finite Cont list of local moves, while h is the corresponding $\mathsf{Homotopy}^\uparrow$ deformation row. The classifier requires these

rows to be matched by finite trace refinement and by the $\mathsf{NameCert}_{\mathsf{Homotopy}^\uparrow}$ ambient-deformation classifier.

Finally inspect λ. It contains exactly the source, crossing, Reidemeister, deformation, endpoint, provenance, and exactness faces. Since each listed face is transported by the classifier clauses above, the ledger is stable under the same hsame and Cont transports. Projecting a classifier witness gives no additional ambient relation beyond these rows. □

Theorem 254.5 (KnotUp public NameCert obligation surface)**.** *For a* $\mathsf{Knot}^\uparrow$ *diagram packet* $\mathcal{K}$ *of Definition 254.1, the public* $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ *obligation surface is exactly the following finite row family: the* $\mathsf{S}^{1\uparrow}$ *source packet* $\mathcal{S}$*, the ambient target row* $\mathcal{A}$*, the crossing ledger* d*, the Reidemeister trace* r*, the* $\mathsf{Homotopy}^\uparrow$ *deformation row* h*, the endpoint rows* e_0 *and* e_1*, the* Pkg *provenance row* ρ*, the finite* Cont *ledger* λ*, the classifier of Definition 254.2, the source boundary of Definition 254.3, and the Homotopy ledger boundary of Definition 254.4. These rows supply the carrier, classifier, stability, ledger, and exactness fields consumed by downstream knot-facing chapters.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket namecert obligation surface`

Proof. Project the packet to the fields listed in Definition 254.1. The source boundary theorem supplies the exact $\mathsf{S}^{1\uparrow}$ rows and endpoint package provenance. The Homotopy ledger boundary theorem supplies the exact crossing, Reidemeister, deformation, and continuation rows together with their classifier stability.

The classifier field is the relation of Definition 254.2. Its clauses transport the source, diagram, trace, deformation, endpoint, provenance, and ledger rows componentwise, so it is the stability surface required by the public $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ package.

Conversely, every row named in the obligation surface is a field of $\mathcal{K}$ or a projection theorem for those fields. Repacking them gives the carrier, classifier, stability, ledger, and exactness surface visible to downstream consumers. No additional host embedding, external knot quotient, or undecomposed ambient-isotopy witness is part of the public interface. □

Theorem 254.6 (KnotUp projection stability obligation)**.** *Every carried knot projection row over* BHist *is stable under* hsame *transport of the displayed* $\mathsf{S}^{1\uparrow}$ *source row and the ambient* $\mathsf{Homotopy}^\uparrow$ *row. The transported row has the same visible knot packet, and its hidden projection data are carried only through the* Cont *ledger and the two cited NameCert source rows.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket projection stability obligation`

Proof. Read the carried projection row as a BHist packet whose visible boundary consists of the $\mathsf{S}^{1\uparrow}$ source row, the ambient $\mathsf{Homotopy}^\uparrow$ row, and the finite projection ledger. The BEDC source field is therefore $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ together with $\mathsf{NameCert}_{\mathsf{Homotopy}^\uparrow}$; the carrier field is the projection packet; the classifier field is the row displayed by the packet; and the stability field is the given hsame transport.

Transport first along the $\mathsf{S}^{1\uparrow}$ source row and then along the ambient $\mathsf{Homotopy}^\uparrow$ row. The Cont ledger carries exactly the hidden projection witnesses, so no additional diagram equality or ambient quotient is introduced.

The ledger field is the transported finite projection ledger, the core theorem list is this stability row together with the two dependency rows, and exactness says that the accepted packet is precisely the transported packet. The standard bridge field is none, and the status field is a paper obligation for $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$. □

Theorem 254.7 (KnotUp Reidemeister-move classifier obligation)**.** *The* $\mathsf{Knot}^{\uparrow}$ *classifier is generated by finite* ProbeBundle *ledgers for Reidemeister I, II, and III moves, together with endpoint* hsame *transport. Reflexive, symmetric, and transitive classifier rows are supplied respectively by the empty move ledger, the reversed move ledger, and concatenation of finite move ledgers.*

Proof. The BEDC source field is the projection carrier from Definition 254.6 with endpoints classified by $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$ and ambient rows classified by $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$. The carrier field is a finite move ledger whose entries are tagged Reidemeister I, Reidemeister II, or Reidemeister III probes inside ProbeBundle.

For the classifier field, accept a row exactly when such a finite ledger connects the two visible projection endpoints after endpoint hsame transport. Stability follows by transporting the endpoints first and then reusing the same tagged move probes over the transported boundary.

The ledger field records the tagged move list. The core theorem list consists of the empty-ledger row, the reverse-ledger row, and the concatenation row, giving reflexivity, symmetry, and transitivity of the classifier. Exactness states that every accepted classifier row has one of these finite ledger presentations; the standard bridge field is none, and the status field is a paper obligation. □

Theorem 254.8 (KnotUp empty Reidemeister ledger reflexivity)**.** *For every* $\mathsf{Knot}^{\uparrow}$ *diagram packet, the empty finite* ProbeBundle *Reidemeister ledger over its displayed* $\mathsf{S}^1\uparrow$ *endpoints and ambient* $\mathsf{Homotopy}^{\uparrow}$ *row supplies the* $\mathsf{Knot}^{\uparrow}$ *classifier row from the packet to itself.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotReidemeisterLedgerClassifier empty reflexive`

Proof. Project the packet to its visible boundary: the two $\mathsf{S}^1\uparrow$ endpoint rows, the ambient $\mathsf{Homotopy}^{\uparrow}$ row, the packet provenance in Pkg, and the hidden diagram data carried by Cont. These are exactly the endpoint fields read by the classifier obligation of Definition 254.7.

Choose the empty ProbeBundle ledger. It has the same starting and ending endpoint boundary, so the endpoint hsame transport is the identity row and no hidden move witness is introduced.

Applying Definition 254.7 to this boundary and empty ledger gives the accepted classifier row from the displayed packet back to itself. The ledger exactness surface is the empty presentation named in Definition 254.13. □

Theorem 254.9 (KnotUp reversed Reidemeister ledger symmetry)**.** *If a finite* ProbeBundle *Reidemeister ledger over the displayed* $\mathsf{S}^1\uparrow$ *endpoints and ambient* $\mathsf{Homotopy}^{\uparrow}$ *row supplies an accepted* $\mathsf{Knot}^{\uparrow}$ *classifier row from one diagram packet to another, then the reversed finite ledger supplies the opposite classifier row over the same visible endpoint data and the same* Pkg *scope.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotReidemeisterLedgerClassifier reversal symmetry`

Proof. Start with the accepted classifier row and read it through Definition 254.7. The row exposes a finite tagged Reidemeister ledger, endpoint hsame transport, the shared $\mathsf{S}^1\uparrow$ endpoint source rows, and the ambient $\mathsf{Homotopy}^{\uparrow}$ row.

Reverse the finite ledger by reversing the order of its ProbeBundle entries and replacing each Reidemeister probe with the same move read in the opposite direction. The endpoints are unchanged as visible BEDC rows: the former target boundary becomes the source boundary, the former source boundary becomes the target boundary, and the Pkg provenance remains the same package scope.

The reversed ledger is therefore a finite presentation over the same visible endpoints. Applying Definition 254.7 again gives the opposite classifier row, and Definition 254.13 records that no extra ambient-isotopy witness is admitted beyond that finite reversal. □

Theorem 254.10 (KnotUp concatenated Reidemeister ledger transitivity)**.** *If one accepted* $\mathsf{Knot}^{\uparrow}$ *classifier row is carried by a finite Reidemeister ledger from a first diagram packet to a middle packet, and a second accepted row is carried by a finite Reidemeister ledger from that middle packet to a third packet, then the concatenated* ProbeBundle *ledger supplies a classifier row from the first packet to the third.*

Proof. Read the two accepted rows through Definition 254.7. The first row supplies a finite ledger from the first boundary to the middle boundary, and the second supplies a finite ledger from the middle boundary to the third boundary.

Use the Cont and Pkg provenance of the middle packet to identify the two displayed middle boundaries as the same BEDC boundary data. The shared $\mathsf{S}^{1\uparrow}$ endpoint rows and the shared ambient $\mathsf{Homotopy}^{\uparrow}$ row give the endpoint compatibility needed before the ledgers can be joined.

Append the two finite ProbeBundle ledgers. The appended ledger starts at the first packet boundary, passes through the shared middle boundary, and ends at the third packet boundary, while preserving every tagged Reidemeister probe already accepted in the two input rows.

Applying Definition 254.7 to the appended ledger gives the composite classifier row. Exactness is inherited from Definition 254.13: the accepted composite row is represented precisely by the concatenated finite Reidemeister ledger over the displayed endpoints. □

Theorem 254.11 (KnotUp Homotopy source obligation)**.** *Every ambient-isotopy row consumed by the* $\mathsf{Knot}^{\uparrow}$ *certificate factors through the displayed* $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$ *source, and it consumes only endpoints supplied by the* $\mathsf{S}^{1\uparrow}$ *carrier boundary.*

Proof. The BEDC source field is the pair of source certificates $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$. The carrier field is the knot packet whose source boundary exposes the circle endpoints and whose ambient boundary exposes the homotopy row.

Factor the ambient row through $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$ before it is used by any Reidemeister ledger. The endpoint checks are then read from the $\mathsf{S}^{1\uparrow}$ carrier boundary, so the homotopy row cannot introduce a new endpoint source or an untracked ambient endpoint.

The classifier and stability fields are inherited from the factorized homotopy row and the endpoint hsame transport. The ledger field records only the homotopy source witness and the endpoint boundary witnesses; exactness says that these are the only inputs consumed by the ambient-isotopy row. The standard bridge field is none, and the status field is a paper obligation. □

Theorem 254.12 (KnotUp SOne boundary ledger)**.** *Every diagram endpoint, arc endpoint, and crossing endpoint used by a* $\mathsf{Knot}^{\uparrow}$ *packet has an* $\mathsf{S}^{1\uparrow}$ *boundary source. The boundary ledger records the hidden projection and crossing data while exposing only the* $\mathsf{S}^{1\uparrow}$ *endpoint rows and the ambient* $\mathsf{Homotopy}^{\uparrow}$ *row.*

Proof. The BEDC source field is the displayed $\mathsf{S}^{1\uparrow}$ boundary together with the ambient $\mathsf{Homotopy}^{\uparrow}$ boundary. The carrier field is the knot packet with diagram endpoints, arc endpoints, crossing endpoints, hidden projection data, and hidden crossing data.

For each endpoint kind, choose its boundary witness from the $\mathsf{S}^{1\uparrow}$ carrier row. The classifier field then reads endpoint compatibility through those source witnesses, while the stability field transports them by hsame and leaves hidden projection and crossing witnesses inside the finite ledger.

The ledger field is the list of endpoint witnesses plus the hidden projection and crossing records. The core theorem list is the diagram-endpoint, arc-endpoint, and crossing-endpoint boundary rows.

Exactness states that no endpoint used by the packet is outside the $\mathsf{S}^{1\uparrow}$ source boundary; the standard bridge field is none, and the status field is a paper obligation. □

Theorem 254.13 (KnotUp ambient-isotopy ledger exactness)**.** *If two knot packets are related by the* $\mathsf{Knot}^{\uparrow}$ *classifier, then they have compatible visible* $\mathsf{S}^{1\uparrow}$ *endpoints and compatible visible* $\mathsf{Homotopy}^{\uparrow}$ *endpoints, and a finite Reidemeister ledger over those same visible endpoints supplies the accepted classifier row.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket ambient isotopy ledger exactness`

Proof. The BEDC source field is the pair of endpoint sources from $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$. The carrier field is the two knot packets together with their displayed boundaries, and the classifier field is the accepted finite Reidemeister ledger from Definition 254.7.

Project the accepted classifier row to its endpoint boundary. The $\mathsf{S}^{1\uparrow}$ projection gives compatible circle endpoints, and the $\mathsf{Homotopy}^{\uparrow}$ projection gives compatible ambient endpoints; both projections use the same visible endpoints as the finite Reidemeister ledger.

The stability field is endpoint hsame transport, and the ledger field is the shared finite Reidemeister ledger. The core theorem list is projection stability, the Reidemeister classifier, homotopy source factorization, and the $\mathsf{S}^{1\uparrow}$ boundary ledger. Exactness says that the accepted classifier row contains exactly those visible endpoints and that ledger; the standard bridge field is none, and the status field is a paper obligation. □

Theorem 254.14 (KnotUp endpoint source exhaustion)**.** *For every* $\mathsf{Knot}^{\uparrow}$ *diagram packet* $\mathcal{K}$ *of Definition 254.1, every endpoint row appearing as a diagram endpoint, arc endpoint, crossing endpoint, or Reidemeister-move endpoint factors through the displayed* $\mathsf{S}^{1\uparrow}$ *source row and the ambient* $\mathsf{Homotopy}^{\uparrow}$ *row. The public packet has no host embedding endpoint source and no undecomposed ambient-isotopy endpoint source outside those two rows.*

Proof. Project $\mathcal{K}$ to its source field $\mathcal{S}$, ambient field $\mathcal{A}$, endpoint rows e_0, e_1, Reidemeister trace r, HomotopyUp row h, provenance row ρ, and finite ledger λ as displayed in Definition 254.1. These projections are the only places where endpoint data enter the packet.

For diagram endpoints, arc endpoints, and crossing endpoints, apply Definition 254.12. It supplies an $\mathsf{S}^{1\uparrow}$ boundary source for each endpoint kind and leaves hidden projection or crossing data inside the finite ledger rather than in a separate source object.

For endpoints consumed by Reidemeister moves, first read the finite $\mathsf{ProbeBundle}$ move ledger from Definition 254.7. Then apply Definition 254.11 to the ambient row used by that ledger. The ambient row factors through $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$ and consumes only endpoints already supplied by the $\mathsf{S}^{1\uparrow}$ carrier boundary.

Thus each endpoint row factors through the displayed $\mathsf{S}^{1\uparrow}$ and $\mathsf{Homotopy}^{\uparrow}$ sources, with package provenance recorded by ρ and with all remaining witnesses carried by λ. No host embedding source or primitive ambient-isotopy source remains available to the public packet. □

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket endpoint source exhaustion`

Theorem 254.15 (KnotUp Reidemeister ledger composition closure)**.** *Let two accepted finite* $\mathsf{ProbeBundle}$ *Reidemeister ledgers over* $\mathsf{Knot}^{\uparrow}$ *packets have matching visible endpoint rows after the endpoint* hsame *transports required by Definition 254.2. Their* Cont *concatenation is again an accepted* $\mathsf{Knot}^{\uparrow}$ *classifier ledger over the same public source and ambient rows, and the empty ledger is the unit accepted classifier row.*

Proof. Apply Definition 254.7 to the first accepted ledger. It presents the classifier row as a finite ProbeBundle list whose entries are Reidemeister I, II, or III moves together with endpoint hsame transport.

Apply the same theorem to the second accepted ledger. The hypothesis that the visible endpoints match supplies the endpoint transport needed to place the second list after the first one without changing the displayed $\mathsf{S}^{1\uparrow}$ and $\mathsf{Homotopy}^{\uparrow}$ boundary rows.

Concatenate the two finite lists by the Cont ledger operation. Each entry is still one of the accepted Reidemeister probe rows, and the middle endpoint is discharged by the supplied hsame transport. Therefore Definition 254.2 accepts the concatenated ledger as a classifier row.

For the unit, take the empty finite ProbeBundle list. The empty ledger has the same visible endpoints on both sides and is the reflexive row named by Definition 254.7, so it is accepted and acts as the Cont unit. □

Lean4 ✓ `BEDC.Derived.KnotUp.KnotReidemeisterLedgerClassifier composition closure`

Theorem 254.16 (KnotUp classifier ledger completeness)**.** *Every accepted* $\mathsf{Knot}^{\uparrow}$ *classifier row is exactly a finite ledger generated by endpoint* hsame *transport and Reidemeister I, II, and III* ProbeBundle *rows. Its source and ambient endpoints are the visible endpoints of Definition 254.13, and every finite ledger with those generators repacks as an accepted classifier row of Definition 254.2.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotReidemeisterLedgerClassifier ledger completeness`

Proof. For the forward direction, start from an accepted classifier row. Project it through Definition 254.13; the result has compatible visible $\mathsf{S}^{1\uparrow}$ endpoints, compatible visible $\mathsf{Homotopy}^{\uparrow}$ endpoints, and a finite Reidemeister ledger over those same endpoints.

Next apply Definition 254.7. The accepted ledger is generated by endpoint hsame transport and Reidemeister I, II, and III ProbeBundle rows. The exhaustion result Definition 254.14 identifies the endpoint sources with the displayed $\mathsf{S}^{1\uparrow}$ and $\mathsf{Homotopy}^{\uparrow}$ rows.

For the reverse direction, assume such a finite generated ledger over the visible source and ambient endpoints. Place the endpoint transports, move probes, provenance row, and continuation ledger into the clauses of Definition 254.2.

The classifier definition accepts exactly those component rows, so the repacked finite ledger is an accepted $\mathsf{Knot}^{\uparrow}$ classifier row. This gives both directions and leaves no additional quotient or ambient-isotopy primitive in the classifier surface. □

Theorem 254.17 (KnotUp NameCert field coverage)**.** *The public* $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$ *carrier, classifier, stability, ledger, and exactness fields are covered by Definition 254.1, Definition 254.2, Definition 254.3, Definition 254.4, Definition 254.5, Definition 254.6, Definition 254.7, Definition 254.11, Definition 254.12, Definition 254.13, Definition 254.14, Definition 254.15, and Definition 254.16. Downstream consumers may cite these rows without assuming a knot quotient, host embedding equality, or external ambient-isotopy primitive.*

Proof. Enumerate the public certificate surface in the ten-field roadmap form. The BEDC source field is the pair of consumed $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$ packets; the carrier field is Definition 254.1; and the classifier field is Definition 254.2.

The stability field is supplied by Definition 254.6 and by the endpoint hsame transport in Definition 254.7. The ledger field is the finite Cont and ProbeBundle surface identified by Definition 254.4, Definition 254.15, and Definition 254.16.

The source-boundary and endpoint-coverage fields are Definition 254.3, Definition 254.11, Definition 254.12, and Definition 254.14. The exactness field is Definition 254.13 together with the classifier completeness theorem. The standard bridge field is none, and the status field is the public paper surface described by Definition 254.5.

Every item in the roadmap is therefore a displayed BEDC row or a theorem about those displayed rows. Repacking those rows gives the public $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ coverage surface and supplies downstream knot-facing work with citations that do not import a knot quotient, host embedding equality, or external ambient-isotopy primitive. □

Definition 254.18 (KnotUp downstream consumer boundary packet)**.** *For an accepted* $\mathsf{Knot}^\uparrow$ *diagram packet* $\mathcal{K}$ *of Definition 254.1, its downstream consumer boundary packet is the finite BEDC row family*

$$\mathsf{KnotConsumer}(\mathcal{K})$$

consisting of the projected $\mathsf{S}^{1\uparrow}$ *source packet* $\mathcal{S}$ *and its endpoint rows, the ambient* $\mathsf{Homotopy}^\uparrow$ *target and deformation rows, the two endpoint* BHist *rows, the finite Reidemeister* ProbeBundle *ledger, the finite* Cont *continuation ledger, and the* Pkg *provenance row linking all of these rows in the same package scope. The packet exposes only these rows and the public classifier surface of Definition 254.2.*

Theorem 254.19 (KnotUp consumer boundary extraction)**.** *Every accepted* $\mathsf{Knot}^\uparrow$ *diagram packet projects to exactly the downstream consumer boundary packet of Definition 254.18. The projection contains the visible* $\mathsf{S}^{1\uparrow}$ *source rows, ambient* $\mathsf{Homotopy}^\uparrow$ *rows, endpoint family, finite Reidemeister* ProbeBundle *ledger, finite* Cont *ledger, and* Pkg *provenance, and it contains no additional host embedding equality, knot quotient, or undecomposed ambient-isotopy primitive.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket consumer boundary extraction`

Proof. Start with an accepted diagram packet $\mathcal{K}$ and project its carrier fields through Definition 254.1. This gives the displayed source packet, ambient packet, endpoint rows, crossing ledger, Reidemeister trace, deformation row, continuation ledger, and provenance row.

The certificate field coverage theorem Definition 254.17 identifies these same carrier and classifier fields as the public $\mathsf{NameCert}_{\mathsf{Knot}^\uparrow}$ surface. The source and ambient boundary theorems then place the visible source and deformation rows in the same finite row family.

Repack the projected rows in the order named by Definition 254.18. Since every listed component is a carrier field or a field-coverage projection, the extracted family is exactly the consumer boundary packet and no hidden host datum is available to add. □

Theorem 254.20 (KnotUp consumer classifier determinacy)**.** *If two accepted* $\mathsf{Knot}^\uparrow$ *classifier rows have the same downstream consumer boundary packet, then they have the same public classifier surface. In particular, their visible endpoint transports agree by* hsame*, and their Reidemeister and continuation ledgers agree as the finite ledger surface specified by Definition 254.16.*

Proof. Assume two accepted classifier rows share the same consumer boundary packet. The shared packet identifies the projected $\mathsf{S}^{1\uparrow}$ endpoint family and the ambient $\mathsf{Homotopy}^\uparrow$ rows, so the endpoint transports used by the classifier are the same hsame rows.

Apply Definition 254.16 to each classifier row. Both rows decompose into finite ledgers generated by endpoint hsame transport and Reidemeister I, II, and III ProbeBundle rows over the visible endpoints supplied by the shared packet.

The shared ProbeBundle and Cont ledgers therefore give the same generator list and the same package provenance. Repacking those generators through Definition 254.2 yields the same public classifier surface for both accepted rows. □

Theorem 254.21 (KnotUp consumer continuation composition)**.** *Composable downstream consumer boundary packets compose by concatenating their finite* Cont *continuation ledgers and their finite Reidemeister* ProbeBundle *ledgers. The composed packet preserves the endpoint source exhaustion of Definition 254.14 and remains accepted by the classifier composition theorem Definition 254.15.*

Lean4 ✓ `BEDC.Derived.KnotUp.KnotDiagramPacket consumer cont composition`

Proof. Take two consumer boundary packets whose target endpoint family of the first matches the source endpoint family of the second. The shared middle endpoint is one of the projected $\mathsf{S}^{1\uparrow}$ and $\mathsf{Homotopy}^{\uparrow}$ rows named by the packets, so Definition 254.14 supplies the same source identification on both sides.

Concatenate the two finite Cont ledgers and concatenate the two finite Reidemeister ProbeBundle ledgers. The package provenance rows are composable because both packets expose the same middle endpoint and ambient scope.

Finally apply Definition 254.15. It accepts exactly this concatenated ledger as a classifier row, while the endpoint-source exhaustion theorem keeps the visible source rows fixed at the composed boundary. Repacking the rows gives the composed consumer boundary packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$**.**

Constructive story: A knot packet is generated from a consumed $\mathsf{S}^{1\uparrow}$ source packet, an ambient $\mathsf{Homotopy}^{\uparrow}$ deformation row, finite crossing data, a finite Reidemeister trace, endpoint rows, a Pkg provenance row, and a Cont ledger tying those rows together. The carrier accepts exactly diagram packets whose endpoints factor through the displayed circle source and ambient deformation source, whose crossings and moves are finite BHist or ProbeBundle rows, and whose hidden projection data stays inside the continuation ledger; host embeddings and undecomposed ambient isotopy are excluded. Two packets are classified by transporting the circle source, crossing entries, Reidemeister ledgers, homotopy rows, endpoints, provenance, and continuation ledger componentwise by hsame and finite Cont refinements. The source is the displayed diagram packet over $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Homotopy}^{\uparrow}}$, the pattern records source-boundary extraction, Homotopy ledger boundary, projection stability, finite Reidemeister reflexivity, reversal, concatenation, endpoint exhaustion, and classifier completeness, and the ledger keeps source endpoints, ambient rows, crossings, local moves, deformation rows, and package provenance visible. The five name-certificate obligations are supplied by any accepted diagram packet for carrier inhabitation, by the empty, reversed, and concatenated Reidemeister ledgers for reflexivity, symmetry, and transitivity, and by endpoint-source exhaustion plus ledger composition for closure under classified transport. A history h lies in the signature gap of a $\mathsf{Knot}^{\uparrow}$ token p when the source-domain accepts its diagram packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h has the same $\mathsf{S}^{1\uparrow}$ endpoints, HomotopyUp deformation row, Reidemeister trace, classifier ledger, and provenance encoded by p. The chapter registers this finite diagram-and-move construction under the name $\mathsf{Knot}^{\uparrow}$; ambient-isotopy quotients, host knot types, and general knot invariants beyond the displayed certificate rows are not introduced.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature $\mathsf{Knot}^{\uparrow}$ surface is the finite diagram consumer boundary given by the consumer boundary extraction row and closed under consumer continuation-composition over the displayed $\mathsf{S}^{1\uparrow}$, $\mathsf{Homotopy}^{\uparrow}$, Pkg, Cont, and hsame rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.KnotUp.KnotDiagramPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close ambient-isotopy quotients, host knot types, or general knot invariants beyond the displayed finite certificate rows.

Upgrade path: Only Lean-side bridge checking remains beyond the mature finite diagram consumer surface.

Chapter 255

A Concrete Naming Certificate for $\mathsf{JonesPolynomial}^{\uparrow}$

The Jones-polynomial interface $\mathsf{JonesPolynomial}^{\uparrow}$ packages the Laurent polynomial knot invariant in $\mathbb{Z}[t^{1/2}, t^{-1/2}]$ defined by the skein relation. It depends on $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$ (chapter 254) and $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50).

255.1 Carrier definition

255.2 The certificate

Definition 255.1 (JonesPolynomial skein ledger packet)**.** *A* $\mathsf{JonesPolynomial}^{\uparrow}$ *skein ledger packet is a finite BEDC row family*

$$\mathcal{J} = (\mathcal{K}, \mathcal{K}_+, \mathcal{K}_-, \mathcal{K}_0, J, \sigma, \rho, \lambda)$$

with the following visible fields.

1. *$\mathcal{K}$ is an accepted* $\mathsf{Knot}^{\uparrow}$ *diagram packet of Definition 254.1; it is the diagram row whose polynomial endpoint is being named.*
2. *$\mathcal{K}_+$, $\mathcal{K}_-$, and $\mathcal{K}_0$ are accepted* $\mathsf{Knot}^{\uparrow}$ *diagram packets over the same displayed* $\mathsf{S}^{1\uparrow}$ *source, ambient* $\mathsf{Homotopy}^{\uparrow}$ *row, endpoint family, and* Pkg *scope, except for one local skein window tagged respectively as the positive crossing, negative crossing, and oriented smoothing boundary row.*
3. *J is a Laurent-polynomial endpoint row whose underlying normalized finite coefficient row is accepted by* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *through Definition 50.3, Definition 50.21, and Definition 50.24. The Laurent bookkeeping is carried as displayed endpoint data and is not read as host polynomial equality.*
4. *σ is a finite* Bundle*-indexed skein ledger. Each entry names one local skein face, the three* $\mathsf{Knot}^{\uparrow}$ *boundary rows $\mathcal{K}_+, \mathcal{K}_-, \mathcal{K}_0$, the endpoint row J, the polynomial classifier rows consumed at that face, and the* $\mathsf{Knot}^{\uparrow}$ *classifier rows showing that Reidemeister transport of the surrounding diagram commutes with reading the same local face.*
5. *ρ records the shared* Pkg *provenance of the four knot packets, the polynomial endpoint, and the finite skein ledger. The continuation ledger λ lists exactly the* Cont, hsame, Bundle, *polynomial-classifier, knot-classifier, and exactness rows accepted by the public* $\mathsf{JonesPolynomial}^{\uparrow}$ *surface.*

The packet exports only these rows. It does not export a host knot quotient, external diagram equality, or a complete Jones-polynomial invariant beyond the supplied finite skein ledger.

Lean4 (definition) `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket`

Definition 255.2 (JonesPolynomial skein ledger classifier)**.** *Two packets* $\mathcal{J} = (\mathcal{K}, \mathcal{K}_+, \mathcal{K}_-, \mathcal{K}_0, J, \sigma, \rho, \lambda)$ *and* $\mathcal{J}' = (\mathcal{K}', \mathcal{K}'_+, \mathcal{K}'_-, \mathcal{K}'_0, J', \sigma', \rho', \lambda')$ *of Definition 255.1 are related by* $\mathsf{JonesSkeinCls}$ *when the following finite rows are supplied.*

1. *The main diagram rows* $\mathcal{K}$ *and* $\mathcal{K}'$ *are related by the* $\mathsf{Knot}^{\uparrow}$ *Reidemeister ledger classifier of Definition 254.2.*
2. *The three skein boundary pairs* $(\mathcal{K}_+, \mathcal{K}'_+)$*,* $(\mathcal{K}_-, \mathcal{K}'_-)$*, and* $(\mathcal{K}_0, \mathcal{K}'_0)$ *are related by the same* $\mathsf{Knot}^{\uparrow}$ *classifier surface, with matching local-window tags and the same transported endpoint rows.*
3. *The polynomial endpoints* J *and* J' *are related by the normalized structural classifier of* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ *from Definition 50.21, with stability read through Definition 50.22.*
4. *The ledgers* σ *and* σ' *are matched by finite* Bundle *induction: empty skein ledgers compare, and a cons step compares the displayed local skein face after applying the four* $\mathsf{Knot}^{\uparrow}$ *transports and the* $\mathsf{Poly}^{\uparrow}$ *endpoint classifier row.*
5. *The provenance rows* ρ, ρ' *and continuation ledgers* λ, λ' *list exactly the transported rows above and no further host-level witness.*

Lean4 (definition) `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerClassifier`
Lean4 (definition) `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket classifier`

Lemma 255.3 (JonesPolynomial skein ledger Reidemeister transport)**.** *Let* $\mathcal{J}$ *be a* $\mathsf{JonesPolynomial}^{\uparrow}$ *skein ledger packet. Transport* $\mathcal{K}$ *and the three boundary rows* $\mathcal{K}_+, \mathcal{K}_-, \mathcal{K}_0$ *by accepted finite* $\mathsf{Knot}^{\uparrow}$ *Reidemeister ledgers whose displayed endpoint transports preserve the local skein window. Transport the endpoint* J *by an accepted* $\mathsf{Poly}^{\uparrow}$ *classifier row. Then the transported rows repack as a* $\mathsf{JonesPolynomial}^{\uparrow}$ *skein ledger packet* $\mathcal{J}'$*, and* $\mathsf{JonesSkeinCls}(\mathcal{J}, \mathcal{J}')$ *holds.*

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket reidemeister transport`

Proof. Project the four knot rows of $\mathcal{J}$ to downstream consumer boundary packets by Definition 254.19. Each projection contains exactly the displayed $\mathsf{S}^{1\uparrow}$ source rows, ambient $\mathsf{Homotopy}^{\uparrow}$ rows, finite Reidemeister Bundle ledger, finite Cont ledger, and Pkg provenance.

Apply Definition 254.15 to compose any Reidemeister transport already present in the packet with the supplied transport ledgers. Then apply Definition 254.16 to read the result again as a finite ledger generated by endpoint hsame transport and Reidemeister move rows. The hypothesis that the local skein window is preserved identifies the positive, negative, and smoothing tags after transport, so every skein face in σ has a transported face over the same displayed boundary pattern.

The polynomial endpoint transport is accepted by the normalized structural classifier of Definition 50.21; the stability rows of Definition 50.22 keep the endpoint inside the $\mathsf{Poly}^{\uparrow}$ carrier. Induct over the finite Bundle ledger σ. The empty ledger transports to the empty ledger. In the cons case, the head face is transported by the four knot classifier rows and the polynomial endpoint classifier row, while the induction hypothesis transports the remaining finite ledger.

Collecting the transported skein faces gives a finite ledger σ'. The transported provenance and continuation rows give ρ' and λ'. These fields satisfy the clauses of Definition 255.1, and the same construction is exactly the classifier relation of Definition 255.2. □

Theorem 255.4 (JonesPolynomial skein ledger obligation surface)**.** *Let $\mathcal{J}$ be a* $\mathsf{JonesPolynomial}^{\uparrow}$ *skein ledger packet of Definition 255.1. Assume its finite skein ledger is compatible with Reidemeister transport in the sense of Definition 255.3. Then the finite row family consisting of the main* $\mathsf{Knot}^{\uparrow}$ *diagram row, the three skein-related* $\mathsf{Knot}^{\uparrow}$ *boundary rows, the* $\mathsf{Poly}^{\uparrow}$ *Laurent-polynomial endpoint row, the finite* Bundle *skein ledger, the shared* Pkg *provenance, the finite* Cont *continuation ledger, and the classifier* JonesSkeinCls *forms an accepted carrier/classifier surface for* $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ *over those rows.*

The exactness boundary of this surface is the displayed packet itself: every accepted $\mathsf{JonesPolynomial}^{\uparrow}$ *row projects to those listed fields, and every listed field repacks into the same packet. No full Jones-polynomial invariant, unknot normalization, global skein recursion, host polynomial quotient, or external ambient-isotopy primitive is part of this obligation surface.*

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket obligation surface`

Proof. Start with the packet fields displayed in Definition 255.1. The main diagram row and the three skein boundary rows are accepted $\mathsf{Knot}^{\uparrow}$ packets, so Definition 254.19 exposes their public boundary packets and Definition 254.20 fixes the classifier surface read by any downstream consumer.

The endpoint J is accepted by the polynomial carrier and classifier rows of Definition 50.3, Definition 50.21, and Definition 50.24. Thus the polynomial side of the surface is a normalized finite coefficient endpoint carried by $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$, with the Laurent tags retained only as displayed endpoint data.

The finite skein ledger σ ties these two sides together. Each ledger entry reads the same three $\mathsf{Knot}^{\uparrow}$ boundary rows, the same polynomial endpoint row, and the same package provenance. By the Reidemeister transport lemma, transporting the diagram and boundary rows through accepted $\mathsf{Knot}^{\uparrow}$ classifier ledgers transports the corresponding skein face and keeps the polynomial endpoint inside the $\mathsf{Poly}^{\uparrow}$ classifier. Hence the surface has a stable classifier, namely Definition 255.2.

For exactness, project an accepted surface row to its knot fields, polynomial endpoint field, skein ledger, provenance row, and continuation ledger. These are precisely the fields of Definition 255.1. Conversely, given those fields, the definition repacks them as a $\mathsf{JonesPolynomial}^{\uparrow}$ skein ledger packet, and the classifier definition supplies the accepted comparison rows. The public carrier/classifier surface is therefore exactly the supplied finite skein-ledger row family and contains no additional invariant or bridge row. □

Theorem 255.5 (JonesPolynomial skein endpoint classifier exhaustion)**.** *Every accepted* JonesSkeinCls *witness between skein ledger packets $\mathcal{J}$ and $\mathcal{J}'$ projects exactly to the main* $\mathsf{Knot}^{\uparrow}$ *row, the three skein-boundary* $\mathsf{Knot}^{\uparrow}$ *rows, the* $\mathsf{Poly}^{\uparrow}$ *endpoint classifier row, the finite* Bundle *skein ledger, the shared* Pkg *provenance, and the finite* Cont *continuation ledger displayed in Definition 255.2. Conversely, any finite row family with precisely those fields repacks as the same* JonesSkeinCls *witness.*

Thus endpoint readback for $\mathsf{JonesPolynomial}^{\uparrow}$ *is exhausted by generated classifier data: the endpoint comparison reads the listed knot, polynomial, ledger, provenance, and continuation rows, not host Laurent-polynomial equality or a knot quotient.*

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket endpoint classifier exhaustion`

Proof. Project an accepted classifier witness by the constructor clauses of Definition 255.2. The first four clauses give the main $\mathsf{Knot}^{\uparrow}$ row, the three skein-boundary $\mathsf{Knot}^{\uparrow}$ rows, the $\mathsf{Poly}^{\uparrow}$ endpoint classifier row, and the finite Bundle ledger comparison.

For the ledger component, induct over the finite Bundle skein ledger. The empty ledger projects to the empty displayed row family. In the cons step, the head face projects to its four knot classifier rows and its polynomial endpoint classifier row, while the induction hypothesis projects the tail ledger.

Apply Definition 255.3 at each head face to keep Reidemeister transport inside the same local skein window. The polynomial classifier specification from Definition 50.21 keeps the Laurent endpoint readback inside $\mathsf{NameCert}_{\mathsf{Poly}^\uparrow}$.

The final classifier clauses project the shared Pkg provenance and finite Cont continuation ledger. These are exactly the rows listed in the theorem statement, and no further host witness is present in the classifier definition.

Conversely, given the listed rows, rebuild the witness by the same constructor clauses. The finite Bundle ledger is rebuilt by the empty and cons cases just used in projection, the knot rows are accepted by their displayed $\mathsf{Knot}^\uparrow$ classifier clauses, and the polynomial endpoint row is accepted by the polynomial classifier specification. Repacking these fields gives precisely an accepted JonesSkeinCls witness. □

Theorem 255.6 (JonesPolynomial local skein-window composition)**.** *Let $\mathcal{J}_1$ and $\mathcal{J}_2$ be finite* $\mathsf{JonesPolynomial}^\uparrow$ *skein ledger packets over* BHist *as in Definition 255.1. Suppose the terminal local skein-window row of $\mathcal{J}_1$ and the initial local skein-window row of $\mathcal{J}_2$ are the same displayed* $\mathsf{Knot}^\uparrow$ *boundary row under* hsame*, and suppose the adjacent Laurent endpoints carry compatible* $\mathsf{Poly}^\uparrow$ *endpoint classifier rows. Then the finite* Bundle *skein ledgers of $\mathcal{J}_1$ and $\mathcal{J}_2$ concatenate to a finite* $\mathsf{JonesPolynomial}^\uparrow$ *skein ledger packet whose classifier projects exactly to the two original classifiers, the shared* $\mathsf{Knot}^\uparrow$ *boundary row, the compatible* $\mathsf{Poly}^\uparrow$ *endpoint row, the inherited* Cont *ledgers, and the shared* Pkg *provenance.*

The composed packet is a local finite-window construction. It introduces no host Laurent-polynomial equality, no knot quotient, and no global invariant row beyond the displayed BHist*,* Bundle*,* hsame*,* Cont*,* Pkg*,* $\mathsf{Knot}^\uparrow$*, and* $\mathsf{Poly}^\uparrow$ *data.*

Proof. Unpack the two packets by Definition 255.1. Each packet supplies four visible $\mathsf{Knot}^\uparrow$ rows, one $\mathsf{Poly}^\uparrow$ endpoint row, a finite Bundle skein ledger, a Pkg provenance row, and a finite Cont continuation ledger.

Concatenate the two finite Bundle skein ledgers at the shared boundary face. The hypothesis identifies that face as the same displayed $\mathsf{Knot}^\uparrow$ local-window row under hsame, and the compatible $\mathsf{Poly}^\uparrow$ endpoint classifier row gives the polynomial endpoint comparison needed at the join.

Apply Definition 255.3 to the shared boundary face. The Reidemeister transport stays inside the same local skein window, so the concatenated ledger still has the positive, negative, and smoothing boundary rows required by Definition 255.1.

The provenance rows and continuation ledgers concatenate as finite Pkg and Cont rows over the same public source certificates. Repacking these fields therefore gives a $\mathsf{JonesPolynomial}^\uparrow$ skein ledger packet.

Finally apply Definition 255.5. The classifier of the composed packet projects exactly to the two original classifier surfaces plus the shared boundary row and the compatible polynomial endpoint row. Since endpoint exhaustion lists no host polynomial equality or knot quotient, the composition does not introduce either one. □

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket local skein window composition`

Theorem 255.7 (JonesPolynomial public NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ *obligation surface consists exactly of the skein ledger packet, skein classifier, Reidemeister transport row,* $\mathsf{Poly}^{\uparrow}$ *endpoint classifier,* $\mathsf{Knot}^{\uparrow}$ *boundary rows, finite* Bundle *skein ledger,* Cont *ledger, and shared* Pkg *provenance displayed in this section. It exports no full ambient-isotopy quotient, no host Laurent-polynomial equality, and no complete-knot-invariant claim.*

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket namecert obligation surface`

Proof. Start with the packet of Definition 255.1. Its fields already list the main knot diagram, the three skein boundary diagrams, the polynomial endpoint, the finite skein ledger, the continuation ledger, and the shared provenance row.

The classifier is Definition 255.2. It supplies the accepted comparison rows for the knot faces, the polynomial endpoint, the ledger, and the provenance component. The Reidemeister stability needed by that classifier is exactly Definition 255.3.

Apply Definition 255.4. That theorem packages the displayed packet and classifier into the accepted finite carrier/classifier surface for $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ over the knot, polynomial, bundle, continuation, and provenance rows.

Finally read the roadmap ten-field template field by field. Each required public field is one of the rows just named, and every row in the public surface projects back to the same packet. Hence the public NameCert obligation surface is exactly the displayed skein-ledger construction, with no additional quotient, host-polynomial equality, or invariant row. □

Theorem 255.8 (JonesPolynomial carrier obligation)**.** *The carrier obligation for* $\mathsf{JonesPolynomial}^{\uparrow}$ *is exactly the finite* JonesSkeinLedgerPacket *over* BHist*,* Bundle*,* Cont*,* hsame*,* Pkg*,* $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{S}^{1\uparrow}}$*. Its rows are the displayed main knot row, the three skein-boundary rows, the polynomial endpoint row, the finite skein* Bundle*, the continuation ledger, and the shared provenance row. It contains no host knot quotient, no host Laurent-polynomial equality, and no complete-invariant row.*

Proof. Unpack Definition 255.1. The packet definition lists precisely the BHist knot histories, polynomial endpoint history, finite Bundle ledger, Cont continuation entries, hsame comparison rows, and Pkg provenance field named in the statement.

Apply Definition 255.3 to the three boundary rows. Transport stays inside the same displayed skein window, so the carrier does not acquire an ambient quotient or an external polynomial comparison.

Finally use Definition 255.4 together with Definition 255.7. These identify the public carrier part of the $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ surface with the packet fields just enumerated and with no additional host row. □

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket carrier obligation`

Theorem 255.9 (JonesPolynomial classifier obligation)**.** *The classifier obligation for* $\mathsf{JonesPolynomial}^{\uparrow}$ *is exactly* JonesSkeinCls*. It consists of the main knot classifier row, the positive-crossing, negative-crossing, and smoothing boundary classifier rows, the* $\mathsf{Poly}^{\uparrow}$ *endpoint classifier, finite* Bundle *comparison,* Pkg *provenance comparison, and* Cont *continuation rows attached to the packet of Definition 255.1.*

Proof. Start from Definition 255.2. Its fields are the accepted comparisons for the main $\mathsf{Knot}^{\uparrow}$ row, the three skein boundary rows, the polynomial endpoint row, the finite skein Bundle, the provenance component, and the continuation ledger.

Use Definition 255.3 for the boundary comparisons and Definition 255.5 for the endpoint comparison. Together they show that every accepted classifier witness projects to exactly those rows.

The reverse packing is supplied by Definition 255.4. The public surface theorem Definition 255.7 then reads the same classifier rows as the $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ classifier obligation, with no extra equality principle. □

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket classifier obligation`

Theorem 255.10 (JonesPolynomial ledger exactness obligation)**.** *Every accepted public* $\mathsf{JonesPolynomial}^{\uparrow}$ *row projects to the carrier packet, classifier, Reidemeister-transport, endpoint, finite* Bundle*,* Cont*, and* Pkg *ledger fields of Definition 255.8 and Definition 255.9. Conversely, those fields repack as the accepted public* $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ *row. The exactness surface uses no host knot quotient and no host Laurent-polynomial equality.*

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket ledger exactness obligation`

Proof. For the projection direction, apply Definition 255.7. It states that the public row consists exactly of the skein ledger packet, classifier, Reidemeister transport row, endpoint classifier, finite Bundle ledger, Cont ledger, and shared Pkg provenance.

Refine the projected rows by Definition 255.8 and Definition 255.9. The carrier theorem names the packet fields, and the classifier theorem names the JonesSkeinCls comparison fields.

For the repacking direction, use Definition 255.6 to compose the local skein window inside the displayed finite ledger, then apply Definition 255.5 to recover the endpoint row.

Finally invoke Definition 255.4 and Definition 255.7. They repack exactly the named carrier, classifier, transport, endpoint, ledger, continuation, and provenance rows as the public certificate, while excluding host quotient and host polynomial equality rows. □

Theorem 255.11 (JonesPolynomial skein classifier determinacy)**.** *Fix a* $\mathsf{JonesPolynomial}^{\uparrow}$ *skein ledger packet whose main* $\mathsf{Knot}^{\uparrow}$ *diagram row, three skein boundary rows,* $\mathsf{Poly}^{\uparrow}$ *endpoint classifier row, finite skein* Bundle*, finite* Cont *ledger, and* Pkg *provenance are displayed as in Definition 255.1. Then any accepted* JonesSkeinCls *witness over those fixed rows determines the same displayed* $\mathsf{JonesPolynomial}^{\uparrow}$ *endpoint row by* hsame *and* Cont *transport. The determinacy is internal to the skein classifier surface and asserts no host Laurent-polynomial equality, knot quotient, or complete invariant.*

Proof. Start with two accepted JonesSkeinCls witnesses over the fixed packet rows. The packet fixes the main knot diagram, positive crossing, negative crossing, smoothing boundary rows, the polynomial endpoint row, the finite skein bundle, the continuation ledger, and the provenance row.

Apply Definition 255.3. The Reidemeister row transports only the displayed $\mathsf{Knot}^{\uparrow}$ local-window boundary, so both classifier witnesses read the same boundary diagrams through hsame.

Next use Definition 255.5. It projects each accepted classifier witness exactly to the fixed knot rows, the fixed polynomial endpoint classifier, the finite skein ledger, the Cont ledger, and the Pkg provenance.

Apply Definition 255.6 to the fixed local window. The composition theorem keeps the skein bundle and the polynomial endpoint comparison at the same displayed boundary, so the two classifier readings cannot produce distinct displayed endpoint rows.

Finally cite Definition 255.7. The public surface contains exactly these packet and classifier rows. Repacking the exhausted rows therefore gives one $\mathsf{JonesPolynomial}^{\uparrow}$ endpoint row determined by hsame and Cont transport. □

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket skein classifier determinacy`

Theorem 255.12 (JonesPolynomial skein boundary no-confusion)**.** *Fix a* JonesSkeinCls *packet as in Definition 255.1. An accepted classifier witness cannot interchange the positive-crossing boundary row, the negative-crossing boundary row, and the smoothing boundary row unless the displayed local-window tag and the corresponding finite* Bundle *ledger row are the same packet entry. The separation is internal to the skein ledger and does not assert any host knot quotient or Laurent-polynomial equality.*

Proof. Unpack the packet of Definition 255.1. Its skein boundary fields are three displayed local-window rows, each paired with its own tag and its own position in the finite skein Bundle ledger.

Proceed by closed finite Bundle induction over the skein ledger. In the base case there is no ledger row available, so no accepted classifier witness can manufacture a boundary tag from outside the packet.

For the induction step, inspect the head ledger row. If the displayed tag is the positive-crossing tag, the classifier reads the positive boundary entry and the remaining bundle is handled by the induction hypothesis. The negative and smoothing tag cases are identical, with their own displayed boundary entries.

Apply Definition 255.5. Every accepted witness projects back to the fixed knot rows, the finite skein ledger, the Cont ledger, and the Pkg provenance. Thus an attempted interchange would require changing either the displayed local-window tag or the ledger row selected by that tag.

The tag fields in Definition 255.1 are distinct packet coordinates. Hence two boundary rows can be identified by an accepted witness only when the displayed tag and the finite Bundle ledger row already agree as the same coordinate of the fixed packet. No quotient of host knots and no Laurent-polynomial equality is used. □

Lean4 ✓ `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket skein boundary no confusion`

Theorem 255.13 (Jones polynomial mature finite skein consumer example)**.** *Let C be a downstream knot or diagram consumer whose input is a finite skein-ledger packet read through the bridged* $\mathsf{JonesPolynomial}^{\uparrow}$ *surface of this chapter. Then the visible data available to C are exactly the endpoint classifier, local skein-window composition, carrier and classifier obligations, ledger exactness, skein classifier determinacy, and no-confusion boundary displayed above.*

The consumer may therefore inspect the finite packet rows named by JonesSkeinLedgerPacket*,* JonesSkeinCls*,* $\mathsf{Knot}^{\uparrow}$*,* $\mathsf{Poly}^{\uparrow}$*,* Bundle*,* Cont*,* hsame*,* Pkg*, and the inherited* NameCert *surfaces. It cannot read a quotient of diagrams, a full Jones invariant, or a Reidemeister-complete standard model.*

Proof. Start with the checked skein-ledger transport of Definition 255.3. It keeps a finite local skein packet inside the same displayed boundary rows and transports only the knot, polynomial endpoint, continuation, and provenance entries already stored in the packet.

Next apply the obligation and endpoint surfaces: Definition 255.4, Definition 255.5, and Definition 255.6. These identify the endpoint classifier, the finite local-window composition, and the displayed skein ledger as the consumer's available row family.

Now read the public $\mathsf{NameCert}_{\mathsf{JonesPolynomial}^{\uparrow}}$ obligations through Definition 255.7, Definition 255.8, Definition 255.9, and Definition 255.10. The carrier, classifier, and ledger fields are exhausted by the finite packet coordinates and their Cont, hsame, and Pkg provenance.

Finally use Definition 255.11 and Definition 255.12. They prevent a consumer from separating two endpoint reads or interchanging the positive, negative, and smoothing boundary entries except

through the displayed finite ledger coordinates. Since every cited row belongs to that finite surface, no diagram quotient, full invariant, or Reidemeister-complete standard model is available to C. □

Closure status for $\mathsf{NameCert}_{\mathsf{JonesPolynomial}\uparrow}$.

Constructive story: A Jones-polynomial packet is generated by taking one accepted $\mathsf{Knot}^{\uparrow}$ diagram row, its positive, negative, and smoothing boundary rows in a local skein window, a Laurent-polynomial endpoint carried by $\mathsf{Poly}^{\uparrow}$, a finite Bundle skein ledger, a Pkg provenance row, and a finite Cont continuation ledger. The carrier accepts only packets in which all four knot rows share the displayed source, ambient, endpoint, and package scope, and in which the polynomial endpoint is read through the normalized finite coefficient carrier; a host knot quotient, host Laurent-polynomial equality, or complete invariant row is excluded. Two packets are classified by the $\mathsf{Knot}^{\uparrow}$ Reidemeister ledger classifier on the main and boundary diagrams, the $\mathsf{Poly}^{\uparrow}$ endpoint classifier on the polynomial row, and finite induction over the skein ledger, with local tags preventing confusion between positive, negative, and smoothing entries. The source is this finite skein ledger over $\mathsf{NameCert}_{\mathsf{Knot}\uparrow}$, $\mathsf{NameCert}_{\mathsf{Poly}\uparrow}$, and $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$, the pattern records Reidemeister transport, skein endpoint exhaustion, local-window composition, classifier determinacy, and no-confusion, and the ledger keeps every knot boundary, polynomial endpoint, local face, continuation row, and provenance row visible. The name-certificate obligations at this seed surface are carried by the accepted packet for inhabitation, by the inherited knot and polynomial classifiers plus finite bundle induction for reflexive, symmetric, and transitive comparison, and by the transport and exhaustion rows for closure under classified Reidemeister and polynomial endpoint movement. A history h lies in the signature gap of a $\mathsf{JonesPolynomial}^{\uparrow}$ token p when the source-domain accepts its skein packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, p names the same local skein faces, four knot rows, polynomial endpoint, and finite ledger. The chapter registers this finite skein-ledger construction under the name $\mathsf{JonesPolynomial}^{\uparrow}$; it does not introduce a full Jones invariant, diagram quotient, Reidemeister-complete standard model, or bridgeChecked verification.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{JonesPolynomial}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The obligation scope is the finite skein ledger over BHist, Cont, hsame, Pkg, $\mathsf{NameCert}_{\mathsf{Knot}\uparrow}$, $\mathsf{NameCert}_{\mathsf{Poly}\uparrow}$, and $\mathsf{NameCert}_{\mathsf{S}^1\uparrow}$ displayed by the carrier, classifier, transport, exhaustion, determinacy, and no-confusion blocks in this chapter.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{JonesPolynomial}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.JonesPolynomialUp.JonesSkeinLedgerPacket\_namecert\_obligation\_surface`

Bridge status: none

Not claimed: This chapter does not claim a full Jones invariant, a quotient of diagrams, Reidemeister-complete standard model, or bridgeChecked verification.

Upgrade path: No further paper-axis upgrade is pending; bridgeChecked remains a formal-axis matter.

Chapter 256

A Concrete Naming Certificate for $\mathsf{ThreeManifold}^{\uparrow}$

The 3-manifold interface $\mathsf{ThreeManifold}^{\uparrow}$ packages a closed orientable manifold of dimension three together with the JSJ and geometric decompositions licensed by Thurston-Perelman geometrisation. It depends on $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$ (chapter 96) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88).

256.1 Carrier definition

Definition 256.1 (ThreeManifold finite carrier)**.** *A* $\mathsf{ThreeManifold}^{\uparrow}$ *carrier is a finite* BHist *packet displaying a closed orientable three-dimensional* $\mathsf{Manifold}^{\uparrow}$ *row, a* $\mathsf{Topology}^{\uparrow}$ *source row, a decomposition ledger row for the visible JSJ and geometric pieces, componentwise* hsame *comparisons,* Cont *rows connecting the decomposition ledger to the source rows, and* Pkg *provenance for the manifold and topology certificates. The carrier exports no checked geometrisation bridge, no host smooth manifold, and no unlogged decomposition object.*

Theorem 256.2 (ThreeManifold carrier obligation)**.** *Every accepted* $\mathsf{ThreeManifold}^{\uparrow}$ *packet is generated by the finite* BHist *carrier of Definition 256.1: its manifold row, topology row, decomposition ledger,* hsame *classifier rows,* Cont *continuation rows, and* Pkg *provenance are all displayed, and the dependency rows from* $\mathsf{Manifold}^{\uparrow}$ *and* $\mathsf{Topology}^{\uparrow}$ *are the only source rows available to downstream consumers.*

Lean4 ✓ `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier obligation surface`

Proof. Project the carrier definition. The packet records the $\mathsf{Manifold}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ dependencies as explicit source rows and stores the decomposition data as a finite ledger attached to them.

The classifier rows are componentwise hsame comparisons over the displayed coordinates. The continuation rows tie those coordinates to the packet readback, and the package rows identify the two dependency certificates.

Since no other coordinate is present in the BHist packet, every accepted readback is confined to the displayed carrier rows. □

Theorem 256.3 (ThreeManifold topology source scope)**.** *The topology source of a* $\mathsf{ThreeManifold}^{\uparrow}$ *packet is exactly the displayed* $\mathsf{Topology}^{\uparrow}$ *row together with its* BHist *data,* hsame *transport,* Cont *ledger,* Pkg *provenance, and the paired* $\mathsf{Manifold}^{\uparrow}$ *dependency row. It cannot be replaced by a host topological space, an external atlas, or an unlogged equivalence relation.*

Lean4 ✓ `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier topology source scope`

Proof. Read the topology coordinate from the carrier. It is paired with the displayed manifold row and with the finite continuation ledger that carries the topology data into the decomposition readback.

Transport along the classifier uses only the named hsame rows. The provenance of the topology source is recorded by Pkg and is not inferred from an ambient topological model.

Thus the topology source scope is exhausted by the displayed Topology$^{\uparrow}$ and Manifold$^{\uparrow}$ dependency rows. □

256.2 The certificate

Theorem 256.4 (ThreeManifold JSJ ledger exactness)**.** *Every JSJ or geometric-decomposition entry visible in a* ThreeManifold$^{\uparrow}$ *packet is read from the finite* BHist *decomposition ledger, the* Manifold$^{\uparrow}$ *source row, the* Topology$^{\uparrow}$ *source row, componentwise* hsame *transport, the* Cont *continuation rows, and* Pkg *provenance. The ledger does not assert a checked geometrisation bridge and does not expose a host decomposition theorem.*

Lean4 ✓ `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier jsj ledger exactness`

Proof. Inspect a decomposition entry. Its inputs are the displayed manifold and topology rows, and its output is a finite ledger row inside the same packet.

Transport of that entry follows the componentwise classifier. The hsame rows move the manifold, topology, decomposition, continuation, and package coordinates together.

The readback therefore has no route to a host JSJ theorem or checked geometrisation bridge; it contains exactly the displayed ledger entry and its dependency provenance. □

Theorem 256.5 (ThreeManifold chart-transition ledger obligation)**.** *Every chart-transition row or piece-boundary row consumed by the visible JSJ/geometric decomposition ledger of a* ThreeManifold$^{\uparrow}$ *packet is read through the displayed* Manifold$^{\uparrow}$ *chart row, the* Topology$^{\uparrow}$ *open-set row, componentwise* hsame *transport, finite* Cont *routing, and* Pkg *provenance. The ledger cannot introduce a host atlas, unlogged triangulation, or external geometrisation object.*

Lean4 ✓ `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier chart transition ledger obligation`

Proof. Project the finite carrier. A chart-transition or piece-boundary row appears only as a coordinate of the displayed decomposition ledger, and the carrier places that ledger beside the Manifold$^{\uparrow}$ and Topology$^{\uparrow}$ source rows.

Route the transition row through those two displayed sources. The manifold row supplies the chart coordinate, the topology row supplies the open-set coordinate, and the finite Cont rows carry the resulting readback into the visible decomposition ledger.

Componentwise hsame transport compares only the displayed coordinates, while Pkg records the provenance of the two dependency certificates. Row exhaustion from Definition 256.6 then rules out any host atlas, unlogged triangulation, or external geometrisation coordinate. □

Theorem 256.6 (ThreeManifold certificate boundary)**.** *Every downstream consumer of* ThreeManifold$^{\uparrow}$ *reads only the displayed* BHist *carrier,* Manifold$^{\uparrow}$ *dependency row,* Topology$^{\uparrow}$ *dependency row, decomposition ledger,* hsame *classifier rows,* Cont *continuation rows, and* Pkg *provenance of Definition 256.1. The certificate boundary excludes unlogged smooth, topological, or geometrisation data.*

Lean4 ✓ `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier certificate boundary`

Proof. Begin with a downstream readback. The carrier obligation theorem confines the readback to the displayed finite packet rows.

Use the topology source theorem for the topology coordinate and the JSJ ledger theorem for the decomposition coordinate. Together they account for every dependency and ledger row that the consumer can inspect.

Because the packet contains no additional smooth, topological, or geometrisation coordinate, the downstream boundary is exactly the displayed BEDC surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{ThreeManifold}^{\uparrow}}$.

Constructive story: The three-manifold packet is a finite BHist carrier over displayed $\mathsf{Manifold}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, decomposition-ledger, classifier, continuation, and package rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ThreeManifold}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The scoped surface is the displayed $\mathsf{Manifold}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, BHist, hsame, Cont, Pkg, carrier, decomposition-ledger, classifier, continuation, and boundary rows of the three-manifold packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ThreeManifold}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ThreeManifoldUp.ThreeManifoldFiniteCarrier\_certificate\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not close checked geometrisation, host JSJ decomposition, smooth manifold semantics, or a standard bridge.

Upgrade path: Bridged closure requires a standard three-manifold bridge over the finite-carrier certificate boundary.

Chapter 257

A Concrete Naming Certificate for $\mathsf{Iwasawa}^{\uparrow}$

The Iwasawa-theory interface $\mathsf{Iwasawa}^{\uparrow}$ packages the projective limit of class groups of cyclotomic $\mathbb{Z}_p$-extensions of a number field together with the Iwasawa main conjecture relating it to a p-adic L-function. It depends on $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ (chapter 174) and $\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$ (chapter 170).

257.1 Carrier definition

Definition 257.1 (Iwasawa cyclotomic tower carrier)**.** *An* $\mathsf{Iwasawa}^{\uparrow}$ *cyclotomic tower carrier is a finite* BHist *packet whose rows are:*

1. *the cyclotomic layer rows read from* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$ *by Definition 174.29;*
2. *the ideal-class endpoint rows read from* $\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$ *by Definition 170.4;*
3. *transition rows between successive displayed levels, recorded as* Cont *ledgers and compared by* hsame*;*
4. *unary level indices identifying the finite window of tower levels;*
5. *one* Pkg *provenance row tying the cyclotomic source, ideal-class source, and transition ledger to the same carried packet.*

The carrier records only these finite BEDC rows. It does not contain a host projective limit, an analytic p-adic L-function, or an equality asserted outside the displayed BHist*,* hsame*,* Cont*, and* Pkg *surface.*

257.2 The certificate

Definition 257.2 (Iwasawa classgroup limit classifier)**.** *For two carriers of Definition 257.1, the* IwaCls *classifier holds when their unary level windows agree by* hsame*, each displayed level has matching* $\mathsf{IdealClass}^{\uparrow}$ *classifier rows, the cyclotomic source rows agree through the classifier exported by* $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$*, and the transition ledgers are compatible under* hsame *after levelwise transport. The agreement is levelwise and ledgerwise; it is not quotient equality of a host inverse limit.*

Theorem 257.3 (Iwasawa transition ledger stability)**.** *If two* $\mathsf{Iwasawa}^{\uparrow}$ *carriers are related by* IwaCls*, then* hsame *transport preserves every accepted transition ledger in Definition 257.1. The*

transported ledger is again accepted over the transported cyclotomic rows and the transported ideal-class rows, with the same unary level index window and Pkg *provenance scope.*

Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger cons transport stability`
Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger transition hsame transport`

Proof. Project the cyclotomic component of the classifier. By Definition 174.29, the downstream Iwasawa packet may read only the displayed source rows, primitive-root endpoint, factorization ledger, and provenance package from $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$.

Project the ideal-class component next. The scoped source certificate of Definition 170.4 transports carried fractional-ideal endpoints, principal-classifier witnesses, and quotient operation rows through the same BHist, hsame, and Pkg surface.

For each adjacent pair of displayed unary levels, compose these transported source projections with the carried Cont transition row. Since IwaCls requires transition-ledger compatibility under hsame, the transported transition row is accepted at the corresponding transported levels. The Pkg provenance row is unchanged except for the same componentwise transport, so no external tower object is introduced. □

Theorem 257.4 (Iwasawa source obligation surface)**.** *The carrier of Definition 257.1, the classifier of Definition 257.2, and the stability theorem Definition 257.3 form the source obligation surface for* $\mathsf{Iwasawa}^{\uparrow}$*. The surface consists exactly of cyclotomic source rows, ideal-class endpoint and classifier rows, unary level indices, transition* Cont *ledgers,* hsame *transport rows, and one* Pkg *provenance packet. It closes carrier formation, classifier agreement, transition stability, source exactness, and finite ledger readback for this packet, but it does not claim the Iwasawa main conjecture or analytic p-adic L-function equality.*

Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger source obligation surface`

Proof. Carrier formation is the packet definition itself: every accepted row is one of the cyclotomic, ideal-class, level-index, transition, or provenance rows listed in Definition 257.1.

Classifier agreement is supplied by Definition 257.2. It compares the same finite rows level by level and records transition compatibility as carried hsame data, so it never appeals to an ambient inverse-limit quotient.

Transition stability is exactly Definition 257.3. It shows that accepted transition ledgers remain accepted after componentwise carrier transport through the cyclotomic and ideal-class sources.

Exactness and ledger readback follow by the reverse projection. Any $\mathsf{Iwasawa}^{\uparrow}$ source row permitted by the surface must be one of the displayed packet rows or a row projected by the cited $\mathsf{Cyclotomic}^{\uparrow}$ and $\mathsf{IdealClass}^{\uparrow}$ source certificates. Repacking these rows gives the stated obligation surface and excludes analytic main-conjecture data from the certificate. □

Theorem 257.5 (Iwasawa window classifier obligations)**.** *The classifier* IwaCls *transports exactly the finite-window rows of Definition 257.1: unary level windows, cyclotomic source rows, ideal-class endpoint and classifier rows, transition* Cont *ledgers,* hsame *comparisons, and the shared* Pkg *provenance packet. No classifier obligation refers to a host projective limit or analytic p-adic L-function row.*

Proof. Project IwaCls through Definition 257.2. The classifier compares unary level windows by hsame, compares cyclotomic source rows through $\mathsf{NameCert}_{\mathsf{Cyclotomic}^{\uparrow}}$, compares ideal-class rows through $\mathsf{NameCert}_{\mathsf{IdealClass}^{\uparrow}}$, and checks transition-ledger compatibility.

Apply Definition 257.3 to the transition rows. It preserves the finite Cont ledger entries over the transported cyclotomic and ideal-class endpoints with the same provenance packet.

Thus every classifier obligation is one of the displayed finite-window rows, and the packet has no slot for host inverse-limit or analytic equality data. □

Theorem 257.6 (Iwasawa finite level exactness)**.** *Every accepted finite* Iwasawa$^{\uparrow}$ *tower window reads exactly the finite level rows displayed in Definition 257.1. The accepted window exposes cyclotomic rows, ideal-class rows, unary indices, adjacent-level transition ledgers,* hsame *transports, and one provenance packet, but it does not expose a host projective limit.*

Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaFiniteLevel exactness`

Proof. Unpack an accepted carrier. Its rows are precisely the five carrier entries: cyclotomic source rows, ideal-class endpoint rows, transition ledgers, unary level indices, and provenance.

Use Definition 257.4 to read exactness in the reverse direction. Any accepted source row must be projected from those finite entries or from the cited cyclotomic and ideal-class source certificates.

Therefore finite-level exactness is bounded by the displayed window itself. No projective-limit quotient is reconstructed from the accepted finite carrier. □

Theorem 257.7 (Iwasawa ledger readback obligations)**.** *Downstream number-theory consumers of the finite* Iwasawa$^{\uparrow}$ *window may read only the cyclotomic source, ideal-class source, transition ledgers, unary indices,* hsame *transports, and provenance packet named by Definition 257.4. These are the complete ledger readback obligations for the finite source surface.*

Proof. Project the consumer read through Definition 257.4. The theorem lists the finite carrier, classifier, stability, exactness, and ledger-readback rows available to the source surface.

The cyclotomic part is bounded by Definition 174.29, and the ideal-class part is bounded by Definition 170.4. The transition part is bounded by Definition 257.3.

Combining these projections leaves exactly the displayed finite-window ledger rows. Analytic main-conjecture rows, host projective limits, and p-adic L-function equalities are outside the readback surface. □

Theorem 257.8 (Iwasawa transition ledger exactness)**.** *For the carrier of Definition 257.1, the accepted transition rows are exactly the adjacent-level* Cont *ledger entries between the displayed cyclotomic rows and the displayed ideal-class rows. Soundness means that every accepted transition row has matching unary endpoints, compatible* hsame *transport, and the* Pkg *provenance tying it to the same cyclotomic and ideal-class packet. Completeness means that every adjacent pair of displayed levels carrying those cyclotomic rows, ideal-class endpoint rows,* hsame *transports, and* Pkg *provenance determines an accepted transition ledger row and no additional transition source.*

Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger finite window exactness`

Proof. For soundness, start with an accepted transition row. By Definition 257.1, it is carried as a Cont ledger between successive displayed unary levels and is packaged with the same cyclotomic source, ideal-class source, and provenance row.

Apply Definition 257.3. The transported ledger remains accepted over the transported cyclotomic and ideal-class rows, and the same Pkg provenance scope is preserved.

For completeness, begin with adjacent displayed levels equipped with the cyclotomic source rows of Definition 174.29, the ideal-class rows of Definition 170.4, compatible hsame transport, and one provenance packet. Repack these rows using Definition 257.4; the only transition slot in

that surface is the adjacent-level Cont ledger. Hence the resulting row is accepted, and the source inventory leaves no second transition kind. □

Theorem 257.9 (Iwasawa downstream consumer boundary)**.** *Every downstream consumer of the finite* $\mathsf{Iwasawa}^{\uparrow}$ *tower window may read only the cyclotomic source rows, ideal-class endpoint and classifier rows, unary level indices, accepted adjacent-level transition ledgers,* hsame *transport rows, and* Pkg *provenance of Definition 257.4. No downstream consumer row is a projective-limit quotient, an analytic main-conjecture row, or a direct p-adic L-function equality row.*

Proof. First project any downstream read through Definition 257.4. The theorem lists exactly the finite carrier, classifier, stability, exactness, and ledger-readback rows that belong to the source surface.

The cyclotomic portion is bounded by Definition 174.29. It supplies only the displayed source rows, primitive-root endpoint, factorization ledger, and provenance package consumed by the tower packet.

The ideal-class portion is bounded by Definition 170.4. It supplies the endpoint and classifier rows needed at the displayed levels, again through the finite BHist, hsame, and Pkg surface.

Finally use Definition 257.8. Transition reads are exactly adjacent-level Cont ledger rows between the already displayed sources. Therefore the consumer boundary is exhausted by the listed finite rows and cannot contain projective-limit quotient data, analytic main-conjecture data, or p-adic L-function equality data. □

Theorem 257.10 (Iwasawa finite source inventory)**.** *Every accepted finite* $\mathsf{Iwasawa}^{\uparrow}$ *source packet contains only the visible* $\mathsf{Cyclotomic}^{\uparrow}$ *tower rows, the* $\mathsf{IdealClass}^{\uparrow}$ *endpoint and classifier rows, the finite* BHist *packet holding the unary level window, the* hsame *comparison rows between transported levels, the adjacent-level* Cont *transition ledger, the* Pkg *provenance row, and the displayed* $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$ *row. In particular, the inventory has no projective limit object, no analytic p-adic L-function row, and no main-conjecture equality row.*

Proof. Project the accepted source packet through Definition 257.4. The carrier, classifier, stability, exactness, and ledger clauses listed there are all finite rows over the displayed unary tower window.

The cyclotomic part is exactly the source boundary of Definition 174.29, and the ideal-class part is exactly the scoped source certificate of Definition 170.4. These two projections supply the named $\mathsf{Cyclotomic}^{\uparrow}$ and $\mathsf{IdealClass}^{\uparrow}$ rows, while the same BHist, hsame, Cont, Pkg, and NameCert rows account for the finite tower packet. Since no projected clause has a projective-limit or analytic slot, the inventory is exhausted by the displayed rows. □

Theorem 257.11 (Iwasawa classifier transport surface)**.** *Let two finite* $\mathsf{Iwasawa}^{\uparrow}$ *source packets be connected by displayed* hsame *transport over their cyclotomic tower rows, ideal-class endpoint rows, finite* BHist *windows, transition* Cont *ledgers, and* Pkg *provenance. Then the transported packet carries the same* $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$ *source inventory: the* $\mathsf{Cyclotomic}^{\uparrow}$ *rows move to the transported tower rows, the* $\mathsf{IdealClass}^{\uparrow}$ *classifier rows move to the transported ideal-class rows, and the adjacent transition row remains the displayed finite* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger provenance hsame transport`

Proof. Begin with the hsame transport rows supplied for the tower window. Apply Definition 257.3; it carries the accepted transition ledger across the transported cyclotomic and ideal-class rows while keeping the same Pkg provenance scope.

Now transport the two source faces separately. The cyclotomic face is stable by the source boundary in Definition 174.29, and the ideal-class face is stable by the classifier rows in Definition 170.4. Repacking these transported rows gives the same finite $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$ inventory, with no new source family introduced by transport. □

Theorem 257.12 (Iwasawa transition source coverage)**.** *Every accepted* $\mathsf{Iwasawa}^{\uparrow}$ *transition row projects to one of the finite source rows of Definition 257.10: either a* $\mathsf{Cyclotomic}^{\uparrow}$ *tower source row, an* $\mathsf{IdealClass}^{\uparrow}$ *endpoint or classifier row, a finite* BHist *window row, an* hsame *transport row, an adjacent-level* Cont *ledger row, a* Pkg *provenance row, or the displayed* $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$ *row. No accepted transition row projects to an external projective-limit, analytic, or quotient source.*

Proof. Take an accepted transition row and project it through Definition 257.8. The projection identifies the transition as an adjacent-level Cont ledger between displayed source rows, not as an ambient tower limit.

Perform the finite case split over the rows listed in Definition 257.10. Cyclotomic cases are read by Definition 174.29; ideal-class cases are read by Definition 170.4; window, transport, provenance, and certificate cases are the corresponding BHist, hsame, Pkg, and NameCert projections of the same packet.

The classifier transport theorem Definition 257.11 keeps these cases stable under displayed hsame movement. Hence every accepted transition row lands in the finite source inventory and no external source remains. □

Closure status for $\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$**.**

Constructive story: An Iwasawa tower window is assembled by taking the already certified cyclotomic rows, the already certified ideal-class endpoints, a finite unary list of levels, and adjacent Cont transition ledgers tying each displayed level to the next. The carrier admits exactly that finite packet, together with one Pkg provenance row binding the cyclotomic source, ideal-class source, level indices, and transition rows; a host projective limit, an analytic p-adic L-function, and any unshown equality are left outside the carrier. Two accepted windows count as the same only when their unary level windows are related by hsame, their cyclotomic and ideal-class rows classify through the dependency certificates, and every transition ledger is transported level by level, so the source specification is the same finite tower packet and the pattern specification is the displayed cyclotomic-endpoint/ideal-class/transition shape. The ledger keeps the raw rows visible as the visible tower window: levels, endpoints, transition continuations, classifier transports, and provenance are all retained rather than collapsed into an inverse-limit object. Once one such finite window is displayed, the five name-certificate obligations follow from the dependency classifiers and finite transport: the carrier is inhabited by the packet, the classifier is reflexive, symmetric, and transitive componentwise, and an accepted packet transported through the classifier remains a packet of the same finite shape. A history h lies in the signature gap of an $\mathsf{Iwasawa}^{\uparrow}$ token p when the source-domain accepts h as this finite tower window, the signature relation pairs it with an answer window and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h must expose exactly the cyclotomic source rows, ideal-class endpoints, unary level indices, adjacent transition ledgers, hsame transports, and provenance encoded by p. The chapter registers this finite-window construction under the name $\mathsf{Iwasawa}^{\uparrow}$; no Iwasawa main conjecture, projective-limit quotient, analytic p-adic L-function, standard bridge, or additional tower primitive is introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$, maturePackageClosed)

Scope closed: The finite tower public surface is bridged to the abstract $\mathsf{Iwasawa}^{\uparrow}$ schema through the finite tower source inventory, classifier transport surface, transition source coverage, cyclotomic source rows, ideal-class endpoint and classifier rows, unary level indices, transition Cont ledgers, hsame transports, Pkg provenance, and finite ledger exactness.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Iwasawa}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.IwasawaUp.IwasawaTransitionLedger\_finite\_window\_exactness`

Bridge status: none

Not claimed: The Iwasawa main conjecture, analytic p-adic L-functions, projective-limit quotient, and standard bridge are not closed by this chapter.

Upgrade path: The paper theory axis is complete for this finite-window surface; standard bridge verification remains a separate formal-axis matter.

Chapter 258

A Concrete Naming Certificate for $\mathsf{ClassField}^{\uparrow}$

The class-field-theory interface $\mathsf{ClassField}^{\uparrow}$ packages the maximal abelian extension of a number field together with the Artin map sending an idele class to a Frobenius automorphism. It depends on $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168) and $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$ (chapter 101).

258.1 Carrier definition

258.2 The certificate

Theorem 258.1 (ClassField carrier and classifier obligations)**.** *A* $\mathsf{ClassField}^{\uparrow}$ *certificate must provide a* BHist *carrier packaging a* $\mathsf{NumField}^{\uparrow}$ *base source, an* $\mathsf{Adele}^{\uparrow}$ *idele-class source, an abelian-extension history row, and a classifier stable under the source* NameCert *classifiers and* hsame*.*

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldSourceCarrier semantic name certificate`

Proof. Unpack the roadmap ten-field template for $\mathsf{ClassField}^{\uparrow}$. The visible carrier row names the base source, the idele-class source, and the abelian-extension history row.

Then read the $\mathsf{NumField}^{\uparrow}$ and $\mathsf{Adele}^{\uparrow}$ certificates as the two named dependency certificates. Their classifiers supply source replacement, while the $\mathsf{ClassField}^{\uparrow}$ row records the remaining classifier as an obligation rather than as a closed field. □

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldCarrierClassifier obligation`

Theorem 258.2 (ClassField Artin and Frobenius stability obligations)**.** *The Artin-map relation and Frobenius endpoint rows of a* $\mathsf{ClassField}^{\uparrow}$ *certificate must transport along the* $\mathsf{Adele}^{\uparrow}$ *classifier, the* $\mathsf{NumField}^{\uparrow}$ *classifier, and* BHist hsame*, and they must be compatible with the chosen extension classifier.*

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldArtinFrobeniusRows stability`

Proof. Carrier transport in the dependency NameCert objects supplies source replacement for the $\mathsf{NumField}^{\uparrow}$ and $\mathsf{Adele}^{\uparrow}$ rows. The BHist comparison supplies the remaining history replacement.

The Artin relation and the Frobenius endpoints are then listed as stability obligations for the class-field classifier. Compatibility with the extension classifier is part of that obligation surface, not a reciprocity theorem. □

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldArtinFrobenius stability obligation`

Theorem 258.3 (ClassField ledger and exactness obligations)**.** *The* $\mathsf{ClassField}^{\uparrow}$ *ledger records the hidden idele representative, the local-prime and Frobenius representative, and the extension presentation. Exactness consists of coverage, soundness, and completeness for the Artin-Frobenius classifier, without claiming reciprocity.*

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldArtinFrobeniusRows ledger exactness`
Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldLedgerExactnessRows transport`

Proof. Separate visible classifier data from hidden representative data. The visible side contains the classifier row and the Artin-Frobenius comparison; the hidden side records the idele representative, local-prime representative, Frobenius representative, and extension presentation.

Identify the three ExactGlobalize-style rows that must be supplied: coverage of the classifier, soundness of accepted Artin-Frobenius rows, and completeness for the visible rows that the classifier is meant to cover. These rows state the obligation surface and do not assert reciprocity. □

Theorem 258.4 (ClassField scoped carrier classifier)**.** *The carrier and classifier obligations of* $\mathsf{ClassField}^{\uparrow}$ *are scoped exactly over* BHist *rows for the number-field source, adele source, abelian-extension carrier, classifier, and ledger, the* $\mathsf{UnaryHistory}$ *witnesses on the source rows,* Cont *composition from the* $\mathsf{NumField}^{\uparrow}$ *row through the* $\mathsf{Adele}^{\uparrow}$ *row to the extension row,* hsame *transport from the classifier row to the extension row, and the two dependency certificates* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldSourceCarrier scoped carrier classifier`

Proof. Unpack Definition 258.1. Its source side names exactly two dependency certificates: $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ for the base number-field row and $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$ for the idele-class row. The class-field carrier is therefore not a free ambient object; it is a BHist package whose visible projections are supplied by those two certificates.

The remaining carrier row is the abelian-extension history. It is still a BHist row, so its comparison data is not an external equality relation. The classifier obligation is the restricted hsame transport that keeps the base row, idele-class row, and extension row inside the same carried package.

Thus every carrier/classifier witness used by the certificate is named by $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$, BHist, or hsame. No extra classifier or host-level carrier is part of the scoped surface. □

Theorem 258.5 (ClassField scoped Artin-Frobenius stability)**.** *The Artin-map and Frobenius stability obligations of* $\mathsf{ClassField}^{\uparrow}$ *are scoped exactly over the predicate* $\mathsf{ClassFieldArtinFrobeniusRows}$ *on base, idele, extension, Artin, and Frobenius* BHist *rows, the* Cont *transports from idele to Artin to Frobenius and from base to Frobenius to extension,* hsame *transport of idele, Artin, Frobenius, and extension rows, and the dependency classifiers supplied by* $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$.

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldArtinFrobenius scope`

Proof. Begin with Definition 258.2. The Artin relation reads its source through the $\mathsf{Adele}^{\uparrow}$ classifier and its base through the $\mathsf{NumField}^{\uparrow}$ classifier. Transport along either source is therefore the transport field already exposed by the corresponding dependency $\mathsf{NameCert}$.

The Frobenius endpoint and the abelian-extension presentation are carried histories. Their replacement step is not a separate Galois-theoretic principle; it is the hsame transport on the named BHist endpoint rows.

After these transports are named, the stability row has a fixed dependency profile: $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$ for idele-class replacement, $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ for base-field replacement, and hsame for endpoint and extension-history replacement. Compatibility with the extension classifier is precisely this repackaging of transported rows. □

Theorem 258.6 (ClassField scoped ledger exactness)**.** *The ledger exactness obligations of* $\mathsf{ClassField}^{\uparrow}$ *are scoped exactly over hidden idele representatives, local-prime representatives, Frobenius representatives, extension-presentation representatives, and the* ExactGlobalizeBase *coverage, soundness, and completeness rows for the visible Artin-Frobenius classifier.*

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassFieldScopedLedger exactness`

Proof. Unpack Definition 258.3. The visible side of the ledger is the Artin-Frobenius classifier over the scoped source rows. The hidden side consists of the idele representative, local-prime representative, Frobenius representative, and extension presentation.

Coverage says that each accepted visible Artin-Frobenius row has one such hidden witness tuple. Soundness says that any row produced from the hidden tuple is accepted by the visible classifier. Completeness says that the accepted visible rows are exhausted by those witness tuples.

These are exactly the three ExactGlobalize rows used here: coverage, soundness, and completeness. They bind the ledger to the named source certificates and BHist representatives without asserting reciprocity or maximal abelian exactness beyond the displayed classifier surface. □

Theorem 258.7 (ClassField reciprocity boundary)**.** *Coverage, soundness, and completeness for the Artin-Frobenius classifier do not assert class-field reciprocity, uniqueness of the maximal abelian extension, or a standard bridge for* $\mathsf{ClassField}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassField reciprocity boundary`

Proof. Read the ledger exactness statement in Definition 258.3 as an ExactGlobalize-style certificate. It names the visible rows covered by the classifier and the hidden representatives used to witness those rows.

Coverage, soundness, and completeness only relate accepted classifier rows to the recorded representatives. They do not identify the classifier with the classical reciprocity map, prove uniqueness of the maximal abelian extension, or supply the bridge object required for a standard bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$**.**

Constructive story: A class field is carried by a source packet whose visible rows are a $\mathsf{NumField}^{\uparrow}$ base, an $\mathsf{Adele}^{\uparrow}$ idele-class source, an abelian-extension history, a chosen classifier row, and a ledger row, all connected by unary history evidence and Cont composition. The carrier accepts exactly those histories in which the base and idele dependency certificates supply the first two rows and the extension endpoint is the continuation result, while reciprocity maps, maximal abelian extension exactness, and standard bridges are not fields of the packet. Its classifier is hsame on the carried extension endpoint together with the dependency classifiers for the number-field and adele rows, so Artin and Frobenius data transport only by the named source classifiers and endpoint history comparisons. The source specification is the NumField-plus-Adele carrier surface, the pattern specification is the Artin-Frobenius row with idele, local-prime, Frobenius, and extension-presentation representatives, and the ledger separates visible classifier rows from those hidden representatives through coverage, soundness, and completeness obligations. The five naming-certificate obligations are supplied by the semantic source carrier: the displayed extension endpoint inhabits the carrier, hsame gives reflexivity, symmetry, and transitivity, and result transport along hsame rebuilds the same source carrier at a classified endpoint. A history h lies in the signature GAP of a $\mathsf{ClassField}^{\uparrow}$ token p when the source accepts h, the signature relation pairs it with an answer extension row and evidence ledger, and token introduction names that answer as p; here that means the base, idele, extension, Artin,

Frobenius, classifier, hidden representatives, and ExactGlobalize rows all line up inside the displayed packet. The chapter registers this construction as $\mathsf{ClassField}^{\uparrow}$ without closing Artin-map laws, class-field reciprocity, maximal abelian extension uniqueness, or a standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper scope binds the public $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$ interface, carrier-classifier row, Artin-Frobenius stability row, ledger exactness rows, and reciprocity boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ClassFieldUp.ClassFieldSourceCarrier\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not close the Artin map laws, maximal abelian extension exactness, reciprocity, or a standard bridge.

Upgrade path: The paper theory axis is mature; bridgeChecked remains a separate formal-axis status for a standard bridge theorem.

Theorem 258.8 (ClassFieldUp public NameCert interface)**.** *The carrier-classifier row of Definition 258.1, the Artin-Frobenius stability row of Definition 258.2, and the ledger exactness row of Definition 258.3 assemble the public* $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$ *interface over the source certificates* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Adele}^{\uparrow}}$*. The exported surface consists exactly of the base number-field source row, the idele-class source row, the abelian-extension history row, the extension classifier, the Artin-map relation row, the Frobenius endpoint rows, the hidden idele representative, the local-prime representative, the Frobenius representative, the extension-presentation representative, and the ExactGlobalize coverage, soundness, and completeness rows for the visible Artin-Frobenius classifier. It exports no class-field reciprocity theorem, no uniqueness theorem for the maximal abelian extension, and no standard bridge.*

Proof. Apply Definition 258.1. This fixes the public source side of the certificate: a $\mathsf{NumField}^{\uparrow}$ base row, an $\mathsf{Adele}^{\uparrow}$ idele-class row, an abelian-extension history row, and the classifier comparing extension presentations after replacement through the two dependency certificates and hsame. Therefore the carrier and classifier slots of $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$ are not ambient host objects; they are the displayed BHist rows together with the two named source certificates.

Apply Definition 258.2. The Artin relation and Frobenius endpoints are the only operation-like rows added to that carrier surface. Their stability is exactly the transport through the $\mathsf{Adele}^{\uparrow}$ classifier on the idele side, the $\mathsf{NumField}^{\uparrow}$ classifier on the base side, and hsame on the extension, Artin, and Frobenius history rows. Thus the stability slot of the public certificate is filled by those displayed Artin-Frobenius rows, with compatibility to the chosen extension classifier and no additional reciprocity law.

Apply Definition 258.3. Coverage projects every accepted public Artin-Frobenius classifier row to a hidden tuple consisting of an idele representative, a local-prime representative, a Frobenius representative, and an extension-presentation representative. Soundness repacks any such displayed tuple as an accepted public row. Completeness says that the accepted public rows are exhausted by those tuples. Hence the ledger and exactness slots of $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$ are precisely the listed ExactGlobalize rows.

The forward projection from any public $\mathsf{NameCert}_{\mathsf{ClassField}^{\uparrow}}$ read therefore lands in one of the carrier, classifier, stability, representative, or ExactGlobalize rows just named. Conversely, a packet containing exactly those rows repacks through the three cited obligations into the same public interface. Since none of the three obligations introduces a classifier for reciprocity, maximal-abelian uniqueness, or a standard bridge, those objects are outside the exported surface. □

Lean4 ✓ `BEDC.Derived.ClassFieldUp.ClassField public namecert interface`

Chapter 259

A Concrete Naming Certificate for $\mathsf{Regulator}^{\uparrow}$

The regulator interface $\mathsf{Regulator}^{\uparrow}$ packages the determinant of logarithms of fundamental units (for number fields) and its Beilinson generalisation to higher K-theory. It depends on $\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$ (chapter 171) and $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168).

259.1 Carrier definition

Definition 259.1 (Regulator root input packet)**.** *A* $\mathsf{Regulator}^{\uparrow}$ *root input packet is a displayed* BHist *tuple*

$$\mathcal{R} = (\mathcal{D}, \mathcal{N}, u, \iota, \nu, \beta, \delta, \rho)$$

whose source rows are the dependency certificates $\mathcal{D} : \mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$ *and* $\mathcal{N} : \mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$*. The unit-facing rows* u *and* ι *are the visible unit and inverse/unit-product rows read from* $\mathcal{D}$*; the unary row* ν *is the Dirichlet-unit rank witness; the row* β *is the finite basis and logarithmic ledger supplied by* $\mathcal{D}$*; the row* δ *is the displayed determinant-layout ledger linking* ν*,* β*, and the* $\mathsf{NumField}^{\uparrow}$ *source rows; and* ρ *is the* Pkg *provenance tying the two dependency certificates to the regulator packet.*

The packet also carries finite Cont *readbacks from* $\mathcal{D}$ *to the unit, inverse, rank, and logarithmic ledger rows, from* $\mathcal{N}$ *to the number-field carrier, embedding, singleton-basis, and ledger rows, and from* ρ *to every exported dependency slot. It contains no analytic regulator value, no host logarithm map, no determinant evaluation in a host field, and no standard bridge row.*

Lean4 ✓ `BEDC.Derived.RegulatorUp.RegulatorTasteGate single carrier alignment`

Theorem 259.2 (Regulator DirichletUnit input boundary)**.** *Every accepted packet of Definition 259.1 projects to exactly the* $\mathsf{DirichletUnit}^{\uparrow}$ *rows needed by a root regulator source: visible unit rows, inverse/unit-product rows, the unary rank witness, the finite basis/logarithmic ledger row, finite* Cont *readbacks, and the* Pkg *provenance attached to* $\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$*. It does not project a determinant, analytic regulator value, host logarithm equality, or standard bridge from the* $\mathsf{DirichletUnit}^{\uparrow}$ *dependency.*

Lean4 ✓ `BEDC.Derived.RegulatorUp.RegulatorRootInputPacket dirichletunit input boundary`

Proof. Project the source row $\mathcal{D}$ from Definition 259.1. The available unit, inverse, rank, and logarithmic rows are precisely the rows named by Definition 171.7 and Definition 171.16.

The packet adds no second Dirichlet-unit source. Its Cont readbacks point from $\mathcal{D}$ to u, ι, ν, and β, and its provenance row ρ records those projections as the same package boundary.

Inspecting the packet fields gives the exclusion clause. Determinant layout is recorded only as the separate regulator-side row δ, while analytic regulator values, host logarithm equality, and bridge rows are not fields of $\mathcal{R}$. □

Theorem 259.3 (Regulator NumField carrier boundary)**.** *Every accepted packet of Definition 259.1 projects to the* $\mathsf{NumField}^{\uparrow}$ *source rows through* $\mathcal{N}$*: the RatUp history carrier, the RatUp endpoint classifier, the identity finite-extension row, the singleton-basis row, the scalar-action row, exact endpoint classification, and the inherited ledger provenance of the public* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *surface. No ambient host number field, quotient of embeddings, or analytic place map is exported by the regulator root packet.*

```
Lean4 ✓  BEDC.Derived.RegulatorUp.RegulatorRootInputPacket numfield finite basis boundary
```

Proof. Project the source row $\mathcal{N}$ from the regulator packet. It is a $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ dependency row, so its public carrier and classifier surface is read through Definition 168.27.

The exactness and ledger clauses are the rows isolated by Definition 168.31. They give the identity finite-extension row, singleton basis, scalar action, exact endpoint classification, and ledger provenance available to a downstream packet.

Repack these projections with the Cont readbacks and Pkg provenance of Definition 259.1. Since no host number-field carrier, embedding quotient, or analytic place map is a component of $\mathcal{R}$, none is exported at the root boundary. □

Theorem 259.4 (Regulator ledger exactness)**.** *The determinant and logarithm data visible in a Definition 259.1 are finite displayed ledger rows: the Dirichlet-unit logarithmic row* β*, the unary rank row* ν*, the number-field source ledger read from* $\mathcal{N}$*, and the determinant-layout row* δ*. These rows specify the shape of the regulator input matrix; they do not assert an analytic regulator value or equality of host logarithms.*

```
Lean4 ✓  BEDC.Derived.RegulatorUp.RegulatorLedgerSpine rows unary
Lean4 ✓  BEDC.Derived.RegulatorUp.RegulatorRootInputPacket ledger exactness
```

Proof. First project the Dirichlet-unit side by Definition 259.2. This gives ν and β as finite BHist ledger rows, read through Cont and package provenance.

Next project the number-field side by Definition 259.3. The source rows available to the regulator are the displayed carrier, classifier, finite-extension, singleton-basis, exactness, and ledger rows of $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$.

The remaining determinant-facing row is δ. By the packet definition it records only a finite layout over ν, β, and the source ledger of $\mathcal{N}$. Repacking these three sources exhausts the regulator ledger, and there is no field from which an analytic regulator value or host logarithm equality could be read. □

259.2 The certificate

Theorem 259.5 (Regulator root NameCert threshold)**.** *The root* $\mathsf{NameCert}_{\mathsf{Regulator}^{\uparrow}}$ *threshold is assembled from the packet of Definition 259.1: the* $\mathsf{NameCert}_{\mathsf{DirichletUnit}^{\uparrow}}$ *source rows, the* $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ *source rows, the visible unit and inverse rows, the unary rank witness, the finite logarithmic ledger, the determinant-layout ledger, the finite* Cont *readbacks, the* hsame *transport rows on displayed*

packet entries, and the Pkg *provenance tying the two dependency certificates to the packet. The threshold exports no analytic regulator value, no host determinant evaluation, no host logarithm equality, and no standard bridge.*

Lean4 ✓ `BEDC.Derived.RegulatorUp.RegulatorRootInputPacket root namecert threshold`

Proof. Build the carrier source from Definition 259.1. Its entries provide the two dependency certificates, the Dirichlet-unit visible rows, the number-field source rows, the determinant-layout row, and the finite readback and provenance rows.

Use Definition 259.2 for the exact Dirichlet-unit projections and Definition 259.3 for the exact number-field projections. These two boundaries bind every dependency row to BHist, Cont, hsame, NameCert, and Pkg data.

Finally use Definition 259.4. It says that the logarithm and determinant-facing entries are finite displayed ledger rows rather than analytic values. Repacking the carrier, dependency, classifier, ledger, readback, and provenance rows gives the stated root threshold, with no additional host determinant, logarithm, or bridge row to export. □

Theorem 259.6 (Regulator dependency-ledger factorization)**.** *Every public read of the root* $\mathsf{NameCert}_{\mathsf{Regulator}^{\uparrow}}$ *threshold factors through exactly three rows: the* $\mathsf{DirichletUnit}^{\uparrow}$ *projection of Definition 259.2, the* $\mathsf{NumField}^{\uparrow}$ *projection of Definition 259.3, and the finite determinant/logarithm layout ledger of Definition 259.4. The factorization exports the finite* BHist*,* Cont*,* hsame*,* NameCert*, and* Pkg *rows of those three sources, and it excludes analytic regulator values, host determinant evaluation, host logarithm equality, and standard bridge rows.*

Lean4 ✓ `BEDC.Derived.RegulatorUp.RegulatorRootInputPacket dependency ledger factorization`

Proof. Project the packet fields from Definition 259.1. The root threshold reads the two dependency certificates, the visible unit-facing entries, the number-field source entries, the determinant-layout entry, the finite readbacks, and the package provenance.

Apply Definition 259.2 and Definition 259.3. These two boundary theorems identify the dependency-facing rows that can be read from the packet: the $\mathsf{DirichletUnit}^{\uparrow}$ unit, inverse, rank, logarithmic, readback, and provenance rows, and the $\mathsf{NumField}^{\uparrow}$ carrier, classifier, finite-extension, singleton-basis, scalar-action, exactness, ledger, and provenance rows.

Now apply Definition 259.4. It isolates the remaining determinant/logarithm information as the finite displayed layout over the Dirichlet-unit rank and logarithmic rows and the number-field source ledger.

Repack the three projected sources as the public threshold surface. Since Definition 259.1 has no field for an analytic regulator value, host determinant evaluation, host logarithm equality, or standard bridge, no public read of $\mathsf{NameCert}_{\mathsf{Regulator}^{\uparrow}}$ can factor through such a row. □

Closure status for $\mathsf{NameCert}_{\mathsf{Regulator}^{\uparrow}}$**.**

Constructive story: A regulator root packet is built by placing a certified $\mathsf{DirichletUnit}^{\uparrow}$ source beside a certified $\mathsf{NumField}^{\uparrow}$ source, then adding the visible unit and inverse rows, the unary rank witness, the finite logarithmic-basis row, and a determinant-layout row connected by finite Cont readbacks. The carrier accepts only packets whose unit-facing rows come from the Dirichlet-unit certificate, whose number-field rows come from the NumField certificate, and whose determinant-facing row is a displayed layout ledger; analytic regulator values, host logarithm maps, determinant evaluation, Beilinson data, and bridge rows have no slot in the packet. Two accepted packets are classified together only by the inherited dependency classifiers and hsame transport on the displayed rank, basis, layout, readback, and provenance rows, so the source specification covers these root inputs and the pattern specification is the finite determinant/logarithm layout assembled over them. The ledger keeps the raw dependency rows and visible regulator rows aligned: a consumer can see the Dirichlet-unit projection, the NumField projection, the rank, the logarithmic ledger, the determinant-layout

ledger, the readbacks, and the Pkg provenance, but not a computed analytic number. Given such a packet, the five name-certificate obligations close on the displayed data: the packet witnesses nonemptiness, the component classifiers are reflexive, symmetric, and transitive, and transport through them preserves the same finite root-input shape. A history h lies in the signature gap of a Regulator$^{\uparrow}$ token p when the source-domain accepts h as this root packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, the dependency rows, rank, logarithmic basis, determinant layout, continuation readbacks, and provenance in h must match the packet encoded by p. The chapter registers this finite determinant-ledger construction under the name Regulator$^{\uparrow}$; it introduces no host regulator value, logarithm equality, determinant computation, standard bridge, or independent analytic carrier.

Theory closure: TheoryGate(NameCert$_{\text{Regulator}^{\uparrow}}$, maturePackageClosed)

Scope closed: The paper bridge is the public root NameCert threshold together with the dependency-ledger factorization surface over the DirichletUnitUp input, NumField carrier boundary, determinant/logarithm ledger, finite Cont readbacks, hsame transport, and Pkg provenance.

Formal verification: FormalStatus(NameCert$_{\text{Regulator}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RegulatorUp.RegulatorRootInputPacket\_root\_namecert\_threshold`

Bridge status: paperBridge

Not claimed: It does not close analytic regulator values, determinant evaluation, host logarithms, Beilinson regulator data, or standard bridges.

Upgrade path: No further paper theory-axis upgrade is recorded for this chapter; bridge verification remains a separate verification-axis obligation.

Definition 259.7 (Regulator rank-zero displayed layout)**.** *Let*

$$\mathcal{R} = (\mathcal{D}, \mathcal{N}, u, \iota, \nu, \beta, \delta, \rho)$$

be a Regulator$^{\uparrow}$ *root input packet in the sense of Definition 259.1. The packet is rank-zero displayed when the unary rank witness is the empty unary row,*

$$\nu\mathsf{hsamee},$$

and the determinant-layout row δ is read only as the finite displayed layout indexed by positions licensed by ν, the Dirichlet-unit ledger β, and the public NumField$^{\uparrow}$ *source ledger of $\mathcal{N}$.*

Theorem 259.8 (Regulator rank-zero layout degeneracy)**.** *Let*

$$\mathcal{R} = (\mathcal{D}, \mathcal{N}, u, \iota, \nu, \beta, \delta, \rho)$$

be an accepted Regulator$^{\uparrow}$ *root input packet. If $\mathcal{R}$ is rank-zero displayed in the sense of Definition 259.7, then the determinant-layout ledger δ is the empty finite layout over the* DirichletUnit$^{\uparrow}$ *and* NumField$^{\uparrow}$ *projections. Consequently the rank-zero packet exports no analytic regulator value, no host determinant evaluation, and no host logarithm equality.*

Lean4 ✓ `BEDC.Derived.RegulatorUp.RegulatorRootInputPacket rank zero layout degeneracy`

Proof. Project the accepted packet through Definition 259.1. Its determinant-facing entries are only the unary rank witness ν, the finite Dirichlet-unit basis and logarithmic ledger β, the NumField$^{\uparrow}$ source ledger read from $\mathcal{N}$, and the displayed determinant-layout ledger δ linking those rows.

Apply Definition 259.2. The DirichletUnit$^{\uparrow}$ side available to the regulator consists of visible unit rows, inverse and unit-product rows, the unary rank witness, the finite basis/logarithmic ledger, finite Cont readbacks, and package provenance. In particular, the Dirichlet-unit dependency contributes no determinant row, no analytic regulator value, and no host logarithm equality.

Apply Definition 259.3 to the source $\mathcal{N}$. The NumField$^{\uparrow}$ side contributes the RatUp reflexive carrier, classifier, identity finite-extension row, singleton-basis row, scalar-action row, exactness

row, and ledger provenance. It contributes no ambient host number field, quotient of embeddings, analytic place map, determinant evaluation, or logarithm equality.

It remains to identify the determinant-layout row under the rank-zero hypothesis. By Definition 259.7, the rank row satisfies $\nu\mathsf{hsamee}$, and δ is indexed only by positions licensed by ν together with the displayed $\mathsf{DirichletUnit}^{\uparrow}$ ledger β and the displayed $\mathsf{NumField}^{\uparrow}$ source ledger. The empty unary row has no positive basis position to license. Hence there is no row at which a logarithmic column, determinant minor, or host evaluation entry can be placed. The only finite determinant-layout compatible with the displayed index set is therefore the empty layout over the two dependency projections.

Finally use Definition 259.4. It says that all regulator determinant and logarithm data visible at the packet boundary are finite displayed ledger rows shaping the input matrix, not analytic values. Since the rank-zero layout is empty and the packet definition contains no field for an analytic regulator value, host determinant evaluation, host logarithm equality, or bridge row, none of those rows can be exported from $\mathcal{R}$. □

Chapter 260

A Concrete Naming Certificate for $\mathsf{Stack}^{\uparrow}$

The algebraic-stack interface $\mathsf{Stack}^{\uparrow}$ packages a sheaf of groupoids on the étale site of schemes satisfying descent and representability axioms (Artin / Deligne-Mumford). It depends on $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ (chapter 151) and $\mathsf{NameCert}_{\mathsf{Scheme}^{\uparrow}}$ (chapter 153).

260.1 Carrier definition

Theorem 260.1 (Stack BHist carrier obligation)**.** *A* $\mathsf{Stack}^{\uparrow}$ *carrier is a finite* BHist *packet containing a displayed* $\mathsf{Scheme}^{\uparrow}$ *site row, a displayed* $\mathsf{Sheaf}^{\uparrow}$ *groupoid-valued presheaf row over that site,* hsame *transport rows for object and arrow comparisons,* Cont *restriction routes for cover refinement, and* Pkg *provenance for the consumed dependency certificates. It contains no host stack object, no host quotient stack, and no external algebraic-space equality.*

Lean4 ✓ `BEDC.Derived.StackUp.StackBHistCarrier obligation surface`

Proof. Read the site coordinate through the $\mathsf{Scheme}^{\uparrow}$ certificate of chapter 153. The site row is a visible BEDC ledger row built from scheme carrier and cover data, so it is already a BHist-scoped input rather than a host site primitive.

Read the groupoid-valued presheaf coordinate through the locality and gluing surface of chapter 151. Its object rows, arrow rows, restriction rows, and classifier comparisons are the rows transported by hsame and routed by Cont over the displayed scheme site.

The remaining coordinates are provenance and transport rows: Pkg records which dependency packets are consumed, while hsame and Cont record replacement and restriction behavior. Since every coordinate has been listed in this finite packet, there is no carrier slot for a host stack object, a quotient stack, or external algebraic-space equality. □

Theorem 260.2 (Stack descent obligation)**.** *For a* $\mathsf{Stack}^{\uparrow}$ *carrier packet, accepted cover-compatible local object rows and arrow rows glue through the* $\mathsf{Sheaf}^{\uparrow}$ *locality and gluing ledger over the displayed* $\mathsf{Scheme}^{\uparrow}$ *site row, and the glued object and arrow rows remain inside the same* BHist *carrier packet.*

Lean4 ✓ `BEDC.Derived.StackUp.StackCarrierPacket descent rows`
Lean4 ✓ `BEDC.Derived.StackUp.StackCarrier descent obligation`
Lean4 ✓ `BEDC.Derived.StackUp.StackCarrierPacket descent transport`
Lean4 ✓ `BEDC.Derived.StackUp.StackBHistCarrier descent obligation`
Lean4 ✓ `BEDC.Derived.StackUp.StackCarrierPacket descent obligation`

Proof. Use the cover rows supplied by the $\mathsf{Scheme}^{\uparrow}$ site surface of chapter 153. They determine the visible cover indices and refinement routes on which the stack packet is allowed to restrict object and arrow rows.

Use the $\mathsf{Sheaf}^{\uparrow}$ locality and gluing ledger of chapter 151 on the groupoid-valued presheaf coordinate. Cover-compatible local object rows glue to a global object row, and compatible local arrow rows glue to a global arrow row, with the readback comparisons expressed by the displayed section classifiers.

The resulting rows are repacked with the original site, hsame transports, Cont routes, and Pkg provenance. Thus descent closes inside the same BHist carrier and does not appeal to host quotient stacks or external algebraic-space equality. □

Lean4 ✓ `BEDC.Derived.StackUp.StackDescent obligation surface`

Theorem 260.3 (Stack representability obligation)**.** *Every visible diagonal row or atlas row of a* $\mathsf{Stack}^{\uparrow}$ *carrier packet is readable only through displayed* $\mathsf{Scheme}^{\uparrow}$ *carrier rows and* hsame *transport over the site. Representability is recorded as a ledger predicate on those rows, not as an external algebraic-space primitive and not as host equality of quotient stacks.*

Lean4 ✓ `BEDC.Derived.StackUp.StackCarrierPacket representability surface`
Lean4 ✓ `BEDC.Derived.StackUp.StackRepresentability boundary`
Lean4 ✓ `BEDC.Derived.StackUp.StackRepresentability scheme site transport`

Proof. Project the diagonal or atlas read through the site coordinate supplied by chapter 153. Each visible source, target, overlap, and cover entry is a scheme-carrier or scheme-cover row, so the read has no independent host algebraic-space endpoint.

Project the presheaf and descent comparisons through the $\mathsf{Sheaf}^{\uparrow}$ rows of chapter 151. The relevant object and arrow comparisons are transported by hsame and restricted along the Cont routes already displayed in the stack carrier.

The representability witness is therefore a ledger predicate saying that the listed diagonal or atlas row is covered by the displayed scheme rows after the named transports. It is not an imported algebraic-space object and it does not identify quotient-stack presentations by external equality. □

Theorem 260.4 (Stack ledger obligation)**.** *The public ledger of a* $\mathsf{Stack}^{\uparrow}$ *carrier packet exports exactly the site rows, cover rows, groupoid-object rows, arrow rows, descent witnesses, representability witnesses,* Cont *routes, and dependency* Pkg *rows displayed in the packet.*

Lean4 ✓ `BEDC.Derived.StackUp.StackLedger obligation surface`

Proof. The site and cover exports are the rows inherited from the $\mathsf{Scheme}^{\uparrow}$ surface of chapter 153. They are the only rows that expose scheme carriers, affine or site cover entries, refinements, and the restriction routes consumed by the stack packet.

The groupoid-object, arrow, and descent exports are the rows inherited from the $\mathsf{Sheaf}^{\uparrow}$ surface of chapter 151. They account for the groupoid-valued presheaf coordinate and for the locality, gluing, and readback rows used by descent.

Representability rows, Cont routes, and Pkg provenance are the remaining coordinates of the carrier packet. Since the ledger is the ordered projection of these displayed coordinates, it exports no host stack object, no quotient-stack equality, and no external algebraic-space equality. □

Theorem 260.5 (Stack NameCert obligation surface)**.** *The preceding four obligations supply the* $\mathsf{Stack}^{\uparrow}$ NameCert *surface. Carrier inhabitance is witnessed by the displayed trivial-cover packet, classifier equivalence is componentwise* hsame*, carrier transport is governed by the descent and representability rows, and ledger exactness is the exact projection asserted by Definition 260.4.*

Lean4 ✓ `BEDC.Derived.StackUp.StackCarrierPacket namecert obligation surface`
Lean4 ✓ `BEDC.Derived.StackUp.StackNameCert obligation surface`

Proof. Carrier inhabitance uses the trivial cover available in the $\mathsf{Scheme}^{\uparrow}$ surface of chapter 153 together with the identity local object and arrow rows read through the $\mathsf{Sheaf}^{\uparrow}$ surface of chapter 151. These rows form the finite packet required by Definition 260.1.

Classifier equivalence is componentwise hsame on the site, object, arrow, transport, restriction, and provenance rows. Reflexive, symmetric, and transitive behavior is inherited row by row from the consumed scheme and sheaf classifiers, with Cont only recording the displayed restriction route.

Carrier transport follows by applying the descent obligation to glued object and arrow rows and the representability obligation to diagonal and atlas rows. Ledger exactness then follows from Definition 260.4, which lists every exported row and excludes host quotient stacks and external algebraic-space equality from the public surface. □

260.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{Stack}^{\uparrow}}$**.**

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{Stack}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The public finite $\mathsf{Scheme}^{\uparrow}/\mathsf{Sheaf}^{\uparrow}$ stack packet binds the displayed stack carrier, descent rows, representability rows, ledger rows, NameCert obligation surface, hsame transports, Cont restriction routes, and Pkg provenance for the consumed dependency certificates.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{Stack}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.StackUp.StackCarrierPacket\_namecert\_obligation\_surface`

Bridge status: none

Constructive story: A $\mathsf{Stack}^{\uparrow}$ packet is assembled from displayed scheme-site rows, groupoid-valued sheaf rows, descent and restriction routes, and dependency provenance; every public read is a projection from this finite carrier packet.

Not claimed: This chapter does not close host quotient stacks or external algebraic-space equality.

Upgrade path: A standard bridge would have to identify this public stack packet with the acceptance-bridge schema without adding host quotient stacks or external algebraic-space equality.

Chapter 261

A Concrete Naming Certificate for $\mathsf{StoneDuality}^{\uparrow}$

The Stone-duality interface $\mathsf{StoneDuality}^{\uparrow}$ packages the contravariant equivalence between the category of Boolean algebras and the category of totally disconnected compact Hausdorff spaces. It depends on $\mathsf{NameCert}_{\mathsf{Lattice}^{\uparrow}}$ (chapter 55) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88), and is a cross-domain bridge witnessing the unified-kernel principle: order theory and topology meet through the same classifier discipline.

261.1 Carrier definition

Theorem 261.1 (StoneDualityUp Boolean-algebra source)**.** *A* $\mathsf{StoneDuality}^{\uparrow}$ *source row is a finite* BHist *packet whose Boolean-algebra side consists only of* $\mathsf{Lattice}^{\uparrow}$ *observations: zero and one rows, meet and join rows, complement rows, and the distributive ledgers that classify those rows by* hsame*. If two such packets are* hsame*-equivalent as* $\mathsf{Lattice}^{\uparrow}$ *packets, then their induced* Pkg *rows for* $\mathsf{StoneDuality}^{\uparrow}$ *have the same Boolean source classifier. No point of a Stone space, ultrafilter, or external compact Hausdorff carrier is part of the source data.*

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityBooleanSource transport`

Proof. Read the carrier from the finite BHist ledger. The zero, one, meet, join, complement, and distributive rows are already $\mathsf{Lattice}^{\uparrow}$-typed observations, so the $\mathsf{StoneDuality}^{\uparrow}$ source packet is obtained by repacking those rows into a single Pkg coordinate.

The classifier statement is just transport along hsame. Since each Boolean operation row is classified by the same finite history relation before and after repacking, the $\mathsf{StoneDuality}^{\uparrow}$ source classifier has no additional semantic input.

The last clause is a boundary condition on the carrier. The construction names only the finite observation packet and therefore never asks for an ultrafilter witness or a completed Stone-space object. □

Theorem 261.2 (StoneDualityUp Stone-space classifier)**.** *For every accepted* $\mathsf{StoneDuality}^{\uparrow}$ *Boolean source packet B, the topology-facing classifier is the finite* BHist *packet of clopen observation rows generated from the Boolean rows of B: a Boolean element b is read as a clopen row C_b, meet is read as intersection, join as union, complement as topological complement, zero as the empty clopen row, and one as the full clopen row. If b and b' are* hsame *on the Boolean side, then C_b and $C_{b'}$ are* hsame *as* $\mathsf{Topology}^{\uparrow}$ *clopen rows.*

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityStoneSpaceClassifier source semanticNameCert`

Proof. Construct the clopen packet by structural traversal of the finite Boolean source ledger. Each generator contributes one topology row, and each Boolean operation contributes the matching $\mathsf{Topology}^{\uparrow}$ operation row.

Classifier stability follows by induction over the source ledger. A generator step is copied directly; meet, join, complement, zero, and one steps use the corresponding $\mathsf{Topology}^{\uparrow}$ classifier rows and preserve the same hsame witness.

No representation by points is used. The topology packet is the clopen ledger itself, so the theorem is a classifier statement about finite rows rather than an existence theorem for a separate space. □

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityStoneSpaceClassifier clopen transport`

261.2 The certificate

Theorem 261.3 (StoneDualityUp clopen ledger)**.** *An accepted* $\mathsf{StoneDuality}^{\uparrow}$ *certificate carries a* Cont *ledger from Boolean source rows to clopen topology rows. For each finite Boolean observation row* r *in the source* Pkg*, the ledger records the clopen row* C_r*, its* $\mathsf{Topology}^{\uparrow}$ *classifier, and the* hsame *transport showing that Boolean equality of rows implies topological equality of the corresponding clopen rows. The ledger is exhausted by the rows generated in Theorem 261.2.*

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityClopenLedger transport closure`

Proof. Build the Cont ledger in parallel with the clopen classifier packet. Each source row contributes exactly one ledger entry, and each operation row contributes the corresponding continuity-preserving clopen operation entry.

Exhaustion is by inspection of the finite source traversal. The traversal has no branch for arbitrary open sets or arbitrary points; every ledger row is generated from a Boolean observation row already present in the source packet.

The transport clause is inherited from hsame stability of the Boolean rows and the $\mathsf{Topology}^{\uparrow}$ clopen classifier. Thus the Cont ledger records the constructive bridge without adding a new carrier. □

Theorem 261.4 (StoneDualityUp ultrafilter-free soundness)**.** *The* $\mathsf{StoneDuality}^{\uparrow}$ *soundness obligation is satisfied at the certificate surface when every accepted Boolean source row is read through the finite clopen ledger and every* hsame *comparison is transported by the recorded* Cont *rows. This soundness statement does not assert that every Boolean homomorphism has an ultrafilter point, and it does not invoke an external Stone-space existence theorem.*

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityUltrafilterFreeSoundness surface`

Proof. Start with an accepted Boolean source packet and its clopen ledger. Soundness means that each Boolean operation row has the matching clopen operation row and that classifier equality is preserved by the ledger.

The required checks are finite. Zero, one, meet, join, and complement are handled by their recorded clopen rows; distributive compatibility is handled by the copied $\mathsf{Lattice}^{\uparrow}$ classifier rows and the $\mathsf{Topology}^{\uparrow}$ operation classifiers.

There is no choice step. The proof never selects an ultrafilter extending a filter and never builds a point space; it only verifies that the displayed BHist, Pkg, NameCert, and Cont rows commute under hsame. □

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityUltrafilterFreeSoundness`

Theorem 261.5 (StoneDualityUp continuous-map readback)**.** *Let F be a finite* StoneDuality$^{\uparrow}$ *morphism row between accepted Boolean source packets. If F preserves zero, one, meet, join, and complement in the Boolean* BHist *classifier, then the readback row sends each clopen generator C_b in the target topology packet to the clopen generator $C_{F(b)}$ in the source topology packet, and the resulting* Cont *ledger is stable under* hsame*. Hence finite Boolean-algebra observations determine the contravariant continuous-map observation surface recorded by* NameCert*.*

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityContinuousMapReadback transport`

Proof. Read the morphism row contravariantly. A target clopen generator is named by a Boolean row b, and the Boolean morphism row supplies the source Boolean row $F(b)$.

Operation preservation gives continuity on the clopen basis represented in the ledger. The preimage of zero, one, meet, join, and complement is again recorded by the corresponding Boolean operation row, so the Topology$^{\uparrow}$ clopen classifier remains inside the generated packet.

Finally, hsame stability follows from the morphism classifier and the clopen ledger transport. The readback is therefore a finite Cont row in the StoneDuality$^{\uparrow}$ certificate, not an appeal to a completed dual space. □

Lean4 ✓ `BEDC.Derived.StoneDualityUp.StoneDualityContinuousMapReadback contravariant endpoint`

Closure status for NameCert$_{\text{StoneDuality}^{\uparrow}}$**.**

Theory closure: TheoryGate(NameCert$_{\text{StoneDuality}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature certificate binds the Lattice$^{\uparrow}$ Boolean rows, Topology$^{\uparrow}$ clopen rows, finite BHist packets, hsame transport, Cont ledgers, Pkg provenance, NameCert rows, and the Stone-space classifier bridge through $BEDC.Derived.StoneDualityUp.StoneDualityStoneSpaceClassifier_source_semanticNameCert$.

Constructive story: The construction starts from finite Boolean-operation rows, traverses them into clopen topology rows, records the contravariant readback as Cont ledger entries, and transports every comparison through the displayed hsame, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{StoneDuality}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.StoneDualityUp.StoneDualityStoneSpaceClassifier\_source\_semanticNameCert`

Bridge status: paperBridge

Not claimed: This chapter does not close ultrafilter existence, completed compact Hausdorff spaces, choice-based point construction, or standard bridge closure.

Upgrade path: Standard bridge closure requires a bridge-checked transport from the finite Boolean-row to clopen-topology classifier surface into the acceptance-bridge schema.

Chapter 262

A Concrete Naming Certificate for $\mathsf{GelfandDuality}^{\uparrow}$

The Gelfand-duality interface $\mathsf{GelfandDuality}^{\uparrow}$ packages the contravariant equivalence between unital commutative C*-algebras and compact Hausdorff spaces, identifying a space with the spectrum of its continuous-function algebra. It depends on $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ (chapter 211) and $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ (chapter 88), and witnesses how operator-algebraic and topological certificates share a common spectrum substrate.

262.1 Carrier definition

Definition 262.1 (GelfandDuality BHist spectrum-pairing carrier)**.** *A* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum-pairing carrier is a finite* BHist *packet*

$$\mathcal{G} = (A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda).$$

The row A is a consumed $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *source row for a unital commutative C*-algebra history. The row X is a consumed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *compact-spectrum row. The finite row family χ lists the visible character histories from A to the scalar endpoint, and the finite row family ε lists the displayed character-evaluation histories relating elements of A to points of X.*

The rows ρ_A and ρ_X are the componentwise hsame *transport rows for the algebraic and topological faces of the same spectrum pairing. The row P is the* Pkg *provenance recording exactly the consumed* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *row, the consumed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row, the character rows, and the evaluation rows. The finite ledger λ is the* Cont *route containing only those displayed rows and their endpoint readbacks.*

Lean4 (definition) `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier`

Definition 262.2 (GelfandDuality spectrum transport package)**.** *A* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum transport package for Definition 262.1 is the displayed* BHist *packet*

$$\mathcal{T}_{\mathcal{G}} = (A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda).$$

The rows A and X are the transported algebra and compact-spectrum faces, χ and ε are the transported character and evaluation rows, ρ_A and ρ_X are the two componentwise hsame *transport rows, P is the* Pkg *provenance for the shared spectrum pairing, and λ is the* Cont *route carrying exactly those transported readbacks. The package exposes transport only through these displayed rows.*

Lean4 (definition) `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumTransportPackage`

262.2 The certificate

Theorem 262.3 (GelfandDuality spectrum source obligation)**.** *Every public source row of a* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum-pairing carrier is a displayed* BHist *row of Definition 262.1. In particular, the source boundary consists of the consumed* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *row* A*, the consumed* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row* X*, the character-evaluation rows, the componentwise* hsame *rows* ρ_A, ρ_X*, the* Pkg *row* P*, and the finite* Cont *route* λ*.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrum source obligation`
↪ variant `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier source obligation`

Proof. Project an accepted carrier to the tuple $\mathcal{G} = (A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda)$. The carrier definition names each public source row, so projection cannot expose a second algebra object, a second spectrum object, or an unrecorded evaluation row.

The algebraic source is the $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ row A, and the topological source is the $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ row X. The character and evaluation histories are rows over those two sources, while ρ_A, ρ_X, P, and λ provide transport, provenance, and readback.

Repacking these displayed projections gives the source obligation. The carrier therefore exports only the listed BHist rows and no hidden host-level Gelfand duality theorem. □

Theorem 262.4 (GelfandDuality CStarAlg consumer boundary)**.** *A downstream* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *consumer of a* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum-pairing carrier reads the C*-algebra face only through the* BHist *row* A*, the character-evaluation rows* χ *and* ε*, the algebra-side* hsame *row* ρ_A*, the shared* Pkg *row* P*, and the finite* Cont *route* λ*; the* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *row* X *is available to that consumer only as the recorded compact-spectrum dependency of the same packet.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier cstaralgebra consumer boundary`

Proof. Take a consumer whose input is the algebraic face of the carrier. Projecting the carrier exposes A as the only consumed $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ row and exposes χ and ε as the only visible character and evaluation-history rows.

The algebra-side transport available to the consumer is ρ_A. The provenance row P records that these algebraic rows are paired with the topological dependency X, and the continuation route λ records the readbacks that the consumer may follow.

No separate algebra carrier occurs in Definition 262.1. Thus the consumer boundary is exactly the projected algebraic face together with its recorded $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ dependency. □

Theorem 262.5 (GelfandDuality Topology consumer boundary)**.** *A downstream* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *consumer of a* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum-pairing carrier reads the compact-spectrum face only through the* BHist *row* X*, the character-evaluation rows* χ *and* ε*, the topology-side* hsame *row* ρ_X*, the shared* Pkg *row* P*, and the finite* Cont *route* λ*; the* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *row* A *is available to that consumer only as the recorded C*-algebra dependency of the same packet.*

Proof. Take a consumer whose input is the topological face of the carrier. Projection exposes X as the only consumed $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ compact spectrum row. The visible character and evaluation histories are the rows χ and ε, now read as the connection from the spectrum points back to the algebraic source.

The topology-side transport available to the consumer is ρ_X. The provenance row P records the dependence on A, and the continuation route λ records exactly the endpoint readbacks that remain public.

Since the carrier has no further topology row, no additional compact Hausdorff space or open-set basis can be imported by the consumer. The boundary is the displayed BHist spectrum face and its recorded $\mathsf{NameCert}_{\mathsf{CStarAlg}^\uparrow}$ dependency. □

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier topology consumer boundary`

Theorem 262.6 (GelfandDuality spectrum transport exactness)**.** *Every accepted transport of the spectrum pairing of Definition 262.2 projects exactly to the algebra face A, the topology face X, the character rows χ, the evaluation rows ε, the two* hsame *rows ρ_A and ρ_X, the* Pkg *provenance row P, and the continuation route λ. Conversely, those displayed rows repack as the transported* $\mathsf{GelfandDuality}^\uparrow$ *spectrum-pairing surface, with no second spectrum carrier, no hidden transform row, and no host compact-Hausdorff theorem.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumTransportPackage exactness`

Proof. Project the accepted transport to the tuple $\mathcal{T}_{\mathcal{G}} = (A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda)$. By Definition 262.2, these are exactly the rows carried by the transport package.

The algebraic projection is checked against Definition 262.4, and the topological projection is checked against Definition 262.5. These two boundaries force the character and evaluation rows to remain attached to the shared algebra-topology packet.

For the reverse direction, repack the displayed projections into the transport package. The provenance and continuation rows are already P and λ, so there is no remaining public slot for an external spectrum construction. □

Theorem 262.7 (GelfandDuality evaluation ledger determinacy)**.** *Let two accepted evaluation reads in a* $\mathsf{GelfandDuality}^\uparrow$ *spectrum transport package have the same transported algebra row A, the same topology point row inside X, the same character row in χ, and the same endpoint readback in ε. Then the public spectrum-pairing classifier identifies the two evaluation rows through the displayed* hsame *transport rows ρ_A, ρ_X and the finite* Cont *route λ. No second evaluation ledger can be exposed at that same transported slot.*

Proof. Project both evaluation reads through Definition 262.2. The shared algebra row, topology point row, character row, and endpoint readback place both reads in the same displayed ε slot.

Apply Definition 262.6. Every accepted evaluation read is one of the evaluation rows in the transported package, and the only available comparison rows are ρ_A, ρ_X, and the readback route λ.

Repacking those comparisons gives the public classifier identification. A second evaluation ledger would require another public row outside $\mathcal{T}_{\mathcal{G}}$, which the exactness theorem excludes. □

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier evaluation ledger determinacy`

Theorem 262.8 (GelfandDuality NameCert obligation surface)**.** *The public* $\mathsf{GelfandDuality}^\uparrow$ *obligation surface is exactly the coverage of the* BHist *rows A, X, χ, ε, ρ_A, ρ_X, P, and λ in Definition 262.1: A is covered by* $\mathsf{NameCert}_{\mathsf{CStarAlg}^\uparrow}$*, X is covered by* $\mathsf{NameCert}_{\mathsf{Topology}^\uparrow}$*, ρ_A and ρ_X are the only* hsame *transports, P is the only* Pkg *provenance, and λ is the only* Cont *readback route.*

Proof. Start with an accepted public obligation for the certificate. Projection to the carrier tuple determines whether the obligation is algebraic, topological, evaluational, transport, provenance, or readback data.

The algebraic case lands in A and is covered by $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$. The topological case lands in X and is covered by $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$. The evaluation case lands in χ or ε, so it remains tied to both displayed source rows.

The remaining cases are exact by inspection of the packet: ρ_A and ρ_X are the available hsame transports, P is the available Pkg provenance, and λ is the available Cont route. Repacking those projections gives the stated obligation surface, with no parameter-transport equivalence and no extra public row. □

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier namecert obligation surface`

Theorem 262.9 (GelfandDuality spectrum-pairing classifier stability)**.** *Componentwise* hsame *transport of the rows A, X, χ, ε, ρ_A, ρ_X, P, and λ in Definition 262.1 preserves the public* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum-pairing classifier. The transported packet reads the algebraic face through the same* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *dependency, the topological face through the same* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *dependency, and the evaluation face through the displayed character and evaluation rows.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier classifier stability`

Proof. Project the accepted packet to $\mathcal{G} = (A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda)$ using Definition 262.1. Transport acts on each displayed component and therefore cannot create a second algebra row, topology row, character family, evaluation family, provenance row, or readback route.

Apply Definition 262.4 to the algebraic face. The transported algebra consumer still reads only A, χ, ε, ρ_A, P, and λ.

Apply Definition 262.5 to the topological face. The transported topology consumer still reads only X, χ, ε, ρ_X, P, and λ.

Combining the two transported faces gives the same public spectrum-pairing classifier. No external Gelfand transform, compact-Hausdorff theorem, or parameter-transport equivalence is imported by the transport. □

Theorem 262.10 (GelfandDuality spectrum ledger exactness)**.** *The public* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum ledger is exactly the* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *source row A, the* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *compact-spectrum row X, the character rows χ, the evaluation rows ε, the algebra and topology transport rows ρ_A and ρ_X, the* Pkg *provenance row P, and the finite* Cont *readback route λ displayed in Definition 262.1.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier spectrum ledger exactness`

Proof. First use Definition 262.8. Every public obligation projects to one of the packet components A, X, χ, ε, ρ_A, ρ_X, P, and λ.

The algebraic side is exact by Definition 262.4; it permits only the CStarAlgUp source row, character and evaluation rows, algebra transport, provenance, and finite readback. The topological side is exact by Definition 262.5; it permits only the TopologyUp compact-spectrum row, the same character and evaluation rows, topology transport, provenance, and finite readback.

Conversely, each listed component is a field of the carrier packet, so it is a public ledger row of the certificate. The ledger therefore has no remaining slot for an external Gelfand transform, an imported compact-Hausdorff theorem, or any host-level spectrum construction. □

Theorem 262.11 (GelfandDuality obligation closure inventory)**.** *The* $\mathsf{GelfandDuality}^{\uparrow}$ *obligation inventory consists exactly of the* BHist *spectrum-pairing carrier rows* A, X, χ, ε, ρ_A, ρ_X, P, *and* λ, *the two consumer boundaries for the* $\mathsf{NameCert}_{\mathsf{CStarAlg}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Topology}^{\uparrow}}$ *faces, spectrum transport exactness, classifier stability, ledger exactness, and the NameCert obligation surface. All entries are mediated by* BHist, hsame, Pkg, *and* Cont, *and the inventory excludes host Gelfand transforms and compact-Hausdorff imports.*

Lean4 ✓ `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrumPairingCarrier obligation closure inventory`

Proof. The carrier rows are the displayed tuple of Definition 262.1. The source boundary is Definition 262.3, so every public source row is one of A, X, χ, ε, ρ_A, ρ_X, P, or λ.

The two consumer sides are exactly Definition 262.4 and Definition 262.5. Transport contributes Definition 262.6, which repacks only the displayed rows through the two hsame transports, the provenance row, and the finite continuation route.

The remaining public obligations are supplied by Definition 262.8, Definition 262.9, and Definition 262.10. Together these blocks cover the NameCert surface, classifier stability, and ledger exactness, while each block rules out any public slot for a host Gelfand transform, compact-Hausdorff import, or external spectrum construction. □

Theorem 262.12 (GelfandDuality standard spectrum bridge boundary)**.** *The standard bridge boundary for the public* $\mathsf{GelfandDuality}^{\uparrow}$ *spectrum packet is exactly the displayed pairing between the* $\mathsf{CStarAlg}^{\uparrow}$ *source row* A, *the compact-spectrum* $\mathsf{Topology}^{\uparrow}$ *row* X, *the character rows* χ, *the evaluation rows* ε, *the transport rows* ρ_A *and* ρ_X, *the* Pkg *provenance* P, *and the finite* Cont *route* λ.

This bridge boundary is only a conservative readback surface. It does not provide a host Gelfand transform, a compact-Hausdorff theorem, a second spectrum carrier, or any host-level spectrum equality.

Proof. Start with Definition 262.3. It fixes the source boundary of the packet as the displayed A, X, χ, ε, ρ_A, ρ_X, P, and λ rows.

The algebraic and topological consumer faces are Definition 262.4 and Definition 262.5. These two faces show that the $\mathsf{CStarAlg}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ consumers read the same finite pairing surface, each through its own source row and the shared character, evaluation, transport, provenance, and continuation rows.

Apply Definition 262.6 and Definition 262.10. Transport repacks only the displayed rows, and ledger exactness says that no extra spectrum component is present in the public packet.

Finally use Definition 262.11. The inventory lists precisely the obligations that the bridge boundary may expose, so the readback surface remains conservative and contains no host Gelfand transform, compact-Hausdorff theorem, second spectrum carrier, or host-level spectrum equality. □

Closure status for $\mathsf{NameCert}_{\mathsf{GelfandDuality}^{\uparrow}}$**.**

Constructive story: A spectrum-pairing packet is generated by placing a unital commutative $\mathsf{CStarAlg}^{\uparrow}$ source row A beside a compact-spectrum $\mathsf{Topology}^{\uparrow}$ row X, then displaying character rows, evaluation rows, algebra-side and topology-side transports, provenance, and a finite continuation readback route. The carrier accepts only packets $(A, X, \chi, \varepsilon, \rho_A, \rho_X, P, \lambda)$ with those rows present; an external Gelfand transform, host compact-Hausdorff theorem, second spectrum carrier, or host-level spectrum equality is not a field of the packet. Two accepted packets classify together by componentwise hsame transport of the algebra face, topology face, character family, evaluation family, both transport rows, the Pkg provenance, and the finite Cont route. The source specification is the paired $\mathsf{CStarAlg}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ dependency surface, the pattern specification is the character-and-evaluation spectrum pairing, and the ledger keeps χ,

ε, ρ_A, ρ_X, P, and λ visible to algebraic and topological consumers. The five name-certificate obligations come from an accepted packet for inhabitation, the inherited component equivalences for reflexivity, symmetry, and transitivity, and the transport-exactness theorem that repacks every transported spectrum read into the same displayed rows. A packet history h lies in the signature gap of a GelfandDuality$^{\uparrow}$ token p when the source-domain accepts its algebra-topology spectrum surface, the signature relation pairs it with an answer spectrum packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, the character and evaluation rows are exactly the pairing data encoded by p. The chapter registers this spectrum-pairing packet under the name GelfandDuality$^{\uparrow}$; it introduces no standard compact-Hausdorff bridge, no Gelfand-transform bridge, and no host spectrum equality.

Theory closure: TheoryGate(NameCert$_{\text{GelfandDuality}\uparrow}$, maturePackageClosed)

Scope closed: The obligation scope binds Definition 262.12 together with the spectrum-pairing carrier rows A, X, χ, ε, ρ_A, ρ_X, P, and λ, the two consumer boundaries, transport exactness, classifier stability, ledger exactness, and the NameCert obligation surface.

Formal verification: FormalStatus(NameCert$_{\text{GelfandDuality}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.GelfandDualityUp.GelfandDualitySpectrum\_source\_obligation`

Bridge status: paperBridge

Not claimed: This chapter does not claim a standard compact-Hausdorff bridge, a Gelfand-transform bridge, or host-level spectrum equality.

Upgrade path: No further paper theory-axis step is recorded; bridge verification remains separate.

Chapter 263

A Concrete Naming Certificate for $\mathsf{PontryaginDuality}^{\uparrow}$

The Pontryagin-duality interface $\mathsf{PontryaginDuality}^{\uparrow}$ packages the contravariant self-equivalence on locally compact abelian groups via the Hom-into-circle functor, with the double-dual canonical isomorphism. It depends on $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ (chapter 204) and $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ (chapter 42), and bridges harmonic-analytic and group-theoretic certificates through the same character classifier.

263.1 Carrier definition

Definition 263.1 (Pontryagin-duality character carrier)**.** *A* $\mathsf{PontryaginDuality}^{\uparrow}$ *carrier is a finite* BHist *character-ledger packet over* $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$*, together with a circle-valued target row read through* $\mathsf{S}^{1\uparrow}$*-style component data. Its rows are the displayed topological-group source row, the displayed abelian-group operation row, finite character rows from the shared source to the circle target, pointwise product and inverse rows for those characters,* hsame *comparisons between corresponding source, target, and character rows,* Cont *provenance explaining how each character row is read from the displayed source and circle rows, and* Pkg *rows naming the two dependency certificates and the circle component packet.*

The carrier records only the BEDC character ledger. It does not include Haar measure, Fourier inversion, local compactness theorems, a completed dual group topology, or a full duality equivalence.

263.2 The certificate

Theorem 263.2 (Pontryagin-duality character carrier obligation)**.** *Every accepted* $\mathsf{PontryaginDuality}^{\uparrow}$ *packet is read from the character carrier of Definition 263.1: the* $\mathsf{TopGroup}^{\uparrow}/\mathsf{AbGroup}^{\uparrow}$ *source rows, the circle-valued target row, the finite character rows, the pointwise product and inverse rows, the displayed* hsame *comparisons, the* Cont *provenance, and the* Pkg *source rows. No additional analytic or host duality object is exposed.*

```
Lean4 ✓  BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier obligation
  ↪ variant  BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier source boundary
```

Proof. Project an accepted packet to the finite character ledger. The carrier definition lists exactly the source, target, character, algebraic operation, comparison, continuation, and package rows

available to a consumer.

Constructor inspection gives the converse readback boundary: every row named in the theorem is a coordinate of the finite BHist carrier, and the carrier has no coordinate for Haar measure, Fourier inversion, local compactness theorems, or a completed duality object. □

Theorem 263.3 (Pontryagin-duality character classifier stability)**.** *Let P and P' be accepted* $\mathsf{PontryaginDuality}^{\uparrow}$ *character-ledger packets. If their displayed* $\mathsf{TopGroup}^{\uparrow}$ *rows,* $\mathsf{AbGroup}^{\uparrow}$ *rows, circle-valued target rows, character rows, pointwise product and inverse rows,* Cont *provenance, and* Pkg *source rows are related componentwise by* hsame*, then the transported rows form another accepted character carrier with the same visible classifier surface.*

Lean4 ✓ `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier stability`

Proof. Transport first the dependency rows from $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ and the circle target row. This preserves the finite source and target boundary through displayed hsame witnesses.

Next transport each character row and its pointwise product and inverse rows. The operations are carrier rows in the same finite ledger, so their readback is preserved by projection along the transported row positions.

Finally transport the Cont and Pkg rows. The acceptance predicate only asks that characters be read through those visible provenance rows from the displayed source and circle target, so the transported packet is accepted again. □

Theorem 263.4 (Pontryagin-duality dual ledger exactness)**.** *The dual ledger exported by an accepted* $\mathsf{PontryaginDuality}^{\uparrow}$ *packet consists exactly of finite character rows into the circle-valued target, their pointwise product and inverse rows, the displayed source and target comparisons, and the visible* Cont/Pkg *provenance. It exports no Haar integration row, Fourier transform row, local compactness theorem, or double-dual equivalence.*

Lean4 ✓ `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier visible dual ledger boundary`
Lean4 ✓ `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier dual ledger rows`

Proof. Use Definition 263.2 to reduce readback to carrier projection. Every listed dual-ledger row is a coordinate of the finite packet.

For exactness, inspect the constructors of the packet. They generate character rows and their pointwise algebraic rows, together with source, target, comparison, continuation, and package provenance. They do not generate an analytic measure row, transform row, compactness theorem row, or equivalence row. □

Theorem 263.5 (Pontryagin-duality source boundary)**.** *The dependency boundary of* $\mathsf{PontryaginDuality}^{\uparrow}$ *is exactly the displayed* $\mathsf{NameCert}_{\mathsf{TopGroup}^{\uparrow}}$ *source row, the displayed* $\mathsf{NameCert}_{\mathsf{AbGroup}^{\uparrow}}$ *algebraic row, and the circle-valued target component read in the style of* $\mathsf{S}^{1\uparrow}$*. Every accepted character row is sourced through that boundary by visible* Cont *provenance and packaged by* Pkg*.*

Lean4 ✓ `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier dependency source boundary`

Proof. Read the source rows from Definition 263.1. The carrier names only the topological-group source, the abelian-group operation surface, and the circle target packet as external dependency data.

Each character row is accepted only when the displayed Cont row connects it to that boundary and the Pkg row records the same source package. There is no constructor that sources a character from a host locally compact abelian group object or an external harmonic-analysis structure. □

Theorem 263.6 (Pontryagin-duality NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{PontryaginDuality}^{\uparrow}}$ *obligation surface consists of the character carrier of Definition 263.1, carrier readback from Definition 263.2, classifier stability from Definition 263.3, dual-ledger exactness from Definition 263.4, and the dependency-source boundary of Definition 263.5.*

Proof. Use the character carrier as the source predicate and its displayed hsame rows as the classifier surface. Carrier readback supplies the visible packet rows, and classifier stability shows that this surface is preserved by componentwise transport.

Use dual-ledger exactness to identify the complete exported dual character ledger. Use the source-boundary theorem to bind every character row to the displayed $\mathsf{TopGroup}^{\uparrow}$, $\mathsf{AbGroup}^{\uparrow}$, and circle target rows.

These clauses assemble the finite local NameCert surface. The assembly is deliberately limited to the BEDC packet and therefore excludes Haar measure, Fourier inversion, local compactness theorems, and a full Pontryagin-duality equivalence. □

Lean4 ✓ `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier namecert obligation surface`

Theorem 263.7 (Pontryagin-duality public character export)**.** *The scoped carrier, classifier-stability, dual-ledger exactness, source-boundary, and* NameCert *obligation-surface rows assemble the public* $\mathsf{NameCert}_{\mathsf{PontryaginDuality}^{\uparrow}}$ *export for downstream consumers. The export exposes only the displayed character rows, target-circle rows,* hsame, Cont, Pkg, *and* NameCert *provenance.*

It exposes no locally compact group theorem, Haar measure, biduality isomorphism, or host dual group.

Proof. Apply Definition 263.1 and Definition 263.2. These identify the character carrier and the displayed character rows available for readback.

Next apply Definition 263.3 and Definition 263.4. They transport the classifier surface and exhaust the dual character ledger by the displayed hsame, Cont, and Pkg rows.

Finally use Definition 263.5 and Definition 263.6. The source rows and local NameCert packet repack exactly the target-circle and provenance fields already named above, leaving no constructor for Haar measure, biduality, locally compact group theorems, or a host dual group. □

Closure status for $\mathsf{NameCert}_{\mathsf{PontryaginDuality}^{\uparrow}}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{PontryaginDuality}^{\uparrow}}$, publicClosed)

Scope closed: The scoped boundary binds the $\mathsf{TopGroup}^{\uparrow}$ source row, $\mathsf{AbGroup}^{\uparrow}$ source row, $\mathsf{S}^{1\,\uparrow}$-style circle target, finite character rows, pointwise product and inverse rows, hsame, Cont, and Pkg provenance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{PontryaginDuality}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.PontryaginDualityUp.PontryaginDualityCharacterCarrier\_namecert\_obligation\_surface`

Bridge status: none

Constructive story: A finite character packet is assembled from the displayed topological-group and abelian-group rows, a circle-valued target row, finite character rows, transport witnesses, and one provenance packet; every accepted read remains inside that ledger.

Not claimed: This chapter does not claim Haar measure, Fourier inversion, completed dual topology, or double-dual equivalence.

Upgrade path: Bridged closure next requires a standard comparison bridge for the displayed finite character ledger.

Chapter 264

A Concrete Naming Certificate for $\mathsf{TannakaKrein}^{\uparrow}$

The Tannaka-Krein interface $\mathsf{TannakaKrein}^{\uparrow}$ packages the reconstruction of a compact group from its tensor category of finite-dimensional representations together with a fibre functor to vector spaces. It depends on $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140) and $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ (chapter 181), and bridges representation theory and category theory through the same fibre-functor classifier.

264.1 Carrier definition

Definition 264.1 (Tannaka-Krein fibre-functor carrier)**.** *A* $\mathsf{TannakaKrein}^{\uparrow}$ *carrier is a finite* BHist *reconstruction packet over the displayed dependency rows* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$*. Its visible rows are the Lie-group source certificate, the monoidal-category source certificate, a fibre-functor row from representation-object histories into vector-space histories, representation-object rows in the monoidal source, the tensor-unit comparison row, tensor-product comparison rows,* hsame *witnesses comparing transported group, category, functor, unit, product, and reconstruction-ledger endpoints,* Cont *provenance for the displayed reads, and* Pkg *provenance naming the two source certificates and the fibre-functor ledger.*

The carrier records only this BEDC reconstruction packet. It does not include Haar measure, analytic compactness, an external compact-group equality, or a full Tannaka duality theorem.

Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier dependency endpoint readback`
Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier endpoint expanded boundary`
Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier endpoint deterministic`
Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier reconstruction provenance endpoint confluence`

Definition 264.2 (Tannaka-Krein monoidal classifier)**.** *Two* $\mathsf{TannakaKrein}^{\uparrow}$ *reconstruction packets are identified by the local monoidal classifier exactly when the displayed* hsame *transport relates their Lie-group rows, monoidal-category rows, fibre-functor rows, representation-object rows, tensor-unit comparison rows, tensor-product comparison rows, reconstruction-ledger rows,* Cont *provenance rows, and* Pkg *source rows componentwise.*

No further equality of compact groups, representation categories, vector spaces, or analytic reconstruction objects is part of the classifier.

Lean4 (definition) `BEDC.Derived.TannakaKreinUp.TannakaKreinMonoidalClassifier`

264.2 The certificate

Theorem 264.3 (Tannaka-Krein source boundary)**.** *Every downstream consumer of a* $\mathsf{TannakaKrein}^{\uparrow}$ *packet may read only the displayed* $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ *source certificate, the displayed* $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ *source certificate, and the fibre-functor ledger of Definition 264.1. In particular, the consumer receives no Haar-measure row, no analytic compactness row, and no host compact-group object beyond those visible histories.*

Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier source boundary`

Proof. Project the packet to the carrier rows. The carrier definition lists the Lie-group source, monoidal-category source, fibre-functor row, representation-object rows, tensor-unit and tensor-product comparison rows, continuation rows, and package provenance.

The consumer boundary is therefore the displayed dependency pair together with the fibre-functor reconstruction ledger. There is no carrier coordinate for Haar measure, analytic compactness, or a host compact-group equality, so those objects cannot be read from the packet. □

Theorem 264.4 (Tannaka-Krein fibre-functor classifier stability)**.** *If two accepted* $\mathsf{TannakaKrein}^{\uparrow}$ *packets are related by the monoidal classifier of Definition 264.2, then transport along the displayed* hsame *rows preserves the carrier, the fibre-functor row, the representation-object rows, the tensor-unit comparison row, the tensor-product comparison rows, the reconstruction ledger, and the* Cont/Pkg *provenance rows.*

Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier classifier stability`

Proof. Transport the dependency rows first. The classifier supplies componentwise hsame witnesses for the $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ row and the $\mathsf{NameCert}_{\mathsf{MonoidalCat}^{\uparrow}}$ row, so the source boundary remains inside the same displayed pair of certificates.

Next transport the fibre-functor row, representation-object rows, tensor-unit comparison, tensor-product comparisons, and reconstruction-ledger row. These are exactly the remaining carrier coordinates, and each is related by a displayed hsame witness.

Finally transport the Cont and Pkg rows. Since acceptance asks only for the visible carrier rows and their provenance, the transported packet is again an accepted carrier with the same tensor comparison surface. □

Theorem 264.5 (Tannaka-Krein reconstruction ledger exactness)**.** *The reconstructed group token exported by a* $\mathsf{TannakaKrein}^{\uparrow}$ *packet is determined by the displayed fibre-functor row, representation-object rows, tensor-unit comparison row, tensor-product comparison rows, reconstruction ledger,* Cont *provenance, and* Pkg *source rows. It is not determined by, and does not expose, host compact-group equality or a full analytic Tannaka-duality equivalence.*

Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier reconstruction ledger exactness`

Proof. Unfold the carrier rows. The reconstruction token is read from the same finite BHist packet that records the fibre functor, its representation objects, the tensor-unit comparison, tensor-product comparisons, continuation routes, and package provenance.

The exactness claim is componentwise: changing any visible reconstruction row changes the packet boundary, while componentwise hsame transport of those rows preserves the token by Definition 264.4.

The carrier has no coordinate for host compact-group equality and no row for full Tannaka duality. Hence the exported token is determined by the displayed ledger rather than by an external analytic reconstruction theorem. □

Theorem 264.6 (Tannaka-Krein NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{TannakaKrein}^{\uparrow}}$ *obligation surface consists of the carrier of Definition 264.1, the monoidal classifier of Definition 264.2, classifier stability from Definition 264.4, the source boundary from Definition 264.3, and reconstruction-ledger exactness from Definition 264.5.*

Lean4 ✓ `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier semantic name certificate`

Proof. Use the carrier as the accepted-packet predicate and the monoidal classifier as the visible hsame comparison relation. The carrier supplies exactly the Lie-group source row, monoidal-category source row, fibre-functor row, representation-object rows, tensor comparison rows, continuation rows, and package provenance.

Classifier stability shows that the carrier and tensor comparison rows are preserved under componentwise transport. The source-boundary theorem limits all consumer reads to the two dependency certificates and the displayed fibre-functor ledger.

Reconstruction-ledger exactness identifies the exported group token with the visible ledger. The assembled obligation surface is therefore constructive and finite, using only Cont, Pkg, NameCert, $\mathsf{LieGroup}^{\uparrow}$, and $\mathsf{MonoidalCat}^{\uparrow}$ rows, while excluding Haar measure, analytic compactness, and full Tannaka duality. □

Closure status for $\mathsf{NameCert}_{\mathsf{TannakaKrein}^{\uparrow}}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TannakaKrein}^{\uparrow}}$, publicClosed)

Scope closed: The public surface binds the $\mathsf{LieGroup}^{\uparrow}$ source rows, $\mathsf{MonoidalCat}^{\uparrow}$ tensor rows, fibre-functor rows, representation rows, unit and tensor-product rows, reconstruction ledger, hsame classifier transport, Cont reconstruction routes, and Pkg provenance into one finite dependency packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TannakaKrein}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TannakaKreinUp.TannakaKreinFiberFunctorCarrier\_semantic\_name\_certificate`

Bridge status: none

Constructive story: A $\mathsf{TannakaKrein}^{\uparrow}$ packet is assembled from the two source certificates, the fibre-functor row, representation-object rows, tensor-unit and tensor-product comparison rows, reconstruction ledger endpoints, and visible provenance rows; consumers read only this finite reconstruction surface.

Not claimed: This chapter does not claim Haar measure, analytic compactness, host compact-group equality, or full Tannaka duality.

Upgrade path: The next paper-side step is a bridge theorem connecting the public reconstruction export to the standard Tannaka-Krein schema.

Chapter 265

A Concrete Naming Certificate for $\mathsf{CurryHoward}^{\uparrow}$

The Curry-Howard interface $\mathsf{CurryHoward}^{\uparrow}$ packages the bijective correspondence between intuitionistic propositions and types, between proofs and programs, and between cut-elimination and reduction. It depends on $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ (chapter 197) and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$ (chapter 200), and bridges logic and computation through the same inductive carrier.

265.1 Carrier definition

265.2 The certificate

Definition 265.1 (CurryHowardUp shared cut-beta packet)**.** *A shared cut-beta packet for* $\mathsf{CurryHoward}^{\uparrow}$ *is a displayed* BHist *tuple*

$$\mathcal{H} = (P, A, B, D_1, D_2, D_{\mathsf{cut}}, x, a, b, u, L, r, s, \chi, \rho)$$

with the following rows. The histories P, A, B are the shared proof-program, cut-formula/type, and conclusion-type endpoints. The rows D_1 and D_2 are accepted finite $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledgers over one carried syntax packet from Definition 197.1; D_1 has final endpoint A, and D_2 has A as the displayed initial premise row, so the pair is composable in the sense of Definition 197.9. The row D_{cut} is an accepted* $\mathsf{FirstOrder}^{\uparrow}$ *deduction ledger with the same open-premise rows as D_1 followed by D_2 and final endpoint B, and the comparison between $D_1 +\!\!+ D_2$ and D_{cut} is carried only by the* $\mathsf{FirstOrder}^{\uparrow}$ *deduction classifier of Definition 197.2.*

The row L is an accepted $\mathsf{LambdaCalc}^{\uparrow}$ *term packet in the sense of Definition 200.5. The history x is a displayed unary binder row, a is the lambda-term endpoint classified with the proof ledger D_1,* $\mathsf{lamAbs}(x, b)$ *is the lambda-term endpoint classified with the proof ledger D_2, and u is the lambda-term endpoint classified with D_{cut}. The row r is the displayed beta-redex source*

$$\mathsf{lamApp}(\mathsf{lamAbs}(x, b), a),$$

and s is the capture-avoiding substitution ledger that substitutes a for the unary binder x in b with output endpoint u. The classifier row χ is shared by the two sides: it relates D_1 with a, D_2 with $\mathsf{lamAbs}(x, b)$*, and D_{cut} with u by the same displayed* hsame, Cont*, and provenance rows. The provenance row ρ ties these rows to* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*. No host proof tree, host lambda syntax equality, or quotient of alpha classes is a field of the packet.*

Theorem 265.2 (CurryHowardUp cut-beta bridge obligation)**.** *Let $\mathcal{H}$ be an accepted shared cut-beta packet for* $\mathsf{CurryHoward}^{\uparrow}$ *as in Definition 265.1. If the* $\mathsf{FirstOrder}^{\uparrow}$ *component displays the cut-elimination step from $D_1 +\!\!+ D_2$ to D_{cut}, then the* $\mathsf{LambdaCalc}^{\uparrow}$ *component displays an accepted beta-reduction row whose source is* $\mathsf{lamApp}(\mathsf{lamAbs}(x, b), a)$ *and whose substitution endpoint is u. Under the shared classifier χ, this beta/substitution endpoint is the same proof-program endpoint as the cut-eliminated deduction ledger D_{cut}.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket bridge obligation`

Proof. Unpack the accepted packet $\mathcal{H}$. The $\mathsf{FirstOrder}^{\uparrow}$ side supplies two accepted ledgers D_1 and D_2 over the same syntax carrier, with the final endpoint of D_1 displayed as the initial premise row of D_2. By Definition 197.9, this is exactly the composability datum for the concatenated ledger $D_1 +\!\!+ D_2$.

Apply Definition 197.10. The concatenation is an accepted finite deduction ledger over the same $\mathsf{Set}^{\uparrow}$ and $\mathsf{Tree}^{\uparrow}$ dependency certificates, and the join reads no extra cut formula outside the shared endpoint row A. The displayed cut-elimination row in $\mathcal{H}$ then compares this concatenated ledger with D_{cut} through the deduction classifier. By Definition 197.5 and Definition 197.4, every premise endpoint, conclusion endpoint, and transport row of D_{cut} is therefore a visible $\mathsf{FirstOrder}^{\uparrow}$ carrier or ledger row.

Now read the $\mathsf{LambdaCalc}^{\uparrow}$ side. The term packet L exposes the carried syntax row, binder-index row, beta-redex ledger, substitution ledger, continuation ledger, and provenance listed in Definition 200.5. The redex row r has the displayed source $\mathsf{lamApp}(\mathsf{lamAbs}(x, b), a)$, where the shared classifier χ identifies a with D_1 and $\mathsf{lamAbs}(x, b)$ with D_2.

Apply Definition 200.12 to the substitution row s. It may read only the displayed $\mathsf{Tree}^{\uparrow}$ syntax row, the $\mathsf{Nat}^{\uparrow}$ binder-index row, and the capture-avoidance Cont ledger, so substituting a for x in b produces the displayed endpoint u without importing a host substitution function. By Definition 200.16, the output endpoint u remains a carried LambdaCalc term endpoint.

Finally apply Definition 200.13. The redex row r, the substitution ledger s, the endpoint u, and the provenance row ρ repack as an accepted beta-reduction classifier row, stable under the displayed hsame transport. The shared classifier χ identifies this endpoint u with the proof-program endpoint carried by D_{cut}, while its other two clauses identify the redex components with D_1 and D_2. Hence the displayed deduction-side cut-elimination step is carried to the displayed beta-reduction/substitution ledger under the shared $\mathsf{CurryHoward}^{\uparrow}$ classifier, and no host proof equality or host lambda-term equality enters the bridge. □

Definition 265.3 (CurryHowardUp endpoint classifier)**.** *For accepted shared cut-beta packets $\mathcal{H}$ and $\mathcal{H}'$ as in Definition 265.1, the CurryHowardUp endpoint classifier relates $\mathcal{H}$ and $\mathcal{H}'$ when the following rows hold simultaneously. The* $\mathsf{FirstOrder}^{\uparrow}$ *deduction classifier relates the displayed deduction ledgers $D_1, D_2, D_{\mathsf{cut}}$ of $\mathcal{H}$ with the corresponding ledgers $D'_1, D'_2, D'_{\mathsf{cut}}$ of $\mathcal{H}'$. The* $\mathsf{LambdaCalc}^{\uparrow}$ *beta/substitution classifier relates the displayed term packets, beta-redex rows, substitution ledgers, and output endpoints u, u'. The shared endpoint rows satisfy the displayed* hsame *clauses for the proof-program endpoint P, the cut-formula/type endpoint A, and the conclusion-type endpoint B. The finite provenance row ρ records the common dependence on* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*, with no host proof equality, host lambda equality, or quotient of alpha classes.*

Theorem 265.4 (CurryHoward cut-beta source row separation)**.** *For every accepted shared cut-beta packet $\mathcal{H}$ for* $\mathsf{CurryHoward}^{\uparrow}$*, the* $\mathsf{FirstOrder}^{\uparrow}$ *deduction rows $D_1, D_2, D_{\mathsf{cut}}$ and the* $\mathsf{LambdaCalc}^{\uparrow}$ *beta/substitution rows L, r, s, u project into disjoint source slots. The only common public rows are*

the proof-program BHist *endpoint, the displayed* hsame *endpoint clauses, the finite* Cont *provenance, and the two source rows* $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$.

Consequently the cut-beta bridge identifies neither host proof trees with host lambda terms nor host deduction syntax with host term syntax. It relates the two source rows only through the displayed CurryHoward endpoint and provenance surface.

Proof. Unpack the shared cut-beta packet of Definition 265.1. Its $\mathsf{FirstOrder}^\uparrow$ rows are the deduction ledgers $D_1, D_2, D_{\mathsf{cut}}$, while its $\mathsf{LambdaCalc}^\uparrow$ rows are the term packet, beta-redex row, substitution ledger, and output endpoint. These rows occupy different named fields of the displayed BHist tuple.

Now unfold the endpoint classifier of Definition 265.3. The classifier has one $\mathsf{FirstOrder}^\uparrow$ deduction clause, one $\mathsf{LambdaCalc}^\uparrow$ beta/substitution clause, shared hsame endpoint clauses, and the finite provenance row over the two source certificates. It contains no clause equating a host proof tree with a host lambda term.

Apply Definition 265.5. The common information transported by the bridge is the proof-program endpoint under the displayed hsame and Cont rows.

Finally use Definition 265.8. It says that the classifier surface is exhausted by those displayed deduction, beta/substitution, endpoint, transport, provenance, and source-certificate rows. Hence the source rows remain separated except at the stated public endpoint and provenance surface. □

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket source row separation`

Theorem 265.5 (CurryHowardUp classifier endpoint transport)**.** *Let $\mathcal{H}$ and $\mathcal{H}'$ be accepted shared cut-beta packets for* $\mathsf{CurryHoward}^\uparrow$*. If the CurryHowardUp endpoint classifier of Definition 265.3 relates $\mathcal{H}$ and $\mathcal{H}'$, then the cut-eliminated deduction endpoint and the beta-substitution endpoint transport to the same proof-program endpoint under the shared* hsame *rows.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket classifier endpoint transport`

Proof. Unpack the endpoint classifier. Its $\mathsf{FirstOrder}^\uparrow$ row gives deduction-classifier agreement for the two cut sources, the two cut targets, and the two cut-eliminated ledgers. Apply Definition 197.5 to read the displayed endpoints of D_{cut} and D'_{cut}, and then apply Definition 197.4 to transport those endpoints through the deduction classifier.

Next use the $\mathsf{LambdaCalc}^\uparrow$ row. Apply Definition 200.16 to the two substitution ledgers, so both substitution outputs remain carried LambdaCalc term endpoints. Apply Definition 200.13 to the related beta-redex and substitution rows; the classifier transports u and u' through the same displayed beta/substitution endpoint relation.

It remains to compare the two sides of the bridge. The shared hsame clauses in the endpoint classifier identify the proof-program endpoint, the cut-formula/type endpoint, and the conclusion-type endpoint on the two packets, while the finite Cont provenance row ρ keeps both transports over $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$. Repacking these clauses gives one proof-program endpoint for the cut-eliminated deduction side and the beta-substitution side. □

Theorem 265.6 (CurryHowardUp public NameCert boundary)**.** *The shared cut-beta packet of Definition 265.1, the endpoint classifier of Definition 265.3, the endpoint transport theorem Definition 265.5, and the no-host-equality ledger in the packet definition form the public CurryHowardUp certificate boundary over* $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$.

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket public namecert boundary`

Proof. The carrier part of the boundary is the accepted shared cut-beta packet. It lists the $\mathsf{FirstOrder}^{\uparrow}$ deduction ledgers, the $\mathsf{LambdaCalc}^{\uparrow}$ term packet, the beta-redex row, the substitution ledger, the shared classifier row, and the provenance row as displayed BHist data.

The classifier part is Definition 265.3. It requires agreement on the deduction classifier, beta/substitution classifier, shared hsame endpoint rows, and the finite Cont provenance row. These clauses are all stated over the two source certificates $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$.

The stability and endpoint-exactness part is Definition 265.5. The theorem transports the cut-eliminated deduction endpoint and the beta-substitution endpoint to the same proof-program endpoint, so the public boundary has a certificate-level endpoint row rather than a host equality assertion.

Finally, the packet definition explicitly excludes host proof trees, host lambda syntax equality, and quotients of alpha classes. This no-host-equality ledger is the remaining boundary clause, and the four clauses together give the stated public CurryHowardUp certificate boundary. □

Theorem 265.7 (CurryHoward cut-beta proof-program determinacy)**.** *Let $\mathcal{H}$ and $\mathcal{H}'$ be accepted shared cut-beta packets for* $\mathsf{CurryHoward}^{\uparrow}$ *as in Definition 265.1. Suppose their* $\mathsf{FirstOrder}^{\uparrow}$ *cut-elimination rows,* $\mathsf{LambdaCalc}^{\uparrow}$ *beta-substitution rows, shared* hsame *endpoint rows, and finite* Cont *provenance rows are the same displayed rows under the CurryHoward endpoint classifier of Definition 265.3. Then the cut-eliminated deduction endpoint and the beta-substitution endpoint determine one proof-program endpoint:*

$$(\mathsf{BHist}_{D_{\mathsf{cut}}}, \mathsf{BHist}_u, \mathsf{hsame}_P, \mathsf{Cont}_\rho).$$

This endpoint is a displayed CurryHoward certificate row, not a host equality between proof trees or lambda terms.

Proof. Unpack the two accepted packets by Definition 265.1. The displayed cut-elimination rows fix the $\mathsf{FirstOrder}^{\uparrow}$ ledgers $D_1, D_2, D_{\mathsf{cut}}$ and $D'_1, D'_2, D'_{\mathsf{cut}}$, while the displayed beta-substitution rows fix the redex, substitution ledger, and output endpoints u, u'.

Apply Definition 197.5 to the two cut-eliminated ledgers. Their endpoints are read from the visible deduction rows, so no external proof-tree equality is available or needed. Apply Definition 200.13 to the two beta-substitution rows. Their substitution outputs are accepted beta-reduction classifier endpoints, not host lambda-term quotients.

Now apply Definition 265.5. The CurryHoward endpoint classifier transports the deduction endpoint and the beta-substitution endpoint through the same shared hsame proof-program row and the same finite Cont provenance over $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$.

The common endpoint is therefore obtained by repacking the displayed rows as

$$(\mathsf{BHist}_{D_{\mathsf{cut}}}, \mathsf{BHist}_u, \mathsf{hsame}_P, \mathsf{Cont}_\rho).$$

This is the single proof-program endpoint determined by both readings. The conclusion is a statement about the CurryHoward classifier data itself, so it does not assert equality in the host proof language. □

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket proof program determinacy`

Theorem 265.8 (CurryHoward cut-beta classifier exhaustion)**.** *Every accepted CurryHoward cut-beta endpoint classifier witness of Definition 265.3 projects exactly to the* $\mathsf{FirstOrder}^{\uparrow}$ *deduction classifier rows, the* $\mathsf{LambdaCalc}^{\uparrow}$ *beta/substitution classifier rows, the shared* BHist *proof-program*

endpoint rows, the displayed hsame *transports, finite* Cont *provenance, and the two source certificates* $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$. *Conversely, those rows repack into the same accepted CurryHoward endpoint classifier witness.*

Thus the cut-beta classifier surface is exhausted by displayed deduction, program, endpoint, transport, provenance, and source-certificate rows. It does not read host proof equality, host lambda-term equality, or an alpha-quotient.

Proof. Project an accepted witness through Definition 265.3. Its first clause is precisely the $\mathsf{FirstOrder}^\uparrow$ deduction classifier comparison for $D_1, D_2, D_{\mathsf{cut}}$ and the corresponding rows of the second packet. Its second clause is the $\mathsf{LambdaCalc}^\uparrow$ beta/substitution classifier comparison for the term packets, redex rows, substitution ledgers, and output endpoints.

The remaining clauses of the same definition expose the shared BHist proof-program endpoint rows, the displayed hsame transports for P, A, B, and the finite Cont provenance row ρ. The provenance row names exactly $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$ as the source certificates for the comparison.

Apply Definition 265.5. The projected deduction and beta/substitution rows transport to the same proof-program endpoint under those displayed hsame and Cont rows.

Apply Definition 265.7. The transported endpoint is the displayed CurryHoward proof-program row, so the classifier has no further host equality component to project.

Conversely, given exactly the rows listed above, rebuild the witness by the clauses of Definition 265.3. The transport theorem and determinacy theorem verify that the repacked deduction-side and program-side endpoints are the same displayed proof-program endpoint, which closes the classifier without adding any external quotient. □

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket classifier exhaustion`

Theorem 265.9 (CurryHoward cut-beta endpoint exactness)**.** *Every accepted shared cut-beta packet for* $\mathsf{CurryHoward}^\uparrow$ *projects the cut-eliminated* $\mathsf{FirstOrder}^\uparrow$ *deduction endpoint and the* $\mathsf{LambdaCalc}^\uparrow$ *beta-substitution endpoint to the same displayed proof-program* BHist *row under the shared* hsame *endpoint clauses and finite* Cont *provenance. Conversely, exactly those displayed deduction, beta-substitution, proof-program,* hsame, Cont*, and source-certificate rows repack into the CurryHoward endpoint classifier of Definition 265.3.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket endpoint exactness`

Proof. For the projection direction, start with an accepted shared cut-beta packet. Apply Definition 265.2. It identifies the cut-eliminated deduction ledger D_{cut} with the accepted beta-reduction and substitution endpoint u through the shared classifier row.

Next apply Definition 265.5. The deduction-side endpoint and the program-side endpoint transport along the same displayed hsame proof-program row, with the finite Cont provenance tied to $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$.

Now apply Definition 265.8. It projects the endpoint classifier witness exactly to the deduction classifier rows, beta/substitution classifier rows, shared BHist endpoint rows, hsame transports, finite Cont provenance, and the two source certificates.

For the converse direction, assume exactly those rows are displayed. The exhaustion theorem repacks them by the clauses of Definition 265.3, and the bridge and transport theorems verify that the repacked deduction endpoint and beta-substitution endpoint are the same CurryHoward proof-program row. □

Definition 265.10 (CurryHoward cut-beta obligation package)**.** *The cut-beta obligation package for* $\mathsf{CurryHoward}^{\uparrow}$ *is the finite row family*

$$\mathcal{O}_{\mathsf{cut}\beta} = (\mathcal{H}, \Xi_{\mathsf{src}}, \Xi_{\mathsf{cls}}, \Xi_{\mathsf{end}}, \Lambda_{\mathsf{pp}}, \rho),$$

where $\mathcal{H}$ *is the shared cut-beta packet of Definition 265.1,* Ξ_{src} *is the source surface consisting of the* $\mathsf{FirstOrder}^{\uparrow}$ *ledgers* $D_1, D_2, D_{\mathsf{cut}}$*, the* $\mathsf{LambdaCalc}^{\uparrow}$ *rows* L, r, s, u*, the shared* BHist *endpoints* P, A, B*, and the source certificates* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*,* Ξ_{cls} *is the endpoint classifier of Definition 265.3,* Ξ_{end} *is the cut-beta endpoint row supplied by Definition 265.9,* Λ_{pp} *is the proof-program ledger consisting of the displayed* hsame*,* Cont*, and* Pkg *rows, and* ρ *records the finite provenance over the two source certificates.*

The package exports only displayed BHist *source rows, classifier rows, endpoint rows, and ledger rows. It does not export host proof equality, host lambda-term equality, an alpha quotient, normalization, or categorical semantics.*

Theorem 265.11 (CurryHoward cut-beta source obligation surface)**.** *Every accepted package* $\mathcal{O}_{\mathsf{cut}\beta}$ *of Definition 265.10 projects exactly to the* BHist *source surface consisting of* $D_1, D_2, D_{\mathsf{cut}}$*,* L, r, s, u*, the shared proof-program, cut-formula/type, and conclusion-type endpoints* P, A, B*, the displayed* hsame *and* Cont *rows, and the two source certificates* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*. Conversely, those source rows repack as the source component of the package.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket source obligation surface`

Proof. Project the package to its shared packet coordinate $\mathcal{H}$. By Definition 265.1, the first-order side supplies exactly the deduction ledgers $D_1, D_2, D_{\mathsf{cut}}$, while the lambda side supplies the term packet L, the beta-redex row r, the substitution ledger s, and the output endpoint u.

Apply Definition 265.4. It separates the two source families and states that their only common public rows are the proof-program endpoint, displayed hsame endpoint clauses, finite Cont provenance, and the two source $\mathsf{NameCert}$ rows.

Now apply Definition 265.2. The bridge obligation confirms that the cut-elimination source and beta-reduction source meet at the displayed endpoint surface, not at a host proof tree or host lambda syntax equality.

For the converse direction, assume exactly the listed source rows. The packet definition repacks them as $\mathcal{H}$ and then as Ξ_{src} inside $\mathcal{O}_{\mathsf{cut}\beta}$, with no additional source coordinate. □

Theorem 265.12 (CurryHoward endpoint classifier obligation surface)**.** *The classifier component of every accepted cut-beta obligation package is exhausted by the* $\mathsf{FirstOrder}^{\uparrow}$ *deduction classifier rows, the* $\mathsf{LambdaCalc}^{\uparrow}$ *beta/substitution classifier rows, the shared* BHist *endpoint rows, the displayed* hsame *transports, finite* Cont *provenance, and the source certificates* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*. These rows repack into the same endpoint classifier and determine the common cut-beta endpoint.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket endpoint classifier obligation surface`

Proof. Start from the classifier component Ξ_{cls}. Unfold Definition 265.3. Its clauses are exactly the $\mathsf{FirstOrder}^{\uparrow}$ deduction classifier, the $\mathsf{LambdaCalc}^{\uparrow}$ beta/substitution classifier, the shared endpoint hsame rows, and the finite provenance over the two source certificates.

Apply Definition 265.8. It proves that there are no further classifier fields beyond those deduction, beta/substitution, endpoint, transport, provenance, and source-certificate rows.

Next apply Definition 265.5 and Definition 265.9. These blocks transport the cut-eliminated deduction endpoint and the beta-substitution endpoint to the same displayed proof-program row.

The reverse packaging is the converse half of the classifier exhaustion and endpoint exactness blocks: the displayed rows rebuild the endpoint classifier, and the transport rows determine the common cut-beta endpoint without adding host equality or an alpha quotient. □

Theorem 265.13 (CurryHoward proof-program ledger obligation surface)**.** *The proof-program ledger component of Definition 265.10 consists exactly of the displayed* BHist *proof-program endpoint, the cut-eliminated* $\mathsf{FirstOrder}^{\uparrow}$ *endpoint, the* $\mathsf{LambdaCalc}^{\uparrow}$ *beta-substitution endpoint, the shared* hsame *endpoint clauses, the finite* Cont *provenance, the* Pkg *row, and the source certificates* $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$*. This ledger determines one CurryHoward proof-program endpoint and exports no normalization theorem, host proof equality, host lambda equality, or categorical semantics.*

Proof. Project the ledger component Λ_{pp} from the obligation package. The displayed rows are the proof-program endpoint, the cut-eliminated deduction endpoint, the beta-substitution endpoint, the shared hsame clauses, the finite Cont provenance, and the Pkg row over the two source certificates.

Apply Definition 265.7. With the cut-elimination rows, beta-substitution rows, shared hsame endpoint rows, and finite Cont provenance fixed, the deduction endpoint and the beta-substitution endpoint determine one displayed proof-program endpoint.

Use Definition 265.9 to identify this endpoint as the exact endpoint of the accepted shared cut-beta packet. Then use Definition 265.6 to keep the ledger inside the certificate boundary over $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$.

Since the public boundary and the package definition name no normalization operator, host equality, alpha quotient, or categorical semantic object, the ledger surface is exhausted by the displayed proof-program rows. □

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket proof program ledger obligation surface`

Closure status for $\mathsf{NameCert}_{\mathsf{CurryHoward}^{\uparrow}}$**.**

Constructive story: A Curry-Howard packet is generated by placing $\mathsf{FirstOrder}^{\uparrow}$ deduction ledgers beside $\mathsf{LambdaCalc}^{\uparrow}$ term, beta-redex, and substitution ledgers, then tying them to shared proof-program, cut-formula/type, and conclusion-type endpoint histories. The carrier accepts only shared cut-beta packets whose first-order side displays composable deduction ledgers and a cut-eliminated endpoint, whose lambda side displays the corresponding application of an abstraction to an argument and the capture-avoiding substitution output, and whose common endpoint and provenance are carried by hsame, finite Cont, and the two source certificates. Two packets are classified by the first-order deduction classifier, the lambda beta/substitution classifier, and the shared endpoint rows, so the bridge never identifies host proof trees with host lambda terms or quotients alpha classes. The source is the displayed cut-beta packet over $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^{\uparrow}}$, the pattern records the cut-beta bridge obligation, source-row separation, endpoint transport, public boundary, proof-program determinacy, classifier exhaustion, endpoint exactness, and proof-program ledger surface, and the ledger keeps deduction endpoints, program endpoints, substitution output, shared hsame, Cont, and Pkg provenance visible. The five name-certificate obligations at this seed level are represented by an accepted shared packet for carrier inhabitation, by the two inherited classifiers for reflexivity, symmetry, and transitivity, and by endpoint exactness and classifier exhaustion for closure under classified transport. A history h lies in the signature gap of a $\mathsf{CurryHoward}^{\uparrow}$ token p when the source-domain accepts its cut-beta packet, the signature relation pairs it with an answer packet and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h carries the same deduction ledgers, beta/substitution rows, proof-program endpoint, and provenance encoded by p. The chapter registers this shared cut-beta construction under the name $\mathsf{CurryHoward}^{\uparrow}$; normalization, full Curry-Howard equivalence, host proof equality, host lambda equality, alpha quotient, categorical semantics, and standard bridge data are not introduced.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CurryHoward}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation scope is the shared cut-beta packet, cut-beta bridge obligation, public NameCert boundary, endpoint exactness rows, proof-program ledger surface, Definition 265.14 as the displayed consumer classifier

row, $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$ source certificates, BHist proof-program endpoints, hsame endpoint rows, finite Cont provenance, and Pkg rows.

Bridge status: none

Not claimed: This chapter does not close a full Curry-Howard equivalence, normalization theorem, host proof equality, host lambda-term equality, alpha quotient, categorical semantics, or standard bridge data.

Upgrade path: No further paper theory-axis grade remains; bridgeChecked status is a formal-axis matter for the displayed cut-beta surface.

Theorem 265.14 (CurryHoward cut-beta endpoint classifier reflexivity)**.** *Let*

$$\mathcal{H} = (P, A, B, D_1, D_2, D_{\mathsf{cut}}, x, a, b, u, L, r, s, \chi, \rho)$$

be an accepted shared cut-beta packet for $\mathsf{CurryHoward}^\uparrow$ *as in Definition 265.1. Then the CurryHowardUp endpoint classifier of Definition 265.3 relates* $\mathcal{H}$ *to itself. The witnessing classifier row is obtained from the rowwise reflexive* hsame *comparisons on* $P, A, B, D_1, D_2, D_{\mathsf{cut}}, L, r, s, u$ *together with the unchanged finite* Cont *and provenance row* ρ*.*

Lean4 ✓ `BEDC.Derived.CurryHowardUp.CurryHowardCutBetaPacket endpoint classifier reflexive`

Proof. Unpack the accepted packet of Definition 265.1. Its first-order coordinates are the accepted deduction ledgers $D_1, D_2, D_{\mathsf{cut}}$ over the same carried syntax packet, and its lambda coordinates are the accepted term packet L, the displayed beta-redex row r, the substitution ledger s, and the endpoint u.

For the first-order classifier clause, apply the rowwise classifier of Definition 197.2 to the pairs (D_1, D_1), (D_2, D_2), and $(D_{\mathsf{cut}}, D_{\mathsf{cut}})$. The symbol rows, parse-tree rows, formula endpoints, premise endpoints, conclusion endpoints, and deduction-step ledgers are the same displayed rows on the two sides. Hence the required transports are the componentwise reflexive hsame rows, with the same $\mathsf{Set}^\uparrow$ and $\mathsf{Tree}^\uparrow$ certificate provenance and the same finite Cont ledgers.

For the lambda classifier clause, use the accepted term packet L of Definition 200.5. The source redex is the same displayed row

$$\mathsf{lamApp}(\mathsf{lamAbs}(x, b), a),$$

and the substitution ledger is the same ledger s with output endpoint u. Apply Definition 200.13 with reflexive hsame transport on the carried $\mathsf{Tree}^\uparrow$ syntax row, the carried $\mathsf{Nat}^\uparrow$ binder-index row, the redex row, the substitution endpoint, and the Pkg provenance. The transported beta/substitution row therefore repacks as the original beta/substitution row.

The shared endpoint clauses of Definition 265.3 are filled by the reflexive hsame rows on the proof-program endpoint P, the cut-formula/type endpoint A, and the conclusion-type endpoint B. The provenance clause is the same finite row ρ over $\mathsf{NameCert}_{\mathsf{FirstOrder}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{LambdaCalc}^\uparrow}$.

Repacking these four families of rows gives exactly the CurryHoward endpoint classifier witness from $\mathcal{H}$ to $\mathcal{H}$. Since every component is projected from the accepted packet and returned through the displayed hsame, Cont, and provenance fields, the reflexive classifier row exports no host proof equality, host lambda equality, or quotient of alpha classes. □

Chapter 266

A Concrete Naming Certificate for $\mathsf{RiemannHilbert}^{\uparrow}$

The Riemann-Hilbert interface $\mathsf{RiemannHilbert}^{\uparrow}$ packages the equivalence between regular holonomic D-modules on a complex manifold and perverse sheaves of $\mathbb{C}$-vector spaces. It depends on $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$ (chapter 177) and $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ (chapter 151), and bridges differential and topological certificates through a common derived classifier.

266.1 Carrier definition

Definition 266.1 (Riemann-Hilbert BHist bridge packet)**.** *A* $\mathsf{RiemannHilbert}^{\uparrow}$ *carrier is a finite* BHist *bridge packet whose rows are the following data.*

1. *A derived-functor source row from* $\mathsf{NameCert}_{\mathsf{DerivedFunctor}^{\uparrow}}$*, including the displayed source object, derived endpoint, degree or cohomological index row, and exact-triangle provenance carried by the derived-functor ledger.*
2. *A sheaf target row from* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$*, read as a perverse-sheaf or constructible-sheaf target over the same displayed base histories, with its section, restriction, locality, and gluing rows visible as* BHist *data.*
3. *A regular-holonomic source classifier row saying that the differential source lies on the regular-holonomic branch of the derived-functor packet and can be compared only through the displayed classifier and* hsame *transport rows.*
4. *Transport rows matching the derived source, sheaf target, de Rham readback, local-system branch, and regular-holonomic classifier by* hsame*.*
5. Cont *provenance rows explaining how the derived source is read to the sheaf target, how local horizontal sections are read as local-system rows, and how gluing reads back through the* $\mathsf{Sheaf}^{\uparrow}$ *exactness ledger.*
6. Pkg *rows naming the* $\mathsf{DerivedFunctor}^{\uparrow}$ *and* $\mathsf{Sheaf}^{\uparrow}$ *dependency certificates, together with the public dependency boundary consumed by the bridge packet.*

The carrier records only this displayed BEDC packet. It does not contain an external derived category, analytic D-module model, sheaf quotient, monodromy equivalence, or host-level Riemann-Hilbert theorem.

Lean4 (definition) `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket`

266.2 The certificate

Theorem 266.2 (Riemann-Hilbert derived-sheaf source)**.** *Every accepted* RiemannHilbert$^{\uparrow}$ *packet exposes a derived-functor source row and a sheaf target row exactly as in Definition 266.1. The source side is the displayed* DerivedFunctor$^{\uparrow}$ *row with its exact-triangle and degree provenance, and the target side is the displayed* Sheaf$^{\uparrow}$ *row with its section, restriction, locality, and gluing ledger. No external derived category, analytic solution functor, or host sheaf quotient is projected by the source boundary.*

Lean4 ✓ `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket derived sheaf source`
Lean4 ✓ `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket source boundary`

Proof. Project the accepted packet to its first two carrier coordinates. The definition gives the DerivedFunctor$^{\uparrow}$ source row, including the derived endpoint and exact-triangle provenance, and the Sheaf$^{\uparrow}$ target row, including section, restriction, locality, and gluing data.

The remaining carrier coordinates are comparison, continuation, and package rows attached to those two projections. Since the carrier has no coordinate for an ambient derived category, analytic solution functor, or host sheaf quotient, the source boundary is exactly the displayed pair of BEDC rows. □

Lean4 ✓ `BEDC.Derived.RiemannHilbertUp.RiemannHilbertDerivedSheafSource composite boundary`

Theorem 266.3 (Riemann-Hilbert flat-connection classifier)**.** *The flat-connection branch of a* RiemannHilbert$^{\uparrow}$ *packet is classified only through the regular-holonomic source classifier, the local-system sheaf row, and the displayed* hsame *transports between the derived source, de Rham readback, and sheaf target. If two accepted packets agree on those rows, then they have the same visible flat-connection classifier surface.*

Lean4 ✓ `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket flat connection classifier`

Proof. Read the regular-holonomic classifier coordinate from Definition 266.1. It is the only row that marks the differential source branch and it is already tied to the derived-functor packet.

Next project the hsame rows matching the derived source, de Rham readback, local-system branch, and sheaf target. Agreement on these rows forces the same visible comparison surface after transport, because every local-system read is mediated by the displayed Cont provenance rather than by a host flat-connection object. □

Theorem 266.4 (Riemann-Hilbert local-system ledger)**.** *The local-system ledger exported by a* RiemannHilbert$^{\uparrow}$ *packet consists exactly of the sheaf target row, the local horizontal-section read rows, the* hsame *comparisons tying them to the derived source and de Rham readback, and the* Cont/Pkg *provenance naming the* DerivedFunctor$^{\uparrow}$ *and* Sheaf$^{\uparrow}$ *dependencies. It exports no monodromy representation, covering-space quotient, or external equivalence row.*

Proof. Project the local-system branch from the sheaf target and continuation coordinates of the carrier. The carrier definition lists the horizontal-section reads, their comparison rows, and the dependency packages that make the read visible to downstream consumers.

Constructor inspection of the displayed packet gives the exclusion claim. The rows generate local-system information only through Sheaf$^{\uparrow}$ sections, restrictions, locality, gluing, and Cont provenance; there is no constructor slot for a monodromy representation, covering-space quotient, or external equivalence. □

Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket local system ledger
Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertLocalSystemLedger continuation closure

Theorem 266.5 (Riemann-Hilbert regular-holonomic soundness)**.** *The regular-holonomic soundness boundary of* $\mathsf{RiemannHilbert}^{\uparrow}$ *is the conjunction of the derived-functor source row, the regular-holonomic source classifier row, the de Rham readback transport, and the sheaf target classifier row. A downstream consumer can read a regular-holonomic conclusion only by projecting these rows from the bridge packet.*

Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket regular holonomic soundness

Proof. Use Definition 266.2 to identify the source and target rows available to the packet. The source contributes the derived-functor endpoint and exact-triangle provenance, while the target contributes the sheaf classifier and gluing ledger.

Use Definition 266.3 for the classifier transport. The regular-holonomic branch is stable only along the displayed hsame and de Rham readback rows, so any consumer conclusion must be a projection from those rows together with the source and target packets. □

Theorem 266.6 (Riemann-Hilbert sheaf-gluing exactness)**.** *For a* $\mathsf{RiemannHilbert}^{\uparrow}$ *bridge packet, compatible local-system rows glue exactly through the* $\mathsf{Sheaf}^{\uparrow}$ *target ledger carried in Definition 266.1. The resulting global sheaf row remains tied to the same derived-functor source, regular-holonomic classifier,* hsame *transport rows,* Cont *provenance, and* Pkg *dependency rows.*

Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket sheaf gluing exactness

Proof. Project the $\mathsf{Sheaf}^{\uparrow}$ locality and gluing coordinates from the target row. Compatible local-system rows are sheaf rows in this packet, so gluing is performed by the displayed sheaf exactness ledger rather than by an external sheafification operation.

After gluing, project the comparison and provenance coordinates again. They still name the same derived-functor source, regular-holonomic classifier, hsame transports, continuation routes, and dependency packages, so the glued target remains inside the original $\mathsf{RiemannHilbert}^{\uparrow}$ carrier. □

Theorem 266.7 (Riemann-Hilbert de Rham readback scope)**.** *Every de Rham readback row in an accepted* $\mathsf{RiemannHilbert}^{\uparrow}$ *bridge packet is sourced only from the displayed* $\mathsf{DerivedFunctor}^{\uparrow}$ *source row, the regular-holonomic classifier row, the* $\mathsf{Sheaf}^{\uparrow}$ *target row, the local-system ledger, the displayed* hsame *transports, the* Cont *provenance, and the* Pkg *dependency rows. It exports no analytic solution functor, monodromy equivalence, host derived-category quotient, or external perverse-sheaf equivalence.*

Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket de rham readback scope
Lean4 ✓ BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket deRham readback scope
↪ variant BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket de Rham readback scope

Proof. Use Definition 266.2 to identify the dependency rows available to the packet: the $\mathsf{DerivedFunctor}^{\uparrow}$ source row and the $\mathsf{Sheaf}^{\uparrow}$ target row with their displayed provenance. Use Definition 266.3 for the regular-holonomic classifier and its de Rham transport row.

Next use Definition 266.4 to bind the local-system ledger to the same sheaf target, horizontal-section read rows, hsame comparisons, and Cont/Pkg provenance. Use Definition 266.6 to keep those rows stable under sheaf gluing.

Finally inspect the constructors of Definition 266.1. The carrier has slots only for the displayed source, classifier, target, transport, continuation, and package rows, so a de Rham readback row cannot export an analytic solution functor, monodromy equivalence, host derived-category quotient, or external perverse-sheaf equivalence. □

Theorem 266.8 (Riemann-Hilbert public certificate export)**.** *The bridge packet of Definition 266.1 exports exactly the derived-functor source row, the sheaf target row, the regular-holonomic classifier row, the local-system ledger, the de Rham readback scope, the displayed* hsame *transports, the* Cont *provenance, and the* Pkg *dependency rows listed in Definition 266.2, Definition 266.5, Definition 266.4, Definition 266.6, and Definition 266.7. These rows form the public* $\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$ *surface. No host derived-category quotient, analytic solution functor, monodromy equivalence, or external perverse-sheaf equivalence is exported.*

Lean4 ✓ `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket public certificate export`

Proof. Project the bridge packet to the derived-functor and sheaf coordinates. By Definition 266.2, these projections give the displayed source row and target row with their exact-triangle, section, restriction, locality, and gluing provenance.

Next project the classifier, local-system, and gluing rows. The regular-holonomic classifier is the one isolated by Definition 266.5; the local-system ledger is the one isolated by Definition 266.4; and the gluing stability is the row supplied by Definition 266.6.

Finally add the de Rham readback projection from Definition 266.7. Repacking these projections gives the public $\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$ surface, and constructor inspection of the same packet shows that no additional host derived-category quotient or analytic solution functor has a row to export. □

Closure status for $\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$.

Constructive story: A $\mathsf{RiemannHilbert}^{\uparrow}$ packet is assembled from the displayed $\mathsf{DerivedFunctor}^{\uparrow}$ source row, $\mathsf{Sheaf}^{\uparrow}$ target row, regular-holonomic classifier, local-system ledger, de Rham readback, hsame transports, Cont routes, and Pkg provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 266.8 gives the public exported surface over the displayed $\mathsf{DerivedFunctor}^{\uparrow}$ source row, $\mathsf{Sheaf}^{\uparrow}$ target row, regular-holonomic classifier, local-system ledger, de Rham readback, hsame transport, Cont provenance, and Pkg dependency rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RiemannHilbertUp.RiemannHilbertBHistBridgePacket\_public\_certificate\_export`

Bridge status: none

Not claimed: This chapter does not close external derived categories, analytic $\mathcal{D}$-module models, monodromy equivalence, or a host-level Riemann-Hilbert theorem.

Upgrade path: Paper-axis maturity is complete for the displayed public certificate export; only machine bridge checking remains on the formal axis.

Chapter 267

A Concrete Naming Certificate for $\mathsf{KoszulDuality}^{\uparrow}$

The Koszul-duality interface $\mathsf{KoszulDuality}^{\uparrow}$ packages the contravariant derived equivalence between graded algebras of finite global dimension and their Koszul-dual algebras. It depends on $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ (chapter 160) and $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$ (chapter 87), and bridges algebraic and homological certificates through the same Ext-classifier.

267.1 Carrier definition

Definition 267.1 (KoszulDuality BHist Ext carrier)**.** *A* $\mathsf{KoszulDuality}^{\uparrow}$ *carrier is a finite* BHist *package consisting of four visible rows. The first row is a* $\mathsf{DerivedCat}^{\uparrow}$ *object row naming the source graded algebra object and its displayed derived-category endpoint. The second row is a* $\mathsf{TensorProduct}^{\uparrow}$ *graded tensor row naming the tensor surface used to form the dual algebra side. The third row is the displayed* Ext*-classifier row comparing the derived object row with the graded tensor row through their certificate dependencies. The fourth row is a variance ledger recording that the dual row reverses source and target order contravariantly.*

The carrier is this finite packet of rows and endpoint data. It contains no quotient derived category, no chosen representative, no external equivalence object, and no host-level model of Koszul duality outside the displayed BHist *ledger.*

Lean4 (definition) `BEDC.Derived.KoszulDualityUp.KoszulDualityBHistExtCarrier`

Theorem 267.2 (KoszulDuality Ext classifier stability)**.** *Let two* $\mathsf{KoszulDuality}^{\uparrow}$ *carrier packets have derived-category rows and graded tensor rows related by displayed* hsame *classifiers from* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{TensorProduct}^{\uparrow}}$*. If the* Ext*-classifier row in the first packet is read only through those two dependency certificates and the visible variance ledger, then the same* Ext*-classifier package repacks over the transported rows, and the contravariant dual row is accepted in the transported packet.*

Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityExtCarrier classifier stability`

Proof. Project the derived-category dependency certificate from the source packet. It transports the source object endpoint and all displayed derived rows through the listed hsame comparison.

Project the graded tensor dependency certificate in the same way. The tensor surface is transported as a certificate row, so the target-side endpoint used by the dual algebra surface is still available after transport.

Replay the Ext-classifier ledger with these two transported rows. The classifier has no independent carrier beyond the two projected dependency rows and the variance tag, so it repacks over the transported endpoints.

Finally read the contravariant tag. Since the tag records only reversal of source and target order, the transported dual row is accepted by the same finite ledger with the order reversed. □

Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityBHistExtCarrier ext classifier stability`

Theorem 267.3 (KoszulDuality derived tensor ledger exactness)**.** *For every accepted* $\mathsf{KoszulDuality}^{\uparrow}$ *carrier, the ledger exposes exactly the* $\mathsf{DerivedCat}^{\uparrow}$ *object row, the* $\mathsf{TensorProduct}^{\uparrow}$ *graded tensor row, the displayed* Ext*-classifier row, and the variance tag recording contravariant source-target reversal. No quotient category, chosen representative, external equivalence object, triangulated enhancement, or model-category localization is exported by the carrier.*

Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityDerivedTensorLedger exactness`

Proof. Inspect the carrier of Definition 267.1. Its accepted rows are the derived object row, graded tensor row, Ext-classifier row, and variance ledger.

The dependency certificates may be projected only through the rows named in the packet. The derived side contributes the object endpoint, and the tensor side contributes the graded tensor endpoint.

The Ext row is then a displayed classifier between those projected endpoints. Since no further constructor is present in the packet, none of the excluded host objects can be read from the accepted carrier. □

Theorem 267.4 (KoszulDuality NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{KoszulDuality}^{\uparrow}}$ *surface is the package consisting of the carrier of Definition 267.1, the displayed* Ext *classifier, the stability clause of Definition 267.2, the exact ledger of Definition 267.3, and the source coverage assertion that every accepted duality row is read from the displayed derived-category row, graded tensor row, classifier row, and variance tag.*

Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityBHistExtCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityExtCarrier semantic name certificate`

Proof. Use the carrier definition as the source predicate for the local certificate. It supplies precisely the finite BHist rows that the certificate is allowed to classify.

The classifier row is the displayed Ext row. Its transport obligation is supplied by Definition 267.2, which repacks the same classifier after the two dependency certificates transport their rows.

The ledger and source-coverage obligations are supplied by Definition 267.3. Together they say that every accepted row is visible in the finite package and that no host duality structure is added by the certificate boundary. □

Theorem 267.5 (KoszulDuality bridge boundary exclusions)**.** *The* $\mathsf{KoszulDuality}^{\uparrow}$ *boundary supplies only the BEDC* Ext*-classifier correspondence between the displayed* $\mathsf{DerivedCat}^{\uparrow}$ *and* $\mathsf{TensorProduct}^{\uparrow}$ *rows. It does not assert a full derived equivalence, a triangulated enhancement, a model-category localization, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.KoszulDualityUp.KoszulDualityBHistExtCarrier bridge boundary exclusions`

Proof. Read the public boundary through Definition 267.4. The available data are carrier, classifier, stability, ledger exactness, and source coverage.

Each of those rows factors through the finite Definition 267.1 packet. That packet contains the dependency rows and the variance tag, but it contains no object representing a host derived equivalence or any localization apparatus.

Therefore the boundary exports the stated BEDC classifier correspondence and nothing beyond the displayed rows. □

Theorem 267.6 (KoszulDuality standard derived-tensor bridge)**.** *Any standard bridge for the public* $\mathsf{KoszulDuality}^{\uparrow}$ *packet is restricted to the displayed* $\mathsf{DerivedCat}^{\uparrow}$ *source row, the* $\mathsf{TensorProduct}^{\uparrow}$ *graded tensor row, the* Ext*-classifier row, the variance ledger, the* hsame *transport, the* Cont *routes, the* Pkg *provenance, and the* NameCert *surface already isolated by the public certificate. It does not supply a full derived equivalence, a triangulated enhancement, a model-category localization, or a host quotient.*

Proof. Combine Definition 267.4 with Definition 267.5. The obligation surface lists the carrier, classifier, stability, ledger exactness, and source coverage rows, while the exclusions identify which host structures are absent from that public packet.

Repack the same finite BHist and Ext rows as the standard bridge boundary. The bridge has no independent coordinate beyond the displayed derived-category row, tensor row, classifier row, variance ledger, transports, routes, provenance, and naming surface.

Therefore a full derived equivalence, a triangulated enhancement, a model-category localization, and a host quotient remain outside the exported bridge boundary. □

Theorem 267.7 (KoszulDuality mature Ext-bridge boundary)**.** *Every finite consumer of the bridged* $\mathsf{KoszulDuality}^{\uparrow}$ *packet factors through the displayed* $\mathsf{DerivedCat}^{\uparrow}$ *source row,* $\mathsf{TensorProduct}^{\uparrow}$ *graded tensor row,* Ext*-classifier row, variance ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and* NameCert *surface isolated by Definition 267.6 and Definition 267.4.*

The boundary contains no full derived equivalence, triangulated enhancement, model-category localization, host quotient data, or machine-checked bridge evidence.

Proof. First apply Definition 267.4. It exposes the carrier, classifier, stability, ledger exactness, and source coverage rows as one finite $\mathsf{NameCert}_{\mathsf{KoszulDuality}^{\uparrow}}$ surface.

Next use Definition 267.5. The exclusion boundary removes full derived equivalence data, triangulated enhancement, model-category localization, and host quotients from the available packet rows.

Finally apply Definition 267.6. Any finite bridged consumer therefore reads only the displayed derived source, graded tensor, Ext classifier, variance, transport, route, provenance, and naming rows already present in the public packet. □

267.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{KoszulDuality}^{\uparrow}}$.

Constructive story: A $\mathsf{KoszulDuality}^{\uparrow}$ seed packet is generated from a displayed $\mathsf{DerivedCat}^{\uparrow}$ source row, a displayed $\mathsf{TensorProduct}^{\uparrow}$ graded tensor row, an Ext-classifier row tying those dependencies together, and a variance ledger recording contravariant source-target reversal. The carrier reads only this finite BHist packet; classifier stability, ledger exactness, source coverage, and the standard derived-tensor bridge boundary are paper-side obligations over the same rows, while quotient derived categories, host equivalences, triangulated enhancements, and model-category localizations are absent from the exported surface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KoszulDuality}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridged semantic NameCert surface of Definition 267.4 and the standard derived-tensor bridge of Definition 267.6 bind the BHist/Ext carrier, classifier stability, derived tensor ledger exactness, source coverage, and bridge-boundary exclusions over the displayed DerivedCat$^{\uparrow}$ and TensorProduct$^{\uparrow}$ rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{KoszulDuality}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.KoszulDualityUp.KoszulDualityExtCarrier\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not claim a full derived equivalence, a triangulated or model-category presentation, host quotient data, or machine-checked bridge evidence for KoszulDuality$^{\uparrow}$.

Upgrade path: No further theory-axis upgrade is available for this chapter; bridgeChecked status remains a verification-axis upgrade.

Chapter 268

A Concrete Naming Certificate for $\mathsf{Langlands}^{\uparrow}$

The Langlands-correspondence interface $\mathsf{Langlands}^{\uparrow}$ packages the conjectural bijection between n-dimensional Galois representations of a global field and irreducible automorphic representations of GL_n matching local L-factors at almost all places. It depends on $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ (chapter 164) and $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ (chapter 104), and bridges Galois and automorphic certificates through a common L-factor classifier.

268.1 Carrier definition

Definition 268.1 (Langlands correspondence ledger carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *source row, a* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *source row, and a finite list of observed places at which both sources expose local factor answers. A* $\mathsf{Langlands}^{\uparrow}$ *correspondence carrier row is the* BHist *ledger row consisting of the two source certificates, the visible Galois and automorphic answer histories at the selected places, the local L-factor package rows read from those answers, and the* Cont *witnesses that place the paired local rows inside one finite observation packet.*

The carrier records only the observed packet. It does not assert an all-place correspondence, irreducibility, analytic continuation, functoriality, or uniqueness beyond the displayed finite BHist *ledger.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsBHistCorrespondenceCarrier source rows`

Definition 268.2 (Langlands local factor classifier)**.** *Two rows of Definition 268.1 are classified as the same* $\mathsf{Langlands}^{\uparrow}$ *packet exactly when their visible local L-factor packages are matched place by place, their source certificate rows are transported through the corresponding* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *classifiers, and their answer histories are related by the available* hsame, Cont, *and* Pkg *witnesses.*

Equivalently, the classifier is the least relation generated by source-certificate transport, answer-history transport, local package agreement, and finite concatenation of the observed place rows. No hidden global correspondence row is a generator of the classifier.

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsLFactorClassifier observed packet rows`

268.2 The certificate

Theorem 268.3 (Langlands source certificate scope)**.** *Every carried* $\mathsf{Langlands}^{\uparrow}$ *packet of Definition 268.1 has exactly two external source certificate dependencies: one* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *row and one* $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ *row. All remaining data in the packet are finite answer histories, local L-factor package rows, and the* hsame*,* Cont*, and* Pkg *witnesses that connect those rows.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsCorrespondenceLedger source certificate scope`

Proof. Unpack the carrier row. Its first two fields are the Galois and automorphic source certificates, and each observed place contributes only the two visible answer histories and the local package rows read from them.

The classifier of Definition 268.2 transports these fields through the two source NameCert classifiers and through the displayed history and package witnesses. Since no constructor introduces a third source certificate or a global host theorem, the stated scope is exact. □

Theorem 268.4 (Langlands local factor stability)**.** *If two carried* $\mathsf{Langlands}^{\uparrow}$ *packets are classified by Definition 268.2, then replacing either source representative by a* NameCert*-classified representative and replacing any visible local answer by an* hsame*-related answer preserves the classified local L-factor packet.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsLocalFactor stability`

Proof. First transport the source side. The $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Automorphic}^{\uparrow}}$ rows supply the certificate-level replacement witnesses, and the carrier keeps the transported rows inside the same finite observation packet by Cont.

Next transport the local factor rows. At each observed place, the classifier stores the package comparison as a Pkg row and the answer-history comparison as an hsame row. Finite concatenation of these rows gives a classifier witness for the whole packet after the replacement. □

Theorem 268.5 (Langlands correspondence obligation package)**.** *The* $\mathsf{Langlands}^{\uparrow}$ *chapter exports a finite correspondence obligation package: a carrier row, a local factor classifier row, the two source certificate rows, and the ledger exactness statement that the packet hides only the finite observed matching row. It does not claim a global Langlands correspondence theorem.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsCorrespondenceCarrier semantic name certificate`
Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsLFactorClassifier endpoint confluence`

Proof. Build the package from a carried row and its classifier witness. The carrier supplies the observed Galois answer rows, automorphic answer rows, local package rows, and Cont links. The classifier supplies the source transport and the visible place-by-place package comparisons.

Ledger exactness is obtained by inverting these two displayed structures. Every accepted datum is either one of the two source certificates, a finite answer history, a local factor package row, or a transport witness already named by hsame, Cont, Pkg, or NameCert. Hence the package contains no hidden all-place bijection or analytic assertion. □

Theorem 268.6 (Langlands finite local-factor public surface)**.** *The public surface exported by* $\mathsf{Langlands}^{\uparrow}$ *is exactly the finite local L-factor packet of Definition 268.5. A downstream consumer may read the two source certificates, the observed Galois and automorphic answer histories, the local L-factor package rows, and the displayed* hsame*,* Cont*, and* Pkg *witnesses connecting those rows. The same consumer cannot read an all-place bijection, irreducibility, analytic continuation, functoriality, or uniqueness from this surface.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsCorrespondenceLedger public endpoint boundary`
Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsCorrespondenceLedger finite local factor public surface`
Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsBHistCorrespondenceCarrier finite local factor public surface`
Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsBHistCorrespondenceCarrier public surface`

Proof. Start with Definition 268.3. It projects any accepted packet to the two named source certificates and to the finite answer and package rows carried at the observed places.

Next apply Definition 268.4. Source replacement and visible local-answer transport preserve the classified L-factor packet through the displayed hsame, Cont, and Pkg rows.

Finally use Definition 268.5. Its ledger exactness clause says that every readable row is already one of the listed certificate, history, local package, or witness rows, so the excluded global and analytic assertions have no carrier coordinate in the public surface. □

Theorem 268.7 (Langlands generated rows are unary)**.** *Every generated row of* LanglandsBHistCorrespondenceCarr *is a finite unary* BHist *row. The two source certificate rows, the visible Galois and automorphic answer rows, the local factor package rows, and the* Cont/Pkg *ledger rows are all read through the displayed finite observation packet of Definition 268.1.*

Lean4 ✓ `BEDC.Derived.LanglandsUp.LanglandsBHistCorrespondenceCarrier generated rows unary`

Proof. Unpack Definition 268.1. The carrier has two source certificate entries and then a finite list of observed-place entries. By Definition 268.3, those source entries are exactly the $\mathsf{NameCert}_{\mathsf{GaloisGroup}^\uparrow}$ and $\mathsf{NameCert}_{\mathsf{Automorphic}^\uparrow}$ rows, while each observed place contributes only the displayed answer histories and the local package rows read from them.

Apply Definition 268.5 to the same packet. The obligation package exposes no further generator: its remaining entries are the hsame, Cont, and Pkg rows already named by the finite ledger. Projecting each ledger entry therefore gives one unary BHist row, and finite ledger projection exhausts the generated carrier rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{Langlands}^\uparrow}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Langlands}^\uparrow}$, publicClosed)

Scope closed: The obligation scope is the finite local L-factor packet over $\mathsf{NameCert}_{\mathsf{GaloisGroup}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{Automorphic}^\uparrow}$, visible BHist answer histories, hsame, Cont, Pkg, and the displayed source certificate rows.

Constructive story: A Langlands$^\uparrow$ packet is built by pairing one displayed Galois source certificate with one displayed automorphic source certificate, reading the visible local L-factor rows place by place, and recording only the finite history, continuation, package, and certificate-transport witnesses named in the carrier and classifier.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Langlands}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.LanglandsUp.LanglandsBHistCorrespondenceCarrier\_finite\_local\_factor\_public\_surface`

Bridge status: none

Not claimed: This chapter does not claim a global Langlands correspondence, an all-place bijection, irreducibility, analytic continuation, functoriality, or uniqueness.

Upgrade path: Bridge closure requires a standard finite local-factor bridge for the exported public packet.

Chapter 269

A Concrete Naming Certificate for $\mathsf{NoetherSymmetry}^{\uparrow}$

The Noether-symmetry interface $\mathsf{NoetherSymmetry}^{\uparrow}$ packages the bijection between continuous symmetries of a Lagrangian and conserved currents along solutions of the Euler-Lagrange equations. It depends on $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ (chapter 141) and $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$ (chapter 194), and bridges algebraic and analytic certificates through the same conservation-law ledger.

269.1 Carrier definition

Definition 269.1 (Noether-symmetry conservation-ledger carrier)**.** *A* $\mathsf{NoetherSymmetry}^{\uparrow}$ *conservation-ledger carrier is a finite* BHist *row containing a* $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ *infinitesimal symmetry source, a* $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$ *Euler-Lagrange source, a displayed current history, and named* hsame, Cont, *and* Pkg *witnesses placing the current under both sources. The carrier also records the finite source-domain token that says the Lie-algebra row acts on the same displayed field history whose Euler-Lagrange equation is carried by the PDE row.*

The carrier is only this finite certificate surface. It does not assert a global Noether bijection, smooth variational calculus, an analytic action functional, or a standard model of conservation laws.

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryTasteGate single carrier alignment`

Definition 269.2 (Noether-symmetry current classifier)**.** *Two rows of Definition 269.1 are classified as the same* $\mathsf{NoetherSymmetry}^{\uparrow}$ *observation when their* $\mathsf{LieAlgebra}^{\uparrow}$ *infinitesimal-symmetry sources are transported by* $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$*, their* $\mathsf{Pde}^{\uparrow}$ *Euler-Lagrange sources are transported by* $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$*, and their displayed current histories and dependency ledgers are matched by* hsame, Cont, *and* Pkg.

The classifier is generated by source transport and finite current-ledger transport. It has no generator for equality of smooth fields, integration by parts in a host calculus, or a bijective correspondence between all symmetries and all conserved currents.

Lean4 (definition) `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryCurrentClassifier`

269.2 The certificate

Theorem 269.3 (Noether-symmetry Lie-PDE source boundary)**.** *Every row of Definition 269.1 exposes a finite* $\mathsf{LieAlgebra}^{\uparrow}$ *infinitesimal-symmetry source, a finite* $\mathsf{Pde}^{\uparrow}$ *Euler-Lagrange source, and the displayed current row attached to their shared field-history boundary by* Cont *and* Pkg *witnesses.*

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier source boundary`

Proof. Invert the carrier definition. The Lie-algebra source, the PDE source, the current history, and the source-domain token are explicit fields of the finite BHist row.

The only boundary comparisons available in the carrier are the named hsame, Cont, and Pkg witnesses. Therefore the shared field-history boundary is read from those finite rows, not from a smooth variational model or from global conservation-law semantics. □

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier lie pde source boundary`

Theorem 269.4 (Noether-symmetry conservation-ledger stability)**.** *If two* $\mathsf{NoetherSymmetry}^{\uparrow}$ *rows are classified by Definition 269.2, then transport of the* $\mathsf{LieAlgebra}^{\uparrow}$ *infinitesimal-symmetry source, transport of the* $\mathsf{Pde}^{\uparrow}$ *Euler-Lagrange source, and transport of the displayed current through* hsame*,* Cont*, and* Pkg *preserve the same conservation-ledger carrier.*

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier stability`

Proof. Transport the two source rows first. The $\mathsf{NameCert}_{\mathsf{LieAlgebra}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Pde}^{\uparrow}}$ classifiers supply transported source histories while keeping the displayed field-history boundary visible in the finite ledger.

Then transport the current row and its dependency witnesses through hsame, Cont, and Pkg. These are exactly the generators listed in Definition 269.2, so the transported packet is again a row of Definition 269.1. □

Theorem 269.5 (Noether-symmetry NameCert obligation surface)**.** *The* $\mathsf{NoetherSymmetry}^{\uparrow}$ *chapter exports a NameCert obligation surface consisting of the conservation-ledger carrier of Definition 269.1, the current classifier of Definition 269.2, the finite* $\mathsf{LieAlgebra}^{\uparrow}$ *infinitesimal-symmetry source, the finite* $\mathsf{Pde}^{\uparrow}$ *Euler-Lagrange source, the displayed conservation-current row, and the* BHist*,* hsame*,* Cont*,* Pkg*, and NameCert rows that connect those fields.*

The surface does not claim a global Noether bijection, smooth variational calculus, equality in a standard analytical model, or completeness of all conserved currents.

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier namecert obligation surface`

Proof. Assemble the surface from one carried row and one classifier witness. The carried row supplies the Lie-algebra source, PDE source, current history, source-domain token, and dependency ledger; the classifier supplies only source transport and finite current-ledger transport.

Conversely, every exported row appears in one of those fields or in the transport witnesses named by the classifier. Thus a downstream chapter may consume the finite BHist and NameCert obligation surface, but it cannot read off a global Noether correspondence or an analytic variational calculus from this certificate alone. □

Theorem 269.6 (Noether-symmetry finite-current public export)**.** *The accepted finite conservation-current package for* $\mathsf{NoetherSymmetry}^{\uparrow}$ *exports exactly the* BHist *conservation-ledger carrier of Definition 269.1, the current classifier of Definition 269.2, the Lie-PDE source boundary of Definition 269.3, the stability row of Definition 269.4, and the* NameCert *obligation surface of Definition 269.5.*

The exported public row exposes only Cont*,* hsame*,* Pkg*,* NameCert*, the finite Lie source, the finite PDE field row, and the conservation-current ledger. It does not expose variational calculus, analytic PDE regularity, smooth manifold data, or a standard Noether theorem.*

Lean4 ✓ `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier public export`

Proof. Project the five displayed rows. The carrier projection gives the finite BHist conservation ledger, the classifier projection gives the current comparison rule, and the source-boundary projection gives the finite Lie source together with the finite PDE field row.

Next use the stability theorem to keep the projected carrier fixed under the allowed hsame, Cont, and Pkg transports. Use the obligation surface theorem to retain exactly the NameCert rows and dependency ledgers already named by the package.

Repack these projections as the public consumer boundary. Since every component of the repacked boundary is one of the five projected rows, and since no projected row contains variational calculus, analytic PDE regularity, smooth manifold data, or a standard Noether theorem, the public export has precisely the stated finite-current surface. □

Theorem 269.7 (Noether-symmetry mature finite-current boundary)**.** *The mature package boundary for* $\mathsf{NoetherSymmetry}^{\uparrow}$ *is exhausted by the conservation-ledger carrier, current classifier, Lie-PDE source boundary, stability row, NameCert obligation surface, and finite-current public export. Every consumer reads only the finite Lie source, finite PDE field row, conservation-current ledger,* hsame*,* Cont*,* Pkg*, and* NameCert *rows already displayed by that surface.*

Proof. Project the conservation-ledger carrier and current classifier. These rows provide the finite current packet and the finite comparison rule used by every accepted $\mathsf{NoetherSymmetry}^{\uparrow}$ read.

Apply the Lie-PDE source boundary and the stability row. They keep the Lie source, PDE field row, conservation-current row, hsame transport, Cont route, and Pkg provenance inside the same finite package boundary.

Use the NameCert obligation surface and the finite-current public export to repack those projections as the consumer-facing package. The public export already lists the exact rows available to consumers, so the mature boundary adds no independent coordinate.

The boundary explicitly excludes a global Noether correspondence, smooth variational calculus, analytic PDE regularity, smooth manifold data, and a standard Noether theorem. Those structures are not read from the finite current package. □

Closure status for $\mathsf{NameCert}_{\mathsf{NoetherSymmetry}^{\uparrow}}$**.**

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{NoetherSymmetry}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 269.6 is the public boundary over the finite Lie source, PDE field row, conservation-current ledger, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NoetherSymmetry}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.NoetherSymmetryUp.NoetherSymmetryConservationLedgerCarrier\_public\_export`

Bridge status: none

Constructive story: A finite conservation-ledger packet is assembled from the displayed Lie-algebra row, PDE row, current classifier row, transport witnesses, and one provenance packet; accepted consumers read only those finite current rows.

Not claimed: This chapter does not claim a full Noether theorem, variational calculus, analytic PDE regularity, smooth manifold data, or standard bridge.

Upgrade path: The paper axis is mature; further progress is Lean and bridge verification for the same finite-current package boundary.

Chapter 270

A Concrete Naming Certificate for $\mathsf{GeomQuantization}^{\uparrow}$

The geometric-quantization interface $\mathsf{GeomQuantization}^{\uparrow}$ packages the construction of a Hilbert space from a symplectic manifold via a prequantum line bundle, polarisation, and metaplectic correction. It depends on $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ (chapter 138) and $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ (chapter 91), and bridges geometric and operator-algebraic certificates through a common polarisation classifier.

270.1 Carrier definition

Definition 270.1 (GeomQuantization BHist source packet)**.** *A* $\mathsf{GeomQuantization}^{\uparrow}$ *source packet is a finite* BHist *package*

$$\mathcal{G} = (\mathcal{S}, \mathcal{H}, L, \Pi, \mu, \rho, \lambda, \tau)$$

where $\mathcal{S}$ *is a dependency row certified by* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$*,* $\mathcal{H}$ *is a dependency row certified by* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$*,* $L : \mathsf{BHist}$ *is the prequantum line-bundle row over the symplectic source,* $\Pi : \mathsf{BHist}$ *is the polarisation classifier row,* $\mu : \mathsf{BHist}$ *is the metaplectic-correction ledger row,* ρ *records the* Pkg *provenance of the symplectic and Hilbert dependency packets,* λ *is the finite* Cont *readback from* $(\mathcal{S}, L, \Pi, \mu)$ *to the Hilbert carrier row, and* τ *is the family of* hsame *transports preserving the source, line-bundle, polarisation, metaplectic, and Hilbert endpoint rows.*

The packet is accepted only when all listed rows project from one displayed Pkg *provenance package. Thus* $\mathsf{GeomQuantization}^{\uparrow}$ *carries a finite history surface from a certified symplectic source to a certified Hilbert target; it does not export an ambient quantization functor, a host Hilbert construction, or uncarried symplectic geometry.*

Lean4 (definition) `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket`

Theorem 270.2 (GeomQuantization source dependency surface)**.** *For every packet of Definition 270.1, the* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *projection and the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *projection are rows of the same* BHist *package. The prequantum line-bundle row, polarisation classifier row, metaplectic ledger row, finite* Cont *readback,* hsame *transports, and* Pkg *provenance are therefore shared dependency data rather than separate certificates.*

Proof. Project the tuple $\mathcal{G}$. Its first two components are the symplectic and Hilbert dependency rows, and its provenance component ρ records both rows inside one package.

The remaining components are read from that package: L gives the prequantum line-bundle row, Π gives the polarisation classifier, μ gives the metaplectic ledger, λ gives the finite continuation to the Hilbert endpoint, and τ gives the history transports.

Repacking these projections returns the same source packet. Since the construction never leaves the displayed BHist package, the two dependency projections share one BEDC carrier surface. □

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket source dependency surface`

Theorem 270.3 (GeomQuantization polarisation classifier stability)**.** *If two packets of Definition 270.1 are related by the carried* hsame *transports on their* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source rows and by the same* Pkg *provenance, then transport of the polarisation classifier preserves the prequantum line-bundle row and the polarisation row, and the finite* Cont *readback lands in the transported* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *row.*

Proof. Begin with the transported symplectic source rows. The packet lists τ as the transport family, so the source comparison is a BEDC history comparison rather than an equality of external symplectic manifolds.

Apply the same transport family to the line-bundle row L and the polarisation row Π. Because both rows are components of the same package, their transported versions remain attached to the transported source.

Finally read the ledger λ. It is the finite Cont path from the transported source, line-bundle, polarisation, and metaplectic rows to the Hilbert endpoint. Repacking that endpoint through the $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ dependency row proves classifier stability. □

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket polarisation classifier stability`

Theorem 270.4 (GeomQuantization ledger exactness)**.** *The* $\mathsf{GeomQuantization}^{\uparrow}$ *ledger is exact for exactly the rows listed in Definition 270.1: the* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *endpoint row, the prequantum line-bundle row, the polarisation classifier row, the metaplectic-correction ledger row, the finite* Cont *readback, the* hsame *transports, and the* Pkg *provenance. Coverage, soundness, and completeness range only over those rows and exclude host Hilbert-space construction and uncarried symplectic geometry.*

Proof. Coverage is projection from an accepted packet. Each accepted packet displays the two dependency rows, the line-bundle row, the polarisation row, the metaplectic ledger, the continuation readback, the transport family, and the provenance row.

For soundness, take exactly such displayed rows with the dependency certificates attached. Repack them as the tuple $\mathcal{G}$, and the carrier definition accepts the resulting package.

For completeness, suppose a public $\mathsf{GeomQuantization}^{\uparrow}$ row is accepted. The carrier definition has no projection for a host Hilbert construction and no projection for uncarried symplectic data. Hence every public row is generated by the listed source, classifier, ledger, transport, continuation, and provenance rows. □

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket ledger exactness`
Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket line ledger transport determinacy`

Theorem 270.5 (GeomQuantization NameCert obligation surface)**.** *The paper-side* $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ *obligation surface consists of the carrier packet of Definition 270.1, the shared dependency surface of Definition 270.2, the polarisation classifier stability row of Definition 270.3, and the ledger exactness row of Definition 270.4. Downstream consumers may project the symplectic dependency, Hilbert dependency, prequantum, polarisation, metaplectic,* Cont*,* hsame*, and* Pkg *rows, but no stronger geometric-quantization bridge is part of this surface.*

Proof. Assemble the carrier first. The definition supplies a finite BHist packet with the two dependency certificates, the prequantum row, the polarisation row, the metaplectic row, continuation readback, transport data, and provenance.

Next use Definition 270.2 to bind the $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ projections to the same package. Use Definition 270.3 to keep the classifier stable under the carried hsame transports.

Finally apply Definition 270.4. Its coverage, soundness, and completeness clauses say that the public certificate is exhausted by the displayed rows. Repacking these rows gives the $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ obligation surface and rules out any unlisted bridge data. □

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket namecert obligation surface`

Theorem 270.6 (GeomQuantization shared-provenance readback exactness)**.** *Any public readback of a* $\mathsf{GeomQuantization}^{\uparrow}$ *packet that consumes both the* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source row and the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *endpoint row factors through the same displayed* Pkg *provenance row, finite* Cont *readback, and carried* hsame *transport family of Definition 270.1. The readback may also project the prequantum line-bundle row, polarisation classifier row, and metaplectic-correction ledger row named by that packet, but it cannot read an ambient quantization functor or host Hilbert construction.*

Proof. Start with the accepted source packet. By Definition 270.2, the symplectic source row and Hilbert endpoint row are projections of one finite BHist package, and their provenance is the single displayed Pkg row ρ.

Next transport the classifier data. The polarisation classifier stability theorem keeps the prequantum line-bundle and polarisation rows attached to the same carried hsame transport family, and it sends the finite Cont ledger to the transported $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ endpoint row.

Finally apply Definition 270.4 together with Definition 270.5. These results exhaust the public certificate by the displayed source, endpoint, classifier, ledger, continuation, transport, and provenance rows. Since no accepted packet field names a host quantization functor or an ambient Hilbert construction, the public readback has no route to either structure. □

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket shared provenance readback exactness`

Theorem 270.7 (GeomQuantization public certificate handoff)**.** *A public* $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ *consumer may read exactly the shared* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *endpoint row, the prequantum line-bundle row, the polarisation classifier row, the metaplectic ledger row, the finite* Cont *readback, the* hsame *transport family, and the* Pkg *provenance supplied by Definition 270.1 and exhausted by Definition 270.5. The handoff exports no host quantization functor, no ambient Hilbert construction, and no uncarried symplectic geometry.*

Lean4 ✓ `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket public certificate handoff`

Proof. Project the accepted source packet. Its displayed coordinates supply the symplectic dependency row, Hilbert endpoint row, prequantum line-bundle row, polarisation classifier, metaplectic ledger, finite continuation readback, transport family, and package provenance.

Apply Definition 270.2 to bind the source and endpoint rows to one provenance package. Then use Definition 270.3 for the classifier transport and Definition 270.4 for the exact public ledger rows.

Finally repack exactly those projected fields as the consumer handoff. The obligation surface of Definition 270.5 exhausts the public projections, so there is no coordinate from which to read a host quantization functor, an ambient Hilbert construction, or uncarried symplectic geometry. □

270.2 The certificate

Closure status for $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$.

Constructive story: A geometric-quantization packet is assembled from one certified $\mathsf{Symplectic}^{\uparrow}$ source row and one certified $\mathsf{Hilbert}^{\uparrow}$ endpoint row, together with the displayed prequantum line-bundle row, polarisation classifier, metaplectic ledger, finite continuation readback, history-sameness transport, and package provenance. The source packet accepts only those rows, so a public consumer may project the shared dependencies and the carried classifier and ledger faces, while ambient quantization functors, host Hilbert construction, uncarried symplectic geometry, and standard bridges remain outside the displayed carrier.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 270.7 gives the public export surface over the scoped $\mathsf{Symplectic}^{\uparrow}$ dependency row, $\mathsf{Hilbert}^{\uparrow}$ endpoint row, prequantum line-bundle row, polarisation classifier, metaplectic ledger, finite Cont readback, hsame transports, and Pkg provenance carried by the source packet, and Definition 270.9 gives the mature public-surface standard presentation.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.GeomQuantizationUp.GeomQuantizationBHistSourcePacket\_public\_certificate\_handoff`

Bridge status: none

Not claimed: This chapter does not close ambient quantization functors, host Hilbert construction, uncarried symplectic geometry, or standard bridges.

Upgrade path: No further paper-axis theory closure remains for the public-surface packet; Lean bridge checking remains a separate verification-axis task.

Definition 270.8 (GeomQuantization public-surface standard presentation)**.** *A standard geometric-quantization presentation is public-surface over a* $\mathsf{GeomQuantization}^{\uparrow}$ *source packet* $\mathcal{G}$ *when its admitted BEDC readback is a tuple*

$$\mathcal{R} = (S, H, L, \Pi, \mu, \lambda, \tau, \rho)$$

whose entries are, respectively, the $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *endpoint row, the prequantum line-bundle row, the polarisation classifier row, the metaplectic-correction ledger row, the finite* Cont *readback, the carried* hsame *transport family, and the* Pkg *provenance row projected from* $\mathcal{G}$ *in the sense of Definition 270.1.*

The readback is conservative when every consumer-visible row factors through those eight projections and their public certificate handoff in Definition 270.7. In particular, the presentation may name the ordinary geometric-quantization words attached to S*,* H*,* L*,* Π*, and* μ*, but it has no separate coordinate for an ambient quantization functor, no separate coordinate for a host Hilbert construction, and no separate coordinate for uncarried symplectic geometry.*

Theorem 270.9 (GeomQuantization public-surface standard bridge)**.** *Every public-surface standard presentation over a* $\mathsf{GeomQuantization}^{\uparrow}$ *source packet conservatively bridges to the public* $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ *certificate. More explicitly, if a standard geometric-quantization presentation is read only through the* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ *endpoint row,*

the prequantum line-bundle row, the polarisation classifier row, the metaplectic-correction ledger row, the finite Cont *readback, the carried* hsame *transport family, and the* Pkg *provenance row of Definition 270.8, then its BEDC export is exactly the public handoff of Definition 270.7. Consequently the bridge cannot expose an ambient quantization functor, a host Hilbert construction, or uncarried symplectic geometry.*

Proof. Let $\mathcal{R} = (S, H, L, \Pi, \mu, \lambda, \tau, \rho)$ be the admitted readback of a public-surface standard presentation over a source packet $\mathcal{G}$. By the definition of the public-surface presentation, each coordinate of $\mathcal{R}$ is a projection from the same packet named in Definition 270.1.

The source and endpoint rows are not independent standard data. By Definition 270.2, S and H are rows of the same finite BHist package, with the same displayed Pkg provenance row ρ. The line-bundle, polarisation, metaplectic, continuation, and transport entries are therefore shared dependency data rather than a second certificate.

The classifier part is stable under the carried history transport. By Definition 270.3, transporting the polarisation classifier keeps the line-bundle and polarisation rows attached to the transported source and sends the finite Cont readback to the transported $\mathsf{NameCert}_{\mathsf{Hilbert}^{\uparrow}}$ endpoint row. Thus the standard presentation has no additional route from the symplectic row to the Hilbert row beyond the displayed public transport and continuation rows.

It remains to identify the public export. By Definition 270.4, the ledger of $\mathsf{GeomQuantization}^{\uparrow}$ is exact for precisely the listed rows. By Definition 270.5, those rows are the local $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ obligation surface. Finally, Definition 270.7 says that a public consumer may read exactly those eight rows and nothing stronger.

Repacking $\mathcal{R}$ through that handoff gives the public $\mathsf{NameCert}_{\mathsf{GeomQuantization}^{\uparrow}}$ certificate. Since the public-surface presentation has no coordinate outside S, H, L, Π, μ, λ, τ, and ρ, there is no BEDC projection from which to read an ambient quantization functor, a host Hilbert construction, or uncarried symplectic geometry. This is exactly the claimed conservative bridge. □

Chapter 271

A Concrete Naming Certificate for $\mathsf{DeformQuantization}^{\uparrow}$

The deformation-quantization interface $\mathsf{DeformQuantization}^{\uparrow}$ packages the formal star product $\star_\hbar$ on a Poisson manifold whose first-order term is the Poisson bracket (Kontsevich formality). It depends on $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ (chapter 138) and $\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$ (chapter 180), and bridges Poisson and noncommutative certificates through the same formal-deformation classifier.

271.1 Carrier definition

271.2 The certificate

Definition 271.1 (DeformQuantization first-order star-product ledger)**.** *Fix a* $\mathsf{Symplectic}^{\uparrow}$ *obligation boundary* Σ *as in Definition 138.2. Fix a* $\mathsf{HopfAlg}^{\uparrow}$ *row* $H = (a, t, s, u, e)$ *whose carrier and classifier are read through Definition 180.1 and Definition 180.2. A first-order star-product ledger for* $\mathsf{DeformQuantization}^{\uparrow}$ *over* (Σ, H) *is a displayed* BHist *row*

$$\mathsf{DQStarLedger}_{\Sigma,H}(\mu_\hbar, \mu_0, \mu_1, \mu_1^{\mathrm{op}}, \kappa, \pi, \Lambda_\star)$$

with the following fields.

1. *The row* $\mu_\hbar$ *is a formal-product row whose multiplication provenance is read through the* $\mathsf{HopfAlg}^{\uparrow}$ *multiplication and tensor rows of* H*.*
2. *The row* μ_0 *is the degree-zero product endpoint of* $\mu_\hbar$ *and is classified with the ordinary commutative product row on the function algebra over the carrier exposed by* Σ*.*
3. *The rows* μ_1 *and* μ_1^{op} *are the degree-one coefficient endpoints of* $\mu_\hbar$ *and of the opposite formal product.*
4. *The row* κ *is the degree-one commutator endpoint, displayed by the continuation row*

$$\mathsf{Cont}(\mu_1, \mu_1^{\mathrm{op}}, \kappa).$$

5. *The row* π *is the Poisson-bracket obligation row attached by the* $\mathsf{DeformQuantization}^{\uparrow}$ *packet to the same symplectic boundary* Σ*.*

6. *The formal-deformation classifier attached to $\Lambda_\star$ contains the bracket exactness comparison*

$$\mathsf{hsame}(\kappa, \pi),$$

and its coverage and soundness clauses say that every bracket read of the formal-deformation classifier factors through π and every accepted degree-one commutator endpoint factors through κ before this comparison is applied.

Theorem 271.2 (DeformQuantization first-order bracket ledger)**.** *Let Σ be a* $\mathsf{Symplectic}^\uparrow$ *obligation boundary and let $H = (a, t, s, u, e)$ be a* $\mathsf{HopfAlg}^\uparrow$ *formal-product row as in Definition 271.1. Let Q be a* $\mathsf{DeformQuantization}^\uparrow$ *packet over (Σ, H) containing the visible ledger row*

$$\mathsf{DQStarLedger}_{\Sigma,H}(\mu_\hbar, \mu_0, \mu_1, \mu_1^{\mathrm{op}}, \kappa, \pi, \Lambda_\star).$$

If μ_0 is read as the degree-zero product endpoint of the star product and κ is read as the degree-one commutator endpoint, then the formal-deformation classifier of Q reads the same degree-one endpoint as the displayed Poisson-bracket obligation row:

$$\mathsf{PoissonBracketOb}_{\Sigma,H}(\pi) \wedge \mathsf{hsame}(\kappa, \pi).$$

Thus the bracket endpoint belongs to the $\mathsf{DeformQuantization}^\uparrow$ *ledger over the supplied* $\mathsf{Symplectic}^\uparrow$ *boundary and* $\mathsf{HopfAlg}^\uparrow$ *formal-product row, not to the* $\mathsf{Symplectic}^\uparrow$ *boundary alone.*

Lean4 ✓ `BEDC.Derived.DeformQuantizationUp.DeformQuantizationStarLedger first order bracket`

Proof. Unpack Definition 271.1. The $\mathsf{HopfAlg}^\uparrow$ side supplies the formal product substrate through the multiplication and tensor provenance rows recorded in Definition 180.5. This places $\mu_\hbar$ inside the same ledger spine as the degree-zero endpoint μ_0 and the two degree-one coefficient endpoints μ_1 and μ_1^{op}.

The commutator endpoint is not an additional classifier choice. It is the row κ displayed by the continuation face

$$\mathsf{Cont}(\mu_1, \mu_1^{\mathrm{op}}, \kappa)$$

inside the same star-product ledger. The degree-zero clause records that the zeroth coefficient is the ordinary product endpoint, while the degree-one clause records that the first antisymmetric endpoint is κ.

The Poisson-bracket clause of the ledger then supplies the row π and the exactness comparison

$$\mathsf{hsame}(\kappa, \pi).$$

By the coverage clause, any bracket read made by the formal-deformation classifier factors through this displayed π row. By the soundness clause, the accepted degree-one commutator read factors through κ before it is compared with π. Therefore the endpoint read from the degree-one commutator is classified with the displayed Poisson-bracket obligation row, giving

$$\mathsf{PoissonBracketOb}_{\Sigma,H}(\pi) \wedge \mathsf{hsame}(\kappa, \pi).$$

The separation from the symplectic dependency is exactly the consumer frontier of Definition 138.11: the $\mathsf{Symplectic}^\uparrow$ boundary supplies carrier, two-form, closedness, nondegeneracy, pairing, and transport rows, but it does not by itself export a Poisson bracket. The bracket endpoint used here is supplied only after the $\mathsf{DeformQuantization}^\uparrow$ packet adds the first-order star-product ledger over the Hopf formal-product row. □

Theorem 271.3 (DeformQuantization star-ledger carrier obligation)**.** *Let Σ be a* $\mathsf{Symplectic}^{\uparrow}$ *obligation boundary and let $H = (a, t, s, u, e)$ be a* $\mathsf{HopfAlg}^{\uparrow}$ *row satisfying Definition 180.1 and Definition 180.2. A* $\mathsf{DeformQuantization}^{\uparrow}$ *packet Q over (Σ, H) has its first-order carrier exactly when it exposes a displayed row*

$$\mathsf{DQStarLedger}_{\Sigma,H}(\mu_\hbar, \mu_0, \mu_1, \mu_1^{\mathrm{op}}, \kappa, \pi, \Lambda_\star)$$

of Definition 271.1 whose formal product provenance is the Pkg *row read from the multiplication and tensor faces of H, whose commutator face is the continuation row* $\mathsf{Cont}(\mu_1, \mu_1^{\mathrm{op}}, \kappa)$*, and whose carrier comparisons are the displayed* hsame *rows of the packet. Thus no separate carrier for Q is admitted beyond the* BHist *ledger row, the* Cont *face, the* hsame *comparisons, and the* Pkg *provenance supplied by Σ and H.*

Proof. Project the $\mathsf{HopfAlg}^{\uparrow}$ side first. By Definition 180.5, the row H supplies the carrier, classifier, tensor-row stability, multiplication and comultiplication provenance through Cont, and the antipode ledger rows. The formal-product provenance of $\mu_\hbar$ is therefore the same Pkg row read from those multiplication and tensor faces.

Next project the $\mathsf{Symplectic}^{\uparrow}$ boundary. The consumer frontier of Definition 138.11 supplies the carrier boundary and transport surface needed by a Poisson consumer, while withholding any independent bracket export. Hence the deformation packet must attach its bracket-facing carrier through the displayed star ledger rather than through a hidden symplectic row.

Finally repack the projections into Definition 271.1. The row $\mu_\hbar$ carries the formal product, $\mu_0, \mu_1, \mu_1^{\mathrm{op}}$ are its coefficient endpoints, κ is displayed by $\mathsf{Cont}(\mu_1, \mu_1^{\mathrm{op}}, \kappa)$, and the packet comparisons are the recorded hsame rows. These fields are exactly the advertised BHist carrier for Q, so any accepted first-order carrier read is covered by that row and by no additional carrier datum. □

Lean4 ✓ `BEDC.Derived.DeformQuantizationUp.DeformQuantizationStarLedger carrier obligation`

Theorem 271.4 (DeformQuantization bracket classifier obligation)**.** *Let Q and Q' be* $\mathsf{DeformQuantization}^{\uparrow}$ *packets over transported rows (Σ, H) and (Σ', H'), with displayed star-product ledger rows*

$$\mathsf{DQStarLedger}_{\Sigma,H}(\mu_\hbar, \mu_0, \mu_1, \mu_1^{\mathrm{op}}, \kappa, \pi, \Lambda_\star)$$

and

$$\mathsf{DQStarLedger}_{\Sigma',H'}(\mu'_\hbar, \mu'_0, \mu'_1, (\mu'_1)^{\mathrm{op}}, \kappa', \pi', \Lambda'_\star).$$

If the $\mathsf{Symplectic}^{\uparrow}$ *and* $\mathsf{HopfAlg}^{\uparrow}$ *carrier-classifier rows transport Σ to Σ' and H to H', then the* $\mathsf{DeformQuantization}^{\uparrow}$ *classifier transports the degree-zero product endpoint, the two first-order coefficient endpoints, the commutator endpoint, and the Poisson-bracket comparison row:*

$$\mathsf{hsame}(\mu_0, \mu'_0) \wedge \mathsf{hsame}(\mu_1, \mu'_1) \wedge \mathsf{hsame}(\mu_1^{\mathrm{op}}, (\mu'_1)^{\mathrm{op}}) \wedge \mathsf{hsame}(\kappa, \kappa') \wedge \mathsf{hsame}(\pi, \pi').$$

Lean4 ✓ `BEDC.Derived.DeformQuantizationUp.DeformQuantizationStarLedger bracket classifier obligation`

Proof. Begin with the transported $\mathsf{HopfAlg}^{\uparrow}$ row. The classifier surface in Definition 180.5 carries the multiplication and tensor provenance rows through the transport from H to H', so the formal-product row $\mu_\hbar$ and the transported row $\mu'_\hbar$ have the same Pkg provenance for the product spine.

The endpoint clauses are then read directly from the two displayed star ledgers. The degree-zero endpoint is transported as the ordinary product endpoint over the transported symplectic

carrier. The two first-order coefficient endpoints are transported as coefficient faces of the same formal-product spine.

It remains to transport the bracket-facing rows. The continuation faces

$$\mathsf{Cont}(\mu_1, \mu_1^{\mathrm{op}}, \kappa)$$

and

$$\mathsf{Cont}(\mu_1', (\mu_1')^{\mathrm{op}}, \kappa')$$

identify the commutator endpoints after the two coefficient endpoints have been transported. The consumer frontier of Definition 138.11 supplies the transported Poisson consumer boundary, and the ledger exactness clause records the corresponding $\mathsf{hsame}(\pi, \pi')$ comparison. Repacking these five transported rows gives the displayed classifier obligation. □

Theorem 271.5 (DeformQuantization first-order ledger exactness obligation)**.** *For every* $\mathsf{DeformQuantization}^{\uparrow}$ *packet* Q *over* (Σ, H) *with displayed ledger*

$$\mathsf{DQStarLedger}_{\Sigma,H}(\mu_\hbar, \mu_0, \mu_1, \mu_1^{\mathrm{op}}, \kappa, \pi, \Lambda_\star),$$

every accepted first-order bracket readback of Q *is covered by the ledger row of Definition 271.1 and is sound for the checked bracket statement of Definition 271.2. Equivalently, an accepted readback factors through the degree-one commutator endpoint* κ*, the Poisson-bracket obligation row* π*, and the exactness comparison* $\mathsf{hsame}(\kappa, \pi)$ *before it is reported as a* $\mathsf{DeformQuantization}^{\uparrow}$ *bracket endpoint.*

Lean4 ✓ `BEDC.Derived.DeformQuantizationUp.DeformQuantizationStarLedger first order ledger exactness`

Proof. Coverage is the first projection. Unpack Definition 271.1: the formal-deformation classifier attached to $\Lambda_\star$ records that every bracket read factors through the displayed row π, and every accepted degree-one commutator endpoint factors through κ.

Soundness is the second projection. The checked ledger theorem Definition 271.2 identifies the endpoint read from the degree-one commutator with the displayed Poisson-bracket obligation row by the comparison

$$\mathsf{PoissonBracketOb}_{\Sigma,H}(\pi) \wedge \mathsf{hsame}(\kappa, \pi).$$

The Hopf provenance and the symplectic frontier rule out the two possible escapes. By Definition 180.5, the formal product and its coefficient endpoints are read through the Pkg and Cont faces supplied by H. By Definition 138.11, Σ supplies the consumer boundary but does not export an independent Poisson bracket. Therefore every accepted first-order readback is both covered by the displayed ledger row and sound for the checked bracket exactness statement. □

Definition 271.6 (DeformQuantization formal-deformation obligation inventory)**.** *For a* $\mathsf{DeformQuantization}^{\uparrow}$ *packet* Q *over a* $\mathsf{Symplectic}^{\uparrow}$ *boundary* Σ *and a* $\mathsf{HopfAlg}^{\uparrow}$ *row* H*, the formal-deformation obligation inventory is the finite list of public rows consisting of the carrier row of Definition 271.3, the bracket classifier row of Definition 271.4, the* Cont *and* hsame *stability rows for the coefficient and commutator endpoints, the first-order ledger row of Definition 271.1, the exactness row of Definition 271.5, and the public certificate rows that expose these data through* Pkg *provenance. The inventory permits reads from* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{HopfAlg}^{\uparrow}}$*,* Cont*,* hsame*,* BHist*, and* Pkg *only.*

Theorem 271.7 (DeformQuantization scoped primitive inventory)**.** *Every accepted first-order obligation row of the* $\mathsf{DeformQuantization}^{\uparrow}$ *inventory of Definition 271.6 factors through exactly the displayed* $\mathsf{Symplectic}^{\uparrow}$ *boundary* Σ*, the* $\mathsf{HopfAlg}^{\uparrow}$ *formal-product row* H*, the coefficient and commutator faces carried by* Cont*, the endpoint comparisons carried by* hsame*, the first-order* BHist *ledger row, and the* Pkg *provenance of that inventory. Conversely, those rows repack into the public first-order obligation surface of* $\mathsf{NameCert}_{\mathsf{DeformQuantization}^{\uparrow}}$*, with no additional bracket source, analytic convergence witness, or formality datum.*

Proof. For the carrier part, apply Definition 271.3. It identifies the accepted first-order carrier with the displayed BHist ledger, the Cont commutator face, the packet hsame comparisons, and the Pkg provenance supplied by the $\mathsf{Symplectic}^{\uparrow}$ and $\mathsf{HopfAlg}^{\uparrow}$ dependencies.

For classifier movement, apply Definition 271.4. Transport of the degree-zero product endpoint, the two first-order coefficient endpoints, the commutator endpoint, and the Poisson-bracket row is componentwise over the transported Σ and H rows.

For readback exactness, apply Definition 271.5. It forces every accepted first-order bracket read through the degree-one commutator endpoint κ, the Poisson-bracket obligation row π, and the comparison $\mathsf{hsame}(\kappa, \pi)$ before the public endpoint is reported.

The remaining source check is Definition 271.8. It rules out any source outside Σ, H, Cont, hsame, BHist, and Pkg. Repacking these projections through Definition 271.9 gives the public first-order obligation surface and no larger primitive boundary. □

Theorem 271.8 (DeformQuantization source-boundary obligation)**.** *Every source read accepted by the inventory of Definition 271.6 factors through the supplied* $\mathsf{Symplectic}^{\uparrow}$ *boundary* Σ *and the supplied* $\mathsf{HopfAlg}^{\uparrow}$ *formal-product row* H*. In particular, a bracket-facing read reaches the public packet only through the symplectic consumer boundary, the Hopf formal-product provenance, the coefficient continuation rows, and the first-order exactness comparison of Definition 271.5.*

Proof. Project the read into the finite inventory. The carrier case is exactly Definition 271.3: it exposes the star-product carrier through the displayed BHist ledger, the Hopf Pkg provenance, the Cont face, and the packet hsame comparisons.

The classifier and stability cases use Definition 271.4. Transport of the degree-zero endpoint, first-order coefficient endpoints, commutator endpoint, and Poisson comparison is therefore controlled by the transported $\mathsf{Symplectic}^{\uparrow}$ and $\mathsf{HopfAlg}^{\uparrow}$ rows, not by an independent deformation source.

For the bracket readback, apply Definition 271.5. It factors the read through κ, π, and $\mathsf{hsame}(\kappa, \pi)$ after the Hopf formal-product row has supplied the coefficient spine and after the symplectic boundary has supplied only the Poisson consumer frontier. Thus every source read is bounded by the two supplied dependencies and the named BEDC transport rows. □

Theorem 271.9 (DeformQuantization public certificate obligation surface)**.** *The inventory of Definition 271.6, together with the source-boundary factorization of Definition 271.8, forms the public* $\mathsf{NameCert}_{\mathsf{DeformQuantization}^{\uparrow}}$ *obligation surface at first order. The surface contains carrier, classifier, stability, ledger, exactness, and public certificate rows over* $\mathsf{Symplectic}^{\uparrow}$*,* $\mathsf{HopfAlg}^{\uparrow}$*,* Cont*,* hsame*,* BHist*, and* Pkg*, and it does not claim Kontsevich formality, analytic convergence, or a full star-product construction beyond the displayed first-order ledger.*

Proof. Assemble the carrier and classifier fields first. The carrier field is supplied by Definition 271.3; the classifier and transported endpoint fields are supplied by Definition 271.4.

Next add stability and exactness. The stability rows are the displayed Cont and hsame fields in the ledger, and the exactness row is Definition 271.5. These rows cover the first-order commutator endpoint and its comparison with the Poisson-bracket obligation row.

Finally apply Definition 271.8. It ensures that every public read is sourced by Σ, H, and the named BEDC rows in the inventory. Repacking those fields gives the stated public obligation surface while leaving full formality and convergence outside the certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{DeformQuantization}^{\uparrow}}$.

Constructive story: A deformation-quantization packet is generated over an accepted Symplectic$^{\uparrow}$ boundary and an accepted HopfAlg$^{\uparrow}$ formal-product row by displaying the formal product endpoint, its degree-zero product, two degree-one coefficient endpoints, their commutator endpoint, the Poisson-bracket obligation row, and the exactness comparison between them. The carrier accepts only this first-order star-product ledger with its Cont commutator face, hsame comparisons, coefficient rows, and Pkg provenance from the two dependencies; Kontsevich formality, analytic convergence, and a full star-product construction beyond the visible first-order ledger are not carrier data. Two accepted packets classify together when the symplectic and Hopf rows transport and the degree-zero endpoint, the two first-order endpoints, the commutator endpoint, and the Poisson row all transport by the displayed hsame comparisons, so the source specification is the supplied dependency pair and the pattern specification is the formal-product ledger whose antisymmetric first-order endpoint is compared with the bracket row. The ledger keeps the raw coefficient and commutator histories visible beside the public bracket endpoint: every bracket read factors through the commutator row, the Poisson row, and the exactness comparison before being reported. Once such a ledger is displayed, the five name-certificate obligations are supplied by the inherited dependency certificates and the componentwise transport rows: the ledger gives a carrier witness, the classifier is reflexive, symmetric, and transitive on accepted endpoints, and transported coefficient and bracket rows remain inside the same first-order surface. A history h lies in the signature gap of a DeformQuantization$^{\uparrow}$ token p when the source-domain accepts its symplectic boundary, Hopf formal-product row, coefficient ledger, and exactness row, the signature relation pairs it with an answer ledger and evidence, and the token-introduction relation names that answer as p; unfolded, the degree-one commutator in h must be hsame to the Poisson-bracket row encoded by p. The chapter registers this first-order ledger construction under the name DeformQuantization$^{\uparrow}$; it adds no analytic deformation object, formality theorem, convergence witness, standard bridge, or independent Poisson-bracket source.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DeformQuantization}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation scope is exactly the carrier row, bracket classifier, coefficient and commutator stability rows, first-order ledger, exactness row, source-boundary factorization, and public certificate rows over Symplectic$^{\uparrow}$, HopfAlg$^{\uparrow}$, Cont, hsame, BHist, and Pkg.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DeformQuantization}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DeformQuantizationUp.DeformQuantizationStarLedger\_first\_order\_bracket`

Bridge status: paperBridge

Not claimed: This seed does not claim Kontsevich formality, full deformation quantization, analytic convergence, a machine-checked standard bridge, or closure beyond the displayed first-order ledger.

Upgrade path: No further paper-axis theory grade remains; bridgeChecked status remains a separate formal-axis upgrade.

Chapter 272

A Concrete Naming Certificate for $\mathsf{ChernWeil}^{\uparrow}$

The Chern-Weil interface $\mathsf{ChernWeil}^{\uparrow}$ packages the cohomology-class invariants of a principal bundle as polynomial expressions in the curvature form of any chosen connection. It depends on $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ (chapter 135) and $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ (chapter 137), and bridges differential and topological certificates through the same characteristic-class classifier.

272.1 Carrier definition

Definition 272.1 (Chern-Weil source envelope)**.** *A* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope is a finite* BHist *packet*

$$\mathcal{W} = (\mathcal{R}, \mathcal{D}, p, \gamma, \lambda)$$

where $\mathcal{R}$ *is a public* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *packet carrying the curvature boundary row and provenance exported by Definition 135.45,* $\mathcal{D}$ *is a* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *packet carrying the cohomology row into which the characteristic class is read,* $p : \mathsf{BHist}$ *is the shared* Cont *provenance row connecting the curvature source to the de Rham projection,* $\gamma : \mathsf{BHist}$ *is the ledger face recording the chosen connection used to read the curvature polynomial, and* $\lambda : \mathsf{BHist}$ *is the characteristic-class row returned by the de Rham classifier after the* Cont *projection.*

The envelope is admitted only when the curvature boundary, the de Rham cohomology row, the shared Cont *provenance, the chosen-connection ledger face, and the characteristic-class row all occur as rows of the same finite history packet. Thus* $\mathsf{ChernWeil}^{\uparrow}$ *carries the concrete curvature-to-cohomology passage rather than an ambient characteristic-class operation.*

Lean4 (definition) `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope`

Definition 272.2 (Chern-Weil characteristic classifier)**.** *Two* $\mathsf{ChernWeil}^{\uparrow}$ *source envelopes* $\mathcal{W}$ *and* $\mathcal{W}'$ *classify the same Chern-Weil object exactly when* hsame *preserves their* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *source rows and the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *classifier returns the same characteristic-class row after projecting both packets through their carried* Cont *provenance rows. Equivalently, the classifier ignores only the hidden connection ledger face* γ *and compares the exported curvature source row together with the de Rham row* λ *read from it.*

Lean4 (definition) `BEDC.Derived.ChernWeilUp.ChernWeilEnvelopeCharacteristicClassifier`

Definition 272.3 (Chern-Weil curvature-to-de Rham source packet)**.** *A* $\mathsf{ChernWeil}^{\uparrow}$ *source packet is a finite BEDC package*

$$\mathcal{W} = (\mathcal{R}, \mathcal{D}, p, \chi, c, \epsilon, \lambda, \pi)$$

where $\mathcal{R}$ *is a* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *carrier packet,* $\mathcal{D}$ *is a* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *carrier packet,* $p : \mathsf{BHist}$ *is the invariant-polynomial row,* $\chi : \mathsf{BHist}$ *is the evaluated curvature-polynomial row,* $c : \mathsf{BHist}$ *is the de Rham cohomology-class endpoint,* ϵ *is the exact-boundary row witnessing connection replacement,* λ *is the finite* Cont *ledger from the curvature Bianchi row to the closed de Rham row, and* π *records the* Pkg *provenance of the curvature, de Rham, and polynomial rows.*

The packet is accepted only when the source curvature rows, the de Rham endpoint rows, the hsame *comparisons, the* Cont *ledgers, the* $\mathsf{ProbeBundle}$ *observations, and the* Pkg *provenance all project from the same displayed history package. Thus the Chern-Weil source is a CurvatureUp-to-DeRhamUp row package, not a host equality between differential forms.*

Definition 272.4 (Chern-Weil characteristic-class classifier)**.** *Two packets of Definition 272.3 have the same Chern-Weil characteristic class when their invariant-polynomial rows classify together, their evaluated curvature rows transport by the carried* hsame *and* Cont *ledgers, and the transported endpoints determine the same de Rham cohomology-class row in the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *classifier. The classifier is therefore agreement of invariant-polynomial curvature rows after de Rham cohomology-class transport; it is not equality of ambient forms in a host calculus.*

Lean4 (definition) `BEDC.Derived.ChernWeilUp.ChernWeilCharacteristicClassClassifier`

Theorem 272.5 (Chern-Weil invariant-polynomial carrier obligation)**.** *Every accepted Chern-Weil row exposes only the source curvature packet, the invariant-polynomial evaluation history, the de Rham class endpoint, the finite transport ledgers, the* $\mathsf{ProbeBundle}$ *observations, and the* Pkg *provenance. In particular, the public carrier does not expose a coordinate connection form, an ambient polynomial algebra, or an external cohomology quotient beyond the displayed* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *rows.*

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope carrier obligation`

Proof. Unpack an accepted packet of Definition 272.3. The tuple projections give exactly the source curvature certificate, the source de Rham certificate, the polynomial row, the evaluated curvature-polynomial row, the class endpoint, the exact-boundary row, the finite ledger, and the provenance row.

The classifier of Definition 272.4 consumes only these projections. It compares the polynomial and evaluated rows by hsame, transports them through the finite Cont ledger, and then reads the resulting endpoint through the de Rham classifier row.

Repacking those projections gives the stated public carrier surface. Since no projection returns a host connection form, an external polynomial algebra, or an uncarried quotient, no accepted Chern-Weil row can expose such data. □

Theorem 272.6 (Chern-Weil connection-change cocycle obligation)**.** *If two packets of Definition 272.3 differ only by replacing the* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *representative inside their* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *source while preserving the carried base, fibre, section, invariant-polynomial, and provenance rows, then the two evaluated curvature-polynomial endpoints are related in* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *by the exact-boundary row* ϵ*. Consequently the characteristic-class classifier transports across the connection change.*

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope connection change cocycle obligation`

Proof. Project the two Chern-Weil packets to their curvature sources. The curvature tensorial transport row carries the section and tangent replacement data through hsame, while preserving the shared base, fibre, invariant-polynomial, and provenance projections.

Evaluate the invariant-polynomial row against the transported curvature boundary row. The evaluation history is part of the Chern-Weil packet, so the two evaluated endpoints are connected by the displayed finite Cont ledger rather than by an unstated analytic homotopy.

The exact-boundary row ϵ is then projected as a de Rham boundary witness from the first endpoint to the second. Reading this witness through the de Rham classifier gives the same cohomology-class endpoint, and repacking the transported rows proves classifier stability under the connection change. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierPacket connection change cocycle obligation`

Theorem 272.7 (Chern-Weil closed-form de Rham class obligation)**.** *For every accepted Chern-Weil packet, the Bianchi-style curvature ledger supplies a closed de Rham class endpoint consumable by the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *classifier. The closedness row is the finite* Cont *consequence of the curvature cyclic ledger, the invariant-polynomial evaluation row, and the transported de Rham endpoint row.*

Proof. Start from the curvature component of the source packet. Its Bianchi ledger is a finite cyclic Cont row among displayed curvature boundaries, and the Chern-Weil packet records the invariant-polynomial evaluation of those boundaries.

Transport the evaluated row along the carried hsame comparisons into the de Rham source packet. The ledger λ records this transport as a BEDC continuation from the Bianchi row to the closed de Rham endpoint.

The de Rham classifier consumes the transported endpoint as a closed class row. Thus closedness is not asserted as an external differential identity; it is the class endpoint projected from the finite curvature ledger and repacked inside $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope closed form derham class obligation`
Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope closed form derham class obligation`

Theorem 272.8 (Chern-Weil NameCert obligation surface)**.** *The* $\mathsf{ChernWeil}^{\uparrow}$ *obligation surface consists exactly of the source packet of Definition 272.3, the characteristic-class classifier of Definition 272.4, the invariant-polynomial carrier row of Definition 272.5, the connection-change exact-boundary row of Definition 272.6, the closed de Rham endpoint row of Definition 272.7, the finite ledgers, and the dependency provenance over* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$.

Proof. Collect the two definitions and the three obligation rows above. They provide the carrier packet, classifier, exposed public fields, connection-change transport, closedness endpoint, ledgers, exact-boundary row, and dependency provenance.

Each field has a consumer: the carrier exposes the source histories, the classifier reads the transported de Rham endpoint, the connection-change row supplies exact-boundary transport, and the closedness row supplies the de Rham class endpoint. Conversely, every consumer reads one of these displayed fields.

Therefore the surface is exact. A downstream $\mathsf{NameCert}_{\mathsf{ChernWeil}^{\uparrow}}$ consumer may project the listed CurvatureUp-to-DeRhamUp rows, but it may not assume a stronger equality of forms, a coordinate curvature model, or a standard bridge absent from the packet. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope namecert obligation surface`

Definition 272.9 (Chern-Weil carrier packet)**.** *A* $\mathsf{ChernWeil}^{\uparrow}$ *carrier packet is a displayed* BHist *tuple*

$$\mathcal{W} = (\mathcal{R}, \mathcal{D}, b, E, \kappa, p, \pi, \omega, [\omega], \rho, \lambda)$$

where $\mathcal{R}$ *is a source* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *packet,* $\mathcal{D}$ *is a source* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *packet,* $b : \mathsf{BHist}$ *is the shared base row,* $E : \mathsf{BHist}$ *is the bundle row,* $\kappa : \mathsf{BHist}$ *is the curvature-boundary row projected from* $\mathcal{R}$*,* $p : \mathsf{BHist}$ *is the invariant-polynomial row,* $\pi : \mathsf{BHist}$ *is the polynomial endpoint row obtained by applying* p *to* κ*,* $\omega : \mathsf{BHist}$ *is the closed differential-form representative row read by* $\mathcal{D}$*,* $[\omega] : \mathsf{BHist}$ *is the de Rham class row,* ρ *records the* Pkg *provenance of the curvature and de Rham dependency packets, and* λ *is the finite* Cont *ledger from the boundary and polynomial rows to the endpoint, representative, and class rows.*

The packet is accepted only when the curvature source row comes from $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$*, the cohomology representative row comes from* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$*, and the displayed* Pkg *provenance binds both sources to the same characteristic-class classifier. Thus the carrier is the finite BEDC history packet for a Chern-Weil class, not an equality between host-level connections, polynomials, forms, or cohomology classes.*

Theorem 272.10 (Chern-Weil curvature polynomial stability obligation)**.** *For packets of Definition 272.9, transporting the* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *boundary row* κ *by inherited* hsame *and by the finite* Cont *ledger transports the polynomial endpoint row* π *under the same characteristic-class classifier. The invariant-polynomial row* p*, the dependency* Pkg *provenance* ρ*, and the de Rham source packet* $\mathcal{D}$ *are retained as ledger data rather than recomputed.*

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierPacket curvature polynomial stability obligation`

Proof. Read the carrier through the roadmap ten-field template of section 9467.18: the source fields are $\mathcal{R}$ and $\mathcal{D}$, the carrier field is the displayed BHist tuple, the classifier field is the characteristic-class classifier, and the ledger field is λ.

Apply Definition 135.45 to project the curvature-boundary row from $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$. The allowed transport of that row is exactly the inherited hsame comparison together with the finite Cont readback exposed by the curvature certificate.

Append the polynomial row p to that transported boundary inside the same finite ledger. Since π is the endpoint row of the displayed ledger, transporting κ transports π with no appeal to host equality of forms or connections. The Pkg provenance and the $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ dependency row remain fixed inputs to the same classifier surface. □

Theorem 272.11 (Chern-Weil de Rham class exactness obligation)**.** *For packets of Definition 272.9, the de Rham class row* $[\omega]$ *is accepted exactly when the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *dependency row reads the polynomial endpoint* π *as a closed cohomology representative* ω*. No additional Chern-Weil class row is available unless it is reached by the displayed* Cont *ledger and classified by the same* $\mathsf{NameCert}$ *dependency surface.*

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope derham class exactness obligation`

Proof. Use the exactness field of the roadmap ten-field template in section 9467.18. Exactness asks that every public row be generated from the listed source, carrier, classifier, stability, and ledger data.

The source row for closed cohomology representatives is the $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ dependency chapter chapter 137. Feed it the polynomial endpoint row π carried by the Chern-Weil packet. Its accepted output is the representative row ω together with the class row $[\omega]$.

Conversely, if $[\omega]$ is displayed as a Chern-Weil class row, the packet definition lists no source other than $\mathcal{D}$ and no path other than λ from π to ω and then to $[\omega]$. Therefore class acceptance is precisely de Rham acceptance of the polynomial endpoint as a closed representative, mediated by BHist, Cont, Pkg, and NameCert rows. □

Theorem 272.12 (Chern-Weil characteristic-class ledger obligation)**.** *In a* $\mathsf{ChernWeil}^{\uparrow}$ *carrier packet, the choice of connection, invariant-polynomial presentation, representative differential form, and class representative is ledger data. Carrier equality is controlled only by the shared* BHist *source rows, inherited* hsame *transport, the finite* Cont *ledger, and the characteristic-class classifier; it is not equality of the chosen connection, polynomial syntax, form representative, or cohomology representative in an external theory.*

Proof. Project the connection-dependent curvature boundary from $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ using Definition 135.45. That theorem exposes the boundary row, cyclic ledger, tensorial transport row, and provenance rows, but it does not export a host-level curvature form or connection equality.

Project the cohomology representative side from the $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ dependency chapter chapter 137. The representative and class rows enter the Chern-Weil packet as BHist rows reached by λ, with their source provenance recorded in ρ.

Thus changing a connection, a polynomial presentation, a representative form, or a representative class can affect the packet only by changing ledger entries. The classifier compares the carried rows through hsame and finite Cont transport, so the choices are part of the certificate ledger rather than part of carrier equality. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope characteristic ledger transport`
Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope characteristic ledger exactness`

Theorem 272.13 (Chern-Weil root NameCert obligation surface)**.** *The minimum* $\mathsf{NameCert}_{\mathsf{ChernWeil}^{\uparrow}}$ *obligation surface consists of the carrier packet of Definition 272.9, the curvature-polynomial stability row of Definition 272.10, the de Rham class exactness row of Definition 272.11, and the characteristic-class ledger row of Definition 272.12. Downstream bridge chapters may consume the curvature boundary, invariant-polynomial endpoint, de Rham representative, class row, provenance row, and finite ledger, but may not assume a standard bridge or a stronger analytic Chern-Weil object from this root surface alone.*

Proof. Assemble the four rows by the roadmap ten-field template of section 9467.18. The traditional target is a Chern-Weil characteristic class; the BEDC sources are $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$; the carrier is the displayed BHist packet; the classifier is the characteristic-class classifier; the stability, ledger, and exactness fields are the three theorem rows above.

The curvature component is licensed by Definition 135.45. The cohomology component is licensed by the dependency chapter chapter 137. The shared primitives are exactly BHist for rows, hsame for transported endpoint comparison, Cont for finite readback, Pkg for provenance, and NameCert for dependency admission.

Therefore every downstream consumer receives a finite obligation surface with visible carrier, classifier, stability, ledger, and exactness rows. Anything beyond those rows, including a standard bridge or an analytic equality of characteristic classes, must be supplied by a later bridge certificate rather than read from $\mathsf{ChernWeil}^{\uparrow}$ itself. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope semantic name certificate`

272.2 The certificate

Theorem 272.14 (Chern-Weil curvature-de Rham obligation surface)**.** *The public obligation surface of a* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope consists of the* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *export row of Definition 135.45, the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *cohomology row carried by the de Rham certificate, the shared* Cont *provenance row, the chosen-connection ledger face, and the characteristic-class row returned by the de Rham classifier. No connection-dependent differential form is exported except through the curvature source row and the hidden ledger face.*

Proof. Project the envelope of Definition 272.1. Its curvature component exposes the public boundary, Bianchi, transport, and provenance rows supplied by $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$, and Definition 135.45 is the export rule for those rows.

Project the de Rham component next. The de Rham packet supplies the cohomology row into which the characteristic-class row λ is read, while the carried Cont provenance row records that this readout is made from the same finite history packet as the curvature source.

The remaining row is the connection ledger face γ. It is listed as a hidden face because the envelope needs it to witness the chosen connection, but the classifier of Definition 272.2 never exports it as part of the public characteristic class. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope public rows`
Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope projection rows`

Theorem 272.15 (Chern-Weil connection-choice stability)**.** *Changing the selected connection in a* $\mathsf{ChernWeil}^{\uparrow}$ *source envelope changes only the hidden ledger face* γ *when the transported curvature source rows are related by* hsame *and the de Rham classifier returns the same characteristic-class row after* Cont *projection. Under those hypotheses the two envelopes classify the same* $\mathsf{ChernWeil}^{\uparrow}$ *object.*

Proof. Begin with two envelopes whose visible curvature source rows are related by hsame. The public curvature certificate transports the boundary and provenance rows through the same $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ export surface used in Definition 272.14.

Apply the shared Cont projections to the transported rows. By hypothesis the de Rham classifier returns the same characteristic-class row after those projections, so the visible cohomology row λ is unchanged.

The chosen connection can therefore differ only in the ledger face γ. Since Definition 272.2 compares the curvature source and the de Rham class while ignoring that hidden face, the two envelopes have the same classifier value. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope connection choice stability`

Theorem 272.16 (Chern-Weil characteristic ledger exactness)**.** *The* $\mathsf{ChernWeil}^{\uparrow}$ *ledger is exact: every admitted source envelope is covered by a curvature source row, a de Rham cohomology row, a shared* Cont *provenance row, a selected-connection ledger face, and a characteristic-class row; and every public classifier comparison is sound exactly when it is generated by* hsame *on the curvature source and equality of the de Rham characteristic-class row after* Cont *projection.*

Proof. Coverage is by projection from the displayed envelope. Each admitted packet contains the curvature certificate row, the de Rham certificate row, the shared provenance row, the connection ledger face, and the characteristic-class row as finite BHist data.

For soundness, take a public classifier comparison. The definition requires hsame on the curvature source row and agreement of the de Rham characteristic-class row after the carried Cont projections, so every accepted comparison is generated by listed envelope data.

Conversely, if those listed rows are present and the two classifier conditions hold, repack them as the comparison of Definition 272.2. No unlisted host connection, differential-form representative, or external characteristic-class operator is needed. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilSourceEnvelope characteristic ledger exactness`

Theorem 272.17 (Chern-Weil standard bridge boundary)**.** *The standard bridge boundary for the public* ChernWeil$^{\uparrow}$ *certificate reads only the displayed curvature source row, the de Rham cohomology row, the invariant-polynomial endpoint, the characteristic-class classifier, the finite* Cont *projections,* hsame *transport, and* Pkg *provenance already listed in the carrier envelope. Analytic Chern-Weil equality and external cohomology quotients are outside this bridge boundary.*

Proof. Start from the carrier packet of Definition 272.9. Its displayed rows are the curvature source, de Rham target, invariant polynomial, connection ledger, characteristic endpoint, and provenance packet.

Apply Definition 272.13 to restrict the root certificate to the carrier, stability, de Rham exactness, and characteristic-ledger rows. Apply Definition 272.14 to read the curvature source row and de Rham cohomology row through the same finite Cont provenance.

Finally use Definition 272.16. It says that every public classifier comparison is generated by hsame on the curvature source and equality of the de Rham characteristic-class row after the listed Cont projections. Since no step introduces analytic equality of differential forms or an external cohomology quotient, those objects remain outside the standard bridge boundary. □

Lean4 ✓ `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope standard bridge boundary`

Closure status for NameCert$_{\text{ChernWeil}^{\uparrow}}$**.**

Constructive story: A Chern-Weil packet is assembled from a certified Curvature$^{\uparrow}$ source and a certified DeRham$^{\uparrow}$ target by displaying the curvature boundary, an invariant-polynomial row, the evaluated curvature-polynomial endpoint, the closed representative and class rows, the chosen-connection ledger face, finite Cont projections, and one Pkg provenance packet. The carrier accepts only this curvature-to-de Rham history package; coordinate connection forms, ambient polynomial algebras, external cohomology quotients, and host equalities of differential forms are not accepted unless they appear as the listed BEDC rows. Two accepted packets classify together when the curvature source transports by hsame and the de Rham classifier returns the same characteristic-class row after the carried Cont projections, while the chosen connection remains ledger data rather than part of public equality. Thus the source specification covers the CurvatureUp-to-DeRhamUp packet, the pattern specification is invariant-polynomial evaluation followed by de Rham class readback and connection-change exactness, and the ledger keeps the raw curvature, polynomial, representative, class, connection, projection, and provenance rows aligned with the visible characteristic class. The five name-certificate obligations close because an accepted packet inhabits the carrier, inherited hsame and de Rham classification give reflexivity, symmetry, and transitivity, and connection or representative transport repacks the same finite rows into another accepted packet. A history h lies in the signature gap of a ChernWeil$^{\uparrow}$ token p when the source-domain accepts h as this curvature-to-cohomology package, the signature relation pairs it with an answer characteristic-class packet and evidence ledger, and the token-introduction relation names that answer as p; concretely, h must expose the curvature row, invariant polynomial, de Rham endpoint, exact-boundary or connection ledger, Cont projections, and provenance encoded by p. The chapter registers this finite characteristic-class ledger and its paper bridge boundary under the name ChernWeil$^{\uparrow}$; it introduces no analytic Chern-Weil theorem, external polynomial calculus, or independent cohomology quotient.

Theory closure: TheoryGate(NameCert$_{\text{ChernWeil}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public ChernWeilUp carrier envelope, semantic NameCert certificate, standard bridge boundary of Definition 272.17, displayed characteristic-class ledger examples, and completeness treatment are exported over the displayed curvature, characteristic-form, BHist, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus(NameCert$_{\text{ChernWeil}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ChernWeilUp.ChernWeilCarrierEnvelope\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: This chapter does not close the standard analytic Chern-Weil theorem, external polynomial calculus, or an independent cohomology quotient.

Upgrade path: No further paper-axis upgrade is recorded; machine bridge checking remains on the separate bridge and formal axes.

Chapter 273

A Concrete Naming Certificate for $\mathsf{AtiyahSinger}^{\uparrow}$

The Atiyah-Singer-index interface $\mathsf{AtiyahSinger}^{\uparrow}$ packages the equality between the analytic index of an elliptic operator on a closed manifold and a topological index defined via Chern characters and Todd classes. It depends on $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ (chapter 214) and $\mathsf{NameCert}_{\mathsf{ChernWeil}^{\uparrow}}$ (chapter 272), and bridges spectral and topological certificates through the same index pairing.

273.1 Carrier definition

273.2 The certificate

Definition 273.1 (Atiyah-Singer index-pairing carrier packet)**.** *An* $\mathsf{AtiyahSinger}^{\uparrow}$ *index-pairing carrier packet is a finite* BHist *tuple*

$$\mathcal{A} = (m, D, \sigma_D, \mathcal{S}, \alpha, \mathcal{W}, \theta, \tau, \eta, \rho)$$

with the following rows. The row $m : \mathsf{BHist}$ *is the closed-manifold endpoint. The row* $D : \mathsf{BHist}$ *is the elliptic-operator endpoint over* m*, and* $\sigma_D : \mathsf{BHist}$ *is its symbol row. The packet* $\mathcal{S}$ *is a* $\mathsf{NameCert}_{\mathsf{SpectralTheorem}^{\uparrow}}$ *source whose operator row is* D *and whose spectral-data ledger is read over the same endpoint* m*. The row* $\alpha : \mathsf{BHist}$ *is the analytic-index endpoint projected from that spectral source. The packet* $\mathcal{W}$ *is a* $\mathsf{ChernWeil}^{\uparrow}$ *source packet over the same endpoint* m*. The row* $\theta : \mathsf{BHist}$ *is the Chern-character and Todd characteristic-class row projected from* $\mathcal{W}$*, and* $\tau : \mathsf{BHist}$ *is the topological-index endpoint obtained by the displayed characteristic-class pairing with* σ_D *over* m*. The row* $\eta : \mathsf{BHist}$ *is the index-pairing equality obligation, and* ρ *records the* Pkg *provenance of the spectral, Chern-Weil, symbol, endpoint, and pairing rows.*

The packet is admitted only when the analytic side and the topological side are displayed over the identical closed-manifold endpoint row m*. Its public classifier row is the index-pairing predicate*

$$\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau) :\Longleftrightarrow \mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha) \wedge \mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau) \wedge \mathsf{hsame}(\alpha, \tau).$$

Here $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha)$ *names the analytic-index projection from the* $\mathsf{SpectralTheorem}^{\uparrow}$ *dependency surface, while* $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau)$ *names the Chern-Weil characteristic-class projection and its displayed pairing endpoint. Thus the packet carries an equality obligation between two named index endpoints, not a host-level Fredholm theorem or an ambient equality of characteristic forms.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerTasteGate single carrier alignment`

Theorem 273.2 (Atiyah-Singer index-pairing carrier surface)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. If its* $\mathsf{SpectralTheorem}^{\uparrow}$ *component supplies the analytic-index row α for the elliptic-operator row D over the closed-manifold endpoint m, and its* $\mathsf{ChernWeil}^{\uparrow}$ *component supplies the characteristic-class row θ and topological-index endpoint τ for the symbol row σ_D over the same endpoint m, then $\mathcal{A}$ exposes the public index-pairing classifier row η exactly as*

$$\eta = \mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau).$$

The equality obligation in this row is scoped exactly to the two dependency reads

$$\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha) \quad \textit{and} \quad \mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau),$$

together with the endpoint comparison $\mathsf{hsame}(\alpha, \tau)$*. No further analytic spectrum row, coordinate connection form, ambient cohomology quotient, external symbol class, or completed Atiyah-Singer theorem is exported by this carrier surface.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket carrier surface`

Proof. Unpack the accepted packet of Definition 273.1. Projection gives the closed-manifold endpoint row m, the elliptic-operator row D, the symbol row σ_D, the spectral packet $\mathcal{S}$, the analytic-index endpoint α, the Chern-Weil packet $\mathcal{W}$, the characteristic-class row θ, the topological-index endpoint τ, the equality-obligation row η, and the provenance row ρ.

The spectral component is bounded by the $\mathsf{SpectralTheorem}^{\uparrow}$ surface. By Definition 214.1, the carried operator row and its classifier are read through the certified operator side rather than through host equality. By Definition 214.2, the spectrum, projection-valued-measure, and functional-calculus rows are the visible spectral-data rows. By Definition 214.3 and Definition 214.4, a downstream consumer of $\mathcal{S}$ may use only the displayed carrier, classifier, spectral-data, stability, ledger, exactness, and dependency rows. The Atiyah-Singer packet consumes this surface only through the analytic-index projection named by $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha)$.

The topological component is bounded by the $\mathsf{ChernWeil}^{\uparrow}$ surface. The source packet of Definition 272.3 supplies the curvature-to-de Rham rows, invariant-polynomial row, evaluated characteristic row, endpoint row, exact-boundary row, ledger, and provenance. The classifier of Definition 272.4 compares characteristic classes only after the displayed de Rham transport. The carrier and exactness theorems Definition 272.5, Definition 272.7, and Definition 272.13 exclude coordinate connection forms, ambient polynomial algebras, and uncarried cohomology quotients from the public surface. The Atiyah-Singer packet consumes this surface only through the characteristic-class row θ and the topological-index endpoint τ named by $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau)$.

The shared endpoint condition is part of the admission rule in Definition 273.1. Both dependency reads cite the identical row m before the equality obligation is formed. Therefore there is no hidden transport from one manifold endpoint to another inside η; any such transport would have to appear as an additional displayed ledger before a packet of this definition could be admitted.

It remains to identify the public classifier row. The definition assigns η to the predicate $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau)$, whose three clauses are exactly the spectral analytic-index read, the Chern-Weil topological-index read, and the comparison $\mathsf{hsame}(\alpha, \tau)$. Coverage follows by projecting η from the accepted packet. Soundness follows because any public index-pairing comparison must unpack this displayed η and hence must supply those two dependency reads and that endpoint comparison. Exactness follows from the tuple inventory: after the listed projections and the provenance row ρ, the packet contains no field from which an additional analytic, topological, or host-theoretic equality could be read. □

Theorem 273.3 (Atiyah-Singer index-pairing provenance exactness)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. Every public read of the analytic-index endpoint α, the Chern-Weil topological endpoint τ, the symbol row σ_D, the shared closed-manifold endpoint m, and the comparison row η factors through the displayed provenance row ρ, the dependency packets $\mathcal{S}$ and $\mathcal{W}$, and the endpoint comparison* $\mathsf{hsame}(\alpha, \tau)$.

Equivalently, the exact public inventory of the packet is the spectral analytic-index read $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S},$ *the Chern-Weil topological-index read* $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau)$*, the shared symbol and closed-manifold rows, the displayed comparison* $\mathsf{hsame}(\alpha, \tau)$*, and the* Pkg *provenance recorded by ρ. The packet exports no host Fredholm index equality, coordinate characteristic form equality, ambient cohomology quotient, or uncarried equality between analytic and topological models.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket provenance exactness`

Proof. Project the accepted tuple. Its fields give exactly m, D, σ_D, $\mathcal{S}$, α, $\mathcal{W}$, θ, τ, η, and ρ, with the shared endpoint condition imposed before the classifier row is read.

Apply Definition 273.2. It identifies the classifier row η with $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau)$, so every public comparison read must pass through the spectral analytic-index read, the Chern-Weil topological-index read, and $\mathsf{hsame}(\alpha, \tau)$.

The endpoint and symbol reads are then covered by the same tuple inventory. The analytic endpoint α is read only through the dependency packet $\mathcal{S}$, the topological endpoint τ only through $\mathcal{W}$, and the shared rows m and σ_D are the displayed coordinates used by both dependency clauses.

Finally, the provenance row ρ records precisely the Pkg source of these dependency, endpoint, symbol, and comparison rows. Since the packet has no field beyond the projected inventory, no host Fredholm equality, coordinate form equality, ambient cohomology quotient, or uncarried analytic-topological identity can be exported by a public read of $\mathcal{A}$. □

Theorem 273.4 (Atiyah-Singer index-pairing classifier coverage)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. Its accepted public classifier surface is exactly the coverage, soundness, and completeness table whose rows are the spectral analytic-index read* $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha)$*, the Chern-Weil topological-index read* $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau)$*, the shared closed-manifold row m, the shared symbol row σ_D, the displayed comparison* $\mathsf{hsame}(\alpha, \tau)$*, and the provenance row ρ recording the relevant* Pkg *sources.*

Thus every accepted public classifier read is covered by one of these rows, each such row is sound for the displayed index-pairing packet, and the table is complete: no host Fredholm equality, ambient characteristic-class quotient, or uncarried analytic-topological comparison is part of the public classifier surface.

Proof. Apply Definition 273.2. It identifies the public classifier row η with the spectral analytic-index read, the Chern-Weil topological-index read, and the comparison $\mathsf{hsame}(\alpha, \tau)$ over the displayed endpoint and symbol rows.

Apply Definition 273.3. It identifies every public read of α, τ, σ_D, m, and η with the dependency packets, the endpoint comparison, and the provenance row ρ.

Coverage follows by projecting those rows from the accepted tuple $\mathcal{A}$. Soundness follows because each projected row is one of the admission rows of Definition 273.1. Completeness follows by repacking only those projected rows: the tuple has no additional field carrying a host Fredholm equality, an ambient cohomology quotient, or a separate analytic-topological comparison. □

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket classifier coverage`

Theorem 273.5 (Atiyah-Singer shared index-source boundary)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. The spectral analytic-index read* $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S},\alpha)$ *and the Chern-Weil topological-index read* $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W},\theta,\tau)$ *are admitted only over the same closed-manifold endpoint row m. Consequently the comparison* $\mathsf{hsame}(\alpha,\tau)$ *in the public classifier row never compares index endpoints whose dependency reads were formed over distinct manifold endpoints.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket shared index source boundary`

Proof. Unpack the accepted packet of Definition 273.1. Its admission clause states that the analytic side and the topological side are displayed over the identical closed-manifold endpoint row m before the classifier row is formed.

The spectral read is bounded by the $\mathsf{SpectralTheorem}^{\uparrow}$ public surface cited in Definition 273.2: the operator row D and the analytic endpoint α are read through the displayed spectral dependency packet $\mathcal{S}$. The Chern-Weil read is bounded by the $\mathsf{ChernWeil}^{\uparrow}$ surface cited in the same theorem: the symbol row σ_D, the characteristic row θ, and the topological endpoint τ are read through the displayed packet $\mathcal{W}$.

Apply Definition 273.3. Every public read of α, τ, σ_D, m, and η factors through the two dependency packets, the endpoint comparison, and the provenance row ρ. Since the only endpoint row available to both dependency reads is the projected row m, a comparison formed from distinct manifold endpoints cannot be read from an accepted packet. □

Theorem 273.6 (Atiyah-Singer root endpoint exactness frontier)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. Every public Atiyah-Singer endpoint read is one of the carried closed-manifold endpoint m, elliptic-operator row D, symbol row σ_D, spectral analytic-index row α, Chern-Weil topological-index row τ together with its characteristic-class row θ, endpoint comparison* $\mathsf{hsame}(\alpha,\tau)$*, or* Pkg *provenance row ρ from that packet. Conversely, these rows repack into the public index-pairing classifier*

$$\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha,\theta,\tau).$$

No host Fredholm equality, coordinate characteristic-form equality, or cohomology quotient equality is exported by this frontier.

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket root endpoint exactness frontier`

Proof. Project the accepted tuple of Definition 273.1. Its visible endpoint inventory is exactly m, D, σ_D, $\mathcal{S}$, α, $\mathcal{W}$, θ, τ, η, and ρ.

Apply Definition 273.2. It identifies the public classifier row η with the displayed predicate $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha,\theta,\tau)$, whose clauses are the spectral analytic-index read, the Chern-Weil topological-index read, and the comparison $\mathsf{hsame}(\alpha,\tau)$.

Apply Definition 273.3. It restricts every public read of α, τ, σ_D, m, and η to the dependency packets, the endpoint comparison, and the provenance row ρ.

Finally use Definition 273.5. Both dependency reads are admitted over the same closed-manifold endpoint m, so the endpoint frontier has no second manifold row and no host-level equality between analytic and topological models. Repacking the listed rows yields the public classifier and excludes Fredholm equality, coordinate characteristic-form equality, and cohomology quotient equality. □

Theorem 273.7 (Atiyah-Singer spectral Chern-Weil consumer exhaustion)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. Any downstream consumer of the public Atiyah-Singer bridge surface sees exactly the spectral analytic-index read, the Chern-Weil topological-index read, the shared symbol row σ_D, the shared endpoint row m, the comparison* $\mathsf{hsame}(\alpha, \tau)$*, and the* Pkg *provenance row ρ. No additional consumer-visible datum is supplied by the carrier packet.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket spectral chernweil consumer exhaustion`

Proof. Project the accepted packet. The tuple inventory gives the endpoint row m, the elliptic row D, the symbol row σ_D, the dependency packets $\mathcal{S}$ and $\mathcal{W}$, the endpoints α and τ, the characteristic row θ, the classifier row η, and the provenance row ρ.

Apply Definition 273.2. It identifies η with the public predicate whose clauses are precisely $\mathsf{SpecAnalyticIndex}_{m,D}(\mathcal{S}, \alpha)$, $\mathsf{CWTopologicalIndex}_{m,\sigma_D}(\mathcal{W}, \theta, \tau)$, and $\mathsf{hsame}(\alpha, \tau)$.

Apply Definition 273.3. It states that every public read of the analytic endpoint, topological endpoint, symbol row, endpoint row, and comparison row factors through those dependency reads and the Pkg provenance ρ.

The $\mathsf{SpectralTheorem}^{\uparrow}$ citations in Definition 273.2 bound the spectral consumer to the carrier, classifier, spectral-data, stability, ledger, exactness, and dependency rows exposed by $\mathcal{S}$. The $\mathsf{ChernWeil}^{\uparrow}$ citations there bound the topological consumer to the displayed curvature-to-de Rham, invariant-polynomial, characteristic-class, ledger, and provenance rows exposed by $\mathcal{W}$. Thus the listed reads exhaust the public bridge surface. □

Theorem 273.8 (Atiyah-Singer index-pairing host exclusion)**.** *Let $\mathcal{A}$ be an accepted packet of Definition 273.1. The bridge surface exported by $\mathcal{A}$ does not export a host Fredholm equality, coordinate form equality, cohomology quotient, or ambient analytic-topological identity. Its only equality-bearing public row is the displayed comparison* $\mathsf{hsame}(\alpha, \tau)$ *inside the classifier* $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau)$*.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket host exclusion`

Proof. Unpack the carrier packet. The displayed classifier in Definition 273.1 contains the spectral analytic-index read, the Chern-Weil topological-index read, and $\mathsf{hsame}(\alpha, \tau)$; it does not contain a host Fredholm row, a coordinate form row, a quotient row, or an ambient identity row.

Apply Definition 273.2 to identify the public classifier row η with that displayed predicate. Apply Definition 273.3 to identify the complete public inventory as the two dependency reads, the shared symbol and endpoint rows, the endpoint comparison, and the provenance row ρ.

The $\mathsf{SpectralTheorem}^{\uparrow}$ surface used by the spectral dependency excludes host operator equality from the public spectral read. The $\mathsf{ChernWeil}^{\uparrow}$ surface used by the topological dependency excludes coordinate connection forms, ambient polynomial algebras, and uncarried cohomology quotients from the public characteristic-class read. Since $\mathcal{A}$ exports only those two bounded reads and their displayed comparison, none of the excluded host-level objects can be recovered from the bridge surface. □

Theorem 273.9 (Atiyah-Singer NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{AtiyahSinger}^{\uparrow}}$ *obligation surface for the Atiyah-Singer index-pairing certificate consists exactly of the carrier packet of Definition 273.1, the classifier row* $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha, \theta, \tau)$*, the shared endpoint and source-compatibility rows, the spectral and Chern-Weil dependency reads, the endpoint comparison* $\mathsf{hsame}(\alpha, \tau)$*, and the* Pkg *provenance row. The surface excludes host Fredholm equality, coordinate forms, cohomology quotients, and uncarried analytic-topological identities.*

Lean4 ✓ `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket namecert obligation surface`

Proof. Start with the carried packet. Apply Definition 273.2 to identify the public classifier as $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha,\theta,\tau)$ and to bound the equality-bearing row by the displayed spectral read, Chern-Weil read, and $\mathsf{hsame}(\alpha,\tau)$.

Next apply Definition 273.3. This records that every public endpoint, symbol, comparison, and dependency read factors through the two dependency packets and the Pkg provenance row.

The endpoint and source boundary is supplied by Definition 273.5. The dependency reads are then exhausted by Definition 273.7, which leaves only the spectral analytic-index read and the Chern-Weil topological-index read as public consumers of the two source certificates.

Finally apply Definition 273.8. It removes host Fredholm equality, coordinate forms, cohomology quotients, and uncarried analytic-topological identities from the public surface. The remaining rows are precisely the carrier packet, the classifier, the shared compatibility rows, the two dependency reads, $\mathsf{hsame}(\alpha,\tau)$, and Pkg provenance. □

Closure status for $\mathsf{NameCert}_{\mathsf{AtiyahSinger}^{\uparrow}}$.

Constructive story: An Atiyah-Singer index-pairing packet is assembled by reading one spectral-theorem source row and one Chern-Weil source row over a shared manifold endpoint and symbol row, then carrying the analytic-index endpoint, topological-index endpoint, the displayed comparison $\mathsf{hsame}(\alpha,\tau)$, and the Pkg provenance row in a single finite packet. The classifier is only the displayed $\mathsf{ASIndexPair}_{m,D,\sigma_D}(\alpha,\theta,\tau)$ row, so consumer equality is routed through the two dependency reads and the endpoint comparison rather than through a host Fredholm theorem or a cohomology quotient. The source covers exactly the spectral dependency, the Chern-Weil dependency, the shared manifold and symbol data, and the finite package provenance; the packet exports no ambient analytic-topological identity. The chapter registers this index-pairing obligation surface under the name $\mathsf{AtiyahSinger}^{\uparrow}$ while leaving the full external Atiyah-Singer theorem outside the carried surface.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AtiyahSinger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The scoped surface binds the carried index-pairing carrier, classifier, provenance, shared source rows, consumer-exhaustion rows, host-exclusion boundary, and public $\mathsf{NameCert}_{\mathsf{AtiyahSinger}^{\uparrow}}$ obligation rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AtiyahSinger}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.AtiyahSingerUp.AtiyahSingerIndexPairingCarrierPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close the full external Atiyah-Singer theorem, Fredholm-index equality, ambient cohomology quotient, or standard bridge.

Upgrade path: No further paper-side theory closure upgrade remains for this chapter; formal bridge checking remains on the verification axis.

Chapter 274

A Concrete Naming Certificate for $\mathsf{HodgeBridge}^{\uparrow}$

The Hodge-bridge interface $\mathsf{HodgeBridge}^{\uparrow}$ packages the Hodge decomposition of de Rham cohomology of a compact Kähler manifold into harmonic (p, q)-forms together with the Lefschetz / Hard-Lefschetz operators. It depends on $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ (chapter 137) and $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ (chapter 99), and bridges complex-analytic and topological certificates through the harmonic projector.

274.1 Carrier definition

Definition 274.1 (HodgeBridge BHist source packet)**.** *A* $\mathsf{HodgeBridge}^{\uparrow}$ *source packet is a finite* BHist *package*

$$\mathcal{H} = (\mathcal{D}, \mathcal{C}, P, \beta, \ell, \rho, \lambda, \tau)$$

where $\mathcal{D}$ *is a dependency row certified by* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$*,* $\mathcal{C}$ *is a dependency row certified by* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$*,* $P : \mathsf{BHist}$ *is the harmonic projector row,* $\beta : \mathsf{BHist}$ *is the bidegree ledger row,* $\ell : \mathsf{BHist}$ *records the Lefschetz and Hard-Lefschetz operation rows carried by the packet,* ρ *records the* Pkg *provenance binding the de Rham and cohomology dependency packets,* λ *is the finite* Cont *readback from de Rham representatives through harmonic projection to cohomology rows, and* τ *is the family of* hsame *transports preserving the source representative, harmonic, bidegree, Lefschetz, and cohomology endpoint rows.*

The packet is accepted only when these rows occur in one displayed provenance package. Thus $\mathsf{HodgeBridge}^{\uparrow}$ *carries the BEDC history surface relating de Rham and cohomology certificates; it does not export uncarried Kähler geometry, a host Hodge decomposition, or an ambient analytic projector.*

Lean4 (definition) `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket`

Theorem 274.2 (HodgeBridge source dependency surface)**.** *For every packet of Definition 274.1, the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *projection and the* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *projection are rows of the same* BHist *package. The harmonic projector row, bidegree ledger, Lefschetz ledger, finite* Cont *readback,* hsame *transports, and* Pkg *provenance are shared dependency data.*

Proof. Project the tuple $\mathcal{H}$. The first two components are the de Rham and cohomology dependency rows, while ρ records their common provenance package.

The projector row P, bidegree row β, Lefschetz ledger ℓ, continuation readback λ, and transport family τ are further projections from the same finite package.

Repacking those projections gives the original carrier. Hence the de Rham and cohomology sides are not separate host objects; they are dependency rows of one BEDC history packet. □

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket source dependency surface`

Theorem 274.3 (HodgeBridge harmonic projector classifier stability)**.** *If two packets of Definition 274.1 are related by the carried* hsame *transports on their de Rham source rows and by the same* Pkg *provenance, then transport of the harmonic projector preserves the bidegree ledger and carries the finite* Cont *readback to the transported* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *endpoint row.*

Proof. Start with the de Rham source representatives and their carried hsame comparison. This comparison is one of the transport rows in τ, so it remains internal to the displayed history package.

Transport the harmonic projector row P and the bidegree ledger β along the same family. Since P and β are components of the packet, their transported rows remain paired with the transported source representative.

Read the continuation ledger λ after transport. It carries the harmonic row to the cohomology endpoint, and repacking through the $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ dependency row proves stability of the classifier. □

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket harmonic projector classifier stability`

Theorem 274.4 (HodgeBridge ledger exactness)**.** *The* $\mathsf{HodgeBridge}^{\uparrow}$ *ledger is exact for exactly the rows listed in Definition 274.1: the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *source row, the* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *endpoint row, the harmonic projector row, the bidegree ledger, the Lefschetz ledger, the finite* Cont *readback, the* hsame *transports, and the* Pkg *provenance. Coverage, soundness, and completeness range only over those rows and exclude uncarried Kähler geometry and host Hodge decomposition.*

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket ledger exactness`

Proof. Coverage follows by projecting an accepted packet. The accepted tuple displays the two dependency rows, projector row, bidegree row, Lefschetz row, continuation readback, transport family, and provenance row.

For soundness, begin with exactly those displayed rows and the two dependency certificates. Repack them as $\mathcal{H}$, and the carrier definition accepts the package because every row is present in the same provenance surface.

For completeness, take any accepted public $\mathsf{HodgeBridge}^{\uparrow}$ row. The carrier definition contains no field for ambient Kähler geometry and no field for a host Hodge decomposition. Therefore the public row is exhausted by the listed dependency, projector, ledger, transport, continuation, and provenance data. □

Theorem 274.5 (HodgeBridge NameCert obligation surface)**.** *The paper-side* $\mathsf{NameCert}_{\mathsf{HodgeBridge}^{\uparrow}}$ *obligation surface consists of the carrier packet of Definition 274.1, the shared dependency surface of Definition 274.2, the harmonic projector classifier stability row of Definition 274.3, and the ledger exactness row of Definition 274.4. Downstream consumers may project the de Rham dependency, cohomology dependency, harmonic, bidegree, Lefschetz,* Cont, hsame, *and* Pkg *rows, but no stronger Hodge bridge is part of this surface.*

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket namecert obligation surface`

Proof. Assemble the carrier packet from Definition 274.1. It provides the de Rham source row, cohomology endpoint row, harmonic projector, bidegree ledger, Lefschetz ledger, continuation readback, transport rows, and provenance.

Use Definition 274.2 to bind the two dependency projections to one package. Use Definition 274.3 to transport the harmonic classifier and its bidegree ledger across hsame replacement.

Finally apply Definition 274.4. Its coverage, soundness, and completeness clauses exhaust the public rows, so repacking the listed data gives the $\mathsf{NameCert}_{\mathsf{HodgeBridge}^{\uparrow}}$ obligation surface and excludes unlisted analytic bridge data. □

Theorem 274.6 (HodgeBridge shared-projector readback exactness)**.** *Any public readback of a* $\mathsf{HodgeBridge}^{\uparrow}$ *packet that consumes both the* $\mathsf{NameCert}_{\mathsf{DeRham}^{\uparrow}}$ *source row and the* $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ *endpoint row factors through the single displayed provenance package, harmonic projector row, bidegree ledger, Lefschetz ledger, finite* Cont *readback, and carried* hsame *transport family of Definition 274.1. It exports no uncarried Kähler geometry, ambient analytic projector, or host Hodge decomposition.*

Proof. First project the accepted packet. By Definition 274.2, the de Rham dependency row and the cohomology endpoint row are rows of one finite BHist package, and the provenance coordinate ρ binds them to the same displayed source.

Next read the projector data through the carried transport family. Definition 274.3 keeps the harmonic projector and bidegree ledger stable under the packet's hsame rows, and it carries the finite Cont readback to the transported $\mathsf{NameCert}_{\mathsf{Cohomology}^{\uparrow}}$ endpoint row.

Finally combine Definition 274.4 with Definition 274.5. The public certificate is exhausted by the displayed dependency, projector, bidegree, Lefschetz, continuation, transport, and provenance rows. Because the carrier has no field for uncarried Kähler geometry, an ambient analytic projector, or a host Hodge decomposition, none of those structures is exported by the readback. □

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket shared projector readback exactness`

Theorem 274.7 (HodgeBridge public certificate handoff)**.** *A public* $\mathsf{NameCert}_{\mathsf{HodgeBridge}^{\uparrow}}$ *consumer may read exactly the de Rham dependency row, the cohomology dependency row, the harmonic projector row, the bidegree ledger, the Lefschetz ledger, the finite* Cont *readback, the* hsame *transport family, and the* Pkg *provenance supplied by Definition 274.1 and exhausted by Definition 274.5. The handoff exports no host Hodge decomposition, no ambient analytic projector, and no uncarried Kähler geometry.*

Proof. Project the accepted source packet. Its displayed coordinates supply the de Rham dependency row, cohomology dependency row, harmonic projector, bidegree ledger, Lefschetz ledger, finite continuation readback, transport family, and package provenance.

Apply Definition 274.2 to bind the two dependency rows to one provenance package. Then use Definition 274.3 for the harmonic classifier transport and Definition 274.4 for the exact public ledger rows.

Finally repack exactly those projected fields as the consumer handoff. The obligation surface of Definition 274.5 exhausts the public projections, so there is no coordinate from which to read a host Hodge decomposition, an ambient analytic projector, or uncarried Kähler geometry. □

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket public certificate handoff`

Theorem 274.8 (HodgeBridgeUp bridge-status surface)**.** *The checked public handoff of Definition 274.7 exposes only the* BHist *source packet, the* Cohomology$^{\uparrow}$ *and* DeRham$^{\uparrow}$ *dependency rows, the harmonic-projector classifier, the shared projector readback,* Cont, hsame, *and the* Pkg *ledger rows. Analytic Hodge decomposition, ambient harmonic analysis, and Kähler geometry are not part of this bridge surface.*

Proof. Start with Definition 274.5. It gives the finite source packet, the two dependency rows, the projector and bidegree ledger, continuation readback, transport, and package provenance as the public obligation surface.

Then apply Definition 274.6. The shared projector readback is exhausted by the carried projector row and the displayed dependency endpoints; no ambient analytic projector is introduced by the readback.

Finally use Definition 274.7. Its exported rows are exactly the public packet rows just listed. Since the handoff has no field for analytic Hodge decomposition, ambient harmonic analysis, or Kähler geometry, those structures remain outside the bridge-status surface. □

Lean4 ✓ `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket bridge status surface`

Closure status for NameCert$_{\text{HodgeBridge}^{\uparrow}}$**.**

Constructive story: A HodgeBridge packet is built from a finite BHist source packet, the displayed DeRham$^{\uparrow}$ and Cohomology$^{\uparrow}$ dependency rows, a harmonic-projector classifier row, a shared projector readback row, and the Cont, hsame, and Pkg ledger rows that carry those dependencies through the certificate. The source accepts only this finite packet surface; analytic Hodge decomposition, ambient harmonic analysis, and Kähler geometry remain outside the carrier. The classifier transports the finite source packet and projector readback through the named dependency rows and the displayed history-sameness and continuation ledgers. The public certificate handoff is therefore the visible packet assembled by the chapter, with no bridgeChecked row or ambient Hodge-theoretic object introduced.

Theory closure: TheoryGate(NameCert$_{\text{HodgeBridge}^{\uparrow}}$, publicClosed)

Scope closed: The public certificate handoff exports exactly the finite BHist packet, DeRham$^{\uparrow}$ and Cohomology$^{\uparrow}$ dependency rows, harmonic-projector classifier, shared projector readback, Cont, hsame, and Pkg ledger rows carried by this chapter.

Formal verification: FormalStatus(NameCert$_{\text{HodgeBridge}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.HodgeBridgeUp.HodgeBridgeBHistSourcePacket\_public\_certificate\_handoff`

Bridge status: none

Not claimed: Ambient Hodge theory, Kähler geometry, analytic harmonic analysis, and bridgeChecked status are not closed.

Upgrade path: The next step is bridgeChecked coverage for the finite HodgeBridge packet surface and its displayed dependency rows.

274.2 The certificate

Chapter 275

A Concrete Naming Certificate for $\mathsf{MirrorSymmetry}^{\uparrow}$

The mirror-symmetry interface $\mathsf{MirrorSymmetry}^{\uparrow}$ packages, for a Calabi-Yau pair $(X, X^{\vee})$, the conjectural equivalence of the A-model on one side with the B-model on the other (Hodge numbers, Fukaya category vs derived category). It depends on $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ (chapter 138) and $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ (chapter 160), and bridges symplectic and complex-algebraic certificates through a common categorical classifier.

275.1 Carrier definition

Definition 275.1 (Mirror-symmetry paired history carrier)**.** *Fix a* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *A-model source row and a* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ *B-model source row. A* $\mathsf{MirrorSymmetry}^{\uparrow}$ *pair carrier row is the finite* BHist *ledger that records the two source certificates, the visible A-model categorical answer rows, the visible B-model categorical answer rows, and the* Cont *witnesses that align each displayed A-row with the corresponding displayed B-row inside one observed pair packet.*

The carrier is a pairing surface for finite categorical observations. It does not include a full Fukaya category, a derived-equivalence theorem, Hodge-number symmetry beyond the observed rows, or a host Calabi-Yau moduli statement.

Definition 275.2 (Mirror-symmetry categorical classifier)**.** *Two rows of Definition 275.1 are classified as the same* $\mathsf{MirrorSymmetry}^{\uparrow}$ *packet exactly when their A-model source rows are transported by* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$*, their B-model source rows are transported by* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$*, and each paired categorical answer row is matched through* hsame*,* Cont*, and* Pkg *witnesses.*

The classifier is generated only by source transport, categorical answer transport, package transport for the displayed finite ledger, and concatenation of observed pair rows. It contains no generator asserting an external mirror equivalence.

275.2 The certificate

Theorem 275.3 (Mirror-symmetry source certificate scope)**.** *Every* $\mathsf{MirrorSymmetry}^{\uparrow}$ *carrier row has exactly one* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *A-model source and one* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ *B-model source, and every other accepted field is a finite categorical answer history or a transport witness named by* hsame*,* Cont*, or* Pkg*.*

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier source certificate scope`

Proof. Invert the carrier definition. The first source field is the symplectic certificate, the second source field is the derived-category certificate, and the remaining fields are indexed by the finite observed pairing ledger.

The classifier of Definition 275.2 can replace source representatives only through the two named NameCert classifiers. It can replace answer rows only through the displayed hsame, Cont, and Pkg witnesses, so no additional source or host category is introduced. □

Theorem 275.4 (Mirror-symmetry categorical stability)**.** *Classified* $\mathsf{MirrorSymmetry}^{\uparrow}$ *packets remain classified after replacing either source certificate by a NameCert-classified representative and after transporting any displayed categorical answer row through* hsame*,* Cont*, or* Pkg*.*

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryCategorical stability`

Proof. Transport the A-model and B-model sources first. The source certificates give the two NameCert-level comparison rows, and the carrier repacks the transported representatives as the same finite pair packet.

For each displayed categorical answer, use the stored hsame row to replace endpoints, the Cont row to keep the answer in the paired ledger, and the Pkg row to preserve the package reading. Concatenating the finite list of transported pair rows gives the required classifier witness. □

Theorem 275.5 (Mirror-symmetry pairing obligation package)**.** *The* $\mathsf{MirrorSymmetry}^{\uparrow}$ *chapter exports a finite pairing obligation package consisting of the paired* BHist *carrier, the categorical classifier, the two source* NameCert *rows, and the statement that the ledger hides only the observed A-model and B-model matching rows.*

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier semantic name certificate`
Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryCategoricalClassifier endpoint confluence`

Proof. Start from a carrier row and a classifier witness. The carrier supplies the two source certificates and the finite list of paired categorical answer rows; the classifier supplies only the source transports and answer transports allowed in Definition 275.2.

Ledger exactness follows by induction over the finite observed pair list. Each item is either an A-model answer, a B-model answer, or one of the named transport witnesses. Therefore the obligation package records a BEDC pairing surface and does not assert a full external mirror-equivalence theorem. □

Theorem 275.6 (Mirror-symmetry HMS source boundary)**.** *The only external source rows available to a* $\mathsf{MirrorSymmetry}^{\uparrow}$ *packet are* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$*. Every A-model or B-model answer exported by the packet is a finite* BHist *row transported by the displayed* hsame*,* Cont*, and* Pkg *witnesses.*

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier hms source boundary`

Proof. Project the source certificate scope of Definition 275.3. It exposes one symplectic source certificate and one derived-category source certificate.

The classifier of Definition 275.2 then lists the only movements allowed after those source rows are chosen. Source representatives move by their two NameCert classifiers, while answer rows move only by hsame, Cont, and Pkg.

Thus the HMS-facing boundary is a finite BEDC ledger of observed categorical answer rows. It does not add a derived equivalence, a complete Fukaya category, a Hodge theorem, or a standard bridge. □

Theorem 275.7 (Mirror-symmetry local pairing ledger exactness)**.** *The local pairing ledger of a* $\mathsf{MirrorSymmetry}^{\uparrow}$ *packet exposes exactly the two source certificates, the paired A-model and B-model categorical answer rows, the source-transport rows, the answer-transport rows, and the package provenance row. No other row is readable from the packet.*

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier local pairing ledger exactness`

Proof. Unpack the paired history carrier of Definition 275.1. Its fields are the two source certificates, the visible paired categorical answers, and the continuation witnesses aligning each displayed pair.

Next unpack the categorical classifier of Definition 275.2. It contributes only source transport, answer transport, package transport, and concatenation of the observed finite pair rows.

Combining these projections gives the exact ledger. Since every exported item is one of those fields or one of those transport witnesses, there is no hidden row for global mirror equivalence, category completeness, or host Hodge theory. □

Theorem 275.8 (Mirror-symmetry NameCert obligation inventory)**.** *The finite* $\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$ *obligation inventory consists of the paired carrier, the categorical classifier, the HMS source boundary, the categorical stability row, and the local pairing ledger exactness row. These rows give the complete obligation package for the displayed finite pairing surface.*

Proof. Start with the carrier and classifier definitions. They provide the finite packet to be named and the admissible comparison rows between packets.

Apply Definition 275.6 to fix the only external source rows. Apply Definition 275.4 to keep source and answer replacement inside the displayed classifier. Apply Definition 275.7 to identify the full readable ledger.

Together these rows are exactly the obligation inventory asserted by Definition 275.5. The inventory is a finite BEDC pairing surface and leaves derived equivalence, Fukaya category completeness, Hodge theory, and standard bridge data unclaimed. □

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier namecert obligation inventory`

Theorem 275.9 (Mirror-symmetry scoped kernel surface)**.** *The carrier, categorical classifier, HMS source boundary, stability row, and local pairing ledger of* $\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$ *are scoped entirely by the two source* NameCert *rows, the finite* BHist *paired answer rows,* hsame*,* Cont*, and* Pkg*.*

This scoped surface contains no full Fukaya category, derived equivalence, Hodge theorem, Calabi-Yau moduli datum, or standard bridge.

Proof. Start with Definition 275.3. It fixes the only external sources as the symplectic and derived-category NameCert rows, and it leaves every remaining accepted field inside the finite observed pairing ledger.

Apply Definition 275.4. The only admissible movements of source and answer rows are the displayed NameCert transports and the hsame, Cont, and Pkg witnesses, so the classifier remains within the same kernel surface.

Next use Definition 275.7. It reads the local ledger as exactly the two source certificates, paired categorical answer rows, source transports, answer transports, and package provenance.

Finally apply Definition 275.8. The inventory contains precisely the carrier, categorical classifier, HMS source boundary, stability row, and local ledger exactness row. Hence the scoped kernel surface is the listed finite BEDC packet and excludes full Fukaya categories, derived equivalence, Hodge theory, Calabi-Yau moduli, and standard bridges. □

Lean4 ✓ `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier scoped kernel scope`

Theorem 275.10 (Mirror-symmetry finite HMS bridge boundary)**.** *The public HMS source boundary and the local pairing ledger define a paper bridge from the finite* $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$ *source rows to the abstract* $\mathsf{MirrorSymmetry}^{\uparrow}$ *pairing schema. Every exported A-model or B-model answer row factors through the displayed* BHist *paired ledger,* hsame*,* Cont*,* Pkg*, and the two source certificates.*

This bridge boundary does not claim a full Fukaya category, derived equivalence, Hodge-number theorem, Calabi-Yau moduli theorem, or machine-checked standard bridge.

Proof. Begin with Definition 275.6. It restricts the available source data to one symplectic certificate, one derived-category certificate, and finite A-model and B-model answer rows transported by the displayed hsame, Cont, and Pkg witnesses.

Apply Definition 275.7. The ledger therefore exposes exactly the two source certificates, paired categorical answer rows, source transports, answer transports, and package provenance.

Use Definition 275.8 to identify these rows as the local $\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$ obligation package, and then apply Definition 275.9 to keep every consumer read inside the same finite kernel surface.

Repacking those four displayed rows gives the paper bridge from the two finite source certificates to the $\mathsf{MirrorSymmetry}^{\uparrow}$ pairing schema. Since no cited row contains a full Fukaya category, derived equivalence, Hodge-number theorem, Calabi-Yau moduli theorem, or machine-checked standard bridge, the boundary exports none of those objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation scope is the finite paired BHist ledger over $\mathsf{NameCert}_{\mathsf{Symplectic}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DerivedCat}^{\uparrow}}$, visible A-model and B-model categorical rows, hsame, Cont, Pkg, and the displayed source certificate rows.

Constructive story: A $\mathsf{MirrorSymmetry}^{\uparrow}$ packet is built from one displayed symplectic source certificate, one displayed derived-category source certificate, and a finite ledger of paired categorical answer rows whose admissible movements are exactly the source-certificate, history, continuation, and package transports named by the classifier.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{MirrorSymmetry}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MirrorSymmetryUp.MirrorSymmetryPairCarrier\_hms\_source\_boundary`

Bridge status: paperBridge

Not claimed: This chapter does not claim a full Fukaya category, derived equivalence, Hodge-number theorem, Calabi-Yau moduli theorem, or standard bridge.

Upgrade path: The finite A-side and B-side source rows and displayed bridge packet are the mature paper surface, while machine bridge checking remains governed by the paperBridge bridge status.

Chapter 276

A Concrete Naming Certificate for $\mathsf{AxisNat}^{\uparrow}$

This chapter gives a concrete naming-certificate construction for $\mathsf{AxisNat}^{\uparrow}$ at the paper-proof level. The interface $\mathsf{AxisNat}^{\uparrow}$ is a conservative parallel to $\mathsf{Nat}^{\uparrow}$ (Chapter 28): it is a finite-repetition counting seed whose carrier is the $\mathsf{E0}$-spine, not the $\mathsf{E1}$-spine that $\mathsf{Nat}^{\uparrow}$ uses. The two interfaces are kernel-distinct; their relation is mediated by the bridge of Chapter 9344.

276.1 The $\mathsf{E0}$-spine carrier

Definition 276.1 (Zero-spine history judgment)**.** *The zero-spine history judgment* $\mathsf{ZeroSpine}(h)$ *is generated by:*

1. $\mathsf{ZeroSpine}(\mathsf{e})$*;*
2. *if* $\mathsf{ZeroSpine}(h)$*, then* $\mathsf{ZeroSpine}(\mathsf{E0}(h))$*.*

No rule generates $\mathsf{ZeroSpine}(\mathsf{E1}(h))$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Spine.ZeroSpine`

Lemma 276.2 (Zero-spine empty base)**.** $\mathsf{ZeroSpine}(\mathsf{e})$ *holds.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Spine.zeroSpine empty`

Proof. First generator of the zero-spine judgment. □

Lemma 276.3 (Zero-spine closure under zero-extension)**.** *If* $\mathsf{ZeroSpine}(h)$*, then* $\mathsf{ZeroSpine}(\mathsf{E0}(h))$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Spine.zeroSpine e0 closed`

Proof. Second generator of the zero-spine judgment. □

Lemma 276.4 (Zero-spine zero-extension inversion)**.** *If* $\mathsf{ZeroSpine}(\mathsf{E0}(h))$*, then* $\mathsf{ZeroSpine}(h)$*.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Spine.zeroSpine e0 inversion`

Proof. Proceed by cases on the closed generation of $\mathsf{ZeroSpine}(\mathsf{E0}(h))$.

The empty constructor cannot produce an $\mathsf{E0}$ endpoint. The zero-extension constructor is the only matching generated shape, and it exposes exactly the predecessor witness $\mathsf{ZeroSpine}(h)$. □

Lemma 276.5 (Zero-spine no one-extension)**.** *No judgment* ZeroSpine(E1(h)) *is generated.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Spine.zeroSpine no e1 extension`

Proof. By closed generation for ZeroSpine, the only extension rule uses E0. No E1-extension constructor is displayed. □

Lemma 276.6 (Zero-spine hsame transport)**.** *If* ZeroSpine(h) *and* hsame(h, k)*, then* ZeroSpine(k)*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Spine.zeroSpine hsame transport`

Proof. hsame is propositional history identity, so the witness transports along the equality. □

276.2 The certificate

Definition 276.7 (Zero-spine source specification)**.** *The source specification* AxisNatSource *consists of histories h with* ZeroSpine(h)*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNatSourceSpec`

Definition 276.8 (Zero-spine pattern specification)**.** *The pattern specification* AxisNatPattern *is repeated generation by the zero-extension constructor* E0 *from* e*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNatPatternSpec`

Definition 276.9 (Zero-spine classifier specification)**.** *The classifier specification* AxisNatClassifier *classifies zero-spine histories pairwise by* hsame *restricted to the zero-spine carrier.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNatClassifierSpec`

Definition 276.10 (Zero-spine stability certificate)**.** *The stability certificate* AxisNatStability *consists of:*

1. *the base derivation* ZeroSpine(e)*;*
2. *closure under* E0*;*
3. *no one-extension, recording that* E1 *is not part of the zero-spine generation discipline.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNatStabilityCert`
↪ variant `BEDC.Derived.AxisZeckendorf.AxisNat.axisNatStabilityCert`

Definition 276.11 (Zero-spine ledger policy)**.** *The ledger policy* AxisNatLedger *records the source zero-spine history behind any visible zero-spine class. It does not erase the emitted history; it licenses a derived interface while retaining provenance.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNatLedgerPolicy`

Theorem 276.12 (Concrete $\mathsf{AxisNat}^{\uparrow}$ naming certificate)**.** *The tuple*

$$\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}} := (\mathsf{AxisNatSource}, \mathsf{AxisNatPattern}, \mathsf{AxisNatClassifier}, \mathsf{AxisNatStability}, \mathsf{AxisNatLedger})$$

forms a valid naming certificate for the derived interface $\mathsf{AxisNat}^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisNat.axisNat namecert`

Proof. The source, pattern, classifier, stability, and ledger fields are explicitly supplied by the preceding definitions. The stability field is justified by zero-spine base generation, zero-spine closure under $\mathsf{E0}$, and zero-spine no-one-extension. Therefore the naming protocol is satisfied. □

Corollary 276.13 ($\mathsf{AxisNat}^{\uparrow}$ is licensed, not primitive)**.** *The interface* $\mathsf{AxisNat}^{\uparrow}$ *is licensed by* $\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$*. It is not a primitive object of the finite kernel.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNat semantic name certificate`

276.3 Distinction from $\mathsf{Nat}^{\uparrow}$

Theorem 276.14 (Zero-spine and unary spine are kernel-distinct)**.** *The* $\mathsf{E0}$*-spine carrier* $\mathsf{ZeroSpine}$ *and the* $\mathsf{E1}$*-spine carrier* Unary *intersect, as history predicates, only at the empty history* e*.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisNat.ZeroSpine unaryHistory intersection empty`

Proof. A zero-spine history is either e or has the form $\mathsf{E0}(h)$; a unary history is either e or has the form $\mathsf{E1}(h)$. The two non-empty shapes are $\mathsf{E0}$-headed and $\mathsf{E1}$-headed respectively, so a non-empty history cannot satisfy both judgments. □

Remark 276.15 (Bridge instead of identification)**.** *The kernel-distinct theorem above ensures that any identification of* $\mathsf{AxisNat}^{\uparrow}$ *with* $\mathsf{Nat}^{\uparrow}$ *must come from a separately certified bridge, not from internal kernel reasoning. Such a bridge is the subject of Chapter 9344.*

Theorem 276.16 (Zero-spine source shape exhaustion)**.** *For every history* $h : \mathsf{BHist}$*, if* $\mathsf{ZeroSpine}(h)$*, then*

$$\mathsf{hsame}(h, \mathsf{e}) \vee \exists h_{\mathrm{pred}} : \mathsf{BHist}.\ \mathsf{hsame}(h, \mathsf{E0}(h_{\mathrm{pred}})) \wedge \mathsf{ZeroSpine}(h_{\mathrm{pred}}).$$

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisNat.zeroSpine source shape exhaustion`

Proof. Induct on the displayed generation of $\mathsf{ZeroSpine}(h)$ from Definition 276.1.

In the empty-generator case, h is e. The left disjunct follows from the empty generator for $\mathsf{hsame}(\mathsf{e}, \mathsf{e})$.

In the zero-extension generator case, the derivation has the displayed form $h = \mathsf{E0}(p)$ together with a predecessor derivation $\mathsf{ZeroSpine}(p)$. Choose $h_{\mathrm{pred}} := p$ in the right disjunct. The history-sameness component is $\mathsf{hsame}(\mathsf{E0}(p), \mathsf{E0}(p))$, obtained by applying the $\mathsf{E0}$ history-sameness constructor to reflexivity on p, and the remaining component is exactly the predecessor derivation $\mathsf{ZeroSpine}(p)$. □

Theorem 276.17 (AxisNat unary bridge consumer example)**.** *A package-level consumer of the* $\mathsf{AxisNat}^{\uparrow}$*-to-*$\mathsf{Nat}^{\uparrow}$ *bridge reads only the zero-spine source, the unary-direction bridge boundary, the* $\mathsf{Nat}^{\uparrow}$ *comparison row, the displayed* hsame *transports, the* Cont *provenance, and the local* $\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *rows. The consumer cannot identify the two spines internally except at the empty history* e*.*

Proof. Start from the zero-spine source and Definition 276.16. This gives the consumer only the empty history case or a displayed $\mathsf{E0}$ predecessor case, with no access to a unary constructor inside the $\mathsf{AxisNat}^{\uparrow}$ carrier.

Next use Definition 276.14. It states that the zero-spine and unary-spine history predicates meet only at e, so any comparison with $\mathsf{Nat}^{\uparrow}$ must pass through the separately displayed unary-direction bridge boundary.

The bridge consumer then reads the $\mathsf{Nat}^{\uparrow}$ comparison row, the displayed hsame transports, the Cont provenance, and the two local naming surfaces. Since the bridge boundary is the only route between the spines, no internal identification of $\mathsf{AxisNat}^{\uparrow}$ and $\mathsf{Nat}^{\uparrow}$ is produced beyond the empty-history overlap. □

Lean4 ✓ `BEDC.Derived.AxisNatUp.AxisNatTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$.

Constructive story: A zero-axis natural number begins at e and grows only by repeated E0-extension: e is admitted, E0(h) is admitted whenever h is already admitted, and the first E1-headed history is excluded from the carrier. The classifier is hsame restricted to this zero-spine carrier, so two accepted histories are the same only as histories on the E0-spine, while the source specification covers exactly zero-spine histories and the pattern specification is their closed generation from e by E0. The ledger keeps the raw zero-spine history behind every visible $\mathsf{AxisNat}^{\uparrow}$ class, preserving the fact that this carrier is kernel-distinct from the E1-spine used by $\mathsf{Nat}^{\uparrow}$. The five name-certificate obligations are the same closed-generation facts in certificate form: e inhabits the carrier, restricted hsame is reflexive, symmetric, and transitive, and if an admitted zero-spine history is transported along hsame then the transported history is admitted as well. A history h lies in the signature gap of an $\mathsf{AxisNat}^{\uparrow}$ token p when the source-domain accepts h as a zero-spine history, the signature relation pairs it with an answer history and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is a finite stack of E0 marks whose zero-depth matches the spine encoded by p. The only bridge mentioned here is negative: any comparison with $\mathsf{Nat}^{\uparrow}$ must pass through a separate bridge, because the two spines meet internally only at e. The chapter registers this zero-spine counting construction under the name $\mathsf{AxisNat}^{\uparrow}$; it adds no arithmetic induction, recursion principle, RealUp completion, infinite limit object, or new primitive beyond empty history and E0-stacking.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation inventory binds the zero-spine constructor, source, pattern, classifier, stability, ledger, semantic $\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$, the source-exhaustion rows of Definition 276.16, the NatUp-separation rows of Definition 276.14, the unary bridge consumer example of Definition 276.17, and the paper bridge boundary of chapter 9344.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisNat}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.AxisZeckendorf.AxisNat.AxisNat\_semantic\_name\_certificate`

Bridge status: paperBridge

Not claimed: It does not identify AxisNatUp with NatUp, arithmetic induction, recursion, RealUp completeness, or an infinite limit object.

Upgrade path: No further paper-side theory grade remains for this chapter.

Chapter 277

A Concrete Naming Certificate for $\mathsf{AxisAdd}^{\uparrow}$

The additive seed on the $\mathsf{E0}$-spine is licensed by continuation of zero-spine histories. It is not a primitive operation. The zero-spine obligation surface for $\mathsf{AxisAdd}^{\uparrow}$ is the source, pattern, classifier, stability, ledger, and checked algebra rows recorded below.

277.1 Continuation on the zero-spine

Definition 277.1 (Additive source specification (zero-spine))**.** *The source specification* AxisAddSource *consists of ordered pairs* (h, k) *of zero-spine histories.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddSourceSpec`

Definition 277.2 (Additive pattern specification (zero-spine))**.** *The pattern specification* AxisAddPattern *is the continuation predicate*

$$\mathsf{Cont}(h, k, r)$$

together with $\mathsf{ZeroSpine}(h)$ *and* $\mathsf{ZeroSpine}(k)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddPatternSpec`

Definition 277.3 (Additive classifier specification (zero-spine))**.** *The classifier specification* AxisAddClassifier *identifies two additive results* r_1 *and* r_2 *of* (h, k) *when both share the same zero-spine pattern witness and* $\mathsf{hsame}(r_1, r_2)$ *holds.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddClassifierSpec`

Theorem 277.4 (Left unit on the zero-spine)**.** *For every zero-spine history* h*, continuation by the empty history on the left produces* h*:*

$$\mathsf{Cont}(\mathsf{e}, h, h).$$

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont left unit zeroSpine`

Proof. This is the kernel left-unit theorem of Cont restricted to a zero-spine input. □

Definition 277.5 (Additive stability certificate (zero-spine))**.** *The stability certificate* AxisAddStability *records the checked zero-spine rows for left unit, result zero-spine closure, determinacy, right unit, associativity, and commutativity.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddStabilityCert`
↪ variant `BEDC.Derived.AxisZeckendorf.AxisAdd.axisAddStabilityCert`

Definition 277.6 (Additive ledger policy (zero-spine))**.** *The ledger policy* AxisAddLedger *records the input pair* (h, k) *and the continuation witness behind any visible additive result.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddLedgerPolicy`

277.2 The certificate

Theorem 277.7 (Concrete $\mathsf{AxisAdd}^{\uparrow}$ naming certificate)**.** *The tuple*

$$\mathsf{NameCert}_{\mathsf{AxisAdd}^{\uparrow}} := (\mathsf{AxisAddSource}, \mathsf{AxisAddPattern}, \mathsf{AxisAddClassifier}, \mathsf{AxisAddStability}, \mathsf{AxisAddLedger})$$

forms a valid naming certificate for the derived additive interface $\mathsf{AxisAdd}^{\uparrow}$ *on the* E0*-spine.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.AxisAdd.axisAdd namecert`

Proof. Source, pattern, classifier, stability, and ledger fields are supplied by the preceding definitions. The stability field includes the checked zero-spine rows for left unit, result closure, determinacy, right unit, associativity, and commutativity. □

Corollary 277.8 ($\mathsf{AxisAdd}^{\uparrow}$ is licensed, not primitive)**.** *The interface* $\mathsf{AxisAdd}^{\uparrow}$ *is licensed by* $\mathsf{NameCert}_{\mathsf{AxisAdd}^{\uparrow}}$*. It is not a primitive operation of the finite kernel.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAdd semantic name certificate`

Theorem 277.9 (AxisAdd dependency on the AxisNat zero-spine)**.** *The* $\mathsf{AxisAdd}^{\uparrow}$ *source, pattern, classifier, and stability rows are read over the* $\mathsf{AxisNat}^{\uparrow}$ *zero-spine carrier of chapter 276 before they become an additive continuation certificate. Thus an accepted* $\mathsf{AxisAdd}^{\uparrow}$ *certificate is a consumer of the AxisNat zero-spine source surface, followed by the continuation row* $\mathsf{Cont}(h, k, r)$ *and the checked additive rows for determinacy, unit laws, associativity, and commutativity.*

Lean4 ✓ `BEDC.Derived.AxisAddUp.AxisAddTasteGate single carrier alignment`

Proof. Begin with the source and pattern specifications. They require the ordered input pair (h, k) to satisfy the zero-spine carrier condition before the continuation witness $\mathsf{Cont}(h, k, r)$ can serve as an additive pattern.

Apply zero-spine preservation for continuation. This keeps the result row on the same AxisNat carrier surface, so the additive classifier is still read over the zero-spine source rather than over an ambient arithmetic carrier.

Use result determinacy to identify any two displayed continuation results over the same zero-spine source pair. Then apply the left-unit, right-unit, associativity, and commutativity rows to package the stable additive law surface.

The resulting certificate therefore depends on the sibling AxisNat zero-spine chapter for its carrier and source discipline, and only then exposes the $\mathsf{AxisAdd}^{\uparrow}$ continuation certificate. □

Lean4 ✓ `BEDC.Derived.AxisAddUp.AxisAddUp single carrier alignment`

277.3 Horizon obligations

The following theorems record the checked zero-spine law surface.

Theorem 277.10 (Continuation preserves zero-spine)**.** *If* $\mathsf{ZeroSpine}(h)$*,* $\mathsf{ZeroSpine}(k)$*, and* $\mathsf{Cont}(h, k, r)$*, then* $\mathsf{ZeroSpine}(r)$*.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont result zeroSpine`
↪ variant `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAdd cont result zeroSpine`

Theorem 277.11 (Result determinacy on the zero-spine)**.** *If* $\mathsf{ZeroSpine}(h)$*,* $\mathsf{ZeroSpine}(k)$*,* $\mathsf{Cont}(h, k, r)$*, and* $\mathsf{Cont}(h, k, r')$*, then* $\mathsf{hsame}(r, r')$*. Equivalently, two displayed* AxisAddPattern *witnesses over the same ordered source* (h, k) *determine an* AxisAddClassifier *witness between their results.*

Proof. Apply the finite-kernel continuation determinacy theorem to the two continuation witnesses over the same ordered source. It yields $\mathsf{hsame}(r, r')$ for the displayed results.

Unfold the AxisAddPattern and AxisAddClassifier specifications. The zero-spine source witnesses and the two continuation witnesses supply the pattern fields, and the determinacy result supplies the classifier equality row. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont result determinacy`

Theorem 277.12 (Right unit on the zero-spine)**.** *For every zero-spine history* h*,* $\mathsf{Cont}(h, \mathsf{e}, h)$*.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont right unit zeroSpine`

Theorem 277.13 (Associativity on the zero-spine)**.** $\mathsf{AxisAdd}^{\uparrow}$ *is associative up to* hsame *on zero-spine histories.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont associative zeroSpine`

Theorem 277.14 (Commutativity on the zero-spine)**.** $\mathsf{AxisAdd}^{\uparrow}$ *is commutative up to* hsame *on zero-spine histories.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont commutative zeroSpine`

Remark 277.15 (Distinct from $\mathsf{Add}^{\uparrow}$)**.** $\mathsf{AxisAdd}^{\uparrow}$ *and* $\mathsf{Add}^{\uparrow}$ *act on different carriers: the first uses* ZeroSpine*, the second uses* Unary*. The two are kernel-distinct, by Theorem 276.14; identification across the two carriers requires the bridge of Chapter 9344.*

Theorem 277.16 (Zero-spine result inversion for $\mathsf{AxisAdd}^{\uparrow}$)**.** *For histories* $h, k, r : \mathsf{BHist}$*, if* $\mathsf{Cont}(h, k, r)$ *and* $\mathsf{ZeroSpine}(r)$*, then*

$$\mathsf{ZeroSpine}(h) \wedge \mathsf{ZeroSpine}(k).$$

Thus a displayed $\mathsf{AxisAdd}^{\uparrow}$ *continuation whose result lies on the* E0*-spine has both its left prefix and right suffix on the same spine.*

Proof. Induct on the displayed derivation of $\mathsf{Cont}(h, k, r)$.

In the empty-tail generator, the continuation is $\mathsf{Cont}(h, \mathsf{e}, h)$ and the result is h. The assumed result witness is exactly $\mathsf{ZeroSpine}(h)$, while $\mathsf{ZeroSpine}(\mathsf{e})$ is supplied by Definition 276.2. Thus $\mathsf{ZeroSpine}(h) \wedge \mathsf{ZeroSpine}(\mathsf{e})$ holds.

In the zero-tail step, the derivation has predecessor $\mathsf{Cont}(h, k_0, r_0)$ and conclusion $\mathsf{Cont}(h, \mathsf{E0}(k_0), \mathsf{E0}(r_0))$. The result assumption is $\mathsf{ZeroSpine}(\mathsf{E0}(r_0))$. By Definition 276.4, obtain $\mathsf{ZeroSpine}(r_0)$. The induction hypothesis applied to the predecessor continuation gives $\mathsf{ZeroSpine}(h) \wedge \mathsf{ZeroSpine}(k_0)$. Applying Definition 276.3 to the second component gives $\mathsf{ZeroSpine}(\mathsf{E0}(k_0))$. Hence the step conclusion is $\mathsf{ZeroSpine}(h) \wedge \mathsf{ZeroSpine}(\mathsf{E0}(k_0))$.

In the one-tail step, the derivation has result $\mathsf{E1}(r_0)$, so the result assumption is $\mathsf{ZeroSpine}(\mathsf{E1}(r_0))$. This contradicts Definition 276.5. Therefore no one-tail continuation can have a zero-spine result, and the implication holds in that branch. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont zeroSpine result inversion`

Corollary 277.17 (Zero-spine source/result equivalence for $\mathsf{AxisAdd}^{\uparrow}$)**.** *For histories $h, k, r : \mathsf{BHist}$ with $\mathsf{Cont}(h, k, r)$,*

$$\mathsf{ZeroSpine}(r) \iff \mathsf{ZeroSpine}(h) \wedge \mathsf{ZeroSpine}(k).$$

Proof. The forward direction is Definition 277.16. The reverse direction is Definition 277.10 applied to the displayed continuation witness. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddCont zeroSpine result sources iff`

Theorem 277.18 (AxisAdd zero-spine standard bridge boundary)**.** *The public zero-spine result inversion and source/result equivalence identify the standard bridge boundary for the* $\mathsf{AxisAdd}^{\uparrow}$ *zero-spine addition surface. The boundary is over* ZeroSpine*,* Cont*,* hsame*, and the displayed ledger for the two source histories, the continuation witness, and the result history. It does not identify this surface with full* $\mathsf{Add}^{\uparrow}$ *and does not add arithmetic outside the zero-spine carrier.*

Proof. The result-inversion theorem reads a displayed $\mathsf{Cont}(h, k, r)$ witness from the result side: when r lies on the zero spine, it recovers the two zero-spine source witnesses. The source/result equivalence supplies the converse direction over the same continuation witness.

Together these two public rows give the bridge boundary. A consumer may move between the zero-spine source pair and the zero-spine result exactly through the displayed Cont ledger and the endpoint classifier hsame.

The carrier is still ZeroSpine rather than the ordinary $\mathsf{Add}^{\uparrow}$ carrier. Hence the boundary exports only the zero-spine surface and leaves full addition identification outside the claim. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAddUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{AxisAdd}^{\uparrow}}$**.**

Constructive story: Zero-axis addition is built by taking two already admitted zero-spine histories and continuing the first by the second with the kernel continuation relation Cont. The carrier for a fixed input pair accepts exactly those result histories displayed by a $\mathsf{Cont}(h, k, r)$ witness with both h and k on the E0-spine; results lacking the two zero-spine inputs or the continuation witness are outside the surface. Two accepted results are classified together when they sit over the same zero-spine input pair and are related by hsame, so the source specification is the ordered zero-spine pair and the pattern specification is the displayed continuation result. The ledger keeps the raw inputs and the continuation witness visible behind the public result, which lets the checked rows state left and right units at e, result closure on the zero-spine, determinacy, associativity, and commutativity without turning this operation into the ordinary $\mathsf{Add}^{\uparrow}$ carrier. For the five name-certificate obligations, the canonical continuation result inhabits the carrier, endpoint hsame gives reflexivity, symmetry, and transitivity, and determinacy plus transport keep any recognized result inside the same accepted pattern. A history r lies in the signature gap of an $\mathsf{AxisAdd}^{\uparrow}$ token p when the source-domain accepts its ordered zero-spine inputs, the signature relation pairs the displayed continuation result with an answer result and evidence ledger, and the token-introduction relation names that answer as p; concretely, r is the Cont sum of the two zero-spine histories encoded by p, up to hsame. The chapter registers this continuation-on-zero-spines construction under the name $\mathsf{AxisAdd}^{\uparrow}$; it introduces no full $\mathsf{Add}^{\uparrow}$ identification, public arithmetic beyond the zero-spine, or independent addition primitive.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AxisAdd}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The closed scope is the zero-spine source and pattern over ZeroSpine, continuation witnesses Cont, endpoint classifier hsame, the AxisAdd$^{\uparrow}$ NameCert tuple, the displayed ledger policy, the public zero-spine result inversion surface, and Definition 277.18.

Formal verification: FormalStatus(NameCert$_{\mathsf{AxisAdd}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.AxisZeckendorf.AxisAdd.AxisAdd\_semantic\_name\_certificate`

Bridge status: bridgeChecked

Not claimed: It does not claim full Add$^{\uparrow}$ identification or public arithmetic beyond the zero-spine.

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 278

A Concrete Naming Certificate for ZeckendorfNormal$^{\uparrow}$

This chapter introduces a Zeckendorf-style normal-form classifier on histories: no two adjacent E1-extensions. The classifier is structural; it does not depend on hsame and does not assert any arithmetic interpretation. The Fibonacci value-preservation reading is a horizon target queued for the formalize pipeline. The carry-classifier chapter of chapter 9345 consumes this chapter's normal-form judgment, the displayed `word_011` rejection row, and the displayed `word_100` admission row as its source/target normality surface.

278.1 The normal-form predicate

Definition 278.1 (Zeckendorf normal-form judgment)**.** *The Zeckendorf normal-form judgment* ZNormal(h) *is generated by:*

1. ZNormal(e)*;*
2. *if* ZNormal(h)*, then* ZNormal(E0(h))*;*
3. ZNormal(E1(e))*;*
4. *if* ZNormal(E0(h))*, then* ZNormal(E1(E0(h))).

No rule attaches E1 *directly on top of another* E1*-extension.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal`

Definition 278.2 (Display words `011` and `100`)**.** *We fix two reference histories used throughout this chapter and Chapter 9345:*

$$\texttt{word_011} := \mathsf{E1}(\mathsf{E1}(\mathsf{E0}(\mathsf{e}))), \qquad \texttt{word_100} := \mathsf{E0}(\mathsf{E0}(\mathsf{E1}(\mathsf{e}))).$$

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.word_011`
↪ variant `BEDC.Derived.AxisZeckendorf.Zeckendorf.word_100`

Theorem 278.3 (`word_100` is normal)**.** ZNormal(`word_100`) *holds.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.znormal_word_100`

Proof. By two applications of the E0-closure rule on top of the E1-after-empty base. □

Theorem 278.4 (`word_011` is not normal)**.** ZNormal(`word_011`) *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.znormal word 011 absurd`

Proof. By cases on a hypothetical derivation of ZNormal(E1(E1(E0(e)))). The only E1-headed generators require either an empty argument or an E0-headed argument; the actual argument is E1(E0(e)), which has neither shape. So no rule generates the judgment. □

278.2 The certificate

Definition 278.5 (Normal-form source specification)**.** *The source specification* ZNormalSource *consists of histories h with* ZNormal(h)*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormalSourceSpec`

Definition 278.6 (Normal-form pattern specification)**.** *The pattern specification* ZNormalPattern *is structural normal-form generation:* E0*-extensions of any normal-form history, and* E1*-extensions only above* e *or above an* E0*-extension.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormalPatternSpec`

Definition 278.7 (Normal-form classifier specification)**.** *The classifier specification* ZNormalClassifier *classifies normal-form histories pairwise by* hsame *restricted to the normal-form carrier.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormalClassifierSpec`

Definition 278.8 (Normal-form stability certificate)**.** *The stability certificate* ZNormalStability *consists of:*

1. *the base derivation* ZNormal(e)*;*
2. *closure under* E0*;*
3. *the* E1*-after-empty base,* ZNormal(E1(e))*;*
4. *closure under* E1 *above an* E0*-extension.*

The exclusion of E1*-on-*E1 *is enforced by closed generation.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormalStabilityCert`
↪ variant `BEDC.Derived.AxisZeckendorf.Zeckendorf.zNormalStabilityCert`

Definition 278.9 (Normal-form ledger policy)**.** *The ledger policy* ZNormalLedger *records the source normal-form history behind any visible normal-form class.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormalLedgerPolicy`

Theorem 278.10 (Concrete $\mathsf{ZeckendorfNormal}^{\uparrow}$ naming certificate)**.** *The tuple*

$$\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}} := (\mathsf{ZNormalSource}, \mathsf{ZNormalPattern}, \mathsf{ZNormalClassifier}, \mathsf{ZNormalStability}, \mathsf{ZNormalLedger})$$

forms a valid naming certificate for the derived interface $\mathsf{ZeckendorfNormal}^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Zeckendorf.zNormal namecert`

Proof. The five fields are supplied by the preceding definitions. The stability field is justified by closed generation of the ZNormal judgment together with the no-one-on-one exclusion. □

Theorem 278.11 (ZNormal adjacent-one inversion)**.** *If a derivation of* $\mathsf{ZNormal}(\mathsf{E1}(h))$ *is displayed, then either* $h = \mathsf{e}$*, or there is a history* k *such that* $h = \mathsf{E0}(k)$ *and* $\mathsf{ZNormal}(\mathsf{E0}(k))$*. In particular, no closed derivation of* $\mathsf{ZNormal}(\mathsf{E1}(h))$ *has an* $\mathsf{E1}$*-headed tail.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal adjacent one inversion`

Proof. Proceed by cases on the displayed derivation of $\mathsf{ZNormal}(\mathsf{E1}(h))$. The $\mathsf{E1}$-after-empty constructor gives the left alternative with $h = \mathsf{e}$.

The $\mathsf{E1}$-above-zero constructor has input $\mathsf{ZNormal}(\mathsf{E0}(k))$ and conclusion $\mathsf{ZNormal}(\mathsf{E1}(\mathsf{E0}(k)))$. This is exactly the right alternative, with $h = \mathsf{E0}(k)$.

The empty constructor and the $\mathsf{E0}$-extension constructor have conclusions whose top constructor is not $\mathsf{E1}$. They cannot match the displayed target. Thus the two alternatives exhaust all closed generators, with no arithmetic interpretation used. □

Theorem 278.12 (ZNormal zero-extension inversion)**.** *Every zero-headed normal form descends to a normal tail: if* $\mathsf{ZNormal}(\mathsf{E0}(h))$ *is derived, then* $\mathsf{ZNormal}(h)$ *is derived.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal zero extension inversion`

Proof. Proceed by cases on the derivation of $\mathsf{ZNormal}(\mathsf{E0}(h))$. The only closed generator whose conclusion has top constructor $\mathsf{E0}$ is the $\mathsf{E0}$-extension rule.

That rule is applied to a predecessor derivation of $\mathsf{ZNormal}(h)$. Project this predecessor derivation as the desired normal tail. The remaining constructors conclude at e or at an $\mathsf{E1}$-headed history, so they do not match the zero-headed target. □

Theorem 278.13 (ZNormal normal-form coverage)**.** *The* $\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}$ *source, pattern, classifier, stability, and ledger rows exhaust exactly the closed constructors of* $\mathsf{ZNormal}$*: the empty row, the* $\mathsf{E0}$*-extension row, the* $\mathsf{E1}$*-after-empty row, and the* $\mathsf{E1}$*-above-zero row. No arithmetic value row, Fibonacci interpretation, or extra classifier constructor is part of the covered surface.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal normal form coverage`

Proof. Unpack the certificate of Definition 278.10. Its source is the normal-form carrier of Definition 278.5, and its pattern row is the closed structural generation of Definition 278.6.

The stability row of Definition 278.8 lists the four generators: empty, zero extension, one after empty, and one above a zero-headed normal form. The ledger row of Definition 278.9 records the source normal-form history behind each visible class.

Apply Definition 278.11 to exclude any hidden $\mathsf{E1}$-on-$\mathsf{E1}$ constructor, and apply Definition 278.12 to read zero-headed judgments back to their normal tails. Hence the displayed certificate covers exactly the closed constructors and nothing from an arithmetic interpretation. □

Corollary 278.14 ($\mathsf{ZeckendorfNormal}^{\uparrow}$ is licensed, not primitive)**.** *The interface* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *is licensed by* $\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}$*. It is not a primitive object of the finite kernel.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal namecert licensed not primitive`

Theorem 278.15 (Zeckendorf normal carry-window determinacy)**.** *For a displayed* $\mathsf{ZNormal}$ *derivation, any finite carry window whose local source word is* `word_011` *is rejected by Definition 278.4, while the corresponding structural target window* `word_100` *is accepted by Definition 278.3. Consequently the Zeckendorf structural carry boundary has a unique normal target window under the displayed* BHist *constructors and the chapter's* hsame *transport. This is only a structural normal-form statement and makes no Fibonacci value-preservation claim.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Carry.ZCarry window determinacy`

Proof. Inspect the source side of the carry window. If it reads `word_011`, then it has an E1-headed tail under another E1-extension. Apply Definition 278.11 and then Definition 278.4; no displayed ZNormal(`word_011`) derivation can be accepted.

Inspect the target side. The word `word_100` is generated by the E1-after-empty base followed by two E0-extensions, so Definition 278.3 supplies the accepted normal target window.

The remaining possible ambiguity is hidden transport along hsame. Apply Definition 278.12 to peel zero-headed target judgments and Definition 278.19 to move accepted normal windows along the chapter's history-sameness comparisons. These operations keep the same displayed BHist constructor shape, so a carry boundary over `word_011` has only the displayed `word_100` normal target.

No arithmetic reading of the two words is used. The argument separates the structural source rejection from the structural target acceptance inside the normal-form classifier alone. □

Theorem 278.16 (ZNormal scoped classifier boundary)**.** *Every accepted* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *classifier row is exactly an* hsame *row between* BHist *witnesses that lie in the closed* ZNormal *source. The only scope inputs are the* BHist *constructors, the closed* ZNormal *generation rules,* hsame *transport, and the* $\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}$ *ledger. No Fibonacci value semantics, arithmetic weight, uniqueness-of-value row, or external number interpretation is read by the classifier boundary.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.Zeckendorf.ZNormal semantic name certificate`

Proof. Unfold the source, pattern, classifier, stability, and ledger rows of Definition 278.10. The source row is exactly the closed ZNormal carrier over BHist, the pattern and stability rows are the four closed generators, and the classifier row is hsame restricted to witnesses recorded by the ledger.

For an accepted row, the ledger supplies the two displayed source witnesses and the classifier supplies the hsame comparison between them. Transport along Definition 278.19 keeps the accepted history inside the same closed normal-form source, so the row is an hsame row between BHist witnesses and nothing wider.

For the converse direction, take an hsame row between two displayed ZNormal source witnesses. The classifier specification reads exactly such restricted history-sameness rows, and the ledger records the source witness behind each visible class, so the row is accepted by the $\mathsf{ZeckendorfNormal}^{\uparrow}$ classifier.

The only constructor boundary that can hide an extra case is an E1-headed history. Apply Definition 278.11: an accepted E1 row is either above e or above an E0-headed normal source, and no E1-on-E1 source can be generated. Thus the scoped classifier boundary is exhausted by the displayed primitives and does not use Fibonacci value semantics. □

Theorem 278.17 (ZeckendorfNormal public normal-form boundary)**.** *The public* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *boundary consists exactly of the closed* ZNormal *source over* BHist*, the four constructor rows for empty, zero-extension, one-after-empty, and one-above-zero normal forms, the restricted* hsame *classifier between displayed normal-form witnesses, and the* $\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}$ *ledger of displayed normal-form witnesses. It excludes Fibonacci value preservation, uniqueness of arithmetic value, and any external number interpretation.*

Lean4 ✓ `BEDC.Derived.ZeckendorfNormalUp.ZNormal public normal form boundary`

Proof. Start from the certificate in Definition 278.10. Its source row is the closed ZNormal predicate, its pattern and stability rows are the four displayed normal-form constructors, and its ledger records the normal-form witness behind each visible class. Definition 278.13 shows that the constructor rows cover the visible normal-form surface. The empty, zero-extension, one-after-empty, and one-above-zero cases are therefore the only public source shapes admitted by the certificate.

The classifier boundary is supplied by Definition 278.16. It identifies every accepted classifier row with an hsame comparison between two histories already lying in the closed ZNormal source.

Finally, Definition 278.19 keeps the restricted classifier inside the same source when a displayed history is moved along hsame. Thus the public boundary is exactly the closed source, the four constructor rows, the restricted classifier, and the displayed-witness ledger.

No step reads an arithmetic value. Fibonacci value preservation, uniqueness of arithmetic value, and external number interpretation are outside this normal-form boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}$.

Constructive story: A Zeckendorf normal-form history is generated by four structural moves: admit e, extend any normal history by E0, admit the single E1(e) case, and extend by E1 only when the tail is already E0-headed and normal. The carrier therefore accepts exactly histories made by those rules and excludes any hidden E1-on-E1 step, as witnessed by the rejection of the displayed word `word_011` while the displayed word `word_100` is accepted. The classifier is hsame restricted to accepted normal histories, so the source specification is the closed normal-form predicate, the pattern specification is the same constructor discipline, and no Fibonacci value or arithmetic weight participates in equality. The ledger keeps the raw normal-form history and its visible class aligned, allowing zero-extension inversion, adjacent-one inversion, and carry-window rejection or acceptance to be read directly from the constructor surface. The five name-certificate obligations are immediate from closed generation and restricted hsame: e inhabits the carrier, the classifier is reflexive, symmetric, and transitive on accepted histories, and transported histories remain normal because transport cannot create an unlisted constructor. A history h lies in the signature gap of a $\mathsf{ZNormal}^{\uparrow}$ token p when the source-domain accepts h as structurally normal, the signature relation pairs it with an answer normal history and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is built by the four normal constructors and is hsame to the normal word encoded by p. The chapter registers this structural normal-form construction under the name $\mathsf{ZNormal}^{\uparrow}$; it introduces no Fibonacci value preservation, uniqueness of arithmetic value, external number interpretation, or additional classifier constructor.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: The seed scope is the closed BHist generation of ZNormal together with the exclusion of adjacent one-extensions.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ZeckendorfNormal}^{\uparrow}}, \mathsf{encodedDef})$

Lean target: `BEDC.Derived.AxisZeckendorf.Zeckendorf.zNormal\_namecert`

Bridge status: none

Not claimed: This chapter does not claim Fibonacci value preservation, uniqueness of arithmetic value, or any arithmetic interpretation of the structural normal form.

Upgrade path: The next public step is a public exported normal-form certificate boundary.

278.3 Horizon: Fibonacci value reading

The classifier above is purely structural. The arithmetic reading—each normal-form history denotes a unique non-negative integer via the Zeckendorf decomposition into Fibonacci numbers—is a horizon target. It must be licensed by a separate $\mathsf{AxisAdd}^{\uparrow}$-compatible bridge before being used in any downstream chapter.

Theorem 278.18 (Zeckendorf value-reading is well-defined, horizon)**.** *There is a function from normal-form histories to non-negative integers that is determined by the recurrence* $W_{n+2} = W_{n+1} + W_n$ *on Fibonacci-indexed positions.*

Lean4 ✓ `BEDC.Derived.ZeckendorfNormalUp.ZNormal fibonacci value horizon`

Theorem 278.19 (ZNormal hsame transport)**.** *If* $\mathsf{ZNormal}(h)$ *and* $\mathsf{hsame}(h, k)$*, then* $\mathsf{ZNormal}(k)$*.*

Lean4 ✓ `BEDC.Derived.ZeckendorfNormalUp.ZNormal hsame transport`

Proof. Proceed by induction on the closed derivation of $\mathsf{ZNormal}(h)$ from Definition 278.1. In each case, invert the displayed hsame comparison by Definition 3.4.

In the empty case, $h = \mathsf{e}$. The comparison $\mathsf{hsame}(\mathsf{e}, k)$ has only the empty aligned branch, so $k = \mathsf{e}$. The empty generator gives $\mathsf{ZNormal}(k)$.

In the zero-extension case, the derivation has predecessor $\mathsf{ZNormal}(h_0)$ and conclusion $\mathsf{ZNormal}(\mathsf{E0}(h_0))$. From $\mathsf{hsame}(\mathsf{E0}(h_0), k)$, constructor inversion gives a history k_0 such that $k = \mathsf{E0}(k_0)$ and $\mathsf{hsame}(h_0, k_0)$. The induction hypothesis applied to the predecessor derivation gives $\mathsf{ZNormal}(k_0)$. Applying the zero-extension generator yields $\mathsf{ZNormal}(\mathsf{E0}(k_0))$, hence $\mathsf{ZNormal}(k)$.

In the one-after-empty case, the derivation concludes $\mathsf{ZNormal}(\mathsf{E1}(\mathsf{e}))$. From $\mathsf{hsame}(\mathsf{E1}(\mathsf{e}), k)$, one-constructor inversion gives a history k_0 such that $k = \mathsf{E1}(k_0)$ and $\mathsf{hsame}(\mathsf{e}, k_0)$. Empty no-confusion forces $k_0 = \mathsf{e}$. The one-after-empty generator therefore gives $\mathsf{ZNormal}(k)$.

In the one-above-zero case, the derivation has predecessor $\mathsf{ZNormal}(\mathsf{E0}(h_0))$ and conclusion $\mathsf{ZNormal}(\mathsf{E1}(\mathsf{E0}(h_0)))$. From $\mathsf{hsame}(\mathsf{E1}(\mathsf{E0}(h_0)), k)$, one-constructor inversion gives a history t such that $k = \mathsf{E1}(t)$ and $\mathsf{hsame}(\mathsf{E0}(h_0), t)$. Zero-constructor inversion then gives a history k_0 such that $t = \mathsf{E0}(k_0)$ and $\mathsf{hsame}(h_0, k_0)$. Apply the induction hypothesis to the predecessor derivation $\mathsf{ZNormal}(\mathsf{E0}(h_0))$ and the comparison $\mathsf{hsame}(\mathsf{E0}(h_0), t)$; this gives $\mathsf{ZNormal}(t)$, hence $\mathsf{ZNormal}(\mathsf{E0}(k_0))$. The one-above-zero generator gives $\mathsf{ZNormal}(\mathsf{E1}(\mathsf{E0}(k_0)))$, which is $\mathsf{ZNormal}(k)$.

These four cases exhaust the closed generators of ZNormal, so the predicate is closed under hsame transport. □

Chapter 279

A Concrete Naming Certificate for $\mathsf{FullAxis}^{\uparrow}$

This chapter records a prefix-thread seal interface over the E0-spine. $\mathsf{FullAxis}^{\uparrow}$ is NOT a metric or Cauchy completion: its boundary token E1(E0(e)) is a finite history, not a limit object, and the chapter explicitly disclaims any reading of the boundary as an infinity. The Cauchy / Real / Topology readings remain in the existing $\mathsf{CompleteMetric}^{\uparrow}$ and related chapters; $\mathsf{FullAxis}^{\uparrow}$ is a structural seal, not a metric completion.

279.1 The prefix thread

Definition 279.1 (Prefix thread)**.** *A prefix thread T is a history-membership predicate T.*member *that contains* e *and is closed under* E0*-extension.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.PrefixThread`

Definition 279.2 (Zero-spine prefix thread)**.** *The zero-spine prefix thread* ZSpineThread *takes T.*member := ZeroSpine*, with empty membership from Lemma 276.2 and* E0*-step from Lemma 276.3.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.zeroSpinePrefixThread`

279.2 Seal certificate

Definition 279.3 (Seal certificate over a prefix thread)**.** *A seal certificate* SealCert(T) *records the structural seal data for a prefix thread T: directedness, monotonicity, prefix-closure, and a ledger policy. The first three fields are skeleton-grade; the ledger field is a horizon obligation queued for the formalize pipeline.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.SealCert`
↪ variant `BEDC.Derived.AxisZeckendorf.FullAxis.zeroSpineSealCert`

279.3 The boundary marker

Definition 279.4 (Boundary marker `boundary_01`)**.** *The boundary marker is the finite history*

$$\texttt{boundary_01} := \mathsf{E1}(\mathsf{E0}(\mathsf{e})).$$

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.boundary 01`

Theorem 279.5 (Boundary marker is not on the zero-spine)**.** ZeroSpine(`boundary_01`) *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.boundary 01 not zeroSpine`

Proof. `boundary_01` has top constructor E1; apply zero-spine no-one-extension. □

Remark 279.6 (Boundary marker is finite, not an infinity)**.** *The boundary marker is a finite history of length two. It does NOT denote a limit, an infinity, or a transfinite stage. Any reading that promotes* `boundary_01` *to an infinity is explicitly rejected (cf. Chapter 9350).*

279.4 The certificate

Definition 279.7 (Full-axis source specification)**.** *For a prefix thread T, the source specification* FullAxisSource(T) *consists of histories h with T.*member(h)*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSourceSpec`

Definition 279.8 (Full-axis pattern specification)**.** *For a prefix thread T, the pattern specification* FullAxisPattern(T) *is repeated* E0*-extension within T.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisPatternSpec`

Definition 279.9 (Full-axis classifier specification)**.** *For a prefix thread T, the classifier specification* FullAxisClassifier(T) *classifies pairs of T-members by joint thread membership.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisClassifierSpec`

Definition 279.10 (Full-axis stability certificate)**.** *For a prefix thread T, the stability certificate* FullAxisStability(T) *bundles the seal certificate* SealCert(T) *with the explicit declaration that boundary tokens are finite, not limits.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisStabilityCert`

Definition 279.11 (Full-axis ledger policy)**.** *The ledger policy* FullAxisLedger *retains the prefix thread and every visible thread-member as part of the construction history of the seal.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisLedgerPolicy`

Theorem 279.12 (Concrete $\mathsf{FullAxis}^{\uparrow}$ naming certificate)**.** *The tuple*

$$\mathsf{NameCert}_{\mathsf{FullAxis}^{\uparrow}} := (\mathsf{FullAxisSource}, \mathsf{FullAxisPattern}, \mathsf{FullAxisClassifier}, \mathsf{FullAxisStability}, \mathsf{FullAxisLedger})$$

specialised to the zero-spine prefix thread forms a valid naming certificate for the derived seal interface $\mathsf{FullAxis}^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.FullAxis.fullAxis namecert`

Proof. The five fields are supplied by the preceding definitions, instantiated at $T = \mathsf{ZSpineThread}$. Stability includes the seal certificate together with the boundary-finite declaration. □

Corollary 279.13 ($\mathsf{FullAxis}^{\uparrow}$ is licensed, not primitive)**.** *The interface* $\mathsf{FullAxis}^{\uparrow}$ *is licensed by* $\mathsf{NameCert}_{\mathsf{FullAxis}^{\uparrow}}$*. It is a structural seal, not a metric completion, and it is not a primitive object of the finite kernel.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxis semantic name certificate`

Theorem 279.14 (FullAxis completion sibling separation)**.** *The* $\mathsf{FullAxis}^{\uparrow}$ *prefix-thread seal is separated from the completion routes of chapter 128 and chapter 38. Its carrier is finite zero-spine membership together with the finite excluded boundary marker* `boundary_01`*, while the completion and* $\mathsf{Real}^{\uparrow}$ *routes consume Cauchy,* $\mathsf{StreamName}^{\uparrow}$*, metric, or seal data. Consequently the* $\mathsf{FullAxis}^{\uparrow}$ *seal exports no metric limit, real-completion row, Cauchy witness, or host-level completion coordinate.*

Lean4 ✓ `BEDC.Derived.FullAxisUp.FullAxisUp completion sibling separation`

Proof. Start with Definition 279.15. The boundary marker `boundary_01` is finite and outside the zero-spine thread, so it cannot serve as a limit witness or completion point.

Apply Definition 279.16. The source, pattern, classifier, stability, ledger, and finite boundary rows exhaust the $\mathsf{FullAxis}^{\uparrow}$ seal surface over the prefix thread.

Now compare the sibling routes. The complete-metric and real chapters consume Cauchy, $\mathsf{StreamName}^{\uparrow}$, metric, or seal rows, none of which is present in the exhausted prefix-thread inventory. Therefore the FullAxis seal remains a structural finite boundary and exports no metric limit or real-completion row. □

Theorem 279.15 (FullAxis prefix-thread boundary disjointness)**.** *For the zero-spine prefix thread of Definition 279.2, the finite boundary marker* `boundary_01` *is outside the thread carrier. Consequently it cannot serve as a thread-member witness, a prefix-thread membership row, or a limit witness for the structural seal.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxis e1 e0 empty boundary exclusion`

Proof. Unfold the zero-spine prefix thread of Definition 279.2. Its membership predicate is exactly $\mathsf{ZeroSpine}$, closed from e by repeated $\mathsf{E0}$-extension.

Apply Definition 279.5. The finite marker `boundary_01` has an $\mathsf{E1}$ head and therefore is not a member of the zero-spine carrier.

Since Definition 279.7 reads source rows only from thread membership, the boundary marker cannot be repacked as a source member. The seal certificate therefore treats it only as a finite excluded boundary token, not as a completion point or infinity. □

The $\mathsf{FullAxis}^{\uparrow}$ seal consumes the $\mathsf{AxisNat}^{\uparrow}$ zero-spine carrier of chapter 276 together with the finite-boundary refusal surface of chapter 554. Thus `boundary_01` is a boundary over the AxisNat zero-spine and not a metric, Cauchy, completion, or Real-limit row.

Theorem 279.16 (FullAxis seal source exhaustion)**.** *The* $\mathsf{FullAxis}^{\uparrow}$ *source, pattern, classifier, stability, and ledger rows are exhausted by zero-spine prefix-thread membership together with the finite boundary exclusion of Definition 279.15. They contain no completion witness, no metric limit, and no thread-member row for* `boundary_01`*.*

Proof. Start with the zero-spine source. By Definition 279.7, the source rows are exactly the members of the chosen prefix thread, and by Definition 279.2 those members are precisely the $\mathsf{ZeroSpine}$ histories.

The pattern and classifier rows add no outside carrier. The pattern row of Definition 279.8 is repeated E0-extension inside the same thread, and the classifier row of Definition 279.9 classifies only pairs already present by joint thread membership.

Apply Definition 279.15. The finite marker `boundary_01` is outside that carrier, so it cannot be read as a thread member or as a limit witness. The licensing corollary Definition 279.13 then repacks the displayed source, pattern, classifier, stability, and ledger rows as the whole structural seal surface. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSeal source exhaustion`

279.5 Horizon obligations

Theorem 279.17 (Boundary-finite witness, horizon)**.** *For every prefix thread T, the seal does not equate any thread-member with a non-thread history that purports to be a limit object.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSourceSpec boundary 01 thread separation`

Theorem 279.18 (Distinct from $\mathsf{Real}^{\uparrow}$, horizon)**.** $\mathsf{FullAxis}^{\uparrow}$ *does not entail any of the algebraic operations of* $\mathsf{Real}^{\uparrow}$ *(Cauchy, limit uniqueness, field structure).*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSeal not real horizon`

Remark 279.19 (Where Real is licensed)**.** *The Cauchy / Real route is licensed inside the* $\mathsf{CompleteMetric}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *chapters.* $\mathsf{FullAxis}^{\uparrow}$ *does not enter that route; any attempt to identify the two interfaces requires a separate bridge.*

Theorem 279.20 (FullAxis prefix-thread obligation inventory)**.** *The* $\mathsf{FullAxis}^{\uparrow}$ *horizon obligation surface consists only of the* BHist*-facing rows displayed by the prefix-thread seal:*

1. *the carrier row supplied by the zero-spine prefix thread;*
2. *the classifier row on jointly visible thread members;*
3. *the stability row recording directedness, monotonicity, prefix-closure, and finite-boundary exclusion;*
4. *the ledger row retaining the visible prefix-thread provenance;*
5. *the zero-spine thread rows generated by* e *and repeated* E0*-extension;*
6. *the finite boundary marker row for* `boundary_01` *as a non-thread history;*
7. *the source-exhaustion row stating that no source outside thread membership is exposed.*

No row of this inventory is a RealUp completion, metric limit, compactness witness, or host-level infinity.

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisPrefixThread obligation inventory`

Proof. Use the prefix-thread definitions Definition 279.1 and Definition 279.2 for the carrier and zero-spine thread rows. The source, classifier, stability, and ledger rows are exactly the displayed fields of Definition 279.7, Definition 279.9, Definition 279.10, and Definition 279.11.

The boundary marker enters only through Definition 279.4. Apply Definition 279.5 and then Definition 279.17: the marker is finite and is not a thread member.

Finally apply Definition 279.16. It repacks the prefix-thread carrier, classifier, stability, ledger, zero-spine thread, boundary marker, and source-exhaustion rows as the whole $\mathsf{FullAxis}^{\uparrow}$ horizon surface, with no completion or limit row exported. □

Theorem 279.21 (FullAxis boundary marker finite obligation)**.** *The marker* `boundary_01` *remains a finite non-thread* BHist *marker in the* $\mathsf{FullAxis}^{\uparrow}$ *obligation surface. It cannot be read as a limit object, completion point, compactness witness, or point at infinity.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisBoundaryMarker finite obligation`

Proof. The definition Definition 279.4 presents `boundary_01` as the finite history $\mathsf{E1}(\mathsf{E0}(\mathsf{e}))$.

Apply Definition 279.5. Since the zero-spine prefix thread exposes only ZeroSpine histories, the boundary marker has no thread-member row.

Now use Definition 279.17. It states that the seal does not equate a thread member with a non-thread history presented as a limit object. The boundary marker is therefore retained only as the finite excluded marker named by Definition 279.15. □

Theorem 279.22 (FullAxis Real route separation obligation)**.** *Every* $\mathsf{Real}^{\uparrow}$*, Cauchy, metric-completion, compactness, or limit reading of a* $\mathsf{FullAxis}^{\uparrow}$ *consumer must factor through the Real, Completion, Metric, or Compact chapters. Such a reading is not projected from the* $\mathsf{FullAxis}^{\uparrow}$ *prefix-thread seal, whose public rows are only the carrier, classifier, stability, ledger, zero-spine thread, finite boundary marker, and source-exhaustion rows listed in Definition 279.20.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSeal real route separation obligation`

Proof. Start from the structural seal surface. By Definition 279.20, the exposed rows are all BHist-facing prefix-thread rows and finite boundary rows.

Apply Definition 279.21. The only named boundary marker is finite and non-thread, so it cannot supply a Cauchy object, metric completion point, compact witness, or limit.

Finally use Definition 279.18. It separates the $\mathsf{FullAxis}^{\uparrow}$ horizon from $\mathsf{Real}^{\uparrow}$ algebraic and completion operations. Therefore any RealUp, Cauchy, metric-completion, compactness, or limit reading must enter through the chapters where those structures are licensed, not through projection from $\mathsf{FullAxis}^{\uparrow}$. □

Theorem 279.23 (FullAxis seal object name alignment)**.** *The critical-path horizon name* $\mathsf{FullAxisSeal}^{\uparrow}$ *is the seal-facing registry name for the same prefix-thread certificate exported here as* $\mathsf{FullAxis}^{\uparrow}$*. The registry alias does not add an object row: the only exported rows remain the zero-spine prefix thread, finite boundary marker, source, pattern, classifier, stability, ledger, and RealUp-separation rows displayed in this chapter.*

Proof. Read the certificate through Definition 279.12. The exported tuple is the source, pattern, classifier, stability, and ledger certificate for the zero-spine prefix thread.

Apply Definition 279.20. It lists the public horizon rows as the prefix-thread carrier, finite boundary marker, classifier, stability, ledger, and boundary-exclusion data, all over the same zero-spine source.

Finally use Definition 279.22. It keeps RealUp, Cauchy, metric-completion, compactness, and limit readings outside the seal-facing registry alias. Thus $\mathsf{FullAxisSeal}^{\uparrow}$ is only the registry name for this exported structural seal surface. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxisSeal object name alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{FullAxis}^{\uparrow}}$.

Constructive story: A full-axis seal starts from a prefix thread: a history-membership predicate containing e and closed under E0-extension, specialized here to the zero-spine thread already generated from the empty history. The carrier admits exactly thread members, while the finite marker `boundary_01` $= \mathsf{E1}(\mathsf{E0}(\mathsf{e}))$ is deliberately kept outside the zero-spine carrier because its head is an E1 rather than an E0. Two visible seal entries classify together by joint membership in

the same thread, so the source specification is prefix-thread membership, the pattern specification is repeated E0-extension inside that thread, and no RealUp, Cauchy, compactness, metric, or limit row is accepted as a source. The ledger keeps the prefix thread, each visible thread member, the finite boundary marker, the boundary-exclusion row, and the public seal alias visible, rather than turning the excluded marker into a completion point. The five name-certificate obligations close on membership itself: e inhabits the carrier, joint-membership classification is reflexive, symmetric, and transitive on thread members, and any classified visible target is already a member of the same admitted thread. A history h lies in the signature gap of a FullAxis$^{\uparrow}$ token p when the source-domain accepts h as a member of the zero-spine prefix thread, the signature relation pairs it with an answer seal row and evidence ledger, and the token-introduction relation names that answer as p; unfolded, h is a finite E0-prefix member and not the finite excluded boundary marker unless p names that marker only as an outside-boundary row. The chapter registers this structural seal under the name FullAxis$^{\uparrow}$; it introduces no RealUp completeness, metric completion, compactness, limit object, infinity reading, or independent seal primitive.

Theory closure: TheoryGate(NameCert$_{\mathsf{FullAxis}\uparrow}$, scopedClosed)

Scope closed: The scoped surface binds the prefix-thread carrier, zero-spine boundary marker, finite-boundary row, ledger policy, public seal alias, and RealUp-route separation rows cited by Definition 279.20, Definition 279.21, Definition 279.22, and Definition 279.23.

Formal verification: FormalStatus(NameCert$_{\mathsf{FullAxis}\uparrow}$, theoremChecked)

Lean target: `BEDC.Derived.AxisZeckendorf.FullAxis.FullAxis\_semantic\_name\_certificate`

Bridge status: none

Not claimed: It does not close RealUp completeness, metric completion, compactness, limits, or any reading of the boundary marker as infinity.

Upgrade path: Public closure requires a single exported public FullAxis$^{\uparrow}$ certificate theorem.

Chapter 280

A Concrete Naming Certificate for $\mathsf{TuringMachine}^{\uparrow}$

The Turing-machine interface $\mathsf{TuringMachine}^{\uparrow}$ packages a deterministic transition function on a finite alphabet together with a BHist tape carrier and a finite head-position witness. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$ (chapter 120), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

280.1 Carrier definition

A $\mathsf{TuringMachine}^{\uparrow}$ token carries: a finite state alphabet, a finite tape alphabet with a designated blank, a deterministic transition function, an initial-state name, and a halting-state predicate. The carrier accepts a configuration history h when there is a $\mathsf{Seq}^{\uparrow}$ trace of $(\mathsf{state}, \mathsf{tape}, \mathsf{head})$ rows whose zero entry is the initial configuration on a given input, every one-step extension matches the transition function, and halted rows repeat. The classifier is hsame on the configuration trace; the ledger keeps the deterministic transition table, head movement, and tape readback visible; the source covers finite alphabets, configurations, and traces; the pattern records initial-row, transition-step, halted-repetition, and tape-readback rows.

Theorem 280.1 (TuringMachine configuration trace carrier)**.** *A configuration trace accepted by the* $\mathsf{TuringMachine}^{\uparrow}$ *carrier is a* $\mathsf{Seq}^{\uparrow}$ *row of* $(\mathsf{state}, \mathsf{tape}, \mathsf{head})$ *histories over* BHist *with a unary time index, an initial configuration row, and the displayed finite state and tape alphabets. The source rows consumed by the carrier are exactly the* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *unary time and head-position rows, the* $\mathsf{NameCert}_{\mathsf{Seq}^{\uparrow}}$ *configuration trace row, and the* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *bounded deterministic-trace row.*

Proof. Unpack the carrier prose above. The accepted history is not a host-level run; it is the displayed $\mathsf{Seq}^{\uparrow}$ trace whose entries are triples of BEDC histories, and whose index row is supplied by $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$.

The initial row is one entry of the same trace. The finite alphabets and configuration components are therefore visible source rows, while $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ supplies the bounded deterministic trace format that keeps the program code, bound, and endpoint readback in the ledger. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineConfigurationTraceCarrier configuration trace surface`

Theorem 280.2 (TuringMachine deterministic step transport)**.** *Let two current configuration rows of a* $\mathsf{TuringMachine}^{\uparrow}$ *trace be related by* hsame*, and let their deterministic transition-table rows be*

transported by the same classifier data. Then the next-step configuration rows produced by the transition table are again related by hsame*. The transport uses the* Cont *trace-extension row and the displayed* $\mathsf{NameCert}_{\mathsf{Seq}^\uparrow}$ *classifier on configuration traces.*

Proof. Read the current configuration comparison through the hsame classifier on the configuration trace. The deterministic transition table is a visible ledger row, so transporting it carries the state update, tape-cell write, and head move to the transported current configuration.

Apply the Cont trace-extension row to append the transported one-step result to the $\mathsf{Seq}^\uparrow$ trace. Since the transition relation is deterministic, there is only one next configuration row over the transported current row, and the $\mathsf{NameCert}_{\mathsf{Seq}^\uparrow}$ classifier records it as the same trace step up to hsame. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineDeterministicStepTransport step stability`

Theorem 280.3 (TuringMachine halted repetition ledger exactness)**.** *Once the halting predicate is displayed for a configuration row in a* $\mathsf{TuringMachine}^\uparrow$ *trace, every later accepted trace-extension ledger row records only repetitions of that halted configuration. No transition-table branch, oracle row, or fresh tape update is available after the halted row.*

Proof. Use the carrier clause that halted rows repeat. The halting predicate is a visible ledger entry, so a later trace extension must cite the halted configuration as its source row rather than reopen the deterministic transition table.

The Cont row then extends the trace by the same configuration history. The classifier for the repeated suffix is the ambient hsame on configuration traces, and the exactness ledger records only the halted configuration, its tape, and its head-position witness. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineHaltedTrace ledger exactness`

Theorem 280.4 (TuringMachine finite tape readback carrier)**.** *Every visible tape readback of a* $\mathsf{TuringMachine}^\uparrow$ *accepted trace is a finite* BHist *row indexed by the* $\mathsf{Nat}^\uparrow$ *head-position witness. The readback surface is carried by the* $\mathsf{NameCert}_{\mathsf{Nat}^\uparrow}$ *head row, the* $\mathsf{NameCert}_{\mathsf{Seq}^\uparrow}$ *configuration trace row, and the visible tape component of the current configuration; it does not expose an infinite tape object.*

Proof. Project a carried configuration row to its tape and head components. The head is classified by the consumed $\mathsf{NameCert}_{\mathsf{Nat}^\uparrow}$ row, while the configuration is one entry of the consumed $\mathsf{NameCert}_{\mathsf{Seq}^\uparrow}$ trace.

The tape readback therefore names only the finite BEDC row addressed by that head-position witness. Transport along hsame preserves the same finite readback row, and the trace ledger records the accessed cell without adding an unbounded external tape carrier. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineFiniteTapeReadbackCarrier finite readback surface`

Theorem 280.5 (TuringMachine obligation surface)**.** *The complete* $\mathsf{TuringMachine}^\uparrow$ *obligation surface over* BHist *is formed by the configuration trace carrier, the* hsame *classifier on configuration traces, the deterministic transition row, the halted-repetition row, the finite tape readback row, and the bounded* $\mathsf{Computable}^\uparrow$ *simulation trace rows. These rows consume exactly the displayed* $\mathsf{Nat}^\uparrow$ *unary time and head-position witnesses, the* $\mathsf{Seq}^\uparrow$ *configuration trace,* Cont *trace-extension data, and the ledger rows for initial configurations, transition steps, halted repetitions, and bounded readback.*

Proof. Collect the carrier rows from Definition 280.1 and the finite readback rows from Definition 280.4. These identify the accepted histories as BHist configuration rows indexed by the consumed $\mathsf{Nat}^{\uparrow}$ and $\mathsf{Seq}^{\uparrow}$ sources.

Next add the deterministic and halted parts. The step transport theorem supplies the deterministic transition row and its Cont/hsame stability, while the halted-repetition theorem supplies the exact repeated suffix.

Finally include the bounded $\mathsf{Computable}^{\uparrow}$ trace row. Since the carrier exposes only the displayed initial row, transition step, halted repetition, finite readback, and bounded-simulation ledger entries, the listed rows exhaust the obligation surface. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineObligationSurface bounded trace ledger`

Theorem 280.6 (TuringMachine source-classifier obligation)**.** *The* $\mathsf{TuringMachine}^{\uparrow}$ *source reads exactly the finite state alphabet, finite tape alphabet with blank row, unary time rows, unary head-position rows,* $\mathsf{Seq}^{\uparrow}$ *configuration trace, deterministic transition table, and* $\mathsf{Computable}^{\uparrow}$ *bounded trace. Classifier transport is* hsame *on configuration trace rows, with the deterministic transition table and finite readback rows transported only through the displayed* Cont *trace-extension surface.*

Proof. Project a token to its source rows. The alphabets, transition table, time indices, head positions, configuration trace, and bounded trace are explicit coordinates of the accepted package.

The classifier has no separate host-machine equality. It compares configuration trace rows by hsame, then transports transition and readback rows along the same displayed Cont extension data.

Because no other source coordinate is available in the package, every admitted classifier transport is obtained from those rows and no oracle, universal machine, or external computation predicate can enter the source. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineSourceClassifierObligation source classifier surface`
Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineSourceClassifierObligation cont transport`

Theorem 280.7 (TuringMachine ledger exactness obligation)**.** *The* $\mathsf{TuringMachine}^{\uparrow}$ *ledger is exhausted by initial-row, transition-step, halted-repetition, finite tape readback, and bounded-simulation rows. It contains no oracle transcript, nondeterministic branch row, universal-machine row, or halting-decision data.*

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineLedgerExactnessObligation rows and boundary`

Proof. Read the ledger fields of an accepted $\mathsf{TuringMachine}^{\uparrow}$ token. The initial row starts the $\mathsf{Seq}^{\uparrow}$ trace, transition-step rows append deterministic successors, and halted-repetition rows append the fixed halted configuration.

Finite tape readback is the projection of a displayed configuration row through the head-position witness, and bounded simulation is the consumed $\mathsf{Computable}^{\uparrow}$ trace prefix.

These are all ledger constructors named by the carrier. Since the package has no field for oracles, branch choice, universal-machine coding, or halting decision, those data are excluded from ledger exactness. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineLedgerExactnessObligation no external rows`

280.2 The certificate

Theorem 280.8 (TuringMachine trace source obligation)**.** *The* $\mathsf{TuringMachine}^{\uparrow}$ *trace source is a* $\mathsf{Seq}^{\uparrow}$ *configuration carrier over* BHist *whose rows are finite triples* $(\mathsf{state}, \mathsf{tape}, \mathsf{head})$*. Its public source surface is the* $\mathsf{Nat}^{\uparrow}$ *unary time row, the* $\mathsf{Nat}^{\uparrow}$ *head-position row, the* $\mathsf{Seq}^{\uparrow}$ *configuration trace row, the finite state and tape alphabets, and the* $\mathsf{Computable}^{\uparrow}$ *bounded deterministic-trace row.*

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineTraceSourceObligation source rows`

Proof. Project the accepted machine token to its trace coordinate. The trace coordinate is already a $\mathsf{Seq}^{\uparrow}$ row, and each entry is a triple of BEDC histories, so the carrier is a finite BHist configuration sequence rather than a host-level execution.

The visible indices are supplied by the consumed $\mathsf{Nat}^{\uparrow}$ rows. The finite alphabets and the bounded deterministic-trace row are ledger coordinates of the same token, so every source row in the theorem is obtained by projection from the displayed carrier package. □

Theorem 280.9 (TuringMachine deterministic step stability)**.** *For a* $\mathsf{TuringMachine}^{\uparrow}$ *trace, one-step transition rows are stable under the displayed* Cont *and* hsame *transport. If current configurations, transition table rows, and head-position witnesses are transported by the public classifier, then the next configurations produced by the deterministic step row are again* hsame*.*

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineStepRow hsame transport`

Proof. Read the current configurations through the hsame classifier on the $\mathsf{Seq}^{\uparrow}$ trace. The transition table is a visible ledger row, so its transported copy determines the same state update, tape write, and head movement over the transported current configuration.

Apply the Cont row for trace extension. Determinism gives a single next row for the transported data, and the $\mathsf{Seq}^{\uparrow}$ classifier records the two extended traces as hsame at the next time index. □

Theorem 280.10 (TuringMachine halted repeat obligation)**.** *If a* $\mathsf{TuringMachine}^{\uparrow}$ *configuration row is marked halted, every accepted later trace row repeats that halted configuration up to* hsame*. The repeated suffix exposes only the halted configuration, its tape row, its head-position witness, and the halted ledger entry.*

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineHaltedTrace repeat obligation`

Proof. Use the halted-row clause of the carrier. Once the halted predicate is visible, the accepted trace-extension field cites the halted configuration as its source instead of reopening the transition table.

The repeated suffix is then built by the same Cont extension row. Since each later entry is classified with the halted configuration by hsame, the ledger contains no additional branch, oracle query, or tape update beyond the repeated halted row. □

Theorem 280.11 (TuringMachine bounded readback soundness)**.** *Every* $\mathsf{Computable}^{\uparrow}$ *bounded readback consumed by* $\mathsf{TuringMachine}^{\uparrow}$ *is read from the displayed finite trace prefix. The readback endpoint is the tape value addressed by the* $\mathsf{Nat}^{\uparrow}$ *head-position witness inside the current configuration row, and no infinite tape carrier or halting-decision row is exported.*

Proof. Project the bounded readback row from the consumed $\mathsf{Computable}^{\uparrow}$ surface. Its bound is a finite trace prefix, and each trace entry is a $\mathsf{Seq}^{\uparrow}$ configuration row with a visible tape component and head-position witness.

The endpoint readback therefore evaluates the displayed tape row at the displayed finite head witness. Transport by hsame preserves that bounded endpoint, while the absence of an infinite tape coordinate prevents the readback from exporting any stronger host computation claim. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineBoundedReadbackSoundness endpoint transport`
Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineBoundedReadback soundness`

Theorem 280.12 (TuringMachine NameCert surface obligation)**.** *The public* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *surface is obtained by repacking the configuration trace carrier, deterministic transition classifier,* Cont *and* hsame *stability rows, halted-repeat exactness, bounded readback exactness, and deterministic transition ledger. This surface binds only the listed* BHist*,* $\mathsf{Seq}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{Computable}^{\uparrow}$*,* Cont*,* hsame*, and ledger rows.*

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineNameCertSurface obligation`
Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineNameCertSurfaceObligation public surface`

Proof. First collect the carrier rows from Definition 280.8. These provide the finite configuration trace, time index, head-position witness, alphabets, and bounded deterministic-trace source.

Next add the stability and exactness rows. The deterministic-step row is stable by Definition 280.9, halted suffixes are exact by Definition 280.10, and bounded readback is exact by Definition 280.11.

Finally repack those rows as the naming certificate ledger. The package has no field for nondeterminism, oracle queries, parallel execution, a universal machine theorem, or a halting-decision classifier, so the public surface is exactly the listed finite-row obligation surface. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineObligationSurface rows`

Theorem 280.13 (TuringMachine public certificate export)**.** *The configuration-trace carrier, deterministic step transport, halted repeat obligation, finite tape readback carrier, bounded readback soundness, source-classifier obligation, and ledger exactness obligation repack into one public* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *certificate export over* BHist*,* hsame*,* Cont*,* Pkg*,* UnaryHistory*, and the bounded* $\mathsf{Computable}^{\uparrow}$ *verdict. The exported packet has the same finite transition table, configuration trace, halted suffix, bounded tape readback, and ledger rows as the component obligations.*

This public certificate export does not claim unbounded halting, a universal machine theorem, nondeterministic execution, oracle rows, or host computation.

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachinePublicCertificate export`

Proof. First collect the visible certificate rows. Use Definition 280.1, Definition 280.2, Definition 280.3, and Definition 280.4 to obtain the finite trace carrier, deterministic step route, halted suffix, and tape readback carrier.

Next add the public stability and exactness rows. Apply Definition 280.8, Definition 280.6, Definition 280.7, and Definition 280.11. These rows supply the BHist source, hsame classifier, Cont transport, Pkg provenance, UnaryHistory time bound, and bounded $\mathsf{Computable}^{\uparrow}$ verdict.

Finally invoke Definition 280.12. The component rows are already exactly the rows required by the public naming surface, so repacking them exports one $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ certificate. Since no component theorem contains an unbounded halting row, universal-machine row, nondeterministic branch, oracle coordinate, or host computation field, the exported certificate contains none either. □

Theorem 280.14 (TuringMachine finite trace standard bridge)**.** *The finite deterministic trace surface exported in Definition 280.13 has a standard bridge to the ordinary finite-trace deterministic machine reading. On the BEDC side the data are the finite state alphabet, finite tape alphabet with blank, transition table, input row, configuration trace, halted suffix, and bounded readback rows. On the ordinary finite-trace side the data are the corresponding state, tape, head position, time bound, configuration trace, halted suffix, and bounded readback rows.*

The bridge preserves these rows both ways: a BEDC accepted finite trace reads as an ordinary bounded deterministic run with the same state, tape, head, bound, trace, halted suffix, and readback values, and an ordinary bounded deterministic run with those rows repacks as the BEDC public certificate surface. The bridge does not add halting decidability, a universal machine, oracle-machine rows, nondeterministic branches, or unbounded computation.

Proof. Read the BEDC-to-standard direction from the public certificate export. The configuration carrier supplies the state, tape, head, and time-bound rows; the deterministic step transport supplies the one-step transition rows; the halted repeat obligation supplies the halted suffix; and the bounded readback theorem supplies the visible tape values.

For the standard-to-BEDC direction, take an ordinary bounded deterministic run with the same finite alphabets, transition table, initial row, trace, halted suffix, and readback rows. These are exactly the rows required by the source, classifier, transport, and ledger obligations in the public certificate export, so the run repacks as the $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ surface.

No extra computational principle is introduced in either direction. Every row used by the bridge is already finite and bounded, so the bridge has no field for halting decidability, universal machines, oracle machines, nondeterminism, or unbounded computation. □

Lean4 ✓ `BEDC.Derived.TuringMachineUp.TuringMachineFiniteTrace standard bridge`

Closure status for $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$**.**

Constructive story: A $\mathsf{TuringMachine}^{\uparrow}$ token names a deterministic finite-state transition table over a finite tape alphabet with a designated blank symbol. A configuration history is built from a $\mathsf{Seq}^{\uparrow}$ trace of (state, tape, head-position) rows whose initial row is the boot configuration on a $\mathsf{Nat}^{\uparrow}$-encoded input, whose one-step rows follow the transition function, and whose halted rows repeat the halted configuration. The classifier is hsame on the configuration trace, transport repacks the trace through the deterministic transition table, and the source binds finite-alphabet, finite-state, finite-trace, and finite-head-displacement rows. The pattern records the initial-row, transition-step, halted-repetition, and finite-tape-readback rows; the ledger keeps the deterministic transition table, head movement, and tape values visible. The five name-certificate obligations follow: the inhabited identity certificate is the boot trace at length zero; classifier stability is reflexive, symmetric, and transitive hsame on traces; transport repacks configurations through the transition function; ledger exactness identifies the accepted history with the bounded simulation row in the sense of chapter 199; the extension boundary fixes the halted-repetition rule. A history h lies in the signature gap of a $\mathsf{TuringMachine}^{\uparrow}$ token p when the source-domain accepts a configuration trace with the right transition table, the signature relation pairs it with the halted output, and token introduction names that output as p. The chapter registers this finite-trace machine surface under the name $\mathsf{TuringMachine}^{\uparrow}$; it is a deterministic-transition-table object with no oracle, nondeterminism, parallelism, halting decision, or universal-machine claim.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridged scope is the certificate export in Definition 280.13 together with the finite-trace standard bridge in Definition 280.14, grounded by Definition 280.5, Definition 280.6, Definition 280.7, Definition 280.1, Definition 280.2, Definition 280.3, and Definition 280.4.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TuringMachineUp.TuringMachineNameCertSurfaceObligation\_public\_surface`

Bridge status: paperBridge

Not claimed: The chapter does not close halting decidability, universal-machine theorems, oracle Turing machines, parallel/nondeterministic machines, or any unbounded standard-model computability theorem beyond the finite-trace deterministic bridge.

Upgrade path: Any machine-checked bridge-status uplift is recorded on the verification axis.

Chapter 281

A Concrete Naming Certificate for $\mathsf{RecursiveFn}^{\uparrow}$

The partial-recursive interface $\mathsf{RecursiveFn}^{\uparrow}$ packages partial functions $\mathsf{Nat}^{\uparrow} \to \mathsf{Nat}^{\uparrow}$ generated by zero, successor, projection, composition, primitive recursion, and bounded minimisation. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{List}^{\uparrow}}$ (chapter 36), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

281.1 Carrier definition

A $\mathsf{RecursiveFn}^{\uparrow}$ token carries an inductive constructor history of generation steps: zero, successor, projection π_i^k, composition row, primitive-recursion row with explicit base and step subterms, and bounded-minimisation row with an explicit unary bound. The carrier accepts a partial-graph value $F(n, m)$ when the constructor-history evaluation on the $\mathsf{Nat}^{\uparrow}$-input row n returns $\mathsf{Nat}^{\uparrow}$-output m within the displayed bound, and the evaluation trace is a $\mathsf{Seq}^{\uparrow}$ object. The classifier is hsame on output rows after the constructor history is fixed; the ledger keeps the constructor sequence, intermediate evaluation rows, and bounded-minimisation witness visible.

Theorem 281.1 (RecursiveFn zero successor projection obligation)**.** *The* $\mathsf{RecursiveFn}^{\uparrow}$ *constructor-history surface contains visible zero, successor, and projection rows over* $\mathsf{Nat}^{\uparrow}$ *inputs. For a displayed finite constructor history, the zero row returns the displayed* $\mathsf{Nat}^{\uparrow}$ *zero output, the successor row transports the input to its displayed successor output, and the projection row* π_i^k *selects the* i*th* $\mathsf{Nat}^{\uparrow}$ *input from the finite input tuple. In each case the accepted graph row is classified by* hsame *on the output once the constructor history is fixed.*

These base constructor rows are finite BHist *and* $\mathsf{Seq}^{\uparrow}$ *rows only. They do not assert unbounded* μ*-recursion totality, oracle queries, or a Church-Turing bridge.*

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnZeroSuccessorProjection obligation surface`

Proof. Inspect the head constructor of the displayed finite constructor history.

In the zero case, the ledger contains no recursive subtrace; the accepted output is the visible $\mathsf{Nat}^{\uparrow}$ zero row, and hsame compares that output row with itself.

In the successor case, the ledger contains the input $\mathsf{Nat}^{\uparrow}$ row and its successor output row. The accepted graph row is obtained by the constructor route from the input to the displayed successor.

In the projection case, the finite input tuple supplies the selected coordinate π_i^k. The ledger records the coordinate choice and the selected $\mathsf{Nat}^{\uparrow}$ row, so no oracle or host computation is introduced. □

Theorem 281.2 (RecursiveFn composition and primitive-recursion obligation)**.** *For a displayed* $\mathsf{RecursiveFn}^{\uparrow}$ *constructor history, composition and primitive recursion are compatible with the visible* $\mathsf{Seq}^{\uparrow}$ *evaluation traces. A composition row accepts exactly when the inner constructor histories evaluate on the displayed* $\mathsf{Nat}^{\uparrow}$ *inputs to intermediate* $\mathsf{Nat}^{\uparrow}$ *rows and the outer history evaluates on those rows. A primitive-recursion row accepts exactly when the base row and each displayed step row appear in order in the finite* $\mathsf{Seq}^{\uparrow}$ *trace, with* hsame *comparing only the final* $\mathsf{Nat}^{\uparrow}$ *output after the constructor history is fixed.*

The obligation is a constructor-history compatibility statement over finite BHist *and* $\mathsf{Seq}^{\uparrow}$ *ledgers. It excludes unbounded μ-recursion totality, oracle queries, and Church-Turing bridge claims.*

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnCompositionPrimitiveRecursion obligation surface`

Proof. Proceed by inspecting the displayed constructor history.

For composition, first read the inner histories. Each one consumes the same visible $\mathsf{Nat}^{\uparrow}$ input tuple and produces an intermediate output row in the $\mathsf{Seq}^{\uparrow}$ evaluation trace. The outer constructor history then consumes exactly those intermediate rows, so the composed graph row is the final row already present in the trace.

For primitive recursion, read the base row at the displayed zero input and then inspect each successor step in the finite recursion trace. The step row uses the previous output row and the current $\mathsf{Nat}^{\uparrow}$ index already recorded in the ledger. The final accepted output is therefore the final visible trace row.

No branch of the inspection adds an unbounded search, an oracle row, or a standard recursion-theory bridge; all movement is through the displayed finite constructor history. □

Theorem 281.3 (RecursiveFn bounded minimisation ledger exactness)**.** *For a displayed bounded-minimisation constructor in* $\mathsf{RecursiveFn}^{\uparrow}$*, the accepted output row is exactly the first witness row recorded in the finite* BHist *ledger under the visible* UnaryHistory *bound, or the displayed failure row when the bounded trace records no witness. The* $\mathsf{Seq}^{\uparrow}$ *evaluation trace contains every tested* $\mathsf{Nat}^{\uparrow}$ *input up to the bound, and* hsame *compares only the resulting bounded output row after the constructor history is fixed.*

The exactness statement is bounded and ledger-local. It does not claim unbounded μ-recursion totality, oracle access, or a Church-Turing bridge.

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnBoundedMinimisationLedger exactness`

Proof. Inspect the bounded-minimisation constructor row. The UnaryHistory coordinate gives the finite bound, and the BHist ledger lists the tested $\mathsf{Nat}^{\uparrow}$ inputs and their $\mathsf{Seq}^{\uparrow}$ evaluation rows in order.

If a witness row appears, take the first such displayed row. Constructor inspection shows that every earlier tested row is recorded as a non-witness, so ledger exactness identifies the accepted output with that first witness.

If no witness row appears, the same finite inspection reaches the displayed failure row at the end of the bounded trace. Since the trace is bounded by the visible unary history, no unbounded search or oracle query is used. □

Theorem 281.4 (RecursiveFn Nat input stability obligation)**.** *Let x and y be displayed* $\mathsf{Nat}^{\uparrow}$ *input rows related by the* $\mathsf{Nat}^{\uparrow}$ *classifier, and fix a finite* $\mathsf{RecursiveFn}^{\uparrow}$ *constructor history. If the displayed* BHist *and* $\mathsf{Seq}^{\uparrow}$ *evaluation trace evaluates the history at x to an accepted output row, then the transported trace evaluates the same history at y to an output row classified by* hsame*. The*

obligation uses only BHist *constructor rows,* $\mathsf{Seq}^{\uparrow}$ *evaluation rows,* $\mathsf{Nat}^{\uparrow}$ *input and output rows, and the fixed constructor ledger.*

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnNatInputStability obligation`

Proof. Inspect the fixed constructor history. For zero, successor, and projection, apply Definition 281.1; the transported input row changes only the displayed $\mathsf{Nat}^{\uparrow}$ input component, and the output comparison is the same hsame row recorded by the constructor ledger.

For composition and primitive recursion, use Definition 281.2. The inner traces, base row, and step rows are already visible $\mathsf{Seq}^{\uparrow}$ rows, so classifier transport repacks each intermediate $\mathsf{Nat}^{\uparrow}$ output and leaves the final output classified by hsame.

For bounded minimisation, apply Definition 281.3. The transported trace uses the same visible bound and the same finite list of tested rows, so the first displayed witness, or the displayed failure row, is transported without adding any unbounded search. □

Theorem 281.5 (RecursiveFn constructor ledger coverage obligation)**.** *Every accepted* $\mathsf{RecursiveFn}^{\uparrow}$ *graph row is covered by exactly one visible constructor case among zero, successor, projection, composition, primitive recursion, and bounded minimisation. In that case the ledger exposes the corresponding finite subtrace: the direct base-constructor row, the inner and outer composition rows, the primitive-recursion base and step rows, or the bounded-minimisation test rows under the displayed unary bound.*

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnConstructorLedger coverage obligation`

Proof. Proceed by the head constructor of the accepted constructor history.

The zero, successor, and projection heads are covered by Definition 281.1. Each head has a distinct constructor tag, so its accepted row cannot also be a composition, primitive-recursion, or bounded-minimisation row.

The composition and primitive-recursion heads are covered by Definition 281.2. Their visible $\mathsf{Seq}^{\uparrow}$ subtraces distinguish the inner-and-outer composition case from the base-and-step recursion case.

The bounded-minimisation head is covered by Definition 281.3. Its UnaryHistory bound and finite test ledger are part of the displayed row, so no other constructor case supplies the same ledger shape. □

Theorem 281.6 (RecursiveFn bounded search scope obligation)**.** *For a displayed bounded-minimisation constructor in* $\mathsf{RecursiveFn}^{\uparrow}$*, the search reads only the* UnaryHistory *bound, the listed* $\mathsf{Nat}^{\uparrow}$ *test rows, and their* $\mathsf{Seq}^{\uparrow}$ *evaluation rows. The accepted row has no unbounded search coordinate, no oracle row, and no hidden host predicate beyond the finite constructor ledger.*

Lean4 ✓ `BEDC.Derived.RecursiveFnUp.RecursiveFnBoundedSearchScope obligation`

Proof. Start with the bounded-minimisation constructor and apply Definition 281.3. The theorem identifies the accepted output with the first visible witness row, or with the displayed failure row when the finite test ledger contains no witness.

The tested rows themselves are ordinary $\mathsf{Nat}^{\uparrow}$ rows in the same finite constructor history. The base-constructor, composition, and primitive-recursion obligations, Definition 281.1 and Definition 281.2, account for the evaluations of those rows inside the listed $\mathsf{Seq}^{\uparrow}$ trace.

Thus every read used by the bounded search is already named in the UnaryHistory, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Seq}^{\uparrow}$ ledger, and there is no exported row for an unbounded search or oracle. □

Theorem 281.7 (RecursiveFn public constructor-history export)**.** *The* $\mathsf{RecursiveFn}^{\uparrow}$ *public export is the finite* $\mathsf{NameCert}_{\mathsf{RecursiveFn}^{\uparrow}}$ *constructor-history surface assembled from the zero, successor, and projection obligation; the composition and primitive-recursion trace obligation; bounded-minimisation ledger exactness;* $\mathsf{Nat}^{\uparrow}$ *input stability; constructor-ledger coverage; and bounded-search scope obligation.*

Its public rows are exactly the displayed BHist *constructor history,* UnaryHistory *bound rows,* $\mathsf{Seq}^{\uparrow}$ *evaluation traces,* $\mathsf{Nat}^{\uparrow}$ *input and output rows, visible* hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The export contains no unbounded* μ*-recursion totality assertion, no oracle row, and no Church–Turing bridge claim.*

Proof. Build the export from the constructor obligations. The base constructor rows come from Definition 281.1, and the composition and primitive-recursion traces come from Definition 281.2.

Add the bounded-search data next. Apply Definition 281.3 for the finite UnaryHistory bound and tested $\mathsf{Seq}^{\uparrow}$ rows, then use Definition 281.6 to keep every search read inside that displayed bounded ledger.

Now attach transport and coverage. The $\mathsf{Nat}^{\uparrow}$ input stability row is supplied by Definition 281.4, and the constructor-ledger coverage row is supplied by Definition 281.5. Together they show that each accepted public graph row has one displayed constructor case and transports only through visible hsame, Cont, Pkg, and local NameCert data.

The six cited obligations exhaust the public export. Since none contains a row for unbounded μ-recursion totality, oracle evaluation, or a Church–Turing bridge, those claims remain outside $\mathsf{NameCert}_{\mathsf{RecursiveFn}^{\uparrow}}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{RecursiveFn}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RecursiveFn}^{\uparrow}$ token names a finite constructor history built from zero, successor, projection π_i^k, composition, primitive recursion with base/step subterms, and bounded minimisation with a displayed unary bound. The carrier accepts a graph row $F(n, m)$ when evaluating the constructor history on the $\mathsf{Nat}^{\uparrow}$-input row n over a $\mathsf{Seq}^{\uparrow}$ trace yields $\mathsf{Nat}^{\uparrow}$-output m within the displayed bound. Classifier control is hsame on outputs once the constructor history is fixed; the source covers $\mathsf{Nat}^{\uparrow}$ inputs and outputs, constructor histories, and $\mathsf{Seq}^{\uparrow}$ evaluation traces; the pattern records constructor-history admissibility, composition row, primitive-recursion base/step row, and bounded-minimisation row; the ledger keeps the constructor sequence, intermediate evaluation rows, and minimisation witness visible. The five name-certificate obligations follow from the inductive constructor-history evaluation: the inhabited identity certificate is the zero constructor; classifier stability is reflexive, symmetric, and transitive hsame on outputs; transport repacks evaluations through composition and recursion; ledger exactness identifies the graph row with the displayed evaluation; the extension boundary fixes the bounded-minimisation rule. A history h lies in the signature gap of a $\mathsf{RecursiveFn}^{\uparrow}$ token p when the source-domain accepts a constructor-history evaluation, the signature relation pairs it with the graph output, and token introduction names that output as p. The chapter registers this finite-constructor-history surface under the name $\mathsf{RecursiveFn}^{\uparrow}$; it is a partial-recursive function object with no general μ-recursion totality claim, no oracle, no Church-Turing bridge, and no standard recursion-theory library.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RecursiveFn}^{\uparrow}}$, publicClosed)

Scope closed: Definition 281.7 binds the constructor-history export over zero, successor, projection, composition, primitive recursion, bounded minimisation, BHist, UnaryHistory, $\mathsf{Seq}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RecursiveFn}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RecursiveFnUp.RecursiveFnBoundedMinimisationLedger\_exactness`

Bridge status: none

Not claimed: The chapter does not close unbounded μ-recursion totality, the Church-Turing thesis, oracle recursive functions, or a standard recursion-theory bridge.

Upgrade path: Bridged closure requires a standard recursive-function bridge over the same constructor-history, trace-compatibility, and bounded-ledger dependencies.

Chapter 282

A Concrete Naming Certificate for $\mathsf{ComplexityClass}^{\uparrow}$

The complexity-class interface $\mathsf{ComplexityClass}^{\uparrow}$ packages a resource-bounded acceptance predicate parametrised by an explicit unary modulus on input length. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ (chapter 280), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

282.1 Carrier definition

A $\mathsf{ComplexityClass}^{\uparrow}$ token carries: a deterministic $\mathsf{TuringMachine}^{\uparrow}$ acceptor, a unary modulus β that bounds the configuration-trace length as a function of the unary input length, and a resource type tag (time, space, or alternation depth). The carrier accepts an input history h when the bounded simulation of the acceptor on h within $\beta(|h|)$ rows reaches a halted accepting configuration. The classifier is hsame on input histories of the same unary length; the ledger keeps the modulus value, the trace length, and the halting verdict visible.

Theorem 282.1 (ComplexityClassUp bounded acceptance carrier)**.** *The* $\mathsf{ComplexityClass}^{\uparrow}$ *bounded acceptance carrier is a finite* BHist *package consisting of a* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *unary input-length row, a* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *deterministic acceptor row, a* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *bounded-simulation row, the unary resource modulus* β*, and the accepted halted verdict. The classifier is* hsame *on input histories of the same unary length, and the carrier exposes no nondeterminism, randomness, oracle computation, average-case complexity, or* P *versus* NP *row.*

Lean4 ✓ `BEDC.Derived.ComplexityClassUp.ComplexityClassBoundedAcceptanceCarrier bounded surface`

Proof. Project the finite input-length row from the $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ coordinate and the bounded configuration trace from the $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ coordinate. These rows determine the BHist source on which the unary modulus β is evaluated.

Read the halted verdict through the $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ ledger. The carrier accepts exactly when that bounded simulation row reaches an accepting halted configuration within the displayed modulus value.

The classifier uses hsame on transported inputs of the same unary length. Since the package has no row for nondeterministic branches, random bits, oracle calls, average-case sampling, or class separation, none of those data can be projected from the carrier. □

↪ variant BEDC.Derived.ComplexityClassUp.ComplexityClassBoundedAcceptanceCarrier bounded acceptance surface

↪ variant BEDC.Derived.ComplexityClassUp.ComplexityClassBoundedAcceptanceCarrier bounded trace surface

Theorem 282.2 (ComplexityClassUp resource modulus monotonicity)**.** *For* $\mathsf{ComplexityClass}^{\uparrow}$*, the unary resource modulus is a visible monotone ledger row: if two* BHist *inputs have unary lengths related by the* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *order row and the smaller input is accepted within* $\beta(n)$ *bounded* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *trace rows, then the larger bound* $\beta(m)$ *is an admissible* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *simulation budget for the* hsame *transported trace. The statement is only a bounded-resource monotonicity claim and does not assert a classical complexity-class collapse.*

Lean4 ✓ BEDC.Derived.ComplexityClassUp.ComplexityClassResourceModulusMonotonicity budget transport

Lean4 ✓ BEDC.Derived.ComplexityClassUp.ComplexityClassResourceModulusMonotonicity bound transport

Proof. Read the two unary input-length rows through $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$. The monotonicity coordinate of the modulus ledger transports the comparison of lengths to the comparison of bounds $\beta(n)$ and $\beta(m)$.

Transport the accepted trace by hsame. The $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ trace rows remain the same deterministic bounded computation after transport, while the enlarged bound only adds unused budget rows.

The $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ bounded-simulation ledger therefore reads the same accepting verdict under the larger budget. Nothing in the argument adds nondeterministic, randomised, oracle, average-case, or separation data. □

Lean4 ✓ BEDC.Derived.ComplexityClassUp.ComplexityClassResourceModulusMonotonicity bound enlargement

Theorem 282.3 (ComplexityClassUp bounded simulation soundness)**.** *Every accepted* $\mathsf{ComplexityClass}^{\uparrow}$ *row has a sound bounded-simulation readback: the* BHist *input, the unary length row, the* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *trace, the unary resource modulus, and the* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *verdict determine the same halted-accepting configuration after* hsame *transport. No unbounded halting predicate or universal-machine theorem is read from this surface.*

Lean4 ✓ BEDC.Derived.ComplexityClassUp.ComplexityClassBoundedSimulation soundness

Proof. Begin with the accepted carrier row. It supplies the input history, unary length, displayed modulus value, deterministic trace, and bounded-simulation verdict.

Use hsame to transport the input and trace rows. The deterministic $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ component fixes each finite transition row, so the transported trace has the same halted endpoint inside the transported budget.

Read the verdict through the $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ ledger. The result is soundness of the bounded accepting simulation only; the carrier contains no coordinate for an unbounded halting decision or a universal-machine simulation theorem. □

Theorem 282.4 (ComplexityClassUp resource ledger exactness)**.** *The* $\mathsf{ComplexityClass}^{\uparrow}$ *resource ledger is exact: for an accepted row, the recorded* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *input length, unary modulus value, realised deterministic* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *trace length, bounded* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *verdict, and* hsame *transport row are precisely the rows used by the carrier. Enlarging a bound uses the monotone modulus row, but the accepted verdict remains the displayed finite* BHist *ledger entry.*

Lean4 ✓ BEDC.Derived.ComplexityClassUp.ComplexityClassResourceLedger membership exactness

Proof. Project the resource ledger from the carrier. Its coordinates are the modulus value, realised trace length, halted verdict, and transport evidence, all over finite BHist rows.

Apply the monotone modulus row only when the budget is enlarged. The underlying deterministic trace and bounded-simulation verdict are not recomputed by an external model; they are the same rows already present in the carrier.

Thus exactness is the equality of the carrier's accepted row with its visible ledger coordinates. There is no additional resource interpretation outside the NatUp, TuringMachineUp, ComputableUp, and hsame surfaces. □

Lean4 ✓ `BEDC.Derived.ComplexityClassUp.ComplexityClassResourceLedgerExactness visible transport`

Theorem 282.5 (ComplexityClassUp NameCert obligation surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{ComplexityClass}^{\uparrow}}$ *obligation surface is obtained by repacking four rows: the bounded acceptance carrier, unary resource-modulus monotonicity, bounded-simulation soundness, and resource-ledger exactness. It depends only on finite* BHist *rows from* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$, *the classifier* hsame*, and the unary resource modulus. It does not claim nondeterminism, randomness, oracle computation, average-case complexity, or* P *versus* NP*.*

Lean4 ✓ `BEDC.Derived.ComplexityClassUp.ComplexityClassNameCertObligationSurface public rows`

Proof. First take the bounded acceptance carrier from Definition 282.1. It supplies the finite input-length, acceptor, bounded trace, modulus, classifier, and verdict rows.

Next add the monotonicity and soundness rows from Definition 282.2 and Definition 282.3. These transport accepted traces by hsame and enlarge resource bounds only through the displayed unary modulus.

Finally use Definition 282.4 to identify the accepted verdict with the visible ledger row. Repacking these four rows gives the public naming-certificate obligation surface, and constructor inversion shows that no nondeterministic, randomised, oracle, average-case, or class-separation coordinate is present. □

Theorem 282.6 (ComplexityClassUp deterministic resource bridge)**.** *The deterministic bounded-resource certificate of* $\mathsf{ComplexityClass}^{\uparrow}$ *bridges to the standard finite resource-class schema exactly through the* $\mathsf{Nat}^{\uparrow}$ *unary input-length row, the* $\mathsf{TuringMachine}^{\uparrow}$ *deterministic trace row, the* $\mathsf{Computable}^{\uparrow}$ *bounded verdict row, the monotone unary resource modulus, and* hsame *transport. The bridge exports no nondeterministic, randomized, oracle, average-case, interactive-proof, or* P*-versus-*NP *row.*

Proof. Begin with the bounded acceptance carrier of Definition 282.1. It supplies the unary length row, deterministic machine trace, bounded simulation verdict, modulus value, and classifier transport needed by the finite resource-class schema.

Next compose resource-modulus monotonicity with bounded simulation soundness. By Definition 282.2 and Definition 282.3, enlarging the unary input bound uses only the monotone modulus row, and the accepted verdict remains the displayed deterministic bounded computation after hsame transport.

Finally apply resource-ledger exactness and the NameCert obligation surface, Definition 282.4 and Definition 282.5. These identify the accepted resource row with the public finite ledger and exclude every nondeterministic, randomized, oracle, average-case, interactive-proof, or class-separation coordinate. □

Closure status for $\mathsf{NameCert}_{\mathsf{ComplexityClass}^{\uparrow}}$.

Constructive story: A $\mathsf{ComplexityClass}^{\uparrow}$ token names a deterministic $\mathsf{TuringMachine}^{\uparrow}$ acceptor together with a displayed unary modulus β and a resource-type tag (time, space, or alternation depth). The carrier accepts an input history h when the bounded simulation of the acceptor on h, in the sense of $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$, halts in an accepting configuration within $\beta(|h|)$ trace rows; the resource-type tag selects whether β bounds trace length, head-cell footprint, or alternation depth. The classifier is hsame on input histories of the same unary length; the source covers unary input lengths, modulus values, configuration-trace lengths, head-cell footprints, and alternation rows; the pattern records halted-acceptance, modulus monotonicity, footprint admissibility, and alternation-depth admissibility rows; the ledger keeps the modulus $\beta(|h|)$, the realised trace length or footprint, the alternation depth, and the halting verdict visible. The five name-certificate obligations are supplied by the bounded-simulation certificate of $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ together with monotonicity of β: the inhabited identity certificate is the trivial accepter at $\beta \equiv 0$; classifier stability is reflexive, symmetric, and transitive hsame on inputs of fixed length; transport repacks bounded simulations through input transport; ledger exactness identifies the accepted row with the bounded-simulation verdict; the extension boundary fixes monotonicity of β in the unary input length. A history h lies in the signature gap of a $\mathsf{ComplexityClass}^{\uparrow}$ token p when the source-domain accepts the bounded-resource simulation, the signature relation pairs it with the halting verdict, and token introduction names that verdict as p. The chapter registers this resource-bounded surface under the name $\mathsf{ComplexityClass}^{\uparrow}$; it is a deterministic-resource-class object with no nondeterministic, randomised, average-case, oracle, or interactive-proof bridge.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ComplexityClass}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature bounded-resource surface is the finite deterministic schema given by the bounded acceptance carrier, resource modulus monotonicity, bounded simulation soundness, resource ledger exactness, public $\mathsf{NameCert}_{\mathsf{ComplexityClass}^{\uparrow}}$ obligation surface, and deterministic resource bridge of Definition 282.1, Definition 282.2, Definition 282.3, Definition 282.4, Definition 282.5, and Definition 282.6. Nondeterministic, probabilistic, and oracle resources are excluded.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ComplexityClass}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: The chapter does not close P-versus-NP, randomised classes, oracle separations, average-case complexity, or interactive-proof systems.

Upgrade path: A checked standard bridge remains a separate formal-axis target for the deterministic finite resource-class schema.

Chapter 283

A Concrete Naming Certificate for $\mathsf{Kolmogorov}^{\uparrow}$

The Kolmogorov-complexity interface $\mathsf{Kolmogorov}^{\uparrow}$ packages a description-length predicate over a deterministic prefix-free decoder, parametrised by a displayed unary length budget. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ (chapter 280), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

283.1 Carrier definition

A $\mathsf{Kolmogorov}^{\uparrow}$ token carries a deterministic prefix-free decoder $\mathsf{TuringMachine}^{\uparrow}$, a unary length budget ℓ, and a target output history h. The carrier accepts a witness when there is a prefix-free description d of unary length at most ℓ that, decoded by the decoder, halts and reads back h. The classifier is hsame on output histories at fixed budget ℓ; the ledger keeps the description d, the unary budget, the decoded trace, and the readback row visible; the pattern records prefix-freeness, budget admissibility, decoded-readback exactness, and budget monotonicity.

Theorem 283.1 (Kolmogorov prefix-free carrier obligation)**.** *The* $\mathsf{Kolmogorov}^{\uparrow}$ *carrier obligation is the finite* BHist *surface whose accepted row consists of a prefix-free description history, a displayed* $\mathsf{UnaryHistory}$ *length row, a fixed-budget* hsame *classifier on decoded output histories, and the dependency rows supplied by* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$*. At a fixed unary budget* ℓ*, the carrier accepts exactly those description rows whose decoder trace is a displayed halted* $\mathsf{TuringMachine}^{\uparrow}$ *trace consumed by the bounded* $\mathsf{Computable}^{\uparrow}$ *readback.*

This obligation records prefix-freeness and budget admissibility only as visible finite rows. It does not assert universal-decoder optimality, randomness extraction, the invariance theorem, or any standard information-theoretic bridge.

```
Lean4 ✓  BEDC.Derived.KolmogorovUp.KolmogorovPrefixFreeCarrier obligation surface
Lean4 ✓  BEDC.Derived.KolmogorovUp.KolmogorovPrefixFreeCarrierObligation finite surface
```

Proof. Inspect the displayed witness row. Its BHist component supplies the description history, its $\mathsf{UnaryHistory}$ component supplies the length budget, and the fixed-budget hsame row supplies the classifier on decoded output histories.

The $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ dependency reads the unary length and budget rows, the $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ dependency reads the deterministic decoder trace, and the $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ dependency reads

the bounded halted output. Since each component is carried in the same finite ledger, the carrier contains exactly the displayed prefix-free and budget rows and no external optimality or information-theoretic structure. □

Theorem 283.2 (Kolmogorov budget monotonicity obligation)**.** *Let a* $\mathsf{Kolmogorov}^{\uparrow}$ *witness over* BHist *accept a description under a unary budget* ℓ *with fixed-budget* hsame *decoded output classifier. If* ℓ' *is obtained from* ℓ *by a displayed* $\mathsf{UnaryHistory}$ *budget extension, then the same description, the same* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *length row, the same* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *halted trace, and the same* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *bounded readback row form an accepted* $\mathsf{Kolmogorov}^{\uparrow}$ *witness at budget* ℓ'*.*

The transported row preserves the decoded readback and enlarges only the visible unary admissibility bound. It does not introduce universal-decoder optimality, randomness extraction, or a standard information-theoretic bridge.

Lean4 ✓ `BEDC.Derived.KolmogorovUp.KolmogorovBudgetMonotonicity budget transport`

Proof. Start with the accepted witness at budget ℓ. The description history, decoder trace, halted readback, and output classifier are already visible in the BHist ledger.

Apply constructor inspection to the displayed $\mathsf{UnaryHistory}$ extension from ℓ to ℓ'. The length-admissibility row for the old budget embeds into the larger unary budget, while the fixed-budget hsame classifier on the decoded output is reused unchanged at the new displayed budget.

The $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ row witnesses the unary bound, and the $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ rows are not rerun. Therefore the accepted readback is preserved exactly, with only the budget-admissibility coordinate enlarged. □

Lean4 ✓ `BEDC.Derived.KolmogorovUp.KolmogorovBudgetMonotonicity budget extension`

Theorem 283.3 (Kolmogorov decoded readback exactness)**.** *For every accepted* $\mathsf{Kolmogorov}^{\uparrow}$ *witness over* BHist*, the ledger identifies the accepted output row with the displayed* $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ *halted decoder trace as read through the bounded* $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ *verdict, while the unary description and budget are the rows certified by* $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ *and* $\mathsf{UnaryHistory}$*. The* hsame *classifier therefore compares only the decoded output histories at the fixed displayed budget.*

The exactness statement closes only the finite decoded-readback ledger. It does not close universal-decoder optimality, randomness extraction, the invariance theorem, or any standard information-theoretic bridge.

Lean4 ✓ `BEDC.Derived.KolmogorovUp.KolmogorovDecodedReadback exactness`

Proof. Read the accepted witness as a finite ledger. The description and budget rows are the $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ and $\mathsf{UnaryHistory}$ coordinates, and the decoder run is the displayed deterministic $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ trace.

The bounded $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ verdict consumes that halted trace and exports a single readback row. Ledger exactness then identifies the accepted $\mathsf{Kolmogorov}^{\uparrow}$ output with that readback row, so the fixed-budget hsame classifier has no additional coordinate to compare.

The proof never replaces the displayed decoder by an optimal universal decoder, never samples a randomness row, and never invokes an information-theoretic bridge; all equalities are inside the finite decoded trace ledger. □

Theorem 283.4 (Kolmogorov public NameCert export)**.** *The prefix-free carrier obligation, budget monotonicity obligation, and decoded readback exactness assemble the public* $\mathsf{NameCert}_{\mathsf{Kolmogorov}^{\uparrow}}$

export over BHist, UnaryHistory, Nat$^{\uparrow}$, TuringMachine$^{\uparrow}$, Computable$^{\uparrow}$, *the fixed-budget* hsame *classification, and the visible prefix-free decoder ledger.*

The exported public surface consists exactly of the carrier row for accepted prefix-free descriptions, the fixed-budget output classifier, the stability rows for transporting the same decoded output across displayed unary budget extensions, the budget transport row, and the decoded-readback exactness row. It does not assert universal-decoder optimality, randomness extraction, an invariance theorem, resource-bounded complexity, or an information-theoretic standard bridge.

Proof. First project Definition 283.1. This supplies the finite carrier: description histories in BHist, displayed UnaryHistory budgets, $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ length rows, $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ halted decoder traces, and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ bounded readback rows.

Next use Definition 283.2. The budget transport keeps the description, decoder trace, readback row, and fixed-budget hsame classifier stable while only enlarging the visible unary admissibility bound.

Finally apply Definition 283.3. The accepted output row is the decoded readback from the displayed halted trace, so the public certificate repacks the carrier, classifier, stability, budget transport, and exactness rows listed in the statement. No optimal universal decoder, randomness row, or standard information-theoretic bridge is added. □

Closure status for $\mathsf{NameCert}_{\mathsf{Kolmogorov}^{\uparrow}}$.

Constructive story: A Kolmogorov$^{\uparrow}$ token names a deterministic prefix-free decoder TuringMachine$^{\uparrow}$ together with a displayed unary length budget ℓ and a target output history h. The carrier accepts a witness when there is a prefix-free description history d of unary length at most ℓ such that running the decoder on d, in the sense of $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$, halts and reads back h. The classifier is hsame on output histories at fixed unary budget; the source covers unary description lengths, budget values, decoder configurations, prefix-freeness rows, and decoded readback histories; the pattern records prefix-freeness admissibility, budget admissibility, decoded-readback exactness, budget monotonicity, and decoder-determinism rows; the ledger keeps the description d, the budget ℓ, the decoded trace, and the readback row visible. The five name-certificate obligations are supplied by the bounded-simulation certificate plus the prefix-free description structure: the inhabited identity certificate is the empty-description trivial decoder; classifier stability is reflexive, symmetric, and transitive hsame at fixed budget; transport repacks descriptions through prefix-extension; ledger exactness identifies the accepted row with the decoded readback at the displayed budget; the extension boundary fixes budget monotonicity. A history h lies in the signature gap of a Kolmogorov$^{\uparrow}$ token p when the source-domain accepts the prefix-free decoded readback, the signature relation pairs it with the decoded output, and token introduction names that output as p. The chapter registers this prefix-free description-budget surface under the name Kolmogorov$^{\uparrow}$; it is a description-length object with no universal-decoder optimality, no resource-bounded variant (K^t, K^s), no randomness extraction, and no information-theoretic standard bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Kolmogorov}^{\uparrow}}$, publicClosed)

Scope closed: The public surface binds BHist, UnaryHistory, Nat$^{\uparrow}$, TuringMachine$^{\uparrow}$, Computable$^{\uparrow}$, prefix-free description rows, bounded decoder traces, budget monotonicity, fixed-budget hsame output classification, and the exported $\mathsf{NameCert}_{\mathsf{Kolmogorov}^{\uparrow}}$ rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Kolmogorov}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: The chapter does not close universal-decoder optimality, resource-bounded Kolmogorov complexity (K^t, K^s), randomness extraction, the invariance theorem, or a standard information-theoretic bridge.

Upgrade path: Bridged closure requires a standard information-theoretic bridge theorem for the exported prefix-free decoder, budget, readback, classifier, and ledger surface.

Chapter 284

A Concrete Naming Certificate for $\mathsf{BusyBeaver}^{\uparrow}$

The busy-beaver interface $\mathsf{BusyBeaver}^{\uparrow}$ packages a finite-state-bounded halting maximum predicate parametrised by a displayed state count and a candidate output bound. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{TuringMachine}^{\uparrow}}$ (chapter 280), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

284.1 Carrier definition

A $\mathsf{BusyBeaver}^{\uparrow}$ token carries a unary state-count n, a finite enumeration of n-state two-symbol $\mathsf{TuringMachine}^{\uparrow}$ codes, a unary candidate output bound B, and a halted-step ledger. The carrier accepts a witness when, for every machine code in the enumeration that halts on the empty tape, its halted output and step count are bounded by B in the sense of $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$. The classifier is hsame on output bounds at fixed unary state count; the ledger keeps the enumeration, the halted bound B, the per-machine readback, and the non-halting witness rows visible.

Theorem 284.1 (BusyBeaver halted-bound admissibility)**.** *For a* $\mathsf{BusyBeaver}^{\uparrow}$ *token with unary state-count* n*, displayed finite enumeration* E *of* n*-state two-symbol* $\mathsf{TuringMachine}^{\uparrow}$ *codes, unary bound* B*, and halted-step ledger* L*, every code* M *in* E *whose empty-input row is recorded in* L *as halted has a* $\mathsf{Computable}^{\uparrow}$ *bounded-trace row in* L*. That row starts from the displayed empty tape, follows the finite* $\mathsf{TuringMachine}^{\uparrow}$ *transition trace for* M*, reads back the halted output row, records the halted step-count row, and compares both rows with* B *through the* $\mathsf{Nat}^{\uparrow}$ *order surface.*

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverHaltedBound admissibility`
Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverHaltedBoundAdmissibility halted trace surface`

Proof. Project the accepted $\mathsf{BusyBeaver}^{\uparrow}$ packet to its finite enumeration and halted-step ledger. Membership of M in E is a displayed finite row, and the halted case is exactly the ledger branch that carries a finite $\mathsf{TuringMachine}^{\uparrow}$ configuration trace from the empty input to a halted row.

Read that halted branch through the $\mathsf{TuringMachine}^{\uparrow}$ finite trace and tape readback rows. They supply the endpoint configuration, output readback, and unary step count without appealing to a host run or to a universal-machine coding theorem.

The carrier clause for $\mathsf{BusyBeaver}^{\uparrow}$ requires this halted branch to be repacked as a $\mathsf{Computable}^{\uparrow}$ bounded trace. The same ledger row supplies the bound comparisons against B in the $\mathsf{Nat}^{\uparrow}$ order, so the accepted witness is admissible exactly for the halted machines already displayed in E. □

Theorem 284.2 (BusyBeaver enumeration completeness)**.** *The finite enumeration surface of a* $\mathsf{BusyBeaver}^{\uparrow}$ *token exhausts the displayed n-state two-symbol* $\mathsf{TuringMachine}^{\uparrow}$ *code rows for its fixed unary state count n. Every admitted machine row is either one of the listed enumeration entries with its corresponding ledger branch, or it is outside the token's carrier surface; no host universal-machine theorem, ambient coding theorem, or external halting search is imported into the enumeration claim.*

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverEnumerationCompleteness finite ledger surface`
Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverEnumerationCompleteness append coverage`

Proof. Unpack the source coordinate of the token. The enumeration is a finite BEDC row whose entries are already typed as n-state two-symbol $\mathsf{TuringMachine}^{\uparrow}$ codes, and the carrier consumes only entries addressed by that row.

For a displayed code row at the same state count and alphabet, enumeration completeness is the finite coverage statement internal to the token: the row is found at one listed position, with the halted or non-halting ledger branch attached there. If no listed position is supplied, the row has no carrier membership witness for this $\mathsf{BusyBeaver}^{\uparrow}$ token.

Thus the proof is finite projection from the enumeration surface, not an argument that a universal simulator can decide which machines halt. The only readback used downstream is the per-entry $\mathsf{TuringMachine}^{\uparrow}$ or $\mathsf{Computable}^{\uparrow}$ ledger row already attached to the finite list. □

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverEnumerationCompleteness finite coverage`

Theorem 284.3 (BusyBeaver bound monotonicity)**.** *Let a* $\mathsf{BusyBeaver}^{\uparrow}$ *token with enumeration E, unary state-count n, bound B, and halted-step ledger L be accepted. If B' is another unary* $\mathsf{Nat}^{\uparrow}$ *bound with $B \leq B'$ in the displayed order surface, then replacing B by B' preserves the accepted witness with the same enumeration and the same halted-step ledger. The transport changes only the bound rows; it does not add a halting-decision row and does not assert computability of the busy-beaver function.*

Proof. Start with an accepted witness at bound B. Each halted entry in the finite enumeration has, by Definition 284.1, a $\mathsf{Computable}^{\uparrow}$ bounded trace whose output and step-count rows are bounded by B.

Transport those two comparisons along the supplied $\mathsf{Nat}^{\uparrow}$ order proof $B \leq B'$. The enumeration row, halted trace, output readback, and step-count ledger are unchanged; only the terminal bound comparison is replaced by the larger unary bound.

Non-halting ledger branches are also unchanged, since they carry no halted output comparison. Repacking the same finite ledger with the transported comparisons yields an accepted $\mathsf{BusyBeaver}^{\uparrow}$ witness at B', with no new halting oracle and no computability claim about the global busy-beaver function. □

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverBoundMonotonicity bound transport`

Theorem 284.4 (BusyBeaver non-halting exclusion obligation)**.** *For a* $\mathsf{BusyBeaver}^{\uparrow}$ *token with unary state-count n, finite enumeration E, unary bound B, and ledger L, a non-halting branch for an entry $M \in E$ is only a visible finite ledger row attached to that enumeration position. It records that the accepted packet has no halted output row for M inside L; it does not supply a halting-decision oracle, a complement enumerator for halting rows, or a method for deciding whether arbitrary n-state* $\mathsf{TuringMachine}^{\uparrow}$ *codes halt.*

Proof. Project the token to the finite enumeration surface of Definition 284.2. Each enumeration position has exactly the ledger branch displayed at that position, so a non-halting row is read as part of the finite packet rather than as the result of a search over machine runs.

The halted branch has a different shape: by Definition 284.1, it carries a finite $\mathsf{TuringMachine}^{\uparrow}$ trace, a halted output row, a step-count row, and $\mathsf{Computable}^{\uparrow}$ bound comparisons. The non-halting branch lacks precisely those halted endpoint fields.

Therefore the row excludes only a halted readback inside this accepted ledger. It gives downstream consumers a visible finite boundary for this token and no procedure for classifying machines outside the displayed branch. □

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverNonhaltingExclusion obligation surface`

Theorem 284.5 (BusyBeaver per-machine readback exactness)**.** *For every halted enumeration entry of an accepted* $\mathsf{BusyBeaver}^{\uparrow}$ *token, the per-machine readback is exactly the bounded* $\mathsf{TuringMachine}^{\uparrow}$ *and* $\mathsf{Computable}^{\uparrow}$ *endpoint already attached to that entry. The readback does not introduce a second simulator, a host computation trace, or a detached output bound; it is the finite trace endpoint, halted output row, step-count row, and B-comparison row carried by the same enumeration position.*

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverPerMachineReadback membership exactness`

Proof. Start from a halted entry M of the finite enumeration. By Definition 284.1, the ledger branch attached to M already contains the $\mathsf{TuringMachine}^{\uparrow}$ transition trace from the empty tape to the halted configuration and the corresponding $\mathsf{Computable}^{\uparrow}$ bounded trace.

The finite projection from the enumeration position supplies the readback key. It points to the same branch of L, so the output, step count, and bound comparison are the endpoint rows already present there.

If the bound is transported as in Definition 284.3, the machine trace and halted readback remain unchanged. Only the terminal $\mathsf{Nat}^{\uparrow}$ comparison is replaced, which preserves exactness of the per-machine endpoint. □

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverPerMachineReadback endpoint exactness`

Theorem 284.6 (BusyBeaver scoped name-certificate surface)**.** *The scoped* $\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$ *surface over a displayed unary state count n, finite enumeration E, unary bound B, and ledger L is exactly the package consisting of halted-bound admissibility, enumeration completeness, bound monotonicity, non-halting exclusion, and per-machine readback exactness. Its public read exposes the enumeration, the halted bound, the halted per-entry* $\mathsf{TuringMachine}^{\uparrow}$ *and* $\mathsf{Computable}^{\uparrow}$ *rows, and the non-halting ledger rows, but it does not expose busy-beaver computability or halting decidability.*

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverHaltingLedger scoped namecert surface`

Proof. First assemble the halted side. Apply Definition 284.1 to obtain the bounded $\mathsf{Computable}^{\uparrow}$ row for each halted entry, and apply Definition 284.5 to identify each consumer read with the endpoint attached to its enumeration position.

Next assemble the enumeration and transport side. Apply Definition 284.2 to keep every admitted machine row inside the displayed finite list, and apply Definition 284.3 to show that increasing the unary bound changes only the terminal comparison rows.

Finally handle the negative branch. Apply Definition 284.4: the non-halting rows are finite ledger projections, not a decision procedure. Repacking these five rows gives the scoped $\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$ surface and preserves the stated non-claims. □

Theorem 284.7 (BusyBeaver per-machine halted-readback determinacy)**.** *Let W and W' be accepted* $\mathsf{BusyBeaver}^{\uparrow}$ *witnesses with the same unary state-count n and the same displayed finite enumeration E of n-state two-symbol* $\mathsf{TuringMachine}^{\uparrow}$ *codes. Let M be one entry of E. Suppose the ledger of W records for M a halted branch from the displayed empty tape with finite transition trace T, halted output row o, and halted step-count row s, and the ledger of W' records for the same entry M a halted branch from the displayed empty tape with finite transition trace T', halted output row o', and halted step-count row s'. Then the carrier ledger classifies the two readbacks componentwise:*

$$T\mathsf{hsame}T', \qquad o\mathsf{hsame}o', \qquad s\mathsf{hsame}s'.$$

Thus, at fixed enumeration entry, the halted readback of an accepted $\mathsf{BusyBeaver}^{\uparrow}$ *witness is determined by the deterministic machine code and the empty-tape initial row, not by the choice of accepted witness packet.*

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverPerMachineReadback halted determinacy`

Proof. Project both accepted witnesses to their common enumeration row. Since the entry is the same displayed $M \in E$, both halted branches use the same finite-state code, the same deterministic transition table, the same blank-tape initial configuration, and the same halting predicate. By Definition 284.5, each public readback is the endpoint already attached to the ledger branch at that enumeration position; no detached simulator or host computation trace is introduced.

Compare the two finite transition traces from the empty-tape initial row. Their zero configurations are classified together because they are the displayed initial configuration of the same machine on the same input. If two compared current configurations are classified by hsame, then Definition 280.9 transports the common transition-table row and classifies the next configurations by hsame again. Induction over the finite trace rows therefore identifies the two deterministic runs up to the first halted row exposed by the halted-step ledger.

It remains to rule out a mismatch of the displayed halted index. Once either trace reaches a halted configuration, the halted-repeat clause of Definition 280.10 says that later accepted trace rows only repeat that halted configuration. The ledger exactness clause of Definition 280.7 gives no second branch choice or fresh transition row after that point. Hence the two halted branches for the same M expose the same halted-step row in the $\mathsf{Nat}^{\uparrow}$ classifier, so $s\mathsf{hsame}s'$.

At that common halted row the configuration traces have already been compared, so the visible tape components and head-position readbacks are compared by the finite readback surface of Definition 280.11. The halted output rows read from those compared endpoints are therefore classified together, $o\mathsf{hsame}o'$. Combining the trace comparison, the halted-step comparison, and the output readback comparison gives $T\mathsf{hsame}T'$, $s\mathsf{hsame}s'$, and $o\mathsf{hsame}o'$ as claimed. □

Lean4 ✓ `BEDC.Derived.BusyBeaverUp.BusyBeaverPerMachineReadback halted readback determinacy`

Theorem 284.8 (BusyBeaver public enumeration-bound export)**.** *For a fixed unary state count and displayed enumeration, the finite enumeration rows, bounded halted-readback rows, non-halting ledger rows, monotone bound transport, and per-machine determinacy assemble a public* $\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$ *export. The public rows are exactly the unary state count, the finite* $\mathsf{TuringMachine}^{\uparrow}$ *enumeration, the unary candidate bound, the halted trace and readback rows, the non-halting branch rows, the* $\mathsf{Nat}^{\uparrow}$ *order comparisons, and the visible* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *provenance.*

The export asserts no computability of the global busy-beaver function, no halting decidability, no asymptotic growth theorem, and no standard recursion-theory bridge.

Proof. Start from Definition 284.6. It packages the fixed unary state count, displayed finite enumeration, candidate unary bound, halted-step ledger, non-halting witness rows, BHist, hsame, Cont, Pkg, and local NameCert data as the scoped certificate surface.

For each displayed enumeration entry, use Definition 284.7. The halted trace, halted output row, and halted step-count row are determined by the displayed machine code and empty-tape initial row, so the public export does not depend on an additional readback choice.

Use Definition 284.3 to transport the unary candidate bound along the displayed $\mathsf{Nat}^{\uparrow}$ order comparisons. Use Definition 284.4 to keep off-table branches recorded as non-halting ledger rows rather than as missing public data.

Combining these rows gives the public $\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$ export for the fixed enumeration and bound. Since the construction only repacks finite enumeration, bounded readback, non-halting, order-comparison, and provenance rows, it does not export global busy-beaver computability, halting decidability, asymptotic growth, or a standard recursion-theory bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$.

Constructive story: A $\mathsf{BusyBeaver}^{\uparrow}$ token names a unary state-count n together with a finite enumeration of n-state two-symbol $\mathsf{TuringMachine}^{\uparrow}$ codes, a candidate unary output bound B, and a halted-step ledger row. The carrier accepts a witness when every code in the enumeration that halts on the empty tape, in the sense of $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$, has its halted output and step count bounded by B; non-halting codes are recorded in the non-halting witness row. The classifier is hsame on output bounds at fixed unary state count; the source covers the unary state count, the finite machine enumeration, the unary output bound, the halted-step ledger, and the non-halting witness; the pattern records halted bound admissibility, finite enumeration completeness, non-halting exclusion, bound monotonicity, and per-machine-readback exactness rows; the ledger keeps the enumeration, the halted bound B, the per-machine readback, and the non-halting witness rows visible. The five name-certificate obligations are supplied by the bounded-simulation certificate plus enumeration-finiteness: the inhabited identity certificate is the trivial $n = 0$ certificate; classifier stability is reflexive, symmetric, and transitive hsame at fixed state count; transport repacks bounded simulations through machine enumeration; ledger exactness identifies the accepted row with the displayed halted bound; the extension boundary fixes bound monotonicity in the unary state count. A history h lies in the signature gap of a $\mathsf{BusyBeaver}^{\uparrow}$ token p when the source-domain accepts the enumeration-bounded readback, the signature relation pairs it with the halted maximum, and token introduction names that maximum as p. The chapter registers this enumeration-bounded halting surface under the name $\mathsf{BusyBeaver}^{\uparrow}$; it is a finite-state-bounded maximum object with no actual computability claim about the busy-beaver function, no asymptotic growth-rate claim, and no halting-decidability bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$, publicClosed)

Scope closed: The public surface binds the unary state count n, the finite enumeration of n-state two-symbol machines, halted-bound admissibility, enumeration completeness, bound monotonicity, non-halting exclusion, per-machine readback exactness, halted-readback determinacy, the halted-step ledger, and the non-halting witness rows through Definition 284.6 and Definition 284.8.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BusyBeaver}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: The chapter does not close busy-beaver-function computability, asymptotic growth-rate theorems, halting decidability, or a standard recursion-theory bridge.

Upgrade path: Standard bridge closure requires a recursion-theory bridge for the same finite enumeration and bounded halted-readback surface.

Chapter 285

A Concrete Naming Certificate for $\mathsf{AbelRuffini}^{\uparrow}$

The Abel-Ruffini interface $\mathsf{AbelRuffini}^{\uparrow}$ packages a non-solvability-by-radicals certificate for a degree-five polynomial over a $\mathsf{NumField}^{\uparrow}$ base. It depends on $\mathsf{NameCert}_{\mathsf{Poly}^{\uparrow}}$ (chapter 50), $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ (chapter 164), $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$ (chapter 117), and $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168).

285.1 Carrier definition

An $\mathsf{AbelRuffini}^{\uparrow}$ token carries: a separable monic polynomial P of degree five over a $\mathsf{NumField}^{\uparrow}$ base K together with three irreducibility, non-trivial-rational-root, and Galois-group-isomorphic-to-S_5 rows. The carrier accepts a non-solvability witness when $\mathsf{Gal}(P/K)$ is isomorphic to S_5 and the derived series of S_5 does not reach the trivial subgroup. The classifier is hsame on the Galois group rows; the ledger keeps the irreducibility witness, the S_5 identification, and the derived-series ledger visible.

Theorem 285.1 (AbelRuffini polynomial Galois obligation)**.** *The* $\mathsf{AbelRuffini}^{\uparrow}$ *source rows are the* $\mathsf{Poly}^{\uparrow}$, $\mathsf{NumField}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, *and* $\mathsf{SymGroup}^{\uparrow}$ BHist *packages for a displayed degree-five polynomial, its base field row, its splitting-field row, and its* S_5 *identification. The carrier reads the polynomial coefficient history, separability and irreducibility rows, the non-trivial-rational-root row, the Galois group package over the splitting field, and the symmetric-group identification row.*

Proof. Project the accepted token to its polynomial and base-field coordinates. The coefficient history is supplied by $\mathsf{Poly}^{\uparrow}$, while the base and splitting field data are supplied by $\mathsf{NumField}^{\uparrow}$ rows.

Next project the group coordinates. The Galois action row is a $\mathsf{GaloisGroup}^{\uparrow}$ package, and the displayed comparison with S_5 is the consumed $\mathsf{SymGroup}^{\uparrow}$ identification.

The carrier has no additional source coordinate for a host field extension or an external classification theorem, so these four package families are exactly the polynomial Galois source surface. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniPolynomialGaloisObligation source surface`

Theorem 285.2 (AbelRuffini derived-series ledger obligation)**.** *The* $\mathsf{AbelRuffini}^{\uparrow}$ *derived-series ledger is a finite* BHist *ledger. Each step exposes the current subgroup row, the next commutator subgroup row, and the* hsame *transport relating the displayed* S_5 *identification to the Galois-group package. The ledger does not import a host solvable-group theorem.*

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniDerivedSeriesLedger obstruction endpoint boundary`

Proof. Read the derived-series field of the accepted package as a finite list of displayed subgroup rows. Each row is a BEDC history, and each successor row is recorded by the displayed commutator-step ledger.

Transport is internal to the same list. The hsame classifier relates the Galois identification row to the corresponding S_5 subgroup row, then carries the step witness to the next displayed subgroup.

Since every step is recorded as an explicit finite ledger row, non-solvability is read from this ledger rather than from an imported abstract solvability theorem. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniDerivedSeriesLedger assoc surface`

Theorem 285.3 (AbelRuffini derived-series finite transport)**.** *A displayed Galois row, S_5 row, subgroup row, commutator row, obstruction row, and continuation chain repack into a finite* $\mathsf{AbelRuffini}^{\uparrow}$ *BEDC transport ledger. The ledger has a unary next row for each displayed commutator step and an endpoint row for the obstruction, with* hsame *comparisons for the subgroup row, the unary next row, and the endpoint row.*

Proof. Start with the finite derived-series ledger from Definition 285.2. It supplies the displayed subgroup rows, the commutator successor rows, and the obstruction row as finite BHist data.

Project unary closure through the three continuation rows: first from the Galois row to the displayed S_5 row, then from the current subgroup row to the unary next commutator row, and finally from the obstruction row to the endpoint row.

The three hsame comparisons are read from these same projections. Repacking the subgroup comparison, next-row comparison, and endpoint comparison gives the finite transport ledger without importing a separate radical-tower or solvable-group theorem. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniDerivedSeriesLedger finite transport`

Theorem 285.4 (AbelRuffini non-radical boundary obligation)**.** *The* $\mathsf{AbelRuffini}^{\uparrow}$ *non-solvability-by-radicals boundary is read only from the polynomial and Galois identification rows together with the finite derived-series ledger. It excludes general degree-n classification, an A_5 simplicity proof, and radical-tower bridge data.*

Proof. Start with the polynomial Galois obligation. It supplies the displayed degree-five polynomial, the splitting-field row, the Galois-group row, and the S_5 identification.

Then apply the derived-series ledger obligation. The finite subgroup ledger records the obstruction row that prevents the displayed series from reaching the trivial subgroup.

The boundary statement is therefore only a readback from these rows. No field of the package names a degree-n classification, an independent A_5 simplicity argument, or a standard radical-tower bridge, so those data remain outside the chapter scope. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniNonradicalBoundary obstruction surface`
↪ variant `BEDC.Derived.AbelRuffiniUp.AbelRuffiniNonradicalBoundary obligation`

Theorem 285.5 (AbelRuffini public certificate export)**.** *The polynomial Galois obligation, derived-series ledger obligation, and non-radical boundary obligation repack into the public* $\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}$ *certificate over the displayed* $\mathsf{Poly}^{\uparrow}$, $\mathsf{NumField}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{SymGroup}^{\uparrow}$, hsame, *and finite derived-series rows. The exported certificate exposes the degree-five polynomial source, base-field row, Galois-group row, S_5 identification, derived-series ledger, and non-solvability-by-radicals boundary,*

while keeping general degree-n Galois solvability, an A_5 simplicity proof, transcendental methods, abstract solvable-group theory, and a standard radical-tower bridge outside its scope.

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniPublicCertificate export`

Proof. First apply Definition 285.1. This supplies the displayed polynomial, number-field base, splitting-field and Galois-group rows, and the consumed $\mathsf{SymGroup}^{\uparrow}$ comparison with S_5.

Next apply Definition 285.2. The derived series is a finite BEDC ledger whose rows are transported through the same hsame comparison, so the public certificate reads only the displayed subgroup steps.

Finally apply Definition 285.4. It identifies the non-solvability boundary as a readback from the polynomial, Galois identification, and finite derived-series rows. Repacking these three obligations yields the public $\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}$ export and preserves all stated non-claims. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniPublicCertificateExport namecert surface`

Theorem 285.6 (AbelRuffini standard radical-tower bridge boundary)**.** *The standard radical-tower bridge for the displayed degree-five* $\mathsf{AbelRuffini}^{\uparrow}$ *certificate may read only the* $\mathsf{Poly}^{\uparrow}$ *coefficient rows, the* $\mathsf{NumField}^{\uparrow}$ *base row, the* $\mathsf{GaloisGroup}^{\uparrow}$ *and* $\mathsf{SymGroup}^{\uparrow}$ *S_5 identification rows, the finite derived-series obstruction ledger, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the* NameCert *rows already exported by Definition 285.5. It adds no general degree-n solvability theorem, no A_5 simplicity proof, no resolvent reduction, and no transcendental method.*

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniStandardRadicalTower bridge boundary`
↪ variant `BEDC.Derived.AbelRuffiniUp.AbelRuffiniPublicCertificate radical tower bridge boundary`

Proof. Project the public certificate export through Definition 285.5. This exposes the coefficient rows, base-field row, Galois-group row, S_5 comparison, derived-series ledger, transport routes, package provenance, and local naming rows as the whole visible packet.

Use Definition 285.1 for the polynomial-Galois coordinates and Definition 285.2 for the finite derived-series obstruction. These obligations account for every row the radical-tower bridge is allowed to consume.

Finally repack the same finite rows as the bridge boundary. Since the packet has no coordinate for a general degree-n theorem, an A_5 simplicity proof, a resolvent reduction, or a transcendental method, none of those objects can be exported by the bridge. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniRadicalTowerBridge standard boundary`

Theorem 285.7 (AbelRuffini degree-five consumer examples)**.** *Finite downstream consumers for polynomial coefficient readback, Galois-group identification, derived-series obstruction, and radical-tower exclusion all read the same displayed degree-five packet exported by the public certificate and the standard radical-tower bridge boundary. The shared packet consists of the* $\mathsf{Poly}^{\uparrow}$ *coefficient rows,* $\mathsf{NumField}^{\uparrow}$ *base row,* $\mathsf{GaloisGroup}^{\uparrow}$ *row,* $\mathsf{SymGroup}^{\uparrow}$ *S_5 identification row, finite derived-series ledger, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

These consumers do not assert a general degree-n solvability theorem, an A_5 simplicity proof, a resolvent reduction, transcendental methods, or machine-checked radical-tower bridge evidence.

Proof. Apply Definition 285.5. It exposes the degree-five polynomial source, base-field row, Galois-group row, S_5 identification, derived-series ledger, non-radical boundary, transports, continuations, package provenance, and local naming rows as one public packet.

The polynomial coefficient and Galois-identification consumers read the polynomial-Galois rows supplied by Definition 285.1. The obstruction consumer reads the finite derived-series rows supplied by Definition 285.2.

Finally apply Definition 285.6. It identifies the radical-tower exclusion consumer as a read of the same public packet rather than as a new general solvability surface. Since the packet has no coordinate for the excluded objects, the four consumers add none of them. □

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniDegreeFiveConsumerExamples`

Theorem 285.8 (AbelRuffini finite consumer completeness)**.** *Every finite downstream consumer of the displayed degree-five non-radical boundary reads only the* $\mathsf{Poly}^{\uparrow}$ *coefficient rows,* $\mathsf{NumField}^{\uparrow}$ *base row,* $\mathsf{GaloisGroup}^{\uparrow}$ *and* $\mathsf{SymGroup}^{\uparrow}$ S_5 *rows, finite derived-series obstruction ledger, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}$ *provenance. Conversely, those displayed rows repack as the same finite consumer surface.*

The consumer surface contains no general degree-n solvability theorem, A_5 simplicity proof, resolvent reduction, transcendental method, or hidden radical-tower assumption.

Lean4 ✓ `BEDC.Derived.AbelRuffiniUp.AbelRuffiniFiniteConsumer completeness`

Proof. Project the polynomial and Galois rows through Definition 285.1. This supplies the degree-five coefficient rows, the number-field base row, the Galois-group row, and the displayed S_5 comparison through $\mathsf{SymGroup}^{\uparrow}$.

Next apply Definition 285.2. The finite obstruction is read as the displayed derived-series ledger, transported through the same hsame rows and package provenance.

Use Definition 285.5 to package these polynomial, base-field, group, obstruction, transport, continuation, package, and naming rows as the public $\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}$ surface.

For the converse direction, start from exactly those displayed rows and repack them by the same public export. Then apply Definition 285.6; it identifies the finite downstream radical-tower consumer as a read of that surface and not as an additional algebraic assumption.

Since no cited row names a general degree-n theorem, an A_5 simplicity proof, a resolvent reduction, a transcendental method, or a hidden radical-tower assumption, every finite consumer is exhausted by the displayed surface and the displayed surface repacks every such consumer. □

Closure status for $\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}$**.**

Constructive story: An $\mathsf{AbelRuffini}^{\uparrow}$ token names a separable monic polynomial P of degree five over a $\mathsf{NumField}^{\uparrow}$ base K together with three witnesses: an irreducibility row, a non-trivial-rational-root row, and a Galois-group identification row $\mathsf{Gal}(P/K) \cong S_5$. The carrier accepts a non-solvability-by-radicals certificate when $\mathsf{Gal}(P/K)$ is isomorphic to S_5 in the sense of $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$, and the derived series of S_5 stops at A_5 without reaching the trivial subgroup. The classifier is hsame on the Galois group identification rows; the source covers polynomial coefficient histories, splitting field carrier rows, Galois group elements, derived-series subgroups, and rational-root exclusion rows; the pattern records irreducibility admissibility, S_5 identification, derived-series exactness, non-radical-tower exclusion, and degree-five admissibility rows; the ledger keeps the polynomial coefficients, the irreducibility witness, the S_5 identification, and the derived-series ledger visible. The five name-certificate obligations are supplied by the $\mathsf{GaloisGroup}^{\uparrow}$ chain plus solvable-group structure: the inhabited identity certificate is a fixed polynomial $x^5 - x - 1$ over $\mathbb{Q}$; classifier stability is reflexive, symmetric, and transitive hsame on Galois group identifications; transport repacks Galois actions through polynomial transport; ledger exactness identifies the carrier row with the S_5 derived-series ledger; the extension boundary fixes the non-radical-tower row. A history h lies in the signature gap of an $\mathsf{AbelRuffini}^{\uparrow}$ token p when the source-domain accepts the polynomial-coefficient history, the signature relation pairs it with the non-solvable Galois identification, and token introduction names that identification as p. The chapter registers this finite Galois-group-based non-solvability surface under the name $\mathsf{AbelRuffini}^{\uparrow}$; it is a degree-five S_5-Galois object whose standard radical-tower bridge boundary reads only the displayed finite rows and does not add general degree-n classification, an A_5 simplicity proof, resolvent reduction, or transcendental method.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridged surface binds the displayed $\mathsf{Poly}^{\uparrow}$, $\mathsf{NumField}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{SymGroup}^{\uparrow}$, hsame, and finite derived-series ledger rows through Definition 285.5, the standard radical-tower bridge boundary of Definition 285.6, the degree-five consumer examples of Definition 285.7, and the finite consumer completeness theorem of Definition 285.8.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AbelRuffini}^{\uparrow}}, \text{unformalized})$

Bridge status: paperBridge

Not claimed: The chapter does not close general degree-n Galois solvability, the A_5 simplicity proof, transcendental methods, abstract solvable-group theory, or machine-checked radical-tower bridge evidence.

Upgrade path: No paper-side theory grade remains for this chapter; formal bridge verification remains on the separate verification axis.

Chapter 286

A Concrete Naming Certificate for $\mathsf{SolvableRadicals}^{\uparrow}$

The radical-tower interface $\mathsf{SolvableRadicals}^{\uparrow}$ packages a tower of radical extensions $K = K_0 \subseteq K_1 \subseteq \cdots \subseteq K_r$ where each $K_{i+1} = K_i(\alpha_i)$ with $\alpha_i^{n_i} \in K_i$. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161), $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ (chapter 164), and $\mathsf{NameCert}_{\mathsf{NumField}^{\uparrow}}$ (chapter 168).

286.1 Carrier definition

A $\mathsf{SolvableRadicals}^{\uparrow}$ token carries a finite tower depth r, a $\mathsf{Seq}^{\uparrow}$-typed sequence of intermediate field rows $K_0, \ldots, K_r$, a sequence of root indices $n_0, \ldots, n_{r-1}$, and a sequence of radicand witnesses α_i with $\alpha_i^{n_i} \in K_i$. The carrier accepts a polynomial P when P splits in K_r and each step is genuinely radical. The classifier is hsame on the tower depth and intermediate-field rows; the ledger keeps the depth r, the root indices, the radicand witnesses, and the splitting verdict visible.

Theorem 286.1 (SolvableRadicals tower-step obligation)**.** *Every accepted* $\mathsf{SolvableRadicals}^{\uparrow}$ *radical-tower row exposes the finite* $\mathsf{Seq}^{\uparrow}$ *tower depth, the root-index rows, the radicand witnesses, and the* $\mathsf{FieldExt}^{\uparrow}$ *radical-step certificate for each adjacent pair of intermediate field rows. For each displayed step* $K_i \subseteq K_{i+1}$*, the ledger records the row* $\alpha_i^{n_i} \in K_i$ *and the corresponding extension row for* $K_{i+1} = K_i(\alpha_i)$*.*

The obligation is only the finite tower-step surface. It does not assert a Galois-correspondence theorem, abstract solvable-group classification, or a radical-closure bridge.

Lean4 ✓ `BEDC.Derived.SolvableRadicalsUp.SolvableRadicalsTowerStepLedger assoc surface`

Proof. Project the accepted packet to its tower-depth coordinate and intermediate field sequence. These rows give the finite $\mathsf{Seq}^{\uparrow}$ spine $K_0, \ldots, K_r$.

For each adjacent pair, read the root-index and radicand coordinates. The $\mathsf{FieldExt}^{\uparrow}$ certificate attached to that pair records the radical-step witness and the equation $\alpha_i^{n_i} \in K_i$ in the same ledger.

Repacking the displayed adjacent-step rows gives the tower-step obligation. No classification of solvable groups or radical closures is invoked. □

Lean4 ✓ `BEDC.Derived.SolvableRadicalsUp.SolvableRadicalsTowerStep obligation`

Theorem 286.2 (SolvableRadicals intermediate-field stability)**.** *For* $\mathsf{SolvableRadicals}^{\uparrow}$*,* hsame *transport of fixed-depth intermediate field rows preserves the displayed radical-step ledger. If two tower*

presentations have the same finite depth and their corresponding intermediate field rows are related by the fixed classifier, then each root-index, radicand, and $\mathsf{FieldExt}^{\uparrow}$ *radical-step certificate transports to the matching adjacent field row.*

The statement is a fixed-depth stability obligation. It does not identify abstract Galois groups or claim a full Galois correspondence.

Proof. Start with two accepted tower rows of the same displayed depth. The classifier relates corresponding intermediate field rows by hsame and keeps the finite index positions fixed.

At each adjacent position, transport the root-index, radicand, and $\mathsf{FieldExt}^{\uparrow}$ radical-step certificate along the corresponding field-row classifiers. Since the positions are fixed by the tower depth, no new step is created and no step is omitted.

The transported packet therefore has the same radical-step ledger at the matching positions. The argument is finite ledger transport rather than a Galois-correspondence or solvable-group classification result. □

Lean4 ✓ `BEDC.Derived.SolvableRadicalsUp.SolvableRadicalsTowerPacket intermediate field stability`

Theorem 286.3 (SolvableRadicals splitting ledger exactness)**.** *In an accepted* $\mathsf{SolvableRadicals}^{\uparrow}$ *packet, the accepted polynomial row is identified with the displayed splitting verdict in the top field* K_r*. The ledger reads the polynomial over* K_0*, transports it through the finite tower, and records the top-field factor rows exactly as the carrier's splitting verdict.*

This exactness statement does not assert a Galois-correspondence theorem, abstract solvable-group classification, transcendental methods, or a standard radical-closure bridge.

Proof. Read the polynomial coordinate over the base field row K_0 and the finite tower coordinate ending at K_r. Both are part of the accepted packet.

Next inspect the splitting verdict. Its factor rows live in the displayed top field, and the ledger ties them to the original polynomial row through the finite tower already exposed by the carrier.

Thus the accepted polynomial row and the top-field splitting verdict are the same ledger surface. No additional correspondence theorem, solvable-group classification, or transcendental method is projected from the packet. □

Lean4 ✓ `BEDC.Derived.SolvableRadicalsUp.SolvableRadicalsTowerPacket splitting ledger exactness`

Theorem 286.4 (SolvableRadicals public NameCert export)**.** *The tower-step obligation, intermediate-field stability row, and splitting-ledger exactness row assemble the public* $\mathsf{NameCert}_{\mathsf{SolvableRadicals}^{\uparrow}}$ *export consumed by* $\mathsf{AbelRuffini}^{\uparrow}$ *and Galois-side users. The export contains only finite tower packets, displayed* $\mathsf{FieldExt}^{\uparrow}$ *source rows, radical-step ledgers,* hsame*,* Cont*,* Pkg*, and local* NameCert *provenance.*

This public surface does not claim the Galois-correspondence theorem, abstract solvable-group classification, transcendental methods, or a solvability-by-radicals standard schema.

Proof. Project Definition 286.1. It supplies the finite tower depth, adjacent intermediate-field rows, root-index rows, radicand witnesses, and displayed $\mathsf{FieldExt}^{\uparrow}$ radical-step certificates.

Use Definition 286.2 to transport the same fixed-depth tower surface through the visible hsame rows. The transport keeps the radical-step ledger attached to the matching adjacent field rows and does not add a group-classification coordinate.

Apply Definition 286.3 to identify the accepted polynomial row with the top-field splitting verdict in the same finite tower ledger.

Repacking the tower-step, stability, and splitting rows gives the exported $\mathsf{NameCert}_{\mathsf{SolvableRadicals}^{\uparrow}}$ surface used by the downstream polynomial consumers. The repacked packet contains only the fields listed in the statement and leaves the standard solvability-by-radicals schema outside the chapter boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{SolvableRadicals}^{\uparrow}}$.

Constructive story: A $\mathsf{SolvableRadicals}^{\uparrow}$ token names a finite tower depth r, a $\mathsf{Seq}^{\uparrow}$-typed sequence of intermediate field rows $K_0, \ldots, K_r$, a sequence of root indices $n_0, \ldots, n_{r-1}$, and a sequence of radicand witnesses $\alpha_i \in K_{i+1}$ with $\alpha_i^{n_i} \in K_i$. The carrier accepts a separable polynomial P over K_0 when each step $K_{i+1} = K_i(\alpha_i)$ is genuinely radical in the sense of $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ and P splits in K_r. The classifier is hsame on the tower depth and intermediate-field rows; the source covers field carriers, root indices, radicand witnesses, splitting witnesses, and tower-depth rows; the pattern records radical-step admissibility, splitting admissibility, tower-depth admissibility, root-of-unity availability, and intermediate-field-stability rows; the ledger keeps the depth r, the root indices, the radicand witnesses, and the splitting verdict visible. The five name-certificate obligations are supplied by the $\mathsf{FieldExt}^{\uparrow}$ tower together with $\mathsf{GaloisGroup}^{\uparrow}$ solvability: the inhabited identity certificate is the trivial $r = 0$ tower; classifier stability is reflexive, symmetric, and transitive hsame on towers of fixed depth; transport repacks radical extensions through field-isomorphism transport; ledger exactness identifies the accepted polynomial with its splitting in K_r; the extension boundary fixes the radical-step rule. A history h lies in the signature gap of a $\mathsf{SolvableRadicals}^{\uparrow}$ token p when the source-domain accepts the radical-tower-splitting witness, the signature relation pairs it with the splitting verdict, and token introduction names that verdict as p. The chapter registers this radical-tower surface under the name $\mathsf{SolvableRadicals}^{\uparrow}$; it is a finite-tower polynomial-splitting object with no Galois-correspondence claim, no general solvable-group identification, no transcendental methods, and no standard radical-closure bridge.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SolvableRadicals}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The obligation scope binds the radical tower-step rows, fixed-depth intermediate-field stability under hsame, and top-field splitting ledger exactness over the displayed $\mathsf{Seq}^{\uparrow}$, $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{NumField}^{\uparrow}$, and polynomial rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SolvableRadicals}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SolvableRadicalsUp.SolvableRadicalsTowerPacket\_intermediate\_field\_stability`

Bridge status: none

Not claimed: The chapter does not close the Galois-correspondence theorem, abstract solvable-group classification, transcendental methods, or a standard radical-closure bridge.

Upgrade path: Bridged closure requires a bridge from the exported radical-tower splitting surface to the standard solvability-by-radicals schema.

Chapter 287

A Concrete Naming Certificate for $\mathsf{DiffGalois}^{\uparrow}$

The differential-Galois interface $\mathsf{DiffGalois}^{\uparrow}$ packages the Picard-Vessiot Galois group of a linear differential equation over a $\mathsf{NumField}^{\uparrow}$-base differential field. It depends on $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ (chapter 161), $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ (chapter 164), $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$ (chapter 193), and $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ (chapter 140).

287.1 Carrier definition

A $\mathsf{DiffGalois}^{\uparrow}$ token carries: a differential field (K, ∂) over a $\mathsf{NumField}^{\uparrow}$ subfield, a linear differential operator $L = \sum a_i \partial^i$ with coefficients in K, a $\mathsf{Seq}^{\uparrow}$-typed solution-space row V of dimension equal to the order of L, and the differential-Galois group G acting on V that fixes K^{∂} pointwise. The carrier accepts a Picard-Vessiot certificate when the solution space exists, the differential-Galois group G acts faithfully on V, and the constants K^{∂} are exactly the G-fixed elements. The classifier is hsame on the solution-space rows; the ledger keeps the differential operator, the solution-space row, the Galois action, and the constant-field witness visible.

Theorem 287.1 (DiffGalois Picard-Vessiot obligation)**.** *An accepted* $\mathsf{DiffGalois}^{\uparrow}$ *Picard-Vessiot row exposes the solution-space, differential-operator, and fundamental-solution rows as finite* BHist *data over* $\mathsf{Seq}^{\uparrow}$, $\mathsf{FieldExt}^{\uparrow}$, *and* $\mathsf{Ode}^{\uparrow}$. *The differential field* (K, ∂) *is read through the displayed* $\mathsf{FieldExt}^{\uparrow}$ *row, the coefficient rows of the linear operator* $L = \sum a_i \partial^i$ *are read through the displayed* $\mathsf{Ode}^{\uparrow}$ *row, and the solution-space basis and fundamental-solution matrix are read through the* $\mathsf{Seq}^{\uparrow}$ *row.*

The obligation is local to the displayed Picard-Vessiot ledger. It does not assert algebraic-group classification, Liouvillian solvability, or an integration-by-quadratures bridge.

Proof. Project the accepted packet to its differential-field and operator coordinates. These rows provide (K, ∂) and the coefficient list of L as finite source data.

Next read the solution-space coordinate. The $\mathsf{Seq}^{\uparrow}$ basis row and the fundamental-solution row are the only witnesses consumed by the carrier, and the classifier compares solution-space histories by the fixed hsame row.

Repacking these coordinates gives the stated obligation surface. No step adds an algebraic-group classification row, a Liouvillian criterion, or an external analytic solution method. □

Lean4 ✓ `BEDC.Derived.DiffGaloisUp.DiffGaloisPicardVessiotPacket solution space obligation`

Theorem 287.2 (DiffGalois faithful action and constant-field exactness)**.** *For an accepted* $\mathsf{DiffGalois}^{\uparrow}$ *packet, the displayed* $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ *action row is faithful on the visible solution-space basis and transports along the fixed solution-space classifier. Two action histories that agree on every displayed basis row are identified by the same* hsame *solution-space classifier. The constant-field row is exactly the fixed-point ledger for this action: a displayed row is accepted as a constant precisely when the ledger records it as fixed, and every displayed fixed row is read back through the same* K^{∂} *coordinate.*

This obligation is a finite action-and-fixed-row statement. It does not classify differential-Galois groups, assert Liouvillian solvability, or supply a standard model-theoretic bridge.

Lean4 ✓ `BEDC.Derived.DiffGaloisUp.DiffGaloisFaithfulActionLedger basis fold surface`

Proof. Start from the action coordinate of the accepted packet. It is already typed as a $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ row acting on the visible solution-space basis.

Faithfulness is read at the displayed basis rows: if two action histories have the same effect on each basis coordinate, the ledger identifies their action rows through the fixed classifier. Transport along hsame changes only the solution-space presentation and keeps the action row attached to the same basis surface.

Now read the constant-field coordinate from the same packet. A displayed constant row is fixed by the action ledger, and a displayed fixed row is read back through K^{∂}, so exactness is an hsame transport comparison between two visible projections of the same Picard-Vessiot data.

Thus the obligation is witnessed by finite projection from the accepted Picard-Vessiot packet rather than by a classification theorem for the ambient group. □

Theorem 287.3 (DiffGalois public certificate export)**.** *The Picard-Vessiot obligation and the faithful-action constant-field exactness obligation repack into the public* $\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$ *boundary. The exported certificate exposes the* $\mathsf{FieldExt}^{\uparrow}$ *differential-field row, the* $\mathsf{Ode}^{\uparrow}$ *operator row, the* $\mathsf{Seq}^{\uparrow}$ *solution-space and fundamental-solution rows, the faithful* $\mathsf{GaloisGroup}^{\uparrow}$ *action row, and the constant-field fixed-row ledger. It excludes Liouvillian solvability, algebraic-group classification, integration-by-quadratures, and standard model-theoretic bridge claims.*

Lean4 ✓ `BEDC.Derived.DiffGaloisUp.DiffGaloisPublicCertificate export`

Proof. Apply Definition 287.1. This supplies the differential-field, operator, solution-space, and fundamental-solution rows as the visible Picard-Vessiot ledger.

Next apply Definition 287.2. This adds the faithful action row and identifies the constant-field coordinate with the fixed-row ledger by hsame transport.

Repacking these rows gives the public $\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$ boundary. No field of the export supplies a Liouvillian criterion, an algebraic-group classification theorem, integration-by-quadratures, or a standard model-theoretic bridge. □

Theorem 287.4 (DiffGalois scoped certificate surface)**.** *The Picard-Vessiot packet, faithful action ledger, constant-field fixed-point exactness, solution-space row, and displayed Galois action rows form the closed scoped* $\mathsf{DiffGalois}^{\uparrow}$ *certificate surface over* $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{Ode}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, BHist, hsame, Cont, *and* Pkg*. Its carrier is the displayed differential-field, operator, solution-space, fundamental-solution, action, and constant-field ledger; its classifier is* hsame *on the solution-space row together with transported Galois action rows; and its visible ledger is exactly the public* $\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$ *boundary of Definition 287.3.*

This scoped surface closes only the finite Picard-Vessiot certificate rows. It does not add algebraic-group classification, Liouvillian solvability, integration-by-quadratures, or a standard model-theoretic differential-Galois bridge.

Lean4 ✓ `BEDC.Derived.DiffGaloisUp.DiffGaloisPicardVessiotPacket scoped certificate surface`

Proof. Start with Definition 287.1. It supplies the differential-field row, operator row, solution-space row, and fundamental-solution row as finite BHist data over the displayed $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{Ode}^{\uparrow}$, and $\mathsf{Seq}^{\uparrow}$ sources.

Next apply Definition 287.2. This adds the faithful $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ action ledger, transports it through the solution-space classifier, and identifies the constant-field coordinate with the fixed-point ledger.

Finally use Definition 287.3. It repacks the Picard-Vessiot rows and faithful-action rows into the public $\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$ boundary. Reading that export as a scoped carrier/classifier/ledger package gives the stated surface over $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{Ode}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, BHist, hsame, Cont, and Pkg, with no additional classification, solvability, quadrature, or model-theoretic bridge row. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$.

Constructive story: A $\mathsf{DiffGalois}^{\uparrow}$ token names a differential field (K, ∂) over a $\mathsf{NumField}^{\uparrow}$ subfield, a linear differential operator $L = \sum a_i \partial^i$ with coefficients in K, a $\mathsf{Seq}^{\uparrow}$-typed solution-space row V of dimension equal to the order of L, and the differential-Galois group G acting on V and fixing the constants K^{∂} pointwise. The carrier accepts a Picard-Vessiot certificate when V is closed under ∂ and contains a fundamental solution row, G acts faithfully on V in the sense of $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$, and $K^{\partial} = V^G$ in the sense that the G-fixed solutions are exactly the constants. The classifier is hsame on the solution-space rows; the source covers differential-field carrier rows, differential-operator coefficients, solution-space basis rows, Galois action rows, and constant-field rows; the pattern records solution-space admissibility, faithful-action admissibility, constant-field exactness, fundamental-solution row, and operator-order admissibility rows; the ledger keeps the differential operator, the solution-space basis, the Galois action, and the constant-field witness visible. The five name-certificate obligations are supplied by $\mathsf{NameCert}_{\mathsf{FieldExt}^{\uparrow}}$ together with $\mathsf{NameCert}_{\mathsf{GaloisGroup}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{Ode}^{\uparrow}}$: the inhabited identity certificate is the order-zero operator; classifier stability is reflexive, symmetric, and transitive hsame on solution-space rows; transport repacks Galois actions through field-isomorphism transport; ledger exactness identifies the accepted certificate with the solution-space basis; the extension boundary fixes the constant-field-fixed-points equation. A history h lies in the signature gap of a $\mathsf{DiffGalois}^{\uparrow}$ token p when the source-domain accepts the Picard-Vessiot certificate, the signature relation pairs it with the differential-Galois group identification, and token introduction names that group as p. The chapter registers this Picard-Vessiot Galois surface under the name $\mathsf{DiffGalois}^{\uparrow}$; it is a finite-order linear-operator object with no algebraic-group classification, no Liouvillian solvability theorem, no integration-by-quadratures bridge, and no standard model-theoretic differential-Galois bridge.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$, publicClosed)

Scope closed: The scoped certificate surface is closed over $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{Ode}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, BHist, hsame, Cont, and Pkg through the displayed Picard-Vessiot ledger.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DiffGalois}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DiffGaloisUp.DiffGaloisPublicCertificate\_export`

Bridge status: none

Not claimed: The chapter does not close algebraic-group classification of differential-Galois groups, Liouvillian solvability theorems, integration-by-quadratures, or a standard model-theoretic differential-Galois bridge.

Upgrade path: A standard bridge would have to identify this public $\mathsf{DiffGalois}^{\uparrow}$ certificate export with the acceptance-bridge schema without adding algebraic-group classification, solvability, quadrature, or model-theoretic bridge data.

Chapter 288

A Concrete Naming Certificate for $\mathsf{GoedelIncompleteness}^{\uparrow}$

The Goedel-incompleteness interface $\mathsf{GoedelIncompleteness}^{\uparrow}$ packages an arithmetised provability predicate over a recursively-axiomatised first-order theory of arithmetic, together with a self-referential fixed-point row. It depends on $\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}$ (chapter 28), $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ (chapter 197), $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ (chapter 198), and $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ (chapter 199).

288.1 Carrier definition

A $\mathsf{GoedelIncompleteness}^{\uparrow}$ token carries: a recursively-enumerated axiom set T over the language of arithmetic, an arithmetised provability predicate $\mathsf{Prov}_T(x)$ via a $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ proof-checking decoder, a Goedel numbering $\ulcorner\cdot\urcorner$ on formulas, and a fixed-point row G with $T \vdash G \leftrightarrow \neg\mathsf{Prov}_T(\ulcorner G\urcorner)$. The carrier accepts an incompleteness witness when T is consistent and G is neither provable nor refutable in T. The classifier is hsame on the fixed-point rows; the ledger keeps the axiom enumeration, the proof-checker, the Goedel numbering, and the fixed-point row visible.

Theorem 288.1 (GoedelIncompleteness proof-checker obligation)**.** *An accepted* $\mathsf{GoedelIncompleteness}^{\uparrow}$ *witness exposes a recursively enumerated axiom row, a* $\mathsf{Computable}^{\uparrow}$ *proof-checker decoder, and the finite proof-verdict ledger over* BHist*. The carrier reads a proof row only through the displayed decoder and records its verdict as a visible* $\mathsf{FirstOrder}^{\uparrow}$ *syntactic row.*

The obligation is syntactic and finite-ledger local. It does not assert semantic completeness, second incompleteness, or a set-theoretic foundations bridge.

Lean4 ✓ `BEDC.Derived.GoedelIncompletenessUp.GoedelIncompletenessProofCheckerLedger verdict nonempty surface`

Proof. Project the accepted packet to its axiom-enumeration coordinate. That row supplies the recursively enumerated theory data in the displayed $\mathsf{FirstOrder}^{\uparrow}$ language.

Read the proof-checker coordinate through the $\mathsf{Computable}^{\uparrow}$ decoder. Each candidate proof is consumed by this finite decoder row, and the result is the visible proof-verdict ledger over BHist.

Repacking these coordinates gives the proof-checker obligation. No semantic model argument, second-incompleteness claim, or external foundations bridge is used. □

Lean4 ✓ `BEDC.Derived.GoedelIncompletenessUp.GoedelIncompletenessWitnessPacket proof checker obligation`

Theorem 288.2 (GoedelIncompleteness fixed-point obligation)**.** *The fixed-point row in an accepted* $\mathsf{GoedelIncompleteness}^{\uparrow}$ *witness carries the displayed* $\mathsf{FirstOrder}^{\uparrow}$ *formula, its Goedel-number row, and the provability-predicate row for the fixed proof-checker decoder. The classifier* hsame *compares fixed-point histories only at the displayed numbering and does not identify formulas across a different coding surface.*

This obligation records the finite fixed-point ledger. It does not assert the Loeb conditions, semantic completeness, or a second-incompleteness theorem.

Proof. Start with the fixed-point coordinate of the accepted packet. It exposes the $\mathsf{FirstOrder}^{\uparrow}$ formula row and its Goedel-number row in the same finite ledger.

Next read the provability-predicate coordinate. It is tied to the displayed proof-checker decoder, so the predicate row refers to the fixed numbering rather than to an ambient coding theorem.

The hsame classifier is then applied only at that fixed numbering. This gives the stated fixed-point obligation without importing semantic or metatheoretic closure beyond the visible rows. □

Lean4 ✓ `BEDC.Derived.GoedelIncompletenessUp.GoedelIncompletenessFixedPointLedger obligation`

Theorem 288.3 (GoedelIncompleteness undecidable row obligation)**.** *Conditionally on the consistency row displayed by an accepted* $\mathsf{GoedelIncompleteness}^{\uparrow}$ *witness, the witness ledger contains both the no-proof row and the no-refutation row for the displayed fixed-point formula. The no-proof row is checked against* $\mathsf{Prov}_T(\ulcorner G \urcorner)$*, and the no-refutation row is checked against the displayed negation row in the same* $\mathsf{FirstOrder}^{\uparrow}$ *syntax.*

The statement is only the accepted finite undecidability ledger. It does not claim second incompleteness, semantic completeness, ω-consistency, or the Loeb conditions.

Lean4 ✓ `BEDC.Derived.GoedelIncompletenessUp.GoedelIncompletenessWitnessPacket undecidable row obligation`

Proof. Read the consistency coordinate, the fixed-point formula, and the proof-checker verdict ledger from the accepted packet. They share the same Goedel numbering and the same $\mathsf{Computable}^{\uparrow}$ decoder.

For the no-proof side, inspect the verdict rows attached to $\mathsf{Prov}_T(\ulcorner G \urcorner)$. The accepted packet records that no displayed proof row verifies the fixed-point formula.

For the no-refutation side, inspect the verdict rows attached to the displayed negation of G. The same proof-checker ledger records that no displayed proof row verifies the refutation. Repacking the two rows gives the conditional undecidable-row obligation. □

Closure status for $\mathsf{NameCert}_{\mathsf{GoedelIncompleteness}^{\uparrow}}$**.**

Constructive story: A $\mathsf{GoedelIncompleteness}^{\uparrow}$ token names a recursively-enumerated axiom set T over the language of arithmetic, an arithmetised provability predicate $\mathsf{Prov}_T(x)$ realised by a $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ proof-checking decoder, a Goedel numbering $\ulcorner \cdot \urcorner$ on formulas, and a self-referential fixed-point row G such that $T \vdash G \leftrightarrow \neg\mathsf{Prov}_T(\ulcorner G \urcorner)$. The carrier accepts an incompleteness witness when T is consistent in the sense that no proof-checker run yields $\bot$, and G is neither provable nor refutable in T. The classifier is hsame on the fixed-point rows at fixed Goedel numbering; the source covers the axiom enumeration, the proof-checker decoder, Goedel-number rows, fixed-point rows, and provability witnesses; the pattern records consistency admissibility, fixed-point admissibility, derivability admissibility, refutability admissibility, and recursive-axiomatisation admissibility rows; the ledger keeps the axiom enumeration, the proof-checker, the Goedel numbering, and the fixed-point row visible. The five name-certificate obligations are supplied by $\mathsf{NameCert}_{\mathsf{Computable}^{\uparrow}}$ for the proof-checker plus $\mathsf{NameCert}_{\mathsf{FirstOrder}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{ModelTheory}^{\uparrow}}$ for the syntactic carrier: the inhabited identity certificate is the empty axiom system over the language of arithmetic; classifier stability is reflexive, symmetric, and transitive hsame on fixed-point rows; transport repacks proof-checks through Goedel-number transport; ledger exactness identifies the accepted witness with the fixed-point identity; the extension boundary fixes the recursive-axiomatisation rule. A history h lies in the signature gap of a $\mathsf{GoedelIncompleteness}^{\uparrow}$ token p when the source-domain accepts the consistent recursively-axiomatised

theory, the signature relation pairs it with the undecidable fixed-point row, and token introduction names that fixed point as p. The chapter registers this self-referential incompleteness surface under the name GoedelIncompleteness$^{\uparrow}$; it is a finite-axiomatisation incompleteness object with no semantic-completeness theorem, no second-incompleteness theorem ($\neg\mathsf{Prov}_T(\bot)$ unprovability), no ω-consistency claim, and no standard set-theoretic foundations bridge.

Theory closure: TheoryGate(NameCert$_{\mathsf{GoedelIncompleteness}^{\uparrow}}$, publicClosed)

Scope closed: The obligation scope binds the proof-checker decoder row, fixed-point formula and numbering row, and conditional no-proof plus no-refutation rows over the displayed FirstOrder$^{\uparrow}$, ModelTheory$^{\uparrow}$, Computable$^{\uparrow}$, and hsame surfaces.

Formal verification: FormalStatus(NameCert$_{\mathsf{GoedelIncompleteness}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.GoedelIncompletenessUp.GoedelIncompletenessFixedPointLedger\_obligation`

Bridge status: none

Not claimed: The chapter does not close the second-incompleteness theorem, ω-consistency, semantic-completeness, the Loeb conditions, or a standard set-theoretic foundations bridge.

Upgrade path: Bridged closure requires the standard bridge from the exported fixed-point ledger to FirstOrder$^{\uparrow}$, ModelTheory$^{\uparrow}$, and Computable$^{\uparrow}$ consumers.

Chapter 289

A Concrete Naming Certificate for $\mathsf{Belief}^{\uparrow}$

The $\mathsf{Belief}^{\uparrow}$ interface is an AI-proposed BEDC chapter. Its carrier sketch and dependency anchors come from the proposal at `papers/bedc/proposals/accepted/`; the seed-stub here records the closurestatus block. Its dependency rows are the finite index spine of chapter 28, the update trace surface of chapter 120, and the probability certificate surface of chapter 184.

Falsifiable prediction: If a public $\mathsf{Belief}^{\uparrow}$ consumer deletes the prior row, observation row, update trace, probability row, or evidence ledger, then it cannot reconstruct the public belief consumer surface of Definition 289.8.

Independence witness: Nearest siblings: nat, seq, probspace, modeltheory, hypothesis-test. The carrier is not bijective to any of them because it binds five simultaneous rows: a finite index spine, an observation row, an update trace, a probability certificate, and an evidence ledger; each named sibling supplies at most a proper projection of that packet rather than the whole observation-update ledger.

289.1 Carrier definition

A finite $\mathsf{Belief}^{\uparrow}$ packet is the observation-update carrier suggested by `BEDC.Derived.BeliefUp.taste_gate`; the Lean touchpoint fixes the chapter name and TasteGate carrier, while the paper surface below records the certificate obligations without marking them as checked. On the Lean side, any future AI-origin upgrade that relies on non-vacuity must keep the existing `FieldFaithful` instance and add a `Nontrivial BeliefUp` instance.

Lean4 ✓ `BEDC.Derived.BeliefUp.taste gate`

Definition 289.1 (Belief observation-update carrier)**.** *A* $\mathsf{Belief}^{\uparrow}$ *observation-update carrier is a finite packet over* BHist *consisting of the following rows.*

1. *A prior row naming the displayed belief state before the observation.*
2. *An observation row naming the finite evidence read by the update.*
3. *An update trace recording the visible constructor route from the prior row and observation row to the posterior row.*
4. *A probability row supplied by* $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ *and classified only through the displayed probability certificate.*

5. *An evidence ledger that exposes exactly the prior, observation, update trace, and probability rows used by the packet.*

The packet is accepted when those rows are present in the same finite BHist *ledger, the update trace is a* $\mathsf{Seq}^{\uparrow}$ *row, and the posterior belief row is the row named by that trace.*

Lean4 (definition) `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier`

Theorem 289.2 (Belief classifier transport obligation)**.** *Let p be an accepted* $\mathsf{Belief}^{\uparrow}$ *packet with prior row, observation row, update trace, and probability row displayed in its evidence ledger. If* hsame *transports each of those four rows to corresponding displayed rows, then the transported rows repack as an accepted* $\mathsf{Belief}^{\uparrow}$ *packet with the same update-trace shape and a posterior row classified by the transported probability certificate.*

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier classifier transport`

Proof. Read the accepted packet through its finite BHist ledger. The prior and observation rows are transported first, so the update trace has the same source rows after transport.

Next transport the update trace as a $\mathsf{Seq}^{\uparrow}$ row. Since the trace records a visible constructor route, the posterior row is obtained by replaying the same finite route on the transported prior and observation rows.

Finally transport the probability row through the displayed $\mathsf{NameCert}_{\mathsf{ProbSpace}^{\uparrow}}$ certificate. The four transported rows fill the same carrier fields, so the packet is accepted with no hidden evidence row. □

Theorem 289.3 (Belief ledger exactness obligation)**.** *For every accepted* $\mathsf{Belief}^{\uparrow}$ *packet, the evidence ledger exposes exactly the prior row, observation row, update trace, and probability row admitted by the carrier. A downstream consumer may read those four rows and the posterior row named by the update trace, but no additional hidden evidence, prior source, or probability witness is part of the packet.*

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier ledger exactness`

Proof. Inspect the carrier definition. Acceptance requires the prior row, observation row, update trace, probability row, and evidence ledger to be displayed in the same finite BHist packet.

The ledger exactness clause then identifies every exported evidence entry with one of those four carrier rows. The posterior is readable only as the endpoint of the displayed update trace, so it does not add an independent hidden evidence coordinate. □

Theorem 289.4 (Belief TasteGate carrier recognition)**.** *Every accepted* $\mathsf{Belief}^{\uparrow}$ *packet is constrained by the TasteGate carrier named by the Lean definition* `BEDC.Derived.BeliefUp.taste_gate`*. In particular, the accepted packet may expose only the prior row, observation row, update trace, probability row, posterior endpoint, evidence ledger, and displayed provenance rows admitted by that carrier boundary.*

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier tastegate carrier recognition`
↪ variant `BEDC.Derived.BeliefUp.BeliefTasteGate carrier recognition`

Proof. Read the accepted packet through the TasteGate carrier boundary named above. The carrier admits the observation-update rows as a finite BHist packet and supplies no constructor for a host belief state, hidden likelihood object, or external update operation.

Projecting the packet therefore leaves only the displayed prior, observation, update trace, probability, posterior endpoint, evidence ledger, and provenance rows. Since every accepted packet must pass through the same carrier boundary, consumer recognition is restricted to those rows. □

Theorem 289.5 (Belief TasteGate carrier obligation scope)**.** *An accepted* $\mathsf{Belief}^{\uparrow}$ *packet leaves seed-level TasteGate recognition only through the carrier rows of Definition 289.1, the classifier transport obligation of Definition 289.2, ledger exactness from Definition 289.3, posterior trace transport from Definition 289.6, finite evidence ledger coverage from Definition 289.7, the public* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$ *surface of Definition 289.8, and the sibling dependency lattice of Definition 289.11.*

The checked TasteGate marker displayed in section 289.1, named `BEDC.Derived.BeliefUp.taste_gate`*, recognizes only the carrier boundary. Scope beyond seed recognition is therefore a paper-side obligation over the displayed prior, observation, update trace, probability, posterior endpoint, evidence ledger,* hsame*,* Cont*,* Pkg*, and sibling rows, not a hidden likelihood object or host belief-update operation.*

Proof. Start with Definition 289.4. The TasteGate boundary admits the finite observation-update rows and no external update primitive.

Project the carrier through Definition 289.1. The prior, observation, update trace, probability row, evidence ledger, and posterior endpoint are the only rows available for scope growth.

Apply Definition 289.2, Definition 289.3, and Definition 289.6. These clauses keep transport, ledger readback, and posterior trace movement attached to the same finite rows.

Finally use Definition 289.7, Definition 289.8, and Definition 289.11. They expose exactly the finite evidence ledger, public naming surface, and $\mathsf{Nat}^{\uparrow}/\mathsf{Seq}^{\uparrow}/\mathsf{ProbSpace}^{\uparrow}$ sibling route. Since the cited TasteGate marker supplies only recognition of the carrier boundary, the stated rows exhaust the obligation scope. □

Theorem 289.6 (Belief posterior trace transport obligation)**.** *Let p be an accepted* $\mathsf{Belief}^{\uparrow}$ *packet. If its prior row, observation row, update trace, and probability row are transported through displayed* hsame *comparisons and* Cont *routes, then the transported rows repack as a* $\mathsf{Belief}^{\uparrow}$ *packet whose posterior endpoint is the endpoint named by the transported update trace.*

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier posterior trace transport`

Proof. Start with the accepted packet and project its four transported input rows. The prior and observation endpoints move through the displayed hsame comparisons, while the update trace moves along the displayed Cont route.

The posterior endpoint is not an independent input. It is read as the endpoint named by the update trace after transport, so replaying the transported trace with the transported prior and observation rows determines the posterior row.

Transport the probability row through the displayed probability certificate and place it with the transported trace data in the same finite ledger. These rows fill the carrier fields again, so the packet repacks under hsame/Cont. □

Theorem 289.7 (Belief finite evidence ledger coverage)**.** *For every accepted* $\mathsf{Belief}^{\uparrow}$ *packet, the finite evidence ledger covers exactly the prior row, observation row, update trace, probability row, and posterior endpoint. No additional likelihood row, hidden prior source, external observation stream, or host update primitive is exported by the ledger.*

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefFiniteEvidenceLedger coverage`

Proof. Inspect the carrier rows. Acceptance places the prior, observation, update trace, probability row, and posterior endpoint in one finite BHist ledger with their displayed provenance.

The ledger coverage clause identifies each readable evidence entry with one of those five rows. Since the posterior endpoint is already the trace endpoint, it does not create a second evidence source.

Thus a downstream consumer can cite exactly the listed rows and no hidden belief-update data. Every permitted read is a projection of the displayed finite ledger. □

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier finite evidence ledger coverage`

Theorem 289.8 (Belief public NameCert surface)**.** *The observation-update carrier, classifier transport, ledger exactness, TasteGate carrier recognition, posterior trace transport, and finite evidence ledger coverage assemble the public* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$ *surface. Its consumer-readable rows are exactly the prior, observation, update trace, probability, posterior endpoint, evidence ledger,* hsame, Cont, *and* Pkg *rows.*

This surface exports no hidden prior source, external observation stream, host update primitive, likelihood object outside the probability certificate, or bridge datum.

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier public namecert surface`

Proof. Project the packet through Definition 289.1. The carrier supplies the prior, observation, update trace, probability, evidence ledger, and posterior endpoint rows inside one finite BHist packet.

Apply Definition 289.2 and Definition 289.3. These obligations give the displayed classifier movement and ledger readback, so a consumer reads only the carrier rows transported through hsame, Cont, and Pkg.

Next use Definition 289.4. The TasteGate marker `BEDC.Derived.BeliefUp.taste_gate` fixes the accepted carrier boundary and contributes no additional evidence row.

Finally apply Definition 289.6 and Definition 289.7. The posterior endpoint is read from the update trace, and the finite ledger covers exactly the listed evidence rows.

The cited clauses exhaust the public $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$ surface. Since no clause exports a hidden prior source, external observation stream, host update primitive, likelihood object outside the probability certificate, or bridge datum, no consumer can read one from the public surface. □

Theorem 289.9 (Belief mature consumer exhaustion)**.** *Every downstream consumer of the public* $\mathsf{Belief}^{\uparrow}$ *packet reads only the prior row, observation row, update trace, probability certificate row, posterior endpoint, finite evidence ledger,* hsame, Cont, Pkg, *and the TasteGate carrier boundary named by* `BEDC.Derived.BeliefUp.taste_gate`*. Every such read factors through Definition 289.8.*

No hidden likelihood object, host update primitive, external observation stream, or extra probability witness is exported by the mature packet surface.

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefObservationUpdateCarrier mature consumer exhaustion`

Proof. Project the consumer read through Definition 289.8. The public surface is already the assembled observation-update carrier with its classifier transport, ledger exactness, TasteGate recognition, posterior trace, and finite evidence coverage rows.

The six source clauses give the exhaustive list. Apply Definition 289.2, Definition 289.3, Definition 289.4, Definition 289.6, Definition 289.7, and Definition 289.8 to reduce each consumer read to one displayed row of the packet.

The checked TasteGate marker displayed in section 289.1, named `BEDC.Derived.BeliefUp.taste_gate`, supplies only the carrier boundary. It contributes no hidden likelihood object, host update primitive, external observation stream, or extra probability witness. □

Theorem 289.10 (Belief finite evidence consumer completeness)**.** *Every finite consumer of an accepted* $\mathsf{Belief}^{\uparrow}$ *packet reads exactly the prior row, observation row, posterior endpoint, finite evidence ledger, classifier transport rows, posterior trace transport rows, and the TasteGate carrier named by* `BEDC.Derived.BeliefUp.taste_gate`*. Conversely, those rows repack as the public belief consumer surface.*

The packet exposes no hidden likelihood object, host update primitive, external observation stream, or extra probability witness beyond those rows.

Lean4 ✓ `BEDC.Derived.BeliefUp.BeliefFiniteEvidenceConsumerCompleteness`

Proof. Apply Definition 289.4. The named TasteGate carrier fixes the accepted $\mathsf{Belief}^{\uparrow}$ boundary without adding an evidence row.

Use Definition 289.6 to route the posterior endpoint and posterior trace through the displayed hsame, Cont, and Pkg coordinates.

Next apply Definition 289.7. This exhausts the finite evidence ledger available to any accepted packet consumer.

Finally use Definition 289.8. The prior, observation, posterior, evidence, classifier-transport, posterior-trace, and TasteGate rows repack as exactly the public belief consumer surface, with no remaining coordinate for a hidden likelihood object, host update primitive, external observation stream, or extra probability witness. □

Theorem 289.11 (Belief sibling dependency lattice)**.** *Every public* $\mathsf{Belief}^{\uparrow}$ *consumer reads* $\mathsf{Nat}^{\uparrow}$ *as the finite index spine,* $\mathsf{Seq}^{\uparrow}$ *as the update trace, and* $\mathsf{ProbSpace}^{\uparrow}$ *as the probability certificate before the TasteGate carrier boundary is opened. The packet exports no hidden likelihood object, host update primitive, or extra probability witness outside those sibling rows and the displayed public* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$ *surface.*

Proof. First apply Definition 289.2. The transported prior, observation, update trace, and probability rows must remain visible finite rows of the same accepted packet, so the finite index spine is read through the displayed $\mathsf{Nat}^{\uparrow}$ dependency before the consumer opens the carrier boundary.

Next use Definition 289.6. The posterior endpoint is determined by the transported update trace, and that trace is the $\mathsf{Seq}^{\uparrow}$ row recorded by the packet rather than a host update primitive.

Apply Definition 289.7. The evidence ledger covers the prior, observation, update trace, probability row, and posterior endpoint, so the probability contribution is exactly the $\mathsf{ProbSpace}^{\uparrow}$ certificate row already present in the finite ledger.

Finally use Definition 289.8. The public $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$ surface repacks these sibling rows and the TasteGate carrier boundary, leaving no coordinate for a hidden likelihood object, host update primitive, or extra probability witness. □

Closure status for $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$**.**

Constructive story: A $\mathsf{Belief}^{\uparrow}$ packet is generated by assembling a finite BHist ledger whose visible rows are the prior, observation, update trace, probability certificate, posterior endpoint, and evidence ledger. The prior and observation rows are the sources; the $\mathsf{Seq}^{\uparrow}$ update trace is the displayed Cont route that carries them to the posterior row; the $\mathsf{ProbSpace}^{\uparrow}$ row supplies the probability coordinate without adding a hidden likelihood object. The classifier reads only rowwise hsame transport of the prior, observation, trace, and probability rows, so the transported packet has the same posterior-trace shape. Ledger exactness and the source specification coincide because every evidence entry is one of the displayed rows.

Nonemptiness is the presence of such a finite accepted ledger, and reflexivity, symmetry, and transitivity are inherited componentwise from the displayed hsame comparisons.

Theory closure: TheoryGate(NameCert$_{\mathsf{Belief}\uparrow}$, maturePackageClosed)

Scope closed: Definition 289.10 and the public NameCert$_{\mathsf{Belief}\uparrow}$ surface bind the observation-update carrier definition together with the classifier-transport and ledger-exactness obligations, TasteGate carrier recognition, posterior trace transport, and finite evidence coverage for the displayed prior, observation, update trace, probability, posterior endpoint, evidence ledger, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{Belief}\uparrow}$, encodedDef)

Lean target: `BEDC.Derived.BeliefUp.taste\_gate`

Bridge status: paperBridge

Origin: ai

Not claimed: Machine-checked standard bridge acceptance remains outside this paper-axis closure claim.

Upgrade path: There is no further paper-axis work for the mature packet surface; machine bridge acceptance remains a separate formal-axis task.

Chapter 290

A Concrete Naming Certificate for $\mathsf{Policy}^{\uparrow}$

The $\mathsf{Policy}^{\uparrow}$ interface is an AI-proposed BEDC chapter. Its carrier sketch and dependency anchors come from the proposal at `papers/bedc/proposals/accepted/`; the seed-stub here records the closurestatus block. Dependencies cited by the proposal: $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$. The substantive sibling route is chapter 289, chapter 189, chapter 185, and chapter 230: $\mathsf{Policy}^{\uparrow}$ consumes belief-state rows, Markov transition rows, random-variable observation rows, and estimator-score rows before selecting an action ledger.

Lean4 (definition) `BEDC.Derived.PolicyUp.taste gate`

290.1 Carrier definition

Definition 290.1 (Policy action-ledger carrier)**.** *A* $\mathsf{Policy}^{\uparrow}$ *carrier is a finite* BHist *action-ledger packet over* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$. *Its rows are belief-state rows, Markov transition rows, estimator-score rows, selected action rows, the* hsame *transport rows comparing corresponding ledger entries, the* Cont *provenance rows explaining how each selected action is read from the displayed belief, transition, and estimator rows, and the* Pkg *source rows naming the four dependency certificates.*

The carrier accepts only packets whose selected-action row is sourced from the displayed dependency rows through the visible Cont *ledger. It contains no host Markov decision process, utility function, optimizer, or external policy object.*

Theorem 290.2 (Policy TasteGate source scope)**.** *Every accepted* $\mathsf{Policy}^{\uparrow}$ *action-ledger packet exposes exactly the four dependency certificates* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ *together with the finite action ledger of Definition 290.1. No host Markov decision process, utility function, optimizer, or external policy object is exported by the packet.*

Proof. Project the carrier rows of Definition 290.1. The source rows are precisely the four named dependency certificates and the finite BHist action ledger whose entries display belief states, transition rows, estimator scores, selected actions, hsame comparisons, Cont provenance, and Pkg source rows.

The acceptance condition reads a selected action only through those displayed rows. Since the carrier definition has no constructor for a host Markov decision process, utility function, optimizer, or external policy object, no accepted packet can expose such a row. □

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedger source scope`

Theorem 290.3 (Policy local action transport)**.** *Let two finite* Policy$^{\uparrow}$ *action-ledger packets have componentwise* hsame *comparisons between their belief-state rows, Markov transition rows, estimator-score rows, and selected-action rows. If the* Cont *provenance and* Pkg *source rows are transported along those comparisons, then the transported rows again form an accepted local* Policy$^{\uparrow}$ *carrier packet over the same four dependency certificates.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier local action transport`

Proof. Transport the four dependency rows componentwise through the displayed hsame comparisons. The belief, transition, estimator, and selected-action entries remain inside the same finite BHist ledger shape.

Next transport the Cont provenance rows and the Pkg source rows. The carrier acceptance condition only asks that the selected-action row be read from the transported belief, transition, and estimator rows through that visible provenance ledger. Therefore the transported packet satisfies the same local carrier predicate. □

Theorem 290.4 (Policy action classifier stability)**.** *Let P and P' be accepted* Policy$^{\uparrow}$ *action-ledger packets over the same four displayed dependency certificates. Suppose the belief-state rows, Markov transition rows, random-variable rows, estimator-score rows, selected-action rows,* Cont *provenance rows, and* Pkg *source rows of P are transported componentwise to the corresponding rows of P' by displayed* hsame *comparisons. Then the transported packet is again accepted by the PolicyUp action-ledger carrier of Definition 290.1, and the selected-action classifier reads the same visible BEDC ledger surface.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier action classifier stability`

Proof. Inspect the finite action-ledger carrier. Its acceptance predicate names only the displayed dependency certificates, the belief, transition, random-variable, estimator, and selected-action rows, and the visible hsame/Cont/Pkg provenance attached to those rows.

Transport each listed coordinate along the supplied hsame rows. The transport preserves the finite BHist ledger shape and leaves the source certificates inside the same four dependency packets.

The selected-action classifier has no access to any row outside that carrier. After the Cont and Pkg rows are transported, the classifier therefore reads the selected action through the transported visible ledger and accepts the packet again. □

Theorem 290.5 (Policy visible continuation provenance coverage)**.** *Every selected-action row in an accepted* Policy$^{\uparrow}$ *packet is read through the visible* Cont *provenance from the displayed* Belief$^{\uparrow}$, MarkovChain$^{\uparrow}$, RandomVar$^{\uparrow}$, *and* Estimator$^{\uparrow}$ *source rows. The packet exposes no host Markov decision process, optimizer, utility function, or external policy object.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier visible cont provenance coverage`

Proof. Project an accepted packet to the rows named by Definition 290.1. The selected-action coordinate is accepted only when a visible Cont row relates it to the displayed belief, transition, random-variable, and estimator rows, with Pkg provenance naming the four source certificates.

No other source is present in the carrier. A host Markov decision process, optimizer, utility function, or external policy object would require an additional readable coordinate, but the carrier has no such coordinate. □

Theorem 290.6 (Policy NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$ *obligation surface consists of the action-ledger carrier of Definition 290.1, the TasteGate source scope of Definition 290.2, action classifier stability from Definition 290.4, visible continuation provenance coverage from Definition 290.5, and local action transport from Definition 290.3.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier semantic name certificate`
↪ variant `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier namecert obligation surface`

Proof. Use the action-ledger carrier as the source predicate. It fixes the finite BHist rows and the four displayed dependency certificates.

Use the TasteGate source-scope theorem to bound the exported sources. Use classifier stability to transport the accepted action classifier along componentwise hsame rows, and use visible provenance coverage to identify the exact Cont rows through which selected actions are read.

Finally apply local action transport to repack transported rows as another accepted carrier. These clauses provide exactly the local BEDC surface named by $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$, without adding host MDP, optimizer, utility, or external policy data. □

Theorem 290.7 (Policy selected-action determinacy)**.** *Let P and Q be accepted* $\mathsf{Policy}^{\uparrow}$ *action-ledger packets over the same transported* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$ *rows. Suppose their belief-state, Markov transition, random-variable, estimator,* Cont, *and* Pkg *rows are matched componentwise by displayed* hsame *transport, and suppose each selected-action row is accepted only through those displayed rows. Then the selected-action classifier assigns P and Q to the same visible selected-action row.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier selected action determinacy`

Proof. Project both accepted packets to the finite action-ledger carrier of Definition 290.1. The carrier exposes the four dependency rows, the local ledger rows, and the hsame/Cont/Pkg transport data, so these are the only coordinates available to the classifier.

Use the supplied componentwise hsame comparisons to transport the displayed belief-state, Markov transition, random-variable, estimator, Cont, and Pkg rows from P to Q. By Definition 290.4, the transported packet remains accepted by the same local carrier and the selected-action classifier reads the same visible ledger surface.

It remains to rule out a second action source. The carrier contains no host MDP, optimizer, utility, or external policy coordinate, and Definition 290.5 makes the visible Cont route exhaustive. Hence two accepted packets with the same transported dependency and provenance rows classify the same selected-action row. □

Theorem 290.8 (Policy dependency source exactness)**.** *Every consumer-visible row of an accepted* $\mathsf{Policy}^{\uparrow}$ *action-ledger packet is one of the four dependency certificate rows* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, *the selected-action row, an* hsame *transport row, a* Cont *provenance row, or a* Pkg *source row naming one of the four displayed certificates.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier dependency source exactness`

Proof. Unfold the carrier in Definition 290.1. Its public packet is a finite BHist ledger whose readable coordinates are the four dependency rows, selected-action entries, hsame comparisons, Cont provenance, and Pkg source rows.

Apply Definition 290.2 to the source side. The source projection exposes exactly the four named dependency certificates and no host MDP, optimizer, utility, or external policy object.

Apply Definition 290.5 to the action side. Each selected action is read through visible Cont provenance from the displayed dependency rows, with Pkg rows naming those sources. Therefore every consumer-visible row belongs to the listed inventory. □

Theorem 290.9 (Policy TasteGate scoped package)**.** *The action-ledger carrier, TasteGate source scope, action classifier stability, visible continuation provenance coverage, local action transport, and* `BEDC.Derived.PolicyUp.taste_gate` *together form the scoped* $\mathsf{Policy}^{\uparrow}$ *BEDC package. This package excludes host Markov decision processes, optimizers, utility functions, and external policy objects from the exported surface.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier tastegate scoped package`

Proof. Start with the five local obligations enumerated in Definition 290.6. They provide the carrier, the bounded source inventory, classifier stability, Cont coverage, and transport closure for accepted action-ledger packets.

Use the TasteGate object `BEDC.Derived.PolicyUp.taste_gate` as the chapter-level admission gate. It packages the local carrier obligations without adding a new consumer-visible row, so the available projections remain the rows already listed in Definition 290.8.

Finally combine source exactness with selected-action determinacy. The transported dependency, Cont, and Pkg rows determine the visible selected action, while the carrier has no constructor for a host MDP, optimizer, utility, or external policy object. Thus the TasteGate package is a scoped BEDC surface and nothing beyond that surface is exported. □

Theorem 290.10 (Policy kernel scope boundary)**.** *The five local obligations of* $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$ *are scoped exactly to the finite* BHist *action-ledger carrier of Definition 290.1, the four dependency certificates* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, *and the displayed* hsame, Cont, *and* Pkg *rows. No host Markov decision process, optimizer, utility function, external policy object, hidden state space, or unlogged action source is readable by those obligations.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier kernel scope boundary`

Proof. Start from the action-ledger carrier of Definition 290.1. Its rows are the finite BHist ledger, the four dependency certificate rows, the visible hsame transport rows, the Cont provenance rows, and the Pkg source rows.

The source side is bounded by Definition 290.2. The classifier and transported carrier reads are bounded by Definition 290.3 and Definition 290.4. The selected-action provenance is bounded by Definition 290.5.

Finally, Definition 290.6 says that these are exactly the five local obligations named by $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$. Since each source, classifier, transport, and ledger read has already been accounted for by the listed rows, no host MDP, optimizer, utility, external policy object, hidden state space, or unlogged action source is exposed. □

Theorem 290.11 (Policy public export surface)**.** *The public* $\mathsf{Policy}^{\uparrow}$ *surface consists exactly of the finite action-ledger carrier of Definition 290.1, the four dependency certificate rows* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, *selected-action determinacy, dependency source exactness, the TasteGate scoped package Definition 290.9, and the kernel-scope boundary Definition 290.10. It exports no host Markov decision process, optimizer, utility function, or external policy row.*

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier public export surface`

Proof. The TasteGate evidence is the chapter's displayed `BEDC.Derived.PolicyUp.taste_gate` row together with the checked scoped package recorded at Definition 290.9. That package admits the action-ledger carrier without adding a consumer-visible row beyond the listed finite carrier, dependency certificates, hsame, Cont, and Pkg provenance.

Apply Definition 290.8 to the dependency side. The only readable sources are the four displayed certificate rows for $\mathsf{Belief}^{\uparrow}$, $\mathsf{MarkovChain}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, and $\mathsf{Estimator}^{\uparrow}$. Apply Definition 290.7 to the action side. Once those source rows and visible continuation provenance are fixed, the selected action row is fixed.

Finally apply Definition 290.10. The kernel boundary has no constructor or projection for a host MDP, optimizer, utility function, or external policy object. Therefore the public export is precisely the action-ledger surface listed in the statement. □

Theorem 290.12 (Policy action-ledger finite consumer coverage)**.** *Every consumer of the* $\mathsf{Policy}^{\uparrow}$ *bridge reads only the finite action-ledger carrier, the four dependency certificate rows* $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$, *selected-action determinacy, the TasteGate scoped package, the kernel-scope boundary, the displayed* hsame, Cont, *and* Pkg *rows, and the local* $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$ *rows. The bridge surface exports no host Markov decision process, optimizer, utility function, external policy object, hidden state space, or unlogged action source.*

Proof. Start from the public surface of Definition 290.11. It lists the finite action-ledger carrier, the four dependency certificate rows, selected-action determinacy, dependency source exactness, the TasteGate scoped package, and the kernel-scope boundary as the exported $\mathsf{Policy}^{\uparrow}$ rows.

Use Definition 290.9 together with the displayed `BEDC.Derived.PolicyUp.taste_gate` row. The TasteGate admission packages the action-ledger carrier without adding any consumer-visible source beyond the finite ledger, dependency certificates, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$ rows.

Finally apply Definition 290.10. That boundary rules out host MDPs, optimizers, utility functions, external policy objects, hidden state spaces, and unlogged action sources. Hence every finite bridge consumer is covered by the displayed action-ledger surface. □

Lean4 ✓ `BEDC.Derived.PolicyUp.PolicyActionLedgerCarrier finite consumer coverage`

Closure status for $\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$**.**

Constructive story: A $\mathsf{Policy}^{\uparrow}$ packet is generated as a finite action ledger over the four displayed dependency certificates $\mathsf{NameCert}_{\mathsf{Belief}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{MarkovChain}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RandomVar}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{Estimator}^{\uparrow}}$. Its visible coordinates are belief-state rows, Markov transition rows, random-variable observation rows, estimator-score rows, selected-action rows, rowwise hsame comparisons, Cont provenance explaining how the selected action is read, and Pkg source rows naming the dependencies. The classifier is componentwise: after transporting those rows by hsame, the same visible continuation ledger still selects the same action coordinate. The ledger and source specification align because every public read factors through one of those dependency rows and no host decision process, optimizer, utility function, or external policy object is present. Nonemptiness is an accepted finite ledger; reflexivity, symmetry, and transitivity are inherited row by row from hsame.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public surface is the action-ledger carrier with the public TasteGate scoped package, TasteGate source scope, action classifier stability, visible continuation provenance coverage, local action transport, finite consumer coverage, and the kernel boundary over the four displayed dependency certificates.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Policy}^{\uparrow}}$, axiomClean)

Bridge status: paperBridge

Origin: ai

Lean4 ✓ `BEDC.Derived.PolicyUp.taste gate`

Not claimed: The chapter does not claim a host Markov decision process, optimizer, utility function, external policy object, or public standard bridge.

Upgrade path: BridgeChecked verification requires a machine-checked standard bridge no-host-leak field.

DyadicRatCore$^{\uparrow}$ exposes the L10 sibling dependency relation: chapter 31 and chapter 37 supply the signed mantissa and denominator ledger, while chapter 126, chapter 301, and chapter 38 consume the finite dyadic tolerance ledger.

Chapter 291

A Concrete Naming Certificate for $\mathsf{DyadicRatCore}^{\uparrow}$

The $\mathsf{DyadicRatCore}^{\uparrow}$ surface names the dyadic rational source layer used by the Phase Real and Completion interface in section 9467.12. Following the Bishop–Bridges constructive-analysis treatment of dyadic rational approximants, the chapter consumes the signed integer and rational certificate surfaces of chapter 31 and chapter 37 through its mantissa and denominator ledger. It keeps each denominator exponent as visible unary history data and never identifies dyadics by a quotient carrier.

291.1 Carrier and classifier

Definition 291.1 (DyadicRatCore signed mantissa carrier)**.** *A* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier row is a finite* BHist *packet* (m, e, ℓ, P) *where* m *is a signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row,* e *is a positive* $\mathsf{UnaryHistory}$ *exponent row,* ℓ *is the denominator ledger displaying the unary tower for* 2^e*, and* P *is the* Pkg *provenance row naming the* $\mathsf{Int}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$ *source certificates. The intended value of the packet is the dyadic rational* $m \cdot 2^{-e}$*, but the carrier stores only the visible mantissa row, positive unary exponent row, denominator ledger, and provenance.*

The carrier contains no quotient class of rational pairs, no hidden integer normal form, and no imported real-number endpoint. A consumer can read a dyadic value only by projecting the displayed $\mathsf{Rat}^{\uparrow}$ *mantissa and unary denominator rows through the visible* Cont *ledger.*

Theorem 291.2 (DyadicRatCore Int/Rat sibling route)**.** *Every public read of an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet* $D = (m, e, \ell, P)$ *factors the signed mantissa through the consumed* $\mathsf{Rat}^{\uparrow}$ *row, the sign and integer provenance through the consumed* $\mathsf{Int}^{\uparrow}$ *row, and the exponent and denominator ledger through the visible unary-history route. The read has no coordinate for a quotient rational, host integer normal form, or* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Proof. Project the four carrier fields in Definition 291.1. The mantissa field m is already a signed $\mathsf{Rat}^{\uparrow}$ row, while the provenance field P records the attached $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ source certificates cited at the start of this chapter.

The exponent field e and ledger field ℓ give the unary-history route for the displayed denominator. A public read can therefore inspect the dyadic packet only by following the mantissa, integer-provenance, rational-provenance, exponent, and ledger rows that are already part of D.

Finally use the carrier exclusion in Definition 291.1. Since the carrier contains no quotient class of rational pairs, no host integer normal form, and no imported real-number endpoint, the sibling route through $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ is the complete public route for the finite dyadic source layer. □

Definition 291.3 (DyadicRatCore common-exponent classifier)**.** *For two accepted dyadic packets $D = (m, e, \ell, P)$ and $D' = (m', e', \ell', P')$, the predicate* $\mathsf{DyadicRatCoreClassifier}(D, D')$ *is the common-exponent scaling classifier: it supplies a positive unary exponent row E above both e and e', transported denominator ledgers from ℓ and ℓ' to E, and a* $\mathsf{Rat}^{\uparrow}$ *classifier row between the two scaled mantissas $m \cdot 2^{E-e}$ and $m' \cdot 2^{E-e'}$.*

The classifier is a BEDC predicate over displayed scaling rows. It is not quotient equality of rational pairs, and it does not collapse the two packets to a host rational number.

Lean4 (definition) `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreClassifier`

Definition 291.4 (DyadicRatCore common-exponent scale packet)**.** *For accepted dyadic packets $D = (m, e, \ell, P)$ and $D' = (m', e', \ell', P')$, a* $\mathsf{DyadicRatCoreCommonExponentScale}(D, D')$ *packet is the finite scale tuple*

$$(E, s, s', r, P_E).$$

Here E is the displayed positive unary exponent row above both e and e', s transports the mantissa and denominator ledger of D to the common denominator 2^E, s' transports the corresponding rows of D' to 2^E, r is the $\mathsf{Rat}^{\uparrow}$ *classifier row comparing the transported mantissas, and P_E is the* Pkg *provenance row binding the same* $\mathsf{Int}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$ *sibling certificates already cited by Definition 291.2. The packet has no coordinate for a quotient rational representative, host denominator selector, host integer normalization, or* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Theorem 291.5 (DyadicRatCore common-exponent classifier stability)**.** *Let $D = (m, e, \ell, P)$ and $D' = (m', e', \ell', P')$ be accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets, and let (E, s, s', r, P_E) be a* $\mathsf{DyadicRatCoreCommonExponent}$ *packet. If D, D', E, s, s', r, P_E are transported componentwise through displayed* hsame, Cont, *and* Pkg *rows that preserve the visible* $\mathsf{Int}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$ *sibling provenance, then the transported tuple is again a common-exponent scale packet and it witnesses the same* $\mathsf{DyadicRatCoreClassifier}$ *comparison at the transported common exponent.*

The classifier read remains confined to the transported mantissa rows, positive unary exponent rows, denominator ledgers, $\mathsf{Rat}^{\uparrow}$ *comparison row, and provenance rows. It does not acquire a quotient rational carrier, host denominator selector, host integer normalization, or* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Proof. Project the carrier rows of D and D' using Definition 291.1. The only source rows available for scaling are the signed mantissas, positive unary exponent histories, denominator ledgers, and Pkg rows carrying the $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ provenance.

Project the common-exponent scale packet of Definition 291.4. The rows s and s' are precisely the displayed transports from the two original exponent ledgers to E, and r is precisely the $\mathsf{Rat}^{\uparrow}$ classifier row between the scaled mantissas.

Transport these rows componentwise through the supplied hsame and displayed Cont data. The transported exponent remains the common positive unary row, the transported ledgers remain the two denominator ledgers at that row, and the transported $\mathsf{Rat}^{\uparrow}$ comparison is still attached to the same sibling provenance.

Finally apply the classifier definition Definition 291.3. It reads exactly the common exponent, transported denominator ledgers, scaled mantissas, and $\mathsf{Rat}^{\uparrow}$ classifier row. Since no other carrier coordinate exists, the transported tuple witnesses the same classifier comparison and cannot import any refused host object. □

Theorem 291.6 (DyadicRatCore tolerance halving closure)**.** *Let $D = (m, e, \ell, P)$ be an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance packet, and suppose a displayed successor unary exponent row e^+ extends e by one denominator-halving step. If the mantissa, denominator ledger, endpoint comparison, distance row, radius row,* hsame *transport, displayed* Cont *replay, and* Pkg *provenance are transported along this successor row, then the resulting packet is again accepted by the dyadic tolerance ledger.*

Equivalently, one displayed unary halving step preserves the finite DyadicRatCore tolerance surface: the accepted rows are still the $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ *mantissa provenance, positive unary exponent history, denominator ledger, dyadic comparison rows, transport rows, continuation rows, and package provenance, with no quotient rational equality, host normalization, selected real endpoint, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Start from the accepted carrier row of Definition 291.1. The exponent data are stored as positive unary history, so adjoining one displayed successor row gives another visible positive unary exponent history rather than a hidden denominator selector.

Transport the denominator ledger along the successor row. The ledger for 2^e is replayed into the ledger for 2^{e^+}, and the mantissa provenance remains attached to the same $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ certificates.

Read the tolerance rows after transport. Endpoint comparisons, distance rows, and radius rows are all part of the same finite dyadic packet, so halving the displayed denominator scale repacks them as the next accepted tolerance window.

Finally use the exclusion clause of the carrier definition and the common-exponent classifier discipline of Definition 291.3. The halved packet still exposes only displayed mantissa, exponent, ledger, comparison, transport, continuation, and provenance rows, so the dyadic tolerance ledger remains accepted without adding quotient rational equality, host normalization, selected endpoints, or ambient real completeness. □

Theorem 291.7 (DyadicRatCore denominator ledger transport)**.** *Let $D = (m, e, \ell, P)$ be an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet, and let $D' = (m', e', \ell', P')$ be obtained from D by displayed* hsame *transport of the mantissa, exponent, denominator ledger, and provenance rows. Then e' is again a positive unary exponent row, ℓ' is the transported denominator ledger for $2^{e'}$, and every finite consumer window that read the denominator of D can read the denominator of D' through the transported* Cont *route.*

```
Lean4 ✓  BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier denominator ledger transport
Lean4 ✓  BEDC.Derived.DyadicRatCoreUp.DyadicRatCorePacket denominator ledger transport
Lean4 ✓  BEDC.Derived.DyadicRatCoreUp.DyadicRatCore denominator ledger transport window
Lean4 ✓  BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier denominator transport
```

Proof. Project the accepted carrier row of Definition 291.1. The positivity of e is a displayed unary-history row, so transporting it along the supplied hsame comparison gives the corresponding positive row for e'.

The denominator ledger is finite and is indexed by the same unary exponent tower. Transport each ledger entry along the displayed exponent comparison and repack the entries with the transported Pkg provenance.

Finally transport the finite Cont route used by a consumer window. The window reads only the visible denominator ledger entries, so the transported route reads exactly the denominator rows of D' and introduces no quotient or real endpoint. □

Theorem 291.8 (DyadicRatCore common-exponent window exactness)**.** *Let $D = (m, e, \ell, P)$ and $D' = (m', e', \ell', P')$ be accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets. Any displayed common-exponent witness*

for DyadicRatCoreClassifier(D, D') *determines a finite* BHist *window whose rows are exactly the common unary exponent row, the two transported denominator ledgers, the two scaled mantissa rows, the* Rat$^{\uparrow}$ *classifier row comparing* $m \cdot 2^{E-e}$ *with* $m' \cdot 2^{E-e'}$*, and the attached* Cont *and* Pkg *provenance. Conversely, every consumer-visible classifier read of the two packets factors through such a window. It has no row from which to read a quotient rational, a host integer normal form, or a* Real$^{\uparrow}$ *endpoint.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCommonExponentWindow exactness`
Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreClassifier common exponent transport`
Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier common exponent window exactness`

Proof. Unpack Definition 291.3. A classifier witness displays the common unary exponent E, the two scaling rows from e and e' to E, and the two denominator ledgers transported along those scaling rows.

The same witness also displays the scaled mantissas and the single Rat$^{\uparrow}$ classifier row comparing them. Repack these rows with the displayed Cont routes and the Pkg provenance inherited from the two accepted packets.

For the reverse direction, inspect the carrier inventory in Definition 291.1. A consumer-visible classifier read can project only the packet rows named there and the classifier rows named in Definition 291.3. Those rows are precisely the common exponent, denominator-ledger, scaled-mantissa, Rat$^{\uparrow}$, Cont, and Pkg rows above, so the read factors through the same finite window and cannot access any quotient rational, host integer normal form, or Real$^{\uparrow}$ endpoint. □

Theorem 291.9 (DyadicRatCore common-exponent e0 exclusion)**.** *Let* $D = (m, e, \ell, P)$ *and* $D' = (m', e', \ell', P')$ *be accepted* DyadicRatCore$^{\uparrow}$ *packets whose classifier is witnessed by a displayed common exponent row* E*. Then* E *cannot be an* e0 *denominator row. Equivalently, any classifier read that tries to use* e0 *as the common exponent lies outside the accepted dyadic classifier surface.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreClassifier common exponent e0 exclusion`

Proof. By Definition 291.3, a classifier witness displays the common exponent row together with the two denominator-ledger scaling rows and the Rat$^{\uparrow}$ comparison row. The exactness window of Definition 291.8 identifies this common exponent as part of the same finite positive-unary denominator ledger transported with the accepted packets.

The carrier discipline of Definition 291.1 admits denominator rows only through positive unary denominator data. The row e0 is excluded by that positive-unary discipline, so no accepted classifier witness can present e0 as its common exponent. □

Theorem 291.10 (DyadicRatCore distance-window stability)**.** *Let* D_0, D_1, D'_0, D'_1 *be accepted* DyadicRatCore$^{\uparrow}$ *packets such that* D_i *is transported to* D'_i *by displayed* hsame*,* Cont*, and* Pkg *rows for* $i = 0, 1$*. Any finite observation window that computes the dyadic distance* $|D_0 - D_1|$ *or the dyadic absolute value* $|D_0|$ *from common-exponent mantissa scaling is stable under this transport: the transported window computes* $|D'_0 - D'_1|$ *or* $|D'_0|$ *from the transported mantissa, exponent, denominator, and provenance rows.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier distance window stability`
Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier distance window transport`
Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier distance window transport closure`

Proof. Choose the common exponent displayed by the finite observation window. The classifier of Definition 291.3 makes the scaling rows visible, so the mantissa difference and sign split are ordinary $\mathsf{Rat}^{\uparrow}$ rows inside the same window.

Transport the two input packets componentwise through the supplied hsame rows and transport the scaling ledger through the corresponding Cont routes. The Pkg rows keep the same $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ source certificates attached to the transported packet.

The distance and absolute-value observations therefore recompute the same finite rational expression at the transported exponent. Since the window has no access to a quotient carrier or real completion endpoint, stability is exactly the repacking of those displayed rows. □

291.2 Certificate surface

Theorem 291.11 (DyadicRatCore arithmetic-window stability)**.** *Let D_0, D_1, D_0', D_1' be accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets such that each D_i is transported to D_i' by displayed* hsame*,* Cont*, and* Pkg *rows. Any finite common-exponent window that reads $D_0 + D_1$, $-D_0$, $D_0 - D_1$, or $D_0 D_1$ is stable under this transport: the transported window reads the corresponding operation on D_0', D_1' using only the displayed* $\mathsf{Rat}^{\uparrow}$ *mantissa rows,* UnaryHistory *exponent rows, denominator ledgers, common-exponent scaling rows,* hsame *comparisons,* Cont *routes, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreArithmeticWindow transport stability`

Proof. Choose the displayed common exponent carried by the arithmetic window. The window first projects the two mantissas to that exponent through the visible denominator ledgers and then applies the corresponding $\mathsf{Rat}^{\uparrow}$ row for sum, negation, difference, or product.

Transport the mantissa, exponent, denominator, and provenance coordinates of each input packet along the supplied hsame rows. The same finite Cont route transports the common-exponent scaling ledger, so the transported window has exactly the rows needed to repeat the arithmetic readback.

No step identifies rational pairs by a quotient or by host equality. The operation row is therefore recovered by recomposing the transported mantissa row with the transported unary denominator ledger and the same Pkg source certificates. □

Theorem 291.12 (DyadicRatCore monotone-radius obligation)**.** *For an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet $D = (m, e, \ell, P)$, the visible dyadic radius row 2^{-e} refines monotonically under any displayed unary extension $e \preceq E$. The refined radius row 2^{-E} is obtained by appending the finite denominator ledger entries from e to E, transporting the mantissa observation through the same* Cont *route, and retaining the same* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier scoped source boundary`

Proof. Project the positive unary exponent row from the carrier. A displayed extension $e \preceq E$ is a finite unary-history continuation, so the additional denominator entries form a visible tail of the same ledger.

Append that tail to the denominator ledger ℓ. The resulting row displays 2^E and hence the radius row 2^{-E}, with the original 2^{-e} radius as the coarser prefix read by the shorter window.

The mantissa row is not changed; only the denominator window is refined. Transporting the readback through the appended Cont route shows monotone radius refinement entirely inside the displayed unary ledger. □

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier monotone radius obligation`

Theorem 291.13 (DyadicRatCore scale-window obligation surface)**.** *The canonical common-exponent scale window, monotone radius obligation, denominator ledger, and arithmetic-window stability together provide the exact dyadic tolerance row consumed by* $\mathsf{StreamName}^{\uparrow}$ *finite windows and* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity checks. The consumed row is the visible dyadic packet formed from the signed mantissa, positive unary exponent, denominator ledger, common-exponent scaling row, monotone radius refinement, arithmetic stability row,* BHist *carrier data,* hsame *transport,* Cont *replay, and* Pkg *provenance; it is not a quotient rational class, host rational equality, or host real distance.*

Proof. First use monotone-radius obligation, Definition 291.12. It refines the dyadic radius by appending visible unary denominator entries and keeps the radius row inside the displayed carrier and continuation surface.

Next use common-exponent exactness, Definition 291.15, together with the denominator ledger transport of Definition 291.7. These rows put the compared packets on one common exponent while preserving the visible mantissa and denominator-ledger sources.

Then apply arithmetic-window stability, Definition 291.11, and the RegSeqRat window-radius handoff, Definition 291.19. The arithmetic and radius windows are the same finite dyadic tolerance packet consumed by StreamName finite windows and RegSeqRat regularity checks.

The cited rows mention only displayed dyadic data, carrier histories, transports, continuations, and provenance. None provides quotient rational classes, host equality, or a host real distance coordinate, so the obligation surface is exact. □

Theorem 291.14 (DyadicRatCore arithmetic-monotone window package)**.** *Let* D_0, D_1, D_0', D_1' *be accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets satisfying the arithmetic-window transport hypotheses of Definition 291.11, and suppose the visible radius rows of the transported packet are refined along displayed unary exponent extensions as in Definition 291.12. Then the transported arithmetic endpoint and the refined radius ledger repack into one public finite window consumed by* RegSeqRat *and* $\mathsf{Real}^{\uparrow}$*. This window reads only mantissa, exponent, denominator, common-exponent, distance and arithmetic,* BHist*,* hsame*,* Cont*, and* Pkg *rows, and it exposes no quotient rational, host equality, completion endpoint, or trichotomy row.*

Proof. First apply Definition 291.11. The transported arithmetic endpoint is read from the common-exponent scaling ledger, the displayed mantissas, the denominator rows, and the transported Pkg provenance.

Next apply Definition 291.12 to the visible unary extension of the radius row. The refined denominator ledger keeps the radius bound inside the same BHist and Cont surface.

The two ledgers have the same public coordinates: mantissa, exponent, denominator, common exponent, arithmetic or distance readback, history comparison, continuation, and package provenance. Repack those coordinates as the shared finite-window surface required by the RegSeqRat and $\mathsf{Real}^{\uparrow}$ consumers. Since neither input theorem exports quotient rational equality, host equality, a completion endpoint, or a trichotomy classifier, the combined window does not introduce any such row. □

Theorem 291.15 (DyadicRatCore common-exponent exactness)**.** *Suppose two classifier witnesses compare accepted packets* D *and* D' *by displayed common exponents* E *and* F*. Then there is a displayed unary exponent* G *extending both* E *and* F *such that transporting each witness to* G *yields the same* $\mathsf{Rat}^{\uparrow}$ *classifier row between the scaled mantissas of* D *and* D'*. The exactness claim is a statement about the displayed scaling ledgers and not about host rational equality.*

Proof. Project the two classifier witnesses of Definition 291.3. Each witness consists of a common unary exponent, two finite scaling ledgers from the packet exponents, and a $\mathsf{Rat}^{\uparrow}$ classifier row between the scaled mantissas.

Take the displayed unary exponent obtained by appending the two finite extension ledgers to a shared exponent G. Transport the E-witness and the F-witness along their denominator-ledger continuations into the same exponent row.

At G both witnesses read the identical scaled mantissa rows through the same $\mathsf{Rat}^{\uparrow}$ source certificate. Constructor inspection of the transported classifier rows therefore gives the same visible classifier row, with no appeal to quotient equality of dyadic pairs. □

Definition 291.16 (DyadicRatCore canonical comparison window)**.** *For accepted packets D and D' of* $\mathsf{DyadicRatCore}^{\uparrow}$*, the canonical comparison window is the finite BEDC packet*

$$(G,\ \Delta_D^G,\ \Delta_{D'}^G,\ M_D^G,\ M_{D'}^G,\ R_G,\ H_G,\ S_G,\ C_G,\ P_G,\ N_G).$$

Here G is a chosen common positive unary exponent, Δ_D^G and $\Delta_{D'}^G$ are the transported denominator ledgers, M_D^G and $M_{D'}^G$ are the scaled mantissa rows, and R_G is the displayed $\mathsf{Rat}^{\uparrow}$ *classifier row between those scaled mantissas. The remaining rows H_G, S_G, C_G, P_G, and N_G are the attached* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance carried by the accepted packets and their transport ledgers. The window is a finite BEDC comparison surface; it is not a quotient equality of dyadic pairs and not a host rational representative.*

Theorem 291.17 (DyadicRatCore canonical-window uniqueness)**.** *If two canonical comparison windows compare the same accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets D and D', then after displayed unary exponent refinement to a common terminal exponent they expose the same transported denominator ledgers, scaled mantissa rows,* $\mathsf{Rat}^{\uparrow}$ *classifier row, and support rows. No quotient rational, host equality, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or trichotomy row can distinguish the two windows.*

Proof. Unfold Definition 291.16. Each window consists of a common positive unary exponent, two transported denominator ledgers, two scaled mantissa rows, one $\mathsf{Rat}^{\uparrow}$ classifier row, and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Apply Definition 291.15 to the two classifier witnesses. Refining both displayed exponents to a common terminal exponent puts the two comparison rows on the same scaled mantissa surface.

Use Definition 291.7 to identify the transported denominator rows after the same exponent refinement. Use Definition 291.10 to keep the finite observation rows stable under the resulting hsame transport.

It remains only to read the carrier inventory. The available rows are exactly the mantissa, exponent, denominator, classifier, history, sameness, continuation, package, and name-certificate rows listed in Definition 291.1. The exclusions in Definition 291.22 remove quotient rational equality, host equality, completed real endpoints, and trichotomy classifiers, so no additional row can separate the two refined windows. □

Theorem 291.18 (DyadicRatCore real-phase source coverage)**.** *An accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet with transported mantissa and displayed* Cont *rows for the real row and the ledger window supplies exactly the real-phase source rows used here: the* $\mathsf{Real}^{\uparrow}$ *constant-history row at the transported mantissa head, the positive unary denominator row, the unary ledger row, the unary transported window row, the displayed readback* hsame *from the real row to the mantissa-head/exponent append, and the displayed readback* hsame *from the transported window to the real-row/ledger append.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier real phase source coverage`

Proof. Start with the accepted $\mathsf{DyadicRatCore}^{\uparrow}$ packet. Its carrier clause gives a $\mathsf{Rat}^{\uparrow}$ mantissa carrier, a positive unary denominator row, and a unary ledger row. Transport the mantissa along the displayed hsame row; the transported mantissa remains a $\mathsf{Rat}^{\uparrow}$ history carrier.

Taking the head of the transported mantissa yields the $\mathsf{Real}^{\uparrow}$ constant-history carrier. The displayed Cont row from that head and the exponent is read back as the real-row append, and the displayed Cont row from the real row and the ledger is read back as the window append.

Finally transport the displayed window along its hsame row. Unary closure of Cont gives the unary transported window, while the two append readbacks are exactly the two displayed hsame rows named in the statement. □

Theorem 291.19 (DyadicRatCore RegSeqRat window radius handoff)**.** *Every downstream* RegSeqRat *finite-window handoff that consumes a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation reads its radius premise through the displayed positive unary exponent, denominator ledger, monotone-radius refinement, distance-window stability,* hsame*,* Cont*, and* Pkg *rows of the* $\mathsf{DyadicRatCore}^{\uparrow}$ *public envelope. Consequently the handoff cannot introduce a quotient rational, host epsilon equality, or* $\mathsf{Real}^{\uparrow}$ *completion endpoint.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreRegSeqRatWindow radius handoff`

Proof. Start with the downstream handoff and apply Definition 291.18 to obtain the real constant-history row, the positive unary denominator row, the unary ledger and window rows, and the two append readbacks.

Use Definition 291.12 to identify the radius premise as a displayed positive-unary refinement over the denominator ledger. Use Definition 291.10 to keep the finite distance window stable under the same hsame transport.

Finally apply Definition 291.23. Its public tuple supplies exactly the exponent, denominator, radius, distance, Cont, and Pkg coordinates consumed by RegSeqRat, so there is no remaining coordinate through which host epsilon equality or a $\mathsf{Real}^{\uparrow}$ completion endpoint could enter the handoff. □

Theorem 291.20 (DyadicRatCore NameCert obligation surface)**.** *The seed* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *obligation surface consists of the signed mantissa carrier of Definition 291.1, the common-exponent scaling classifier of Definition 291.3, denominator ledger transport from Definition 291.7, dyadic distance and absolute-value window stability from Definition 291.10, arithmetic-window stability from Definition 291.11, monotone radius refinement from Definition 291.12, common-exponent exactness from Definition 291.15, real-phase source coverage from Definition 291.18, and exactness of the visible mantissa, exponent, denominator,* hsame*,* Cont*, and* Pkg *rows. It supplies a named dyadic source surface for* $\mathsf{StreamName}^{\uparrow}$*,* RegSeqRat*, and* $\mathsf{Real}^{\uparrow}$*, but it supplies no standard bridge and no* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier namecert obligation surface`

Proof. The carrier and classifier clauses are exactly Definition 291.1 and Definition 291.3. They determine which finite BEDC rows may be read as a dyadic packet and how two such packets are compared by common-exponent scaling.

The ledger clause is Definition 291.7; it keeps the positive unary denominator tower visible under hsame transport. The observation clause is Definition 291.10; it keeps distance and absolute-value windows inside the displayed $\mathsf{Rat}^{\uparrow}$ and unary ledger rows.

The arithmetic, radius, common-exponent, and real-phase source clauses are Definition 291.11, Definition 291.12, Definition 291.15, and Definition 291.18. Together they identify the finite arithmetic rows, the radius refinement rows, the common-exponent comparison rows, and the real-row/window readbacks used by downstream real-construction chapters.

Exactness follows by inspection of the listed rows: every readable component of the dyadic source is one of the mantissa, exponent, denominator, provenance, transport, or continuation entries. Thus the surface is a seed source for later real-construction chapters and not a bridge to host rationals or completed reals. □

Theorem 291.21 (DyadicRatCore source-boundary SemanticNameCert)**.** *For any accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier with mantissa* m*, exponent* e*, ledger* ℓ*, and provenance packet* p*, the source-boundary predicate*

$$\mathsf{row} \in \mathsf{Source}_{m,e,p} \iff \exists \ell'.\, \mathsf{DyadicRatCore}^{\uparrow}(m, e, \ell', p) \wedge \mathsf{hsame}(\mathsf{row}, \ell')$$

carries a SemanticNameCert *whose carrier, pattern, and ledger predicates are this same boundary predicate and whose equality relation is* hsame*. The same certificate exposes the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa carrier, positive* UnaryHistory *exponent, unary ledger, and unary provenance rows. It does not identify dyadic packets by quotient rational equality and does not introduce a completed* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreSourceBoundary semanticNameCert`

Proof. Begin with the accepted carrier of Definition 291.1. Its visible coordinates give the signed $\mathsf{Rat}^{\uparrow}$ mantissa, the positive unary exponent, the unary ledger, and the unary provenance packet. The source-boundary row is then the ledger component transported by hsame inside the same mantissa, exponent, and provenance packet.

The certificate fields are the rows already packaged by Definition 291.20 and the scoped boundary inventory below. Reflexivity, symmetry, transitivity, and carrier transport are exactly the displayed hsame rows; pattern soundness and ledger soundness are the same witness read in the pattern and ledger positions.

Thus the SemanticNameCert is a certificate on the finite source boundary alone. All data used by the proof are the displayed carrier, hsame, ledger, and provenance rows, so no quotient rational equality or completed $\mathsf{Real}^{\uparrow}$ endpoint enters the construction. □

Theorem 291.22 (DyadicRatCore scoped source boundary)**.** *The scoped* $\mathsf{DyadicRatCore}^{\uparrow}$ *source boundary is exactly the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, the positive* UnaryHistory *exponent row, the denominator ledger, the common-exponent scaling classifier, the arithmetic-window and distance-window rows, monotone-radius refinement, common-exponent exactness, real-phase source coverage,* BHist *carrier data,* hsame *transport,* Cont *readback, and* Pkg *provenance listed in this chapter. It exports no quotient of dyadic pairs, host rational equality, standard bridge, or completed* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Proof. The carrier and classifier boundaries are the displayed rows of Definition 291.1 and Definition 291.3. They supply the signed mantissa, positive unary exponent, denominator tower, BHist tuple, hsame transport, Cont readback, and Pkg provenance that can be read from an accepted dyadic packet.

The denominator, arithmetic, distance, radius, and common-exponent clauses are respectively Definition 291.7, Definition 291.11, Definition 291.10, Definition 291.12, and Definition 291.15. These rows say how the same visible packet supports finite dyadic computation under displayed unary denominator transport.

The real-phase and NameCert clauses are Definition 291.18 and Definition 291.20. The first contributes the real constant-history row, unary ledger/window rows, and append readbacks; the second packages those rows with the separate arithmetic, distance, radius, classifier, and provenance obligations. Hence the listed primitives are precisely the scoped boundary exported by this chapter. □

Theorem 291.23 (DyadicRatCore public readback envelope)**.** *The public* DyadicRatCore$^{\uparrow}$ *consumer interface is exactly the tuple consisting of the signed mantissa carrier, common-exponent classifier, denominator ledger transport, arithmetic-window stability, distance-window stability, monotone-radius refinement, common-exponent exactness, real-phase source coverage,* BHist *carrier rows,* hsame *transport,* Cont *readback, and* Pkg *provenance. Every downstream* StreamName$^{\uparrow}$*,* RegSeqRat*, or* Real$^{\uparrow}$ *dyadic read factors through this envelope and cannot read a quotient rational, host rational equality, standard bridge, or completed real endpoint.*

Proof. Start with an arbitrary public consumer read of a DyadicRatCore$^{\uparrow}$ packet. By Definition 291.1 and Definition 291.3, the only carrier and comparison rows available to that read are the signed mantissa, positive unary exponent, denominator ledger, common-exponent scaling witness, BHist data, hsame rows, Cont routes, and Pkg provenance.

The finite denominator, arithmetic, distance, radius, and exactness reads are then forced through the named certificate rows. Use Definition 291.7, Definition 291.11, Definition 291.10, Definition 291.12, and Definition 291.15 to identify the visible rows that remain available under transport and denominator refinement.

Finally apply Definition 291.18 for the real constant-history row, unary ledger/window rows, and append readbacks, and apply Definition 291.22 for the full public dyadic source surface. Since the carrier inventory contains no quotient rational, host equality row, standard bridge, or completed real endpoint, none of those objects can be exported by the public consumer certificate. □

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier public readback envelope`

Theorem 291.24 (DyadicRatCore public bridge consumer exactness)**.** *Every standard dyadic-source consumer admitted through the public bridge reads exactly the signed* Rat$^{\uparrow}$ *mantissa row, positive* UnaryHistory *exponent row, denominator ledger, common-exponent classifier, arithmetic window, distance window, radius window,* BHist *carrier data,* hsame *transport,* Cont *readback, and* Pkg *provenance already enumerated by Definition 291.23. Conversely, every public envelope row with precisely those coordinates supplies the finite observation interface consumed by* StreamName$^{\uparrow}$*,* RegSeqRat*, and* Real$^{\uparrow}$*. The bridge exports no quotient rational, host equality row, completion object, or* Real$^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier public bridge consumer exactness`

Proof. For the consumer-to-envelope direction, apply Definition 291.23. It lists exactly the mantissa, exponent, denominator, classifier, finite-window, carrier, transport, readback, and provenance rows visible to a public DyadicRatCore$^{\uparrow}$ read.

The bridge admission cannot enlarge that inventory. Use Definition 291.22 to restrict the downstream StreamName$^{\uparrow}$, RegSeqRat, and Real$^{\uparrow}$ reads to the displayed dyadic source rows, and use Definition 38.272 for the standard dyadic-source shape consumed at the bridge boundary.

For the envelope-to-consumer direction, start with one of the public envelope rows. Its signed mantissa, positive unary exponent, denominator ledger, common-exponent classifier, finite arithmetic and distance windows, radius refinement, BHist rows, hsame transport, Cont readback,

and Pkg provenance are exactly the coordinates requested by the standard dyadic-source bridge. Repacking them gives the finite observation interface used by $\mathsf{StreamName}^{\uparrow}$, RegSeqRat, and $\mathsf{Real}^{\uparrow}$.

The exclusion clauses are constructor inspections of the same public envelope and bridge boundary. Neither theorem supplies a quotient-rational row, a host equality row, a completion object, or a real-completeness field, so no admitted consumer can read one. □

Theorem 291.25 (DyadicRatCore standard source bridge)**.** *The public envelope of Definition 291.23 determines a bridge packet whose BEDC side is exactly the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, positive* UnaryHistory *exponent row, denominator ledger, common-exponent classifier, arithmetic and distance windows, monotone-radius refinement,* BHist *data,* hsame *transport,* Cont *readback, and* Pkg *provenance carried by the envelope. Its standard side is the usual dyadic source interface* (m, e) *with positive unary exponent and common-exponent comparison. The bridge exports no quotient rational, host rational equality, completed real, or real completeness claim.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier standard source bridge`

Proof. Apply Definition 291.23 to obtain the public tuple. Its visible coordinates give the signed mantissa, positive unary exponent, denominator ledger, finite arithmetic and distance windows, BHist data, hsame transport, Cont readback, and dependency provenance required on the BEDC side.

Use Definition 291.15 to read the standard comparison row. It identifies comparison of two displayed dyadic packets with comparison after lifting their mantissas to a common positive unary exponent, which is exactly the common-exponent comparison expected by the usual source schema.

Use Definition 291.12 to keep radius and distance observations stable under denominator refinement. Then apply Definition 291.22 to check that the downstream $\mathsf{StreamName}^{\uparrow}$, RegSeqRat, and $\mathsf{Real}^{\uparrow}$ boundary consumes only this dyadic source surface. Constructor inspection of the same envelope shows that there is no row for a quotient rational, host rational equality, completed real, or real completeness theorem. □

Theorem 291.26 (DyadicRatCore standard bridge denominator-refinement stability)**.** *Let* P *and* P' *be public* $\mathsf{DyadicRatCore}^{\uparrow}$ *bridge packets. Suppose that* P' *is obtained from* P *by a displayed positive-unary denominator refinement: the exponent row is extended inside* UnaryHistory*, the denominator ledger is the corresponding tower for the refined power of* 2*, and the public* hsame *and* Cont *rows exhibit the same dyadic source after the displayed rescaling. Then the standard dyadic source bridge of Definition 291.25 transports exactly the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, common-exponent classifier, distance window, monotone-radius row,* BHist *carrier data,* hsame *transport,* Cont *readback, and* Pkg *provenance from* P *to* P'*. The transported bridge packet exports no quotient rational, host equality, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or real-completeness row.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier standard bridge denominator refinement stability`

Proof. Start with the public envelope of Definition 291.23. It exposes precisely the mantissa, positive unary exponent, denominator ledger, classifier, finite window, carrier, transport, readback, and provenance rows available to a public $\mathsf{DyadicRatCore}^{\uparrow}$ packet.

Apply Definition 291.15 to compare P and P' after lifting their mantissas to the displayed common positive unary exponent. The hypothesis that the refinement is shown inside UnaryHistory supplies the same common-exponent classifier row for the refined packet.

Next use Definition 291.12. The positive-unary denominator refinement can only pass through the displayed monotone-radius row, so the finite distance window and radius observation are read at the refined denominator without introducing a new ambient rational object.

The public bridge consumer exactness theorem, Definition 291.24, transports the remaining classifier windows through the named hsame and Cont rows. Thus the carrier data, readback, and dependency provenance seen by the consumer of P' are the same public rows repackaged at the refined exponent.

Finally repackage those rows by Definition 291.25. Its exclusion clause is unchanged under the refinement: none of the cited public rows contains a quotient-rational representative, a host equality witness, a completed $\mathsf{Real}^{\uparrow}$ endpoint, or a real-completeness field. □

Theorem 291.27 (DyadicRatCore standard bridge denominator-refinement composition)**.** *Let P, P', and P'' be public* $\mathsf{DyadicRatCore}^{\uparrow}$ *bridge packets. Suppose that P' is obtained from P by a displayed positive-unary denominator refinement, and that P'' is obtained from P' by another displayed positive-unary denominator refinement. Then the standard dyadic source bridge of Definition 291.25 transports from P to P'' by composing the two displayed* UnaryHistory *exponent extensions, denominator ledgers, common-exponent classifier rows, distance and radius windows,* BHist *carrier data,* hsame *transports,* Cont *readbacks, and* Pkg *provenance rows. The composed transport exports no quotient rational, host equality, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier standard bridge denominator refinement composition`

Proof. Apply Definition 291.26 to the refinement from P to P'. This gives the transported signed mantissa, common-exponent classifier, distance window, monotone-radius row, carrier data, transport, readback, and provenance at the first refined positive-unary exponent.

Apply the same theorem to the refinement from P' to P''. The second application transports exactly the same public bridge inventory through the second displayed exponent extension and denominator ledger.

Use Definition 291.15 to identify the classifier row for the two-step exponent extension with the classifier row obtained by composing the two displayed common-exponent lifts. Use Definition 291.12 to read the finite distance and radius windows through the composed denominator refinement.

The public rows obtained after the two transports are still the rows listed by Definition 291.24. Repacking them through Definition 291.25 gives the standard dyadic source bridge from P directly to P''.

The exclusion clause is inherited from the two single-step bridge packets and from the public source bridge. Neither step introduces a quotient-rational representative, host equality witness, completed $\mathsf{Real}^{\uparrow}$ endpoint, or real-completeness field, so the composed bridge cannot export one. □

Theorem 291.28 (DyadicRatCore RegSeqRat bridge handoff exactness)**.** *Every* RegSeqRat *finite-window handoff that consumes a* $\mathsf{DyadicRatCore}^{\uparrow}$ *public envelope through the standard source bridge reads exactly the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, positive* UnaryHistory *exponent row, denominator ledger, common-exponent classifier, arithmetic window, distance window, radius window,* BHist *carrier data,* hsame *transport,* Cont *readback, and* Pkg *provenance listed by Definition 291.23. Conversely, every public envelope row with those visible coordinates supplies the dyadic observation interface*

admitted by the RegSeqRat *handoff. The handoff exports no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier regseqrat bridge handoff exactness`

Proof. For the forward direction, apply Definition 291.19. It identifies the downstream handoff boundary as a finite read of the displayed dyadic source rows and excludes quotient rationals, host epsilon equality, and completed $\mathsf{Real}^{\uparrow}$ endpoints from that boundary.

Next apply Definition 291.23 and Definition 291.24. These results give the exact public inventory: the signed mantissa, positive unary exponent, denominator ledger, classifier, arithmetic, distance, and radius windows, BHist data, hsame transport, Cont readback, and Pkg provenance. Use Definition 291.25 to read the same inventory as the standard dyadic source packet consumed at the bridge boundary.

For the converse direction, start with a public envelope row carrying precisely those coordinates. Repack the signed mantissa, positive unary exponent, denominator ledger, common-exponent classifier, finite windows, carrier data, transport, readback, and provenance as the dyadic observation interface already admitted by the standard source bridge and by the RegSeqRat handoff boundary.

The exclusion clauses are the same carrier-inventory inspection. None of the referenced rows is a quotient-rational representative, a host equality proof, a completed $\mathsf{Real}^{\uparrow}$ endpoint, or a real-completeness field, so neither direction can export one. □

Theorem 291.29 (DyadicRatCore RegSeqRat radius monotone-window extraction)**.** *Every* RegSeqRat *finite-window handoff consuming a* $\mathsf{DyadicRatCore}^{\uparrow}$ *public envelope through the standard source bridge exposes a monotone unary radius window whose denominator ledger, common-exponent classifier, distance window,* BHist *carrier row,* hsame *transport,* Cont *readback, and* Pkg *provenance are exactly the rows listed by Definition 291.12, Definition 291.10, Definition 291.25, and Definition 291.28. The extraction exports no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or standard bridge data beyond the finite bridge packet already displayed.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier regseqrat radius monotone window extraction`

Proof. Project the RegSeqRat handoff through the standard source bridge of Definition 291.25. The bridge exposes the signed mantissa row, positive unary exponent row, denominator ledger, common-exponent classifier, distance window, carrier data, transport rows, readback rows, and package provenance of the public envelope.

Read the distance and radius windows from that projection. The distance component is the finite row of Definition 291.10, while the radius component is the positive-unary denominator row refined by Definition 291.12.

Use the monotonicity clause to refine the requested unary radius window. Appending the displayed denominator tail preserves the same mantissa observation, common-exponent classifier, BHist carrier row, hsame transport, Cont readback, and Pkg provenance.

Finally apply Definition 291.28. Its exclusion clause rules out quotient rationals, host equality, completed real endpoints, and any standard bridge data not present in the finite window, so the extracted radius window is exactly the displayed dyadic-to-RegSeqRat window. □

Theorem 291.30 (DyadicRatCore RegSeqRat radius-window composition)**.** *Two successive* RegSeqRat *finite-window handoffs that consume* $\mathsf{DyadicRatCore}^{\uparrow}$ *public envelopes through the standard source bridge compose to a single monotone radius-window extraction. The visible rows of the composed handoff are exactly the denominator ledger, common-exponent classifier, distance window,* BHist

carrier row, hsame *transport,* Cont *readback, and* Pkg *provenance from the first and second windows, read through the same standard dyadic source bridge. The composed extraction exports no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier regseqrat radius window composition`

Proof. First compose the two dyadic bridge packets by Definition 291.27. This identifies the denominator refinement produced by the first handoff with the source denominator row consumed by the second, and it keeps the common-exponent classifier and distance window inside the displayed dyadic bridge inventory.

Next apply Definition 291.28 to each handoff. The only rows visible to the downstream RegSeqRat consumer are the denominator ledger, classifier, finite distance and radius windows, carrier data, transport rows, readback rows, and package provenance.

Finally apply Definition 291.29 to the composed packet. Monotonicity turns the two finite radius reads into one radius-window extraction, and the inherited exclusion clauses remove quotient rationals, host equality, completed real endpoints, and real-completeness data from the composed boundary. □

Theorem 291.31 (DyadicRatCore directed refinement common window)**.** *Let P, P', and P'' be public* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets. Suppose two displayed denominator-refinement routes through the standard source bridge carry P to P' and carry P' to P''. Then any two* RegSeqRat *finite-window handoffs consuming the resulting refined packets factor through one common monotone unary radius window.*

The rows of this common window are exactly the signed mantissa row, refined exponent row, refined denominator ledger, common-exponent classifier, distance-window rows, BHist *carrier rows,* hsame *transport rows,* Cont *readback rows, and* Pkg *provenance rows named by Definition 291.25, Definition 291.27, Definition 291.28, and Definition 291.30. The common window exports no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier directed refinement common window`

Proof. First compose the two displayed denominator-refinement routes by Definition 291.27. The composed bridge route identifies the refined denominator ledger carried by P' with the source denominator ledger consumed by the route into P'', while leaving the signed mantissa, refined exponent, common-exponent classifier, distance rows, carrier rows, transport rows, readback rows, and package provenance inside the displayed standard source inventory.

Next apply Definition 291.28 to the two RegSeqRat handoffs. Each handoff reads only the finite dyadic bridge rows: signed mantissas, refined unary exponents, denominator ledgers, common-exponent classifiers, distance and radius windows, BHist carrier data, hsame transport, Cont readback, and Pkg provenance.

Now use Definition 291.30 for the two handoff windows, and then Definition 291.29 for the composed packet. The resulting monotone unary radius window is common to both routes because both are read through the same composed denominator-refinement ledger.

Finally inspect the exclusion clauses of Definition 291.23 and Definition 291.25. Neither envelope has a row for quotient rationals, host equality, completed real endpoints, or real completeness, so no RegSeqRat handoff factored through the common window can export such data. □

Theorem 291.32 (DyadicRatCore directed refinement radius handoff)**.** *Every directed-refinement common-window read of* $\mathsf{DyadicRatCore}^{\uparrow}$ *that feeds a* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer exposes the common exponent, transported denominator ledgers, dyadic radius row, monotone radius witness,*

and $\mathsf{RegSeqRat}^{\uparrow}$ *handoff before any* $\mathsf{Real}^{\uparrow}$ *seal can consume it. The handoff exports no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier directed refinement radius handoff`

Proof. Apply Definition 291.31. It places both refined packets on one common monotone unary radius window with the shared exponent, denominator ledger, classifier, distance rows, transport, readback, and provenance already visible.

Use Definition 291.29 to read the dyadic radius row and monotone radius witness from that common window.

Finally apply Definition 291.19. The $\mathsf{RegSeqRat}^{\uparrow}$ consumer receives the finite radius handoff before any $\mathsf{Real}^{\uparrow}$ seal can inspect it, and the displayed carrier rows contain no quotient rational, host equality row, completed real endpoint, or real-completeness coordinate. □

Theorem 291.33 (DyadicRatCore finite radius-window cofinality)**.** *Every finite family of public* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets whose* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumers read them through displayed directed-refinement radius handoffs factors through one common monotone unary radius window. The common window carries the shared refined exponent, denominator ledger, common-exponent classifier, distance rows,* BHist *carrier rows,* hsame *transports,* Cont *readbacks, and* Pkg *provenance for the whole finite family.*

The common window exports no quotient rational, host equality row, completed $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice selector, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreFiniteRadiusWindowCofinality`

Proof. Induct on the finite family of displayed directed-refinement handoffs. For the empty family, take the vacuous finite window with no consumer rows. For a singleton, apply Definition 291.29 to the single public handoff and read its monotone unary radius window.

For the induction step, assume the first finite subfamily has already been placed on one common monotone unary radius window. Compose that accumulated window with the next directed-refinement handoff by Definition 291.27 and Definition 291.30. The composition keeps the refined exponent, denominator ledger, classifier, distance rows, carrier data, transports, readbacks, and provenance inside the same displayed dyadic bridge inventory.

Apply Definition 291.31 to identify the composed bridge packet with a common monotone unary radius window for the accumulated subfamily and the new handoff. The induction invariant is preserved because the window is enlarged only by displayed denominator-refinement rows and finite $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows.

Finally use Definition 291.32 at the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer boundary. Its exclusion clause, together with the exclusions in the bridge and radius-window composition results, rules out quotient rationals, host equality rows, completed real endpoints, countable-choice selectors, and real-completeness fields from the cofinal window. □

Theorem 291.34 (DyadicRatCore finite radius-window directed meet)**.** *Let two displayed common monotone unary radius windows be obtained from the same finite family of public* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets and directed-refinement handoffs. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *terminal consumer of either window factors through their displayed directed meet. The meet carries exactly the shared refined exponent, denominator ledger, common-exponent classifier, distance rows,* BHist *carrier rows,* hsame *transports,* Cont *readbacks,* Pkg *provenance, and local NameCert row.*

No quotient rational, host equality row, selected $\mathsf{Real}^{\uparrow}$ *limit, countable-choice selector, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row distinguishes the two displayed windows.*

Proof. Apply Definition 291.33 to each finite-family presentation. Both presentations therefore expose the same finite public packet family through a common monotone unary radius window with the refined exponent, denominator ledger, classifier, distance rows, carrier rows, transports, readbacks, and provenance already displayed.

Compose the two denominator-refinement routes by Definition 291.27. Then apply Definition 291.31 to identify the composed handoff as a common directed-refinement window for the two displays. This common handoff is the displayed directed meet because both terminal routes are read through the same finite family and the same refined denominator ledger.

Finally use Definition 291.32 and Definition 291.37 at the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ boundary. Their non-escape clauses leave only the displayed dyadic rows available to terminal consumers, so no quotient rational, host equality row, selected real limit, countable-choice selector, metric-completeness datum, or ambient real-completeness row can distinguish the two windows after passage to the meet. □

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier finite radius window directed meet`

Theorem 291.35 (DyadicRatCore finite radius-window filtered meet)**.** *Let a finite family of public* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets be equipped with displayed directed-refinement radius handoffs into* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *terminal consumers, and let a retained finite subfamily of those terminal consumers be selected. The retained consumers factor through the displayed directed meet of the restricted monotone unary radius windows obtained from the retained handoffs. The visible rows of that restricted meet are exactly the refined exponent, denominator ledger, common-exponent classifier, distance rows,* BHist *carrier rows,* hsame *transports,* Cont *readbacks,* Pkg *provenance, and local* NameCert *rows inherited from the ambient finite-family meet.*

The restricted meet exports no quotient rational, selected $\mathsf{Real}^{\uparrow}$ *limit, countable-choice selector, metric-completeness datum, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, or aggregate bridge/status row.*

Proof. Apply Definition 291.33 to the retained finite family of displayed handoffs. This supplies a common monotone unary radius window whose rows are restricted to the retained consumers while keeping the refined exponent, denominator ledger, classifier, distance rows, carrier rows, transports, readbacks, provenance, and local certificate rows inside the displayed dyadic inventory.

Compare this restricted window with the ambient finite-family window by Definition 291.34. Since the retained handoffs are a subfamily of the ambient presentation, the directed meet is obtained by forgetting only the consumer rows outside the retained subfamily and by keeping the common denominator-refinement rows already present in the ambient meet.

Finally use Definition 291.32 and Definition 291.37 at the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ boundary. These results force every retained terminal consumer to read through the finite radius handoff and exclude quotient rationals, selected real limits, countable-choice selectors, metric-completeness data, ambient real-completeness rows, and aggregate bridge/status rows from the restricted meet. □

Theorem 291.36 (DyadicRatCore finite radius-window meet associativity)**.** *Let* W_0*,* W_1*, and* W_2 *be three displayed common monotone unary radius windows over the same finite family of public* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets and directed-refinement handoffs. The displayed meet obtained by first meeting* W_0 *with* W_1 *and then meeting that result with* W_2 *exposes the same finite BEDC rows as the displayed meet obtained by first meeting* W_1 *with* W_2 *and then meeting* W_0 *with that result.*

The common row inventory is the refined exponent, denominator ledger, common-exponent classifier, distance rows, BHist *carrier rows,* hsame *transports,* Cont *readbacks,* Pkg *provenance, local* NameCert *row, and the downstream* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *terminal faces.*

No quotient rational, host equality row, selected $\mathsf{Real}^{\uparrow}$ *limit, countable-choice selector, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row distinguishes the two parenthesizations.*

Proof. Apply Definition 291.33 to the finite family underlying W_0, W_1, and W_2. Each displayed window is therefore a presentation of the same finite dyadic packet family through the same kind of monotone unary radius handoff, with the refined exponent, denominator ledger, classifier, distance rows, carrier rows, transports, readbacks, provenance, and local certificate row already visible.

Next apply Definition 291.34 to the pair W_0, W_1 and then to its displayed result with W_2. Apply the same directed-meet theorem to the pair W_1, W_2 and then to W_0 with that displayed result. In both orders the meet is computed over the identical finite family of public packets and directed-refinement handoffs, so the displayed row inventory is the directed meet of the same finite data rather than a datum depending on parentheses.

The retained consumer faces are checked by Definition 291.35. Filtering either parenthesized meet to the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ terminal faces forgets the same non-retained rows and preserves the same refined denominator, classifier, carrier, transport, readback, provenance, and certificate rows.

Finally use Definition 291.37 at the terminal boundary. Since both parenthesizations restrict to the same displayed directed meet of the same finite family, their terminal consumers cannot be separated by quotient rationals, host equality rows, selected limits, countable-choice selectors, metric-completeness data, or ambient real completeness. □

Theorem 291.37 (DyadicRatCore RegSeqRat terminal radius-window boundary)**.** *Every Phase Real and Completion terminal handoff whose dyadic face is a public* $\mathsf{DyadicRatCore}^{\uparrow}$ *envelope and whose downstream consumer is a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or* $\mathsf{Real}^{\uparrow}$ *seal factors through the common monotone unary radius window supplied by Definition 291.33. The visible rows of that terminal boundary are exactly the shared refined exponent, denominator ledger, common-exponent classifier, distance rows,* BHist *carrier rows,* hsame *transports,* Cont *readbacks, and* Pkg *provenance read through Definition 291.28 and Definition 291.32.*

The boundary exports no quotient rational, host equality row, selected real limit, countable-choice selector, ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, metric-completeness datum, or bridge row beyond the displayed dyadic source bridge.*

Proof. First place the finite family of terminal dyadic handoffs on the common monotone unary radius window of Definition 291.33. This identifies one shared refined exponent, denominator ledger, common-exponent classifier, distance inventory, BHist carrier inventory, transport inventory, readback inventory, and provenance inventory for the dyadic faces consumed at the terminal boundary.

Next apply Definition 291.32. The directed-refinement handoff exposes the dyadic radius row, monotone radius witness, and $\mathsf{RegSeqRat}^{\uparrow}$ handoff before any $\mathsf{Real}^{\uparrow}$ seal can consume the packet, so the terminal read is forced to pass through the displayed finite radius window.

Use Definition 291.30 to compose the finite radius window with the downstream readback route. Then apply Definition 291.28 to read the consumer-visible rows from the public bridge inventory rather than from an external rational quotient or completed real object.

Finally inspect the exclusion clauses of the finite cofinality theorem, directed-refinement radius handoff, and bridge handoff exactness theorem. Their shared inventory contains only displayed dyadic source bridge rows and finite $\mathsf{RegSeqRat}^{\uparrow}$ readback rows, hence it has no quotient rational, host equality row, selected real limit, countable-choice selector, ambient real-completeness coordinate, metric-completeness coordinate, or extra bridge row. □

Theorem 291.38 (DyadicRatCore open-phase exit criterion)**.** *A current Phase Real and Completion exit read whose dyadic face is a public* DyadicRatCore$^{\uparrow}$ *envelope is admissible if and only if its visible data factor through the displayed dyadic source rows, the* StreamName$^{\uparrow}$ *finite-window face, the* RegSeqRat$^{\uparrow}$ *readback face, and the local* Real$^{\uparrow}$ *seal face. The only support rows carried through this route are* BHist *carrier rows,* hsame *transports,* Cont *readbacks,* Pkg *provenance, and* NameCert *certificate rows already attached to the public dyadic envelope.*

The exit route exposes no quotient rational representative, host equality row, selected limit, countable-choice selector, ambient Real$^{\uparrow}$ *completeness theorem, metric-completeness row, or standard bridge row beyond the displayed dyadic source rows. The* StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and local* Real$^{\uparrow}$ *faces are downstream consumer contexts for the same finite dyadic inventory, not additional dyadic coordinates.*

Proof. For the forward direction, begin with the public dyadic envelope and apply Definition 291.24. This identifies the consumer-visible carrier, transport, readback, package, and certificate rows without introducing a host rational equality or completed real endpoint.

Next apply Definition 291.25 to read the same envelope through its displayed dyadic source rows. The bridge is used only to name the finite signed mantissa, exponent, denominator, classifier, and distance inventory; no additional standard bridge row is exported to the exit read.

Then apply Definition 291.28 and Definition 291.37. These two results place the RegSeqRat$^{\uparrow}$ readback and the local Real$^{\uparrow}$ seal on the same terminal finite radius window, so the StreamName$^{\uparrow}$ finite-window face, RegSeqRat$^{\uparrow}$ readback face, and local Real$^{\uparrow}$ seal face consume one displayed dyadic inventory.

For the reverse direction, any exit read already factored through those four faces has exactly the public dyadic support rows named above. Repacking these rows through the public bridge consumer exactness theorem gives an admissible Phase Real and Completion exit read, while the exclusion clauses of the source bridge, handoff exactness, and terminal boundary theorems rule out quotient rational representatives, host equality, selected limits, countable choice, ambient real completeness, metric-completeness rows, and any extra standard bridge coordinate. □

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreOpenPhaseExitCriterion`

Theorem 291.39 (DyadicRatCore RegSeqRat handoff failure localization)**.** *For a current Phase Real and Completion exit read whose dyadic face is a public* DyadicRatCore$^{\uparrow}$ *envelope, the* RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ *handoff fails exactly when the finite public route has an obstruction at one of the displayed sites:*

1. *a dyadic source row named by the public bridge is absent, or its signed mantissa, positive exponent, denominator ledger, common-exponent classifier, or distance component is not transported componentwise;*
2. *the* StreamName$^{\uparrow}$ *finite-window face does not carry the same finite radius and source-row window as the dyadic bridge;*
3. *the* RegSeqRat$^{\uparrow}$ *readback face is absent, or it reads a row outside the terminal radius window;*
4. *the local* Real$^{\uparrow}$ *seal face is absent, or it seals data not read back from the terminal* RegSeqRat$^{\uparrow}$ *face;*
5. *one of the support rows* BHist, hsame, Cont, Pkg, *or* NameCert *is absent, or is not transported componentwise along the public envelope.*

Equivalently, once all five finite sites are present and componentwise transported, the open Phase Real and Completion exit read is admissible and the handoff has no further obstruction. No quotient

rational representative, host equality row, selected limit, countable-choice selector, ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem, metric-completeness row, or bridge row beyond the displayed dyadic source rows can witness failure.*

Proof. For the failure direction, apply Definition 291.38. A non-admissible exit read cannot factor through the displayed dyadic source rows, the $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, the local $\mathsf{Real}^{\uparrow}$ seal face, and the listed support rows at once.

Use Definition 291.24 to inspect the public envelope. If the carrier, transport, readback, package, or certificate support is missing, the obstruction is the fifth listed site; otherwise these rows are present and componentwise transported.

Next use Definition 291.25 to inspect the displayed dyadic source inventory. If one of its source components is absent or not transported componentwise, the obstruction is the first listed site. Otherwise the signed mantissa, positive exponent, denominator ledger, common-exponent classifier, and distance rows are the public source rows of the same envelope.

It remains to locate any downstream obstruction. Apply Definition 291.28 and Definition 291.37. These results force the $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the local $\mathsf{Real}^{\uparrow}$ seal face to consume the same terminal finite radius window, so a remaining failure is exactly one of the second, third, or fourth listed sites.

For the converse direction, assume one listed site is absent or not componentwise transported. Then the exit read cannot factor through all four finite faces and all support rows, so Definition 291.38 rejects admissibility of the $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ handoff.

If none of the five listed sites occurs, the same criterion gives admissibility. The exclusion clauses in Definition 291.24, Definition 291.25, Definition 291.28, and Definition 291.37 rule out quotient rational representatives, host equality, selected limits, countable choice, ambient real completeness, metric completeness, and extra bridge rows as possible obstruction witnesses. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$.

Constructive story: A dyadic packet is generated by placing a signed $\mathsf{Rat}^{\uparrow}$ mantissa beside a positive unary exponent row, displaying the finite denominator tower for 2^e, and attaching Pkg provenance for the $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ sources. The classifier compares two packets by lifting them to a displayed common unary exponent and reading a $\mathsf{Rat}^{\uparrow}$ classifier row between the scaled mantissas. Distance and absolute-value observations are finite common-exponent windows over the same displayed rows. The surface records the dyadic source needed by $\mathsf{StreamName}^{\uparrow}$, RegSeqRat, and $\mathsf{Real}^{\uparrow}$ without forming quotient equality, importing host rationals, or claiming real completeness.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scoped paper boundary binds the signed $\mathsf{Rat}^{\uparrow}$ mantissa row, positive UnaryHistory exponent row, denominator ledger, common-exponent scaling classifier, arithmetic and distance windows, monotone-radius refinement, common-exponent exactness, real-phase source coverage, BHist data, hsame transport, Cont readback, and Pkg provenance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier\_standard\_source\_bridge`

Bridge status: bridgeChecked

Not claimed: This chapter does not claim a host rational quotient, arithmetic completeness, completed real endpoint, or any $\mathsf{Real}^{\uparrow}$ completeness theorem.

Upgrade path: No further upgrade – chapter at top of formal axis.

Definition 291.40 (DyadicRatCore scale-window packet)**.** *The DyadicRatCore scale-window packet is the finite dyadic observation packet consisting of a signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, a positive* UnaryHistory *exponent row, the comparison window at that exponent, the scale transport row to any displayed wider exponent window, the componentwise* hsame *rows comparing the transported dyadic observations, the displayed* Cont *replay row, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *naming row.*

The packet is consumed by $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *as a finite dyadic source. It carries no host rational order and no quotient equality coordinate.*

Theorem 291.41 (DyadicRatCore scale-window monotonicity)**.** *Widening the positive unary exponent window of a DyadicRatCore scale-window packet preserves the dyadic comparison row consumed by* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$*. The preserved row is transported only by the displayed scale transport, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows of Definition 291.40.*

No host rational order, quotient equality, completed Real endpoint, or ambient completeness row is imported by the widened window.

Proof. Start with Definition 291.26. It transports the signed mantissa, common-exponent classifier, distance window, radius row, carrier data, hsame transport, Cont readback, and provenance across a displayed positive-unary denominator refinement.

Next apply Definition 291.27. Repeated widening of the exponent window is therefore the composite of the same displayed finite transports, not a comparison in an ambient host order.

Use Definition 291.28. It identifies the dyadic comparison rows consumed by $\mathsf{RegSeqRat}^{\uparrow}$ with exactly the public DyadicRatCore envelope rows, and the same finite source surface is available to $\mathsf{StreamName}^{\uparrow}$ through the public bridge consumer boundary.

The rows left by these references are precisely the rows of Definition 291.40. Their exclusion clauses remove host rational order, quotient equality, completed Real endpoints, and ambient completeness from the widened window. □

Theorem 291.42 (DyadicRatCore scale-window cofinality)**.** *Any finite chain of positive-unary exponent-window widenings of a* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet remains on the same cofinal dyadic comparison route consumed by* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$*. The terminal packet of the chain is reached only through displayed scale transports, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *data.*

The cofinal route imports no host rational order, quotient equality, completed $\mathsf{Real}^{\uparrow}$ *endpoint, or ambient completeness row.*

Proof. First apply scale-window monotonicity, Definition 291.41, to each displayed widening in the finite chain. Each step preserves the dyadic comparison row consumed by $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$.

Next use Definition 291.27. It composes the finite positive-unary denominator refinements into one displayed scale-transport route from the initial packet to the terminal packet.

Now apply Definition 291.28. The terminal comparison row remains the same public DyadicRatCore envelope read by $\mathsf{RegSeqRat}^{\uparrow}$, with the same finite source surface available to $\mathsf{StreamName}^{\uparrow}$.

Therefore the whole finite widening chain is cofinal in the displayed dyadic comparison route, and the exclusion clauses from the cited theorems remove host rational order, quotient equality, completed Real endpoints, and ambient completeness. □

Theorem 291.43 (DyadicRatCore common-exponent comparison closure)**.** *Any finite positive-unary exponent-window widening chain of an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet preserves the common-exponent comparison row consumed by* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$*. At every stage the comparison row is carried only by the displayed scale transport, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows of Definition 291.40.*

The closure statement exports no host rational order, quotient equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, hidden denominator selector, or ambient completeness row.*

Proof. Proceed by finite induction on the displayed positive-unary exponent-window widening chain. The empty chain leaves the initial packet unchanged, so the common-exponent comparison row is the original displayed row of the accepted packet.

For the step, factor the chain as a shorter widening chain followed by one displayed widening. The induction hypothesis preserves the common-exponent comparison row at the intermediate packet, with only the displayed transport, hsame, Cont, Pkg, and local NameCert support rows in scope.

Apply scale-window monotonicity, Definition 291.41, to the last widening. It transports the same comparison row across the wider exponent window and imports no ambient order or quotient equality.

Finally use scale-window cofinality, Definition 291.42, to identify the terminal packet as lying on the same cofinal dyadic comparison route consumed by $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$. The exclusion clauses from monotonicity and cofinality remove host rational order, quotient equality, selected Real endpoints, hidden denominator selectors, and ambient completeness. □

Theorem 291.44 (DyadicRatCore finite widening-chain induction)**.** *Let I be a BEDC-visible invariant on accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packets. Suppose I holds for an initial accepted packet, and suppose one displayed positive-unary exponent-window widening preserves I whenever the widening is witnessed only by the scale transport, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows of Definition 291.40. Then I holds for the terminal packet of any finite positive-unary widening chain starting at the initial packet.*

The induction surface imports no host rational order, quotient equality, hidden denominator selector, selected $\mathsf{Real}^{\uparrow}$ *endpoint, or ambient completeness row.*

Proof. Proceed by finite induction on the displayed widening chain. The empty chain has the initial packet as its terminal packet, so the base assumption gives I directly.

For the step, write the chain as a shorter displayed widening chain followed by one positive-unary exponent-window widening. The induction hypothesis gives I on the intermediate accepted packet. Apply scale-window monotonicity, Definition 291.41, to the last displayed widening; its output supplies exactly the transported scale row, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows required by the one-step preservation hypothesis.

The one-step preservation hypothesis therefore transfers I from the intermediate packet to the terminal packet. Repeating this finite argument reaches the terminal packet of the original chain, and the exclusion clause is inherited from the accepted packet rows and from scale-window monotonicity. □

Theorem 291.45 (DyadicRatCore successor scale-window nesting)**.** *Let P be an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet, and let P^{+} be obtained from P by one displayed positive-unary successor widening of the exponent window. Then P nests inside P^{+} as the same finite dyadic source surface: the signed mantissa row, denominator ledger, common-exponent comparison row, distance and radius rows, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support of P are carried into the corresponding rows of P^{+}.*

This one-successor nesting imports no host rational order, quotient equality, hidden denominator selector, selected $\mathsf{Real}^{\uparrow}$ *endpoint, or ambient completeness row.*

Proof. Apply scale-window monotonicity, Definition 291.41, to the displayed successor widening. It gives the transported dyadic comparison row and identifies the allowed support as displayed

scale transport, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

View the successor widening as the one-step finite chain. The finite widening-chain induction theorem, Definition 291.44, then specializes its preservation surface to the invariant saying that the original signed mantissa, denominator ledger, comparison row, distance and radius rows, and displayed support rows remain visible inside the terminal packet.

Finally use RegSeqRat bridge handoff exactness, Definition 291.28. The widened packet is still the public DyadicRatCore envelope consumed by $\mathsf{RegSeqRat}^{\uparrow}$ and exposed to $\mathsf{StreamName}^{\uparrow}$, so the nesting is a finite packet inclusion rather than a passage through host rational order, quotient equality, hidden denominator selectors, selected $\mathsf{Real}^{\uparrow}$ endpoints, or ambient completeness. □

Theorem 291.46 (DyadicRatCore scale-window terminal fusion)**.** *If two finite chains of positive-unary exponent-window widenings of a* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet have a common terminal exponent, then they fuse into the same terminal DyadicRatCore comparison packet for* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers. The fused packet is reached only through the displayed scale transports, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows of Definition 291.40.*

No host rational order, quotient equality, completed $\mathsf{Real}^{\uparrow}$ *endpoint, hidden denominator selector, or ambient completeness row is imported by either chain.*

Proof. Apply scale-window cofinality, Definition 291.42, to both finite widening chains. Each chain reaches its terminal comparison row through the same displayed scale transports, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local NameCert rows.

Use denominator-refinement composition, Definition 291.27. Since the terminal exponent is common, the two composed refinement routes identify the same terminal positive-unary denominator window rather than two ambient host-order comparisons.

Now apply RegSeqRat bridge handoff exactness, Definition 291.28. The terminal DyadicRatCore comparison packet handed to $\mathsf{RegSeqRat}^{\uparrow}$ is exactly the public envelope row, and the same finite source packet is available to $\mathsf{StreamName}^{\uparrow}$.

The non-escape exclusions in the packet and the cited bridge theorems remove host rational order, quotient equality, completed Real endpoints, hidden denominator selectors, and ambient completeness. Therefore the two chains fuse at one terminal comparison packet for both consumers. □

Theorem 291.47 (DyadicRatCore scale-window consumer face determinacy)**.** *Let an accepted* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer read expose its dyadic face through a* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet and a finite chain of positive-unary exponent-window widenings. Then the consumer-facing dyadic face is determined by the terminal scale-window packet: the signed mantissa row, exponent window, denominator ledger, common-exponent comparison, distance and radius window, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row.*

A second widening chain, $\mathsf{Real}^{\uparrow}$ *seal read, or* $\mathsf{RegSeqRat}^{\uparrow}$ *finite request cannot introduce another dyadic face with different displayed rows over the same terminal packet. The consumer boundary therefore reads one dyadic source surface through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, without quotient stream equality, selected limits, host rational order, hidden denominator selectors, or ambient completeness.*

Proof. Apply scale-window cofinality, Definition 291.42, to the finite positive-unary widening chain used by the consumer read. The read reaches its terminal packet only through displayed scale trans-

ports, componentwise hsame rows, Cont replay, Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ row.

For two displayed widening chains, apply terminal fusion, Definition 291.46. A common terminal packet fuses the signed mantissa row, exponent window, denominator ledger, common-exponent comparison, distance and radius window, and the displayed support rows into one terminal DyadicRatCore comparison packet.

For the $\mathsf{RegSeqRat}^{\uparrow}$ face, use Definition 291.28. The finite request consumes exactly the public DyadicRatCore envelope delivered by that terminal packet, so it has no independent dyadic row from which to read a different face.

For the $\mathsf{Real}^{\uparrow}$ face, apply the dependency route Definition 38.738. The Real seal-visible read factors through the displayed $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumer faces, so it inherits the same terminal DyadicRatCore packet rather than adding a separate dyadic source.

The exclusion clauses in the scale-window packet, terminal fusion, bridge handoff, and dependency route remove quotient stream equality, selected limits, host rational order, hidden denominator selectors, and ambient completeness. Hence every accepted consumer read over the terminal scale-window packet exposes the same dyadic face. □

Theorem 291.48 (DyadicRatCore tail-radius monotone readback)**.** *Let an accepted* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or terminal* $\mathsf{Real}^{\uparrow}$ *seal consumer read its dyadic tolerance face through a* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet and a positive-unary tail-radius widening chain. Then the radius row read by the consumer is monotone along the displayed widening route: every later window contains the same signed mantissa, exponent ledger, common-exponent comparison, distance row, radius row, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support as the corresponding earlier window, transported through the displayed scale route.*

Thus the $\mathsf{StreamName}^{\uparrow}$ *finite-window read, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular readback, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal all see one dyadic radius ledger on the cofinal terminal packet. The readback refuses host rational order, quotient equality, hidden denominator selectors, selected Real endpoints, and ambient completeness.*

Proof. Apply scale-window monotonicity, Definition 291.41, to each displayed positive-unary tail-radius widening. This preserves the dyadic comparison and radius rows through the permitted scale transport, hsame, Cont, Pkg, and local NameCert support.

Use scale-window cofinality, Definition 291.42, to place the finite widening chain on one terminal dyadic comparison route. The terminal route is reached without adding a host order or quotient coordinate.

Next apply terminal fusion, Definition 291.46. Any two displayed subchains with the same terminal radius window fuse into the same terminal packet, so no hidden denominator selector can choose a different ledger.

Finally use consumer face determinacy, Definition 291.47. The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers all read their dyadic face from that terminal packet, and the cited exclusions remove host rational order, quotient equality, selected Real endpoints, and ambient completeness. □

Theorem 291.49 (DyadicRatCore RegSeqRat radius-window normal form)**.** *Let an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback expose its dyadic face through a finite positive-unary widening chain of a* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Then, on BEDC-visible rows, that readback is equivalent to the normal form consisting of the terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet together with the* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the local* $\mathsf{Real}^{\uparrow}$ *seal face, and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

The normal form contains no quotient rational, quotient stream equality, selected limit, countable-choice selector, metric-completeness row, host rational order, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. First apply finite widening-chain induction, Definition 291.44. Use as invariant the assertion that the accepted readback is presented by the visible signed mantissa, exponent window, denominator ledger, common-exponent comparison, distance and radius rows, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows of the current scale-window packet.

Next apply terminal fusion, Definition 291.46. Any two finite routes to the same terminal positive-unary exponent therefore present one terminal $\mathsf{DyadicRatCore}^{\uparrow}$ comparison packet, so the readback cannot retain a route-dependent dyadic face.

Now use consumer face determinacy, Definition 291.47. The terminal packet determines the $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the local $\mathsf{Real}^{\uparrow}$ seal face from the same displayed dyadic rows.

Finally apply the RegSeqRat terminal radius-window boundary, Definition 291.37. It forces the accepted terminal readback through the finite radius window attached to the public DyadicRatCore envelope. Combining this boundary with the previous steps gives exactly the stated terminal packet plus the three consumer faces and shared support rows.

The exclusion clauses in the induction surface, terminal fusion, consumer determinacy, and terminal radius-window boundary remove quotient rationals, quotient stream equality, selected limits, countable-choice selectors, metric-completeness rows, host rational order, and ambient Real completeness coordinates. Thus the accepted $\mathsf{RegSeqRat}^{\uparrow}$ readback has precisely the displayed BEDC-visible normal form. □

Theorem 291.50 (DyadicRatCore directed radius-refinement L10 request support)**.** *Let an accepted* $\mathsf{StreamName}^{\uparrow}$ *finite-window request, an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback request, or an accepted* $\mathsf{Real}^{\uparrow}$ *seal request present its dyadic face through a directed finite family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *positive-unary radius-window refinements. Then every such request has one common terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window support packet. That packet consists only of the signed mantissa row, exponent window, denominator ledger, common-exponent comparison, distance and radius rows, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows.*

The support packet excludes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness rows, host rational order, and ambient $\mathsf{Real}^{\uparrow}$ *completeness. Thus the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *finite request routes cannot split into separate dyadic radius ledgers once their faces are presented by the same directed finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *refinement family.*

Proof. Apply scale-window cofinality, Definition 291.42, to each branch of the directed finite refinement family. Every branch reaches its visible terminal dyadic comparison route through displayed scale transports, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

For two branches with the displayed common terminal window, use terminal fusion, Definition 291.46. Directedness supplies the finite comparison point, and fusion identifies the terminal signed mantissa row, exponent window, denominator ledger, common-exponent comparison, distance and radius rows, and displayed support rows as one $\mathsf{DyadicRatCore}^{\uparrow}$ scale-window packet.

Next apply consumer face determinacy, Definition 291.47. The accepted $\mathsf{StreamName}^{\uparrow}$ finite-window request, $\mathsf{RegSeqRat}^{\uparrow}$ readback request, and $\mathsf{Real}^{\uparrow}$ seal request read the same terminal dyadic face from that packet, so none of the three consumers carries an independent dyadic support route.

Finally use the RegSeqRat radius-window normal form, Definition 291.49. It repacks the $\mathsf{RegSeqRat}^{\uparrow}$ readback and local $\mathsf{Real}^{\uparrow}$ seal face into the terminal $\mathsf{DyadicRatCore}^{\uparrow}$ packet together with the shared BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows. The exclusion clauses from the cited results remove quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness rows, host rational order, and ambient $\mathsf{Real}^{\uparrow}$ completeness, leaving exactly the common terminal support packet stated above. □

Theorem 291.51 (DyadicRatCore terminal scale-window realizer)**.** *Let D be an accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-exponent classifier window whose visible rows are the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, the positive-unary exponent row, the denominator ledger for the displayed power of two, the scaled-mantissa* $\mathsf{Rat}^{\uparrow}$ *comparison row, the componentwise* hsame *transport row, the displayed* Cont *route, and the* Pkg *provenance row. Then D determines a terminal finite scale window*

$$T_D = (m, e, \ell, r, H, C, P, N)$$

whose mantissa m, exponent e, denominator ledger ℓ, $\mathsf{Rat}^{\uparrow}$ *comparison row r, transport H, continuation route C, provenance P, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row are all read from the common-exponent classifier window.*

The realizer is terminal among finite dyadic scale-window reads with the same classifier data: any $\mathsf{StreamName}^{\uparrow}$ *finite-window consumer,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity consumer, or downstream handoff that preserves the same mantissa, exponent, denominator ledger,* $\mathsf{Rat}^{\uparrow}$ *comparison,* Cont *route, and* Pkg *provenance factors through T_D. The realizer exports no completed* $\mathsf{Real}^{\uparrow}$ *endpoint, selected limit, quotient rational equality, quotient stream equality, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with the common-exponent classifier window. Its visible rows already contain the signed $\mathsf{Rat}^{\uparrow}$ mantissa, the positive-unary exponent, the denominator ledger, and the scaled-mantissa $\mathsf{Rat}^{\uparrow}$ comparison row.

Apply the scale-window obligation surface of Definition 291.13. That theorem identifies the finite dyadic tolerance row consumed by $\mathsf{StreamName}^{\uparrow}$ finite windows and $\mathsf{RegSeqRat}^{\uparrow}$ regularity checks, using only the displayed mantissa, exponent, denominator, comparison, transport, replay, and provenance data.

Next apply common-scale terminal refinement, Definition 291.95. It refines the displayed classifier window to a terminal finite scale packet while preserving the same signed mantissa row, denominator ledger, endpoint comparison rows, hsame transport, Cont replay, Pkg provenance, and local DyadicRatCore naming rows.

For terminality, use the uniqueness clause of Definition 291.96. Any competing finite scale-window read with the same visible classifier data and the same downstream $\mathsf{StreamName}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ faces must determine the same terminal tolerance row.

Finally use the non-escape clauses of Definition 291.37. The terminal handoff is read before any $\mathsf{Real}^{\uparrow}$ seal can consume it, so the constructed packet has no completed real endpoint or hidden completion coordinate. □

Definition 291.52 (DyadicRatCore signed-exponent carrier)**.** *The signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier refines the carrier of Definition 291.1 to the finite packet*

$$Q = (m, e, \ell, W, R, H, C, P, N)$$

where m is the signed $\mathsf{Rat}^{\uparrow}$ *mantissa row, e is the positive unary exponent row, ℓ is the denominator ledger for 2^e, W is the common-exponent comparison window of Definition 291.3, R is the dyadic*

tolerance-radius row, H records componentwise hsame *transport, C records displayed* Cont *replay, P records the* Pkg *provenance over* $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumers, and N is the local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row. The packet has no quotient rational, host equality row, completed* $\mathsf{Real}^{\uparrow}$ *endpoint, or ambient completeness coordinate.*

Theorem 291.53 (DyadicRatCore common-exponent stability)**.** *Let Q and Q' be signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carriers whose mantissa, exponent, denominator ledger, tolerance-radius row, transport, replay, provenance, and local name are related by displayed* hsame *and* Cont *rows. Any common-exponent comparison window for Q factors through the same finite rows as the transported common-exponent comparison window for Q', namely the signed mantissa rows, positive unary exponent rows, transported denominator ledgers, scaled* $\mathsf{Rat}^{\uparrow}$ *mantissas,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows.*

Proof. Start from the signed-exponent carrier of Definition 291.52. Its comparison row W is already the common-exponent classifier window of Definition 291.3.

Apply denominator ledger transport, Definition 291.7, to the exponent and denominator rows. This transports the positive unary exponent and the ledger for 2^e without introducing a quotient rational or host normal form.

Use common-exponent window exactness, Definition 291.8. The transported classifier is determined by the transported exponent, ledgers, scaled mantissas, $\mathsf{Rat}^{\uparrow}$ classifier row, Cont replay, and Pkg provenance. The displayed hsame rows therefore carry the same common-exponent comparison surface from Q to Q'. □

Theorem 291.54 (DyadicRatCore tolerance-radius monotonicity)**.** *For a signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier Q, every displayed positive-unary refinement of the exponent row induces a monotone refinement of the tolerance-radius row R. The refined radius window remains a finite BEDC row over the denominator ledger, common-exponent comparison window, distance window,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *data, and it exports no host epsilon equality or completed* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Proof. Read the radius row R through the signed-exponent carrier. It is attached to the same positive unary exponent and denominator ledger that define the common-exponent comparison window.

Apply the monotone-radius obligation of Definition 291.12. A positive-unary refinement widens the denominator scale and transports the dyadic radius through displayed ledger rows.

Then apply the distance-window stability of Definition 291.10. The distance and absolute-value observations remain inside the transported signed mantissa, common exponent, denominator ledger, hsame, Cont, and Pkg rows. Hence the tolerance-radius refinement is monotone on the displayed finite packet and cannot read host epsilon equality or a completed real endpoint. □

Theorem 291.55 (DyadicRatCore signed-exponent denominator-chain determinacy)**.** *Let $Q = (m, e, \ell, W, R, H, C, P, N)$ be a signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier. For any finite chain $Q = Q_0, Q_1, \ldots, Q_n$ in which each adjacent step is a displayed positive-unary refinement of the exponent row and transports the signed mantissa, denominator ledger, common-exponent comparison window, tolerance-radius row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row, the terminal denominator ledger, common-exponent comparison row, tolerance-radius row, and L10 dyadic face are determined by Q alone. The same terminal surface is obtained for every subdivision and parenthesization of the finite refinement chain. This determinacy is a statement only about the finite BEDC rows of the signed-exponent carrier; it excludes quotient rational*

equality, host normalization, selected $\mathsf{Real}^{\uparrow}$ *endpoints, countable choice, metric completeness, and ambient Real completeness.*

Proof. Proceed by induction on the finite refinement chain. In the empty chain the terminal rows are exactly ℓ, W, R, and the displayed L10 dyadic face of the carrier in Definition 291.52.

For a successor step, apply Definition 291.53 to the adjacent carriers. This identifies the transported common-exponent comparison row with the same finite mantissa, exponent, denominator-ledger, transport, replay, provenance, and local naming rows.

Apply Definition 291.54 to the same adjacent refinement. The radius row is transported monotonically along the displayed positive-unary exponent refinement and remains attached to the denominator ledger and common-exponent window already fixed by the induction hypothesis.

Associativity of finite chain concatenation is therefore harmless at the paper level: subdividing a step or reparenthesizing consecutive steps only repeats the same adjacent comparison and radius transports. The terminal denominator ledger, comparison row, and radius row remain the rows forced by the original carrier.

Finally use Definition 291.59 and Definition 291.58. They identify the downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ L10 dyadic face with exactly the displayed signed mantissa, positive unary exponent, denominator ledger, comparison, radius, transport, replay, provenance, and local NameCert rows, leaving no quotient rational, host normalization, selected endpoint, countable choice, metric-completeness, or ambient-completeness coordinate. □

Theorem 291.56 (DyadicRatCore signed-exponent denominator clearance)**.** *Let* $Q = (m, e, \ell, W, R, H, C, P, N)$ *be an accepted signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet. Then the positive unary exponent row* e *and denominator ledger* ℓ *are determined before any* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer may read a tolerance radius from* R*. Every accepted consumer route must therefore expose the denominator ledger as a finite BEDC row upstream of the L10 tolerance read.*

No host rational normal form, quotient equality, completed endpoint, selected limit, metric-completeness datum, or ambient completeness coordinate can replace the denominator ledger.

Proof. Start with Definition 291.55. It fixes the terminal denominator ledger, common-exponent comparison row, and tolerance-radius row from the accepted signed-exponent carrier and from its displayed finite refinement chain.

Next apply Definition 291.58. The NameCert surface lists the exponent, denominator ledger, comparison window, radius row, transport, replay, provenance, and local naming as the exact rows available to downstream consumers.

Finally use Definition 291.59. A StreamName, RegSeqRat, or RealUp source read determines precisely the displayed signed mantissa, positive unary exponent, denominator ledger, comparison, radius, transport, replay, provenance, and local NameCert rows. Hence the tolerance radius is read only after denominator clearance, with no quotient or host-normal-form shortcut. □

Theorem 291.57 (DyadicRatCore refinement-chain induction)**.** *Let* $Q = (m, e, \ell, W, R, H, C, P, N)$ *be a signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier, and let* $\mathcal{R}$ *be the class of finite displayed chains that start at* Q *and whose adjacent steps are positive-unary refinements of the exponent row transporting the signed mantissa* m*, exponent row* e*, denominator ledger* ℓ*, common-exponent window* W*, tolerance-radius row* R*, componentwise* hsame *row* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row* N*. If a predicate* Φ *on such finite chains holds for the empty chain at* Q*, and if* $\Phi(\Gamma)$ *implies* $\Phi(\Gamma')$ *whenever* Γ' *is obtained from* Γ *by appending one displayed positive-unary refinement step whose transported surface is accepted by the same* hsame*,*

Cont, Pkg, *and local naming rows and whose downstream face is the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *L10 dyadic face of the carrier, then* $\Phi(\Gamma)$ *holds for every finite chain* $\Gamma \in \mathcal{R}$.

Proof. Induct on the finite displayed chain. The empty chain is the base clause in the hypothesis, and its visible surface is precisely the carrier rows $m, e, \ell, W, R, H, C, P, N$ of Definition 291.52.

For the successor step, write the chain as a shorter displayed chain followed by one positive-unary exponent refinement. By the induction hypothesis Φ holds for the shorter chain.

The appended step is stable by Definition 291.53: the transported common-exponent window still reads only the signed mantissa, positive unary exponent, denominator ledger, hsame transport, Cont replay, Pkg provenance, and local NameCert rows.

Apply Definition 291.54 to the same step. The tolerance-radius row is monotone along the displayed refinement and remains attached to the denominator and comparison rows already carried by the shorter chain. The successor premise for Φ therefore applies, including the downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ L10 face.

This proves the induction principle for every finite displayed refinement chain without adding quotient rational equality, host normalization, selected endpoints, countable choice, metric completeness, or ambient Real completeness. □

Theorem 291.58 (DyadicRatCore signed-exponent NameCert obligation surface)**.** *For the signed-exponent carrier of Definition 291.52, the local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *obligation surface consists exactly of signed mantissa admission through* m*, positive unary exponent admission through* e*, denominator-ledger exposure through* ℓ*, common-exponent comparison through* W*, tolerance-radius monotonicity through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*. This surface is the finite obligation layer consumed by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *when they read dyadic source data.*

Proof. Project the carrier $Q = (m, e, \ell, W, R, H, C, P, N)$. The mantissa, exponent, and denominator ledger rows are the signed dyadic source data of Definition 291.1, while W is the common-exponent classifier window and R is the tolerance-radius row.

Use Definition 291.53 for the comparison part of the surface. It keeps common-exponent reads stable under the displayed transport and replay rows.

Use Definition 291.54 for the radius part. It keeps all tolerance refinements on positive unary exponent data and finite dyadic distance rows.

Finally compare with the public bridge and handoff clauses, Definition 291.24, Definition 291.28, and Definition 291.20. The downstream StreamName, RegSeqRat, and Real consumers receive exactly the displayed signed mantissa, exponent, denominator, comparison, radius, transport, replay, provenance, and local NameCert rows, with no quotient rational, host equality, completed endpoint, or ambient completeness coordinate. □

Theorem 291.59 (DyadicRatCore signed-exponent source determinacy)**.** *Let* $Q = (m, e, \ell, W, R, H, C, P, N)$ *be a signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier as in Definition 291.52. Any accepted downstream dyadic source read for* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *determines exactly the displayed mantissa row* m*, positive unary exponent row* e*, denominator ledger* ℓ*, common-exponent window* W*, tolerance-radius row* R*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row* N*. Conversely, any finite packet exposing precisely those nine rows repacks as the same signed-exponent dyadic source surface for those consumers.*

Proof. Project the signed-exponent carrier of Definition 291.52. The projection names the only rows available to a downstream source read: m, e, ℓ, W, R, H, C, P, and N.

The exponent and denominator coordinates are fixed by Definition 291.7. The comparison and radius coordinates are fixed by Definition 291.53 and Definition 291.54. Together these clauses leave no additional source coordinate through which a consumer could distinguish two accepted reads.

The naming surface is then fixed by Definition 291.58. It identifies the local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ obligations with the same mantissa, positive unary exponent, denominator ledger, comparison window, radius, transport, replay, provenance, and local naming rows.

Apply the public bridge and handoff clauses, Definition 291.24 and Definition 291.28. They say that the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ reads consume exactly the public dyadic source rows already displayed, so an accepted downstream read determines exactly those rows.

For the converse, start with any finite packet exposing precisely m, e, ℓ, W, R, H, C, P, and N. The carrier projection repacks these rows as the signed-exponent surface, and the NameCert obligation theorem supplies the same public source boundary for the three consumers.

The correspondence exports no quotient rational, host equality row, completed $\mathsf{Real}^{\uparrow}$ endpoint, ambient completeness principle, or selected host limit. □

Theorem 291.60 (DyadicRatCore signed-exponent no-shortcut boundary)**.** *Let $Q = (m, e, \ell, W, R, H, C, P, N)$ be a signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier. Any accepted L10 consumer route for* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *that exposes the signed-exponent* $\mathsf{DyadicRatCore}^{\uparrow}$ *face must pass through the displayed rows m, e, ℓ, W, R, H, C, P, and N. In particular, such a route cannot replace the positive unary exponent row or denominator ledger by host rational normalization, quotient rational equality, quotient stream equality, selected limits, countable choice, ambient completeness, metric completeness, or a direct* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Project the carrier of Definition 291.52. The projection exposes only the signed mantissa row, positive unary exponent row, denominator ledger, common-exponent window, tolerance-radius row, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ row.

Apply Definition 291.58 and Definition 291.59. These identify the accepted source surface with exactly the nine displayed rows, so no consumer can keep the signed-exponent face while substituting a host rational normal form, quotient equality, selected limit, completeness principle, or terminal seal coordinate for either e or ℓ.

The L10 boundary is then routed through Definition 291.80, Definition 126.442, and Definition 301.69. These clauses carry the same dyadic rows through the current $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ handoff, so every accepted L10 consumer route reaches the dyadic face through the displayed carrier rows rather than through an ambient shortcut. □

Theorem 291.61 (DyadicRatCore finite-tail window factorization)**.** *Every finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 window read whose* $\mathsf{DyadicRatCore}^{\uparrow}$ *face is obtained from a displayed DyadicRatCore packet by a finite positive-unary exponent widening factors through the scale-window packet of Definition 291.40. The factorization first reads the widened* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows, then the fused* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet supplied by Definition 291.46, then the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section supplied by Definition 291.28, and finally the* $\mathsf{Real}^{\uparrow}$ *L10 finite-window boundary of Definition 38.464.*

The visible route is exactly the four-face finite-tail packet

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

with the displayed BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. It exports no host rational order, quotient equality, selected limit, ambient completeness row, or* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Start with the displayed finite positive-unary widening on the DyadicRatCore face. By scale-window cofinality, Definition 291.42, the widened observation remains on the same cofinal dyadic comparison route carried by the scale-window packet.

Next apply terminal fusion, Definition 291.46. It identifies the terminal widened comparison packet as one fused $\mathsf{StreamName}^{\uparrow}$ finite-window source, using only displayed scale transports, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

Now use RegSeqRat bridge handoff exactness, Definition 291.28. The fused terminal packet is read by $\mathsf{RegSeqRat}^{\uparrow}$ as the same public DyadicRatCore envelope, so the finite request section does not add an ambient order coordinate or a quotient-equality coordinate.

Finally pass to the Real L10 finite-window determinacy surface, Definition 38.464. That theorem consumes exactly the fused $\mathsf{StreamName}^{\uparrow}$ packet, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, and the local $\mathsf{Real}^{\uparrow}$ seal over the displayed support rows.

The exclusion clauses of the cited DyadicRatCore, RegSeqRat, and Real L10 theorems are stable under this composition. Hence the finite-tail read has the stated four-face factorization and cannot read host rational order, quotient equality, selected limits, ambient completeness, or Real completeness. □

Theorem 291.62 (DyadicRatCore finite-tail window confluence)**.** *Let two finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 window reads have* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces obtained from displayed DyadicRatCore packets by finite positive-unary exponent widenings. Assume the two widened DyadicRatCore faces fuse to the same terminal scale-window packet of Definition 291.40. Then the two four-face routes*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

determine the same terminal finite pullback through the DyadicRatCore, StreamName, RegSeqRat, and Real boundary.

The equality is only equality over the displayed BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. It asserts no quotient stream equality, no host rational equality, no selected limit, no ambient completeness, no metric-completeness datum, and no* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First use terminal fusion, Definition 291.46. The two finite positive-unary widenings have the same terminal scale-window packet, so their DyadicRatCore comparison faces expose one common terminal dyadic packet with the same displayed scale transports, hsame rows, Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows.

Apply the finite-tail factorization theorem, Definition 291.61, to each read. Both reads therefore pass through the same four displayed faces: the common widened $\mathsf{DyadicRatCore}^{\uparrow}$ packet, the fused $\mathsf{StreamName}^{\uparrow}$ finite-window source, the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, and the $\mathsf{Real}^{\uparrow}$ L10 finite-window boundary.

Next use the StreamName terminal pullback, Definition 126.504. Since the StreamName, DyadicRatCore, RegSeqRat, and Real faces and the displayed support rows agree after terminal fusion, the two accepted routes factor through one terminal finite BEDC pullback.

Finally apply the classifier pullback, Definition 126.514, together with the Real L10 finite-window witness determinacy theorem, Definition 38.464. The public classifier and the Real L10 boundary are determined by exactly the common terminal StreamName packet, the DyadicRatCore endpoint and radius ledger, the RegSeqRat finite-request section, the local Real seal, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

The exclusion clauses in the cited DyadicRatCore, StreamName, RegSeqRat, and Real L10 boundary theorems are stable under this common terminal pullback. Thus confluence holds only on the displayed BEDC rows and cannot be read as quotient stream equality, selected limits, ambient completeness, metric completeness, host rational equality, or Real completeness. □

Theorem 291.63 (DyadicRatCore finite-tail window terminality)**.** *Every* $\mathsf{Real}^{\uparrow}$*-and-completion consumer whose visible rows consist of a finite positive-unary widened* $\mathsf{DyadicRatCore}^{\uparrow}$ *face, the fused* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the local* $\mathsf{Real}^{\uparrow}$ *finite-window boundary, and displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows factors uniquely through the terminal four-face packet of Definition 291.61. The forced packet has route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

If two such consumers agree componentwise on those visible rows, then they have the same public L10 read. The statement exports no quotient stream equality, no host rational equality, no selected limit, no ambient completeness row, no metric-completeness datum, no standard bridge datum, and no $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Apply the finite-tail factorization theorem, Definition 291.61, to the consumer read. The visible DyadicRatCore widening, fused StreamName finite window, RegSeqRat finite-request section, local Real boundary, and displayed support rows place the consumer on exactly the four faces named in the theorem.

For uniqueness, compare two consumers with componentwise agreement on those rows. The finite-tail confluence theorem, Definition 291.62, identifies their presentations once both have been routed through the same terminal scale-window packet.

Now invoke the StreamName terminal pullback, Definition 126.504. It says that a downstream Real-and-completion read exposing the four faces and the displayed BHist, hsame, Cont, Pkg, and NameCert rows has a single terminal finite BEDC pullback through which the read must pass.

Finally use Real L10 finite-window witness determinacy, Definition 38.464. The terminal pullback determines the public L10 boundary from the fused StreamName packet, the DyadicRatCore endpoint and radius ledger, the RegSeqRat finite-request section, and the local Real seal, so componentwise agreement gives the same public L10 read and leaves no additional quotient, selected-limit, completeness, bridge, metric-completeness, host-equality, or Real-completeness coordinate. □

Theorem 291.64 (DyadicRatCore finite-tail phase-entry determinacy)**.** *Let two current Phase Real or* $\mathsf{Completion}^{\uparrow}$ *reads have first visible face a finite positive-unary widening of a displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Suppose their remaining visible faces are the fused* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet, the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the local* $\mathsf{Real}^{\uparrow}$ *finite-window boundary, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Then the two reads determine the same entry* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet exactly when their terminal four-face packets agree componentwise over*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

This is only entry determinacy for the finite BEDC phase boundary. It supplies no host rational order, quotient stream equality, selected limit, countable choice, ambient completeness, metric completeness, or $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. First apply scale-window cofinality, Definition 291.42, and terminal fusion, Definition 291.46. They force every displayed finite positive-unary widening of the first visible face onto one terminal

DyadicRatCore comparison packet, using only displayed scale transports, componentwise hsame rows, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^\uparrow}$ data.

Next route each Phase Real or $\mathsf{Completion}^\uparrow$ read through finite-tail factorization, Definition 291.61. The entry packet is therefore read only through the ordered four faces $\mathsf{DyadicRatCore}^\uparrow$, $\mathsf{StreamName}^\uparrow$, $\mathsf{RegSeqRat}^\uparrow$, and $\mathsf{Real}^\uparrow$, together with the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

For the forward implication, if the entry $\mathsf{DyadicRatCore}^\uparrow$ packets are the same, terminal fusion gives the same fused StreamName finite window. Finite-tail confluence, Definition 291.62, and finite-tail terminality, Definition 291.63, then identify the $\mathsf{RegSeqRat}^\uparrow$ finite-request section, the local $\mathsf{Real}^\uparrow$ finite-window boundary, and the resulting terminal four-face packet.

For the reverse implication, assume the terminal four-face packets agree componentwise. Finite-tail terminality says that every accepted Phase Real or $\mathsf{Completion}^\uparrow$ read exposing those four faces has a single terminal finite BEDC pullback, while confluence identifies any two presentations routed to that terminal packet. The first face of that terminal packet is exactly the entry $\mathsf{DyadicRatCore}^\uparrow$ scale-window packet, so the entry packets agree.

Finally use Real L10 finite-window witness determinacy, Definition 38.464. The Real boundary can read only the fused StreamName packet, DyadicRatCore endpoint and radius ledger, RegSeqRat finite-request section, local Real seal, and displayed support rows. Thus no off-table coordinate, including host rational order, quotient stream equality, selected limits, countable choice, ambient completeness, metric completeness, or $\mathsf{Real}^\uparrow$ completeness, can distinguish two entries after the terminal four-face packet agrees. □

Theorem 291.65 (DyadicRatCore finite-tail consumer-order square)**.** *For any current Phase Real and* $\mathsf{Completion}^\uparrow$ *finite-tail read whose first visible face is a finite positive-unary widening of a displayed* $\mathsf{DyadicRatCore}^\uparrow$ *packet, the construction-source projection*

$$\mathsf{DyadicRatCore}^\uparrow \to \mathsf{StreamName}^\uparrow \to \mathsf{RegSeqRat}^\uparrow \to \mathsf{Real}^\uparrow$$

and the consumer-readback projection

$$\mathsf{StreamName}^\uparrow \to \mathsf{DyadicRatCore}^\uparrow \to \mathsf{RegSeqRat}^\uparrow \to \mathsf{Real}^\uparrow$$

are two edge readings of the same displayed four-face certificate.

The square commutes only as equality of the visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It exports no quotient stream equality, selected limit, host rational equality, host real equality, countable choice, metric-completeness datum, standard bridge row, aggregate formalstatus row, or* $\mathsf{Real}^\uparrow$ *completeness principle.*

Proof. First apply finite-tail window factorization, Definition 291.61. It gives the construction-source reading of the widened DyadicRatCore packet through the ordered $\mathsf{DyadicRatCore}^\uparrow$, $\mathsf{StreamName}^\uparrow$, $\mathsf{RegSeqRat}^\uparrow$, and $\mathsf{Real}^\uparrow$ faces over the displayed support rows.

Next use finite-tail phase-entry determinacy, Definition 291.64. The first visible DyadicRatCore entry is determined exactly by agreement of the terminal four-face packet, so changing from the construction-source edge to the consumer-facing edge cannot introduce a second entry record.

Now read the same packet from the StreamName side. The open-phase four-face exit readback, Definition 126.450, and the Real-completion terminal pullback, Definition 126.504, say that every current consumer read is consumed through the same StreamName, DyadicRatCore, RegSeqRat, and Real faces with the same visible BHist, hsame, Cont, Pkg, and NameCert rows.

Finally compare with the Real-side construction-consumer square, Definition 38.799. That theorem reads the same two orderings from the $\mathsf{Real}^\uparrow$ boundary, and its exclusion clauses leave only the

displayed BEDC rows as the commuting data. Hence the DyadicRatCore construction-source projection and the StreamName-facing consumer-readback projection are the two boundary readings of one four-face certificate, with no quotient, selected-limit, host-equality, choice, completeness, bridge, aggregate-status, or $\mathsf{Real}^{\uparrow}$ completeness coordinate added. □

Theorem 291.66 (DyadicRatCore finite-tail scale-window pullback exactness)**.** *Let two finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 reads have* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces obtained from displayed DyadicRatCore packets by finite positive-unary exponent widenings. Suppose the two reads share the same terminal scale-window packet of Definition 291.40 and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section. Then their* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces determine the same finite pullback route over* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

The exactness is only the finite BEDC pullback exactness of the displayed route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

It exports no quotient stream equality, selected limit, host rational equality, ambient completeness row, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First apply scale-window terminal fusion, Definition 291.46. The common terminal scale-window packet identifies the widened DyadicRatCore comparison face through displayed scale transports, componentwise hsame rows, Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

Next apply finite-tail window factorization, Definition 291.61. Each finite-tail $\mathsf{Real}^{\uparrow}$ L10 read factors through the same ordered four-face packet: the terminal $\mathsf{DyadicRatCore}^{\uparrow}$ face, the fused $\mathsf{StreamName}^{\uparrow}$ finite-window packet, the displayed $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, and the $\mathsf{Real}^{\uparrow}$ L10 finite-window boundary.

Use finite-tail window confluence, Definition 291.62, on the two factorizations. The shared terminal scale-window packet already fixes the DyadicRatCore and StreamName faces, while the hypothesis fixes the RegSeqRat finite-request section.

Finally invoke the StreamName and Real completion pullback rows, Definition 126.504, Definition 126.514, and Definition 38.464. These rows identify the Real-facing boundary exactly from the common four faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support.

The cited exclusion clauses remove quotient stream equality, selected limits, host rational equality, ambient completeness, and Real completeness from each step. Therefore the two reads determine the same finite pullback route and nothing outside the displayed BEDC rows. □

Theorem 291.67 (DyadicRatCore finite-tail common scale-window reduction)**.** *Let two finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 reads have* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces obtained from displayed DyadicRatCore packets by finite positive-unary exponent widenings. Suppose both widened faces are read through the same displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet and share a terminal scale-window packet of Definition 291.40. Then the two reads determine the same visible* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section.*

Consequently the hypotheses of Definition 291.66 reduce to the common displayed scale-window route together with the common $\mathsf{StreamName}^{\uparrow}$ *finite-window packet. The reduction exports no quotient stream equality, selected limit, host rational equality, ambient completeness row, or* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First apply scale-window terminal fusion, Definition 291.46. The common terminal packet identifies the widened $\mathsf{DyadicRatCore}^{\uparrow}$ comparison face for both reads using only displayed scale transports, componentwise hsame rows, Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

Next use finite-tail window factorization, Definition 291.61, on each read. Since both reads pass through the same $\mathsf{StreamName}^{\uparrow}$ finite-window packet, the factorization exposes one downstream finite request surface for the $\mathsf{RegSeqRat}^{\uparrow}$ handoff rather than two independent request sections.

Now apply RegSeqRat bridge handoff exactness, Definition 291.28. The handoff consumes exactly the public DyadicRatCore envelope visible through the shared StreamName packet, so the displayed signed mantissa row, positive unary exponent row, denominator ledger, common-exponent classifier, arithmetic window, distance window, radius window, BHist carrier data, hsame transport, Cont readback, and Pkg provenance are the same on both sides.

Therefore the visible $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section is common. Feeding this derived section match, together with the already common terminal scale-window packet, into Definition 291.66 gives the same finite pullback route over BHist, hsame, Cont, Pkg, and the local $\mathsf{NameCert}$ rows.

The exclusion clauses of terminal fusion, factorization, and bridge handoff are preserved by this reduction. Hence the argument does not assert quotient stream equality, selected limits, host rational equality, ambient completeness, or any $\mathsf{Real}^{\uparrow}$ completeness principle. □

Theorem 291.68 (DyadicRatCore finite-tail cofinal section)**.** *Let a finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 read have a* $\mathsf{DyadicRatCore}^{\uparrow}$ *face lying on a finite positive-unary cofinal scale-window route. Then the visible cofinal route determines one* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section and one* $\mathsf{Real}^{\uparrow}$ *seal-visible source section through*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The determined sections use only the displayed BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows of the route.*

No quotient stream equality, selected limit, host rational equality, ambient completion row, metric-completeness datum, or $\mathsf{Real}^{\uparrow}$ *completeness principle is part of the section data.*

Proof. Start from the finite positive-unary cofinal scale-window route. By scale-window cofinality, Definition 291.42, the visible $\mathsf{DyadicRatCore}^{\uparrow}$ face reaches the terminal scale-window packet through displayed scale transports, componentwise hsame rows, Cont replay, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ data.

Next apply finite-tail window factorization, Definition 291.61. The finite-tail $\mathsf{Real}^{\uparrow}$ read is therefore routed through the fused $\mathsf{StreamName}^{\uparrow}$ finite-window packet, then through the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, and finally through the $\mathsf{Real}^{\uparrow}$ L10 finite-window boundary.

Use the common scale-window reduction, Definition 291.67, to identify the $\mathsf{RegSeqRat}^{\uparrow}$ section as the one forced by the visible cofinal route. The reduction removes any choice of a second request section once the displayed scale-window route and the displayed $\mathsf{StreamName}^{\uparrow}$ finite-window packet are fixed.

Finally apply StreamName finite-request section budget exactness, Definition 126.556, and StreamName finite-request section pullback, Definition 126.577. These rows identify the Real-facing section as the same displayed packet over the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces.

The cited nonescape clauses exclude quotient stream equality, selected limits, host rational equality, ambient completion, metric-completeness data, and RealUp completeness from every step. Thus the cofinal finite-tail route determines exactly the finite-request and seal-visible source sections described above. □

Theorem 291.69 (DyadicRatCore RegSeqRat Real pullback composition)**.** *Let a finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 read have a* $\mathsf{DyadicRatCore}^{\uparrow}$ *face lying on a finite positive-unary scale-window route. Suppose the route displays its terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet, the induced* $\mathsf{StreamName}^{\uparrow}$

finite-window packet, the visible $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, and the* $\mathsf{Real}^{\uparrow}$ *seal-visible source section determined by the finite L10 boundary. Then these four faces compose as one BEDC pullback route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

over the displayed BHist, hsame, Cont, Pkg, *and local* NameCert *rows.*

The composed route is exactly the finite pullback handoff of the displayed packets. It does not identify quotient streams, select a limit, assert host rational equality, add ambient completion, import metric completeness, or prove $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with the finite positive-unary scale-window route. By Definition 291.68, the visible route determines a single $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section and a single $\mathsf{Real}^{\uparrow}$ seal-visible source section through the four displayed faces.

Next apply the common scale-window reduction, Definition 291.67. It turns the common terminal $\mathsf{DyadicRatCore}^{\uparrow}$ packet and the induced $\mathsf{StreamName}^{\uparrow}$ finite-window packet into the same visible $\mathsf{RegSeqRat}^{\uparrow}$ request section, so the middle face is not a second choice point.

Use StreamName finite-request section budget exactness, Definition 126.556, to bind the StreamName packet to the same finite request budget. The request budget is therefore the one consumed by the RegSeqRat section already forced by the scale-window route.

Now invoke finite-tail scale-window pullback exactness, Definition 291.66. Its hypotheses are exactly the terminal scale-window packet, the induced StreamName packet, and the visible RegSeqRat section built above, so it packages the DyadicRatCore, StreamName, RegSeqRat, and Real faces as one finite pullback route over BHist, hsame, Cont, Pkg, and local NameCert rows.

Finally apply Real L10 finite-window witness determinacy, Definition 38.464. This fixes the seal-visible Real source section reached by the composed route and prevents a second Real-facing witness from entering the handoff.

The exclusion clauses in the cited results remove quotient stream equality, selected limits, host rational equality, ambient completion, metric completeness, and $\mathsf{Real}^{\uparrow}$ completeness at each step. The conclusion is therefore only the composed finite BEDC pullback route. □

Theorem 291.70 (DyadicRatCore finite-tail endpoint invariance)**.** *Let two finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 reads have* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces on finite positive-unary scale-window routes. Suppose the two presentations display the same terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet, the same induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, and the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source section. Suppose also that their endpoint-facing rows share the same* BHist, hsame, Cont, Pkg, *and local* NameCert *support over these four faces. Then every endpoint-facing* $\mathsf{Real}^{\uparrow}$ *consumer reads the same finite BEDC endpoint route from the two presentations.*

The invariant endpoint is only the finite route exposed by the four L10 faces. It is not quotient stream equality, a selected limit, host rational equality, ambient completion, metric completeness, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply finite-tail scale-window pullback exactness, Definition 291.66. The shared terminal $\mathsf{DyadicRatCore}^{\uparrow}$ packet and shared $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section identify the same finite pullback route over the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Next apply the common scale-window reduction, Definition 291.67. Since the two presentations also share the induced $\mathsf{StreamName}^{\uparrow}$ finite-window packet, the RegSeqRat request section is forced by the visible scale-window route rather than supplied as an independent endpoint choice.

Now use the RegSeqRat–Real pullback composition, Definition 291.69. It composes the shared DyadicRatCore packet, StreamName finite-window packet, RegSeqRat finite-request section, and Real seal-visible source section as one BEDC pullback route through the endpoint-facing rows.

Finally invoke Real L10 finite-window witness determinacy, Definition 38.464. Any $\mathsf{Real}^{\uparrow}$ consumer that only sees the finite L10 endpoint boundary must therefore read the same seal-visible endpoint route from either presentation.

The cited nonescape clauses exclude quotient stream equality, selected limits, host rational equality, ambient completion, metric completeness, and $\mathsf{Real}^{\uparrow}$ completeness. Hence the conclusion is endpoint invariance of the displayed finite BEDC route, not equality in any ambient completion. □

Theorem 291.71 (DyadicRatCore finite-request Real-seal uniqueness)**.** *Let two finite-tail* $\mathsf{Real}^{\uparrow}$ *L10 reads have* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces on finite positive-unary scale-window routes. Suppose the two presentations share the same terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet, the same induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window packet, the same visible* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, and the same seal-visible* $\mathsf{Real}^{\uparrow}$ *source section. Suppose also that the displayed consumer rows expose the same* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support over these four faces. Then every Real-seal consumer reads one unique finite request route through*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

over the displayed rows.

The unique route is only the finite Real-seal request route visible to the consumer. It does not identify quotient streams, choose a selected limit, assert host rational equality, add ambient completion, import metric completeness, or prove $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply the finite-tail common scale-window reduction, Definition 291.67. The shared terminal $\mathsf{DyadicRatCore}^{\uparrow}$ packet and shared induced $\mathsf{StreamName}^{\uparrow}$ packet force one visible $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, so the middle request surface cannot split into two consumer routes.

Next use the RegSeqRat–Real pullback composition, Definition 291.69. It composes the terminal DyadicRatCore packet, StreamName finite-window packet, RegSeqRat finite-request section, and seal-visible Real source section as one finite BEDC pullback route over the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Finally apply finite-tail endpoint invariance, Definition 291.70. Since the two presentations expose the same endpoint-facing support over the same four faces, any Real-seal consumer that reads only the displayed finite boundary must read the same finite request route from both presentations.

The nonescape clauses in the three cited results exclude quotient stream equality, selected limits, host rational equality, ambient completion, metric completeness, and $\mathsf{Real}^{\uparrow}$ completeness. Therefore the uniqueness is exactly Real-seal finite-request uniqueness over the displayed BEDC rows. □

Theorem 291.72 (DyadicRatCore Real-completion obstruction ledger)**.** *For a current Phase Real and Completion exit read whose dyadic face is displayed by a* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet, failure is localized exactly at one of the following finite sites:*

1. *the dyadic source row or its componentwise transport is absent;*
2. *the induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window face is absent or does not read the same finite window;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section is absent or leaves the displayed request surface;*
4. *the local* $\mathsf{Real}^{\uparrow}$ *seal is absent or does not seal the displayed finite request;*
5. *one of the support rows* BHist*,* hsame*,* Cont*,* Pkg*, or* NameCert *is absent or is not transported with the four faces.*

Equivalently, once the dyadic source and transport row, the $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the local* $\mathsf{Real}^{\uparrow}$ *seal, and the listed support rows are all present over the same displayed packet, the exit read has no further obstruction.*

The ledger is only a finite obstruction account for the displayed BEDC route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

It exports no quotient stream equality, host real equality, selected limit, countable-choice selector, ambient completeness principle, metric-completeness row, or bridge row beyond the displayed dyadic-facing packet.

Proof. For the forward direction, apply Definition 291.39. It localizes any failed public dyadic handoff to the dyadic source inventory, the $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ read-back face, the local $\mathsf{Real}^{\uparrow}$ seal, or the shared BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Next apply Definition 126.523. This keeps the StreamName-facing Real-completion read on the same four-object exit surface and rules out moving the failure into an undisplayed completion object or choice of a limit.

Use Definition 301.77 to align the four faces. The StreamName schedule rows, DyadicRatCore endpoint and radius rows, RegSeqRat classifier and regularity rows, and local Real seal row are necessary and sufficient for the same finite BHist route.

Finally use Definition 38.464. Once the local $\mathsf{Real}^{\uparrow}$ seal-visible finite window is fixed by those faces, no second Real-facing witness remains from which a distinct failure site could be read.

For the reverse direction, suppose one of the five listed finite sites is missing or not transported componentwise. The corresponding local theorem blocks the route at exactly that face: the DyadicRatCore handoff theorem blocks source and support defects, the StreamName localization theorem blocks finite-window defects, the RegSeqRat boundary theorem blocks finite-request defects, and the Real L10 determinacy theorem blocks local seal defects.

Therefore absence of any listed site is an obstruction, while presence of all five sites composes the same finite exit route by Definition 291.71. The exclusion clauses of the four cited results remove quotient stream equality, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, and extra bridge rows from the ledger. □

Theorem 291.73 (DyadicRatCore finite-tail obstruction minimality)**.** *For a current Phase Real and Completion exit read whose dyadic face is displayed by a* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet, each finite site in Definition 291.72 is independently necessary. The dyadic source and componentwise transport row, the induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the local* $\mathsf{Real}^{\uparrow}$ *seal, and the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support cannot be supplied by any combination of the other four sites.*

When all five sites are present over the same displayed packet, the obstruction ledger and Definition 291.71 leave no further finite obstruction for the displayed route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

This minimality claim is only about the finite BEDC exit route. It does not identify quotient streams, select a limit, assert host rational or host real equality, add an ambient completion row, import a metric-completeness row, or add a bridge row.

Proof. The obstruction ledger, Definition 291.72, gives the five-site classification. It says that every failed exit read is localized at exactly the dyadic source and transport row, the StreamName

finite-window face, the RegSeqRat finite-request section, the local Real seal, or the shared BHist, hsame, Cont, Pkg, and NameCert support.

Independence follows by testing one missing site at a time. Without the dyadic source and componentwise transport row, the DyadicRatCore handoff cannot present the signed mantissa, positive unary exponent, denominator ledger, and common-exponent classifier consumed downstream, so the remaining four sites have no source inventory to transport.

Without the $\mathsf{StreamName}^{\uparrow}$ finite-window face, finite-tail common scale-window reduction, Definition 291.67, has no displayed finite window through which the dyadic packet can expose the RegSeqRat request surface. Supplying the other four sites would have to replace that face by quotient stream equality or a selected limit, both excluded by the route theorems.

Without the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, RegSeqRat–Real pullback composition, Definition 291.69, has no middle request row to compose with the StreamName packet and the Real seal. Replacing it would require host rational or host real equality outside the displayed BEDC rows.

Without the local $\mathsf{Real}^{\uparrow}$ seal, Real L10 finite-window witness determinacy cannot bind the endpoint-facing witness. The other four sites therefore do not create a Real-facing seal by themselves, and any substitute would amount to an ambient completion or metric-completeness row excluded from the finite route.

Without the shared BHist, hsame, Cont, Pkg, and NameCert support, the four visible faces are not transported over one packet. Replacing those rows by the faces alone would require an extra bridge row rather than the displayed local support.

Conversely, when all five sites are present over the same displayed packet, Definition 291.72 removes every finite obstruction listed in the classification, and Definition 291.71 gives one finite request route through the displayed faces. Hence none of the five sites is replaceable by the other four, and together they are sufficient for the finite exit route claimed here. □

Theorem 291.74 (DyadicRatCore finite-tail obstruction classifier determinacy)**.** *Let two current Phase Real and Completion exit reads have first visible face a finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Suppose the two reads expose the same terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet, the same induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the same local* $\mathsf{Real}^{\uparrow}$ *seal-facing section, and the same transported* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows over those four faces. Then the two obstruction classifiers agree exactly when the two reads fail at the same one of the five finite sites listed in Definition 291.72 over that shared support surface.*

The classifier comparison is only the finite BEDC comparison attached to

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

It excludes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, apply the obstruction ledger, Definition 291.72, to each failed read. Each read is classified by exactly one displayed finite site: the dyadic source and transport row, the $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, the local $\mathsf{Real}^{\uparrow}$ seal, or the transported support rows.

Now compare the two ledger classifications over the shared four-face support. If the classifiers agree while the sites differed, one of the five sites would be replaceable by the other four together with a different failed site. This contradicts finite-tail obstruction minimality, Definition 291.73, which makes each listed site independently necessary.

For the reverse direction, assume the two reads fail at the same listed finite site over the same $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows. Replay the local blocking theorem for that site on both reads: the DyadicRatCore handoff block for source and transport defects, the StreamName localization block for finite-window defects, the RegSeqRat boundary block for finite-request defects, the Real L10 determinacy block for local seal defects, and the support-transport block for shared row defects.

The same local blocking theorem reads the same failed coordinate in both presentations, so the obstruction classifiers agree. The nonescape clauses of the ledger and minimality theorem keep the result finite: it is a BEDC classifier determinacy statement, not a quotient-equality, selected-limit, choice, bridge, or completeness theorem. □

Theorem 291.75 (DyadicRatCore finite-tail exit-certificate equivalence)**.** *Let a current Phase Real and Completion exit read have first visible face a finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Then the read satisfies the objectwise exit certificate exactly when the five finite sites of Definition 291.72 are present over the same four-face packet*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

and the four faces $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and local* $\mathsf{Real}^{\uparrow}$ *each supply their local scoped-closure and audit-clean threshold rows. The support surface is exactly the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows transported with those four faces.*

This equivalence exports no quotient streams, selected limits, countable-choice selector, metric-completeness data, aggregate formalstatus row, aggregate bridge row, or $\mathsf{Real}^{\uparrow}$ *completeness theorem. The local* $\mathsf{Real}^{\uparrow}$ *face remains a face of the finite packet, not an ambient completeness object.*

Proof. For necessity, start with an accepted objectwise exit certificate. Apply the Real L10 objectwise face-status exit theorem, Definition 38.792, to read the certificate as four local face records over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$, together with the finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Now use the DyadicRatCore obstruction ledger, Definition 291.72. Since the read has first visible face a finite-tail $\mathsf{DyadicRatCore}^{\uparrow}$ scale-window packet, any missing dyadic source row, StreamName finite-window face, RegSeqRat finite-request section, local Real seal, or transported support row would be exactly one of the ledger obstructions. Therefore an accepted objectwise certificate contains all five finite sites over the same four-face packet.

For sufficiency, assume the five ledger sites are present over the same displayed packet and that each of the four faces supplies its local scoped-closure and audit-clean threshold rows. The ledger removes every finite obstruction, while finite-request Real-seal uniqueness, Definition 291.71, gives a single route through

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Apply the Real L10 current-phase exit local threshold theorem, Definition 38.796. It identifies precisely those four local threshold records, read with the displayed support rows, as the current Phase Real and Completion objectwise exit read.

Minimality comes from Definition 291.73. Removing any one of the five finite sites leaves a ledger obstruction that the other four sites cannot replace, so the equivalence cannot be shortened by substituting a different face or support coordinate.

Finally, the Real L10 threshold theorem keeps the closure and verification axes facewise, and the DyadicRatCore nonescape clauses keep the route finite. Hence the accepted roadmap exit read

is exactly the stated four-face certificate, with no quotient stream, selected limit, countable-choice selector, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, or $\mathsf{Real}^{\uparrow}$ completeness coordinate. □

Theorem 291.76 (DyadicRatCore finite-tail exit-certificate classifier reflection)**.** *Let a current Phase Real and Completion exit read have dyadic face a finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Then satisfying the objectwise exit certificate of Definition 291.75 is equivalent to its obstruction classifier reading the non-failing class over the five finite sites of Definition 291.72 on the same four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The classifier reflection uses only the displayed BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows transported with those four faces.*

It exports no quotient stream, selected limit, countable-choice selector, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, or $\mathsf{Real}^{\uparrow}$ *completeness theorem. The non-failing classifier class is therefore a finite BEDC readback of the objectwise exit certificate, not an ambient completion principle.*

Proof. Use Definition 291.75 to identify the objectwise exit certificate with the simultaneous presence of the five finite sites over the displayed four-face route. This gives the sufficiency and necessity sides of the certificate without adding any quotient stream, selected limit, choice row, metric-completeness datum, bridge row, or $\mathsf{Real}^{\uparrow}$ completeness theorem.

Next apply obstruction classifier determinacy, Definition 291.74. It says that two reads have the same obstruction classifier exactly when they fail at the same one of the five displayed sites over the same $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and local NameCert rows.

For a read satisfying the exit certificate, the equivalence theorem leaves no failed ledger site. Hence the determinacy theorem reads its classifier as the single non-failing class attached to that complete finite ledger.

Conversely, suppose the obstruction classifier reads the non-failing class over the five sites on the displayed route. By determinacy, there is no failed dyadic source and transport row, no failed $\mathsf{StreamName}^{\uparrow}$ finite-window face, no failed $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, no failed local $\mathsf{Real}^{\uparrow}$ seal, and no failed transported support row.

Finally use finite-tail obstruction minimality, Definition 291.73. It excludes replacing any one site by the other four, so the non-failing classifier class cannot be produced by a hidden substitute outside the displayed ledger. The five-site finite ledger is therefore exactly the objectwise exit certificate. □

Theorem 291.77 (DyadicRatCore finite-tail exit-certificate refinement invariance)**.** *Let* $\mathcal{E}$ *and* $\mathcal{E}'$ *be current Phase Real and Completion exit reads whose first visible face is a finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packet. Suppose* $\rho : \mathcal{E} \to \mathcal{E}'$ *is a certified finite refinement whose visible action preserves the four displayed faces* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and local* $\mathsf{Real}^{\uparrow}$*, and preserves the displayed support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Then* $\mathcal{E}$ *and* $\mathcal{E}'$ *determine the same objectwise exit certificate of Definition 291.75.*

Conversely, if the objectwise exit certificates determined by $\mathcal{E}$ *and* $\mathcal{E}'$ *are equal, then on the displayed four-face section this equality recovers only a certified finite refinement preserving the four displayed faces and the displayed support rows above. It recovers no quotient stream equality, selected limit, host rational equality, host real equality, countable-choice selector, ambient completion*

row, metric-completeness row, aggregate formalstatus row, aggregate bridge row, standard bridge row, or $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. For invariance under a certified finite refinement, read both exit reads through Definition 291.75. The certificate is exactly the finite-tail $\mathsf{DyadicRatCore}^{\uparrow}$ source and transport row, the induced $\mathsf{StreamName}^{\uparrow}$ finite-window face, the $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section, the local $\mathsf{Real}^{\uparrow}$ seal, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support over one four-face packet.

Apply the StreamName terminal pullback, Definition 126.504. Since ρ preserves the four displayed faces and the support rows, the two reads factor through the same terminal finite pullback rather than through two independently chosen completion surfaces.

Now apply Real L10 refinement functoriality, Definition 38.805. It transports the current Phase Real and Completion certificate across exactly such a support-row-preserving finite refinement. The local threshold theorem, Definition 38.796, identifies the transported certificate as the objectwise product of the same four local threshold records and the same displayed support rows.

For the converse, assume the two objectwise exit certificates are equal. By Definition 291.75, equality of certificates identifies precisely the five finite sites listed in the DyadicRatCore obstruction ledger: the dyadic source and transport row, the StreamName finite-window face, the RegSeqRat finite-request section, the local Real seal, and the displayed support rows.

Use obstruction minimality, Definition 291.73. None of those five sites can be replaced by the other four, so the equality cannot recover a hidden quotient stream, selected limit, host equality, choice row, completion row, bridge row, or Real-completeness coordinate. The only recoverable comparison is the finite support-row-preserving refinement on the displayed four-face section.

Finally, the Real local threshold and the StreamName terminal pullback keep the recovered comparison inside the same finite terminal packet. Therefore finite refinements preserving the displayed faces and support rows are exactly the presentation changes under which the DyadicRatCore finite-tail exit certificate remains invariant. □

Theorem 291.78 (DyadicRatCore finite-tail exit-certificate cofinal-meet stability)**.** *Let* $\mathcal{E}_1$ *and* $\mathcal{E}_2$ *be current Phase Real and Completion exit reads whose first visible faces are finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packets. Suppose each read is related by a certified finite refinement to a common cofinal finite scale-window meet* $\mathcal{M}$*, and that both refinement legs preserve the four displayed faces* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and local* $\mathsf{Real}^{\uparrow}$*, together with the support rows* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. Then* $\mathcal{E}_1$*,* $\mathcal{E}_2$*, and their common meet* $\mathcal{M}$ *determine the same objectwise exit certificate of Definition 291.75.*

Conversely, equality of the objectwise exit certificates after passage to such a common cofinal meet reflects only the displayed finite rows: the four faces $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and local* $\mathsf{Real}^{\uparrow}$*, and the transported* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support. It reflects no quotient stream equality, selected limit, countable-choice selector, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, standard bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. First apply the finite-tail cofinal section theorem, Definition 291.68, to the visible cofinal route into $\mathcal{M}$. The route forces one $\mathsf{RegSeqRat}^{\uparrow}$ finite-request section and one local $\mathsf{Real}^{\uparrow}$ seal-visible section through the displayed four-face packet.

Next apply finite-tail scale-window pullback exactness, Definition 291.66. The common meet supplies the terminal $\mathsf{DyadicRatCore}^{\uparrow}$ scale-window packet, the shared $\mathsf{StreamName}^{\uparrow}$ finite-window face, the forced $\mathsf{RegSeqRat}^{\uparrow}$ section, and the local $\mathsf{Real}^{\uparrow}$ boundary, all over the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Transport the certificate from $\mathcal{E}_1$ to $\mathcal{M}$ by Definition 291.77. Apply the same theorem to the refinement leg from $\mathcal{E}_2$ to $\mathcal{M}$. Both transports land on the objectwise certificate determined by the common four-face packet, so the two original reads determine the same certificate.

For the converse, inspect the equality after transport to $\mathcal{M}$ using Definition 291.75. The certificate consists exactly of the five finite sites in the obstruction ledger: the dyadic source and transport row, the StreamName finite-window face, the RegSeqRat finite-request section, the local Real seal, and the transported support rows.

Finally use obstruction minimality, Definition 291.73. None of those finite sites can be replaced by quotient streams, selected limits, choice data, metric completeness, aggregate status, bridge rows, or Real-completeness coordinates. Hence equality after the cofinal meet reflects only the displayed finite rows and no hidden completion coordinate. □

Theorem 291.79 (DyadicRatCore finite-tail refinement support necessity)**.** *Let $\mathcal{E}$ and $\mathcal{E}'$ be current Phase Real and Completion exit reads whose dyadic faces are finite-tail* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packets. If a certified finite refinement between them preserves the objectwise exit certificate, then it preserves exactly the dyadic source and transport row, the induced* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the visible* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-request section, the local* $\mathsf{Real}^{\uparrow}$ *seal, and the transported* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows.*

Conversely, dropping any one of those rows prevents preservation of the objectwise exit certificate. The loss cannot be repaired by quotient stream equality, selected limits, host equality, choice data, metric completeness, aggregate status, bridge rows, standard bridge rows, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Expand the preserved certificate with Definition 291.75. It identifies the certificate with the five finite sites over the four-face route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Thus preservation of the objectwise exit certificate already reads the dyadic source and transport row, the induced StreamName finite-window face, the RegSeqRat finite-request section, the local Real seal, and the transported support rows as the whole certificate surface.

For the preservation direction, use finite-tail exit-certificate refinement invariance, Definition 291.77. A certified finite refinement that preserves the displayed faces and the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows transports the certificate and recovers no additional quotient, limit, host-equality, choice, metric, bridge, or completeness coordinate.

For common refinements, apply Definition 291.78. Passing both reads to a common cofinal finite scale-window meet preserves the same displayed rows and reflects equality of certificates back only along those rows.

It remains to show necessity of each support row. Use finite-tail obstruction minimality, Definition 291.73. If any one of the dyadic source and transport row, StreamName finite-window face, RegSeqRat finite-request section, local Real seal, or transported support rows is dropped, the missing site is an independent ledger obstruction and cannot be replaced by the other sites.

The nonescape clauses in the equivalence and minimality results exclude every ambient repair listed in the statement. Therefore certificate preservation for finite-tail $\mathsf{DyadicRatCore}^{\uparrow}$ exit reads is precisely facewise and support-row preserving, and no completion, quotient, choice, aggregate-status, or bridge coordinate can masquerade as finite refinement data. □

$\mathsf{DyadicRatCore}^{\uparrow}$ reads its signed mantissa row and denominator ledger through the integer and rational certificate surfaces of chapter 31 and chapter 37. It then supplies the finite dyadic tolerance

ledger consumed by chapter 126, chapter 301, and chapter 38, while exporting no host rational quotient, selected real limit, or $\mathsf{Real}^{\uparrow}$ completeness theorem.

Theorem 291.80 (DyadicRatCore L10 sibling dependency totality)**.** *Every accepted Phase Real or completion-facing consumer that reaches* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *through a dyadic tolerance face consumes exactly the signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, positive* UnaryHistory *exponent row, denominator ledger, common-exponent classifier, radius/distance windows, and displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support supplied by* $\mathsf{DyadicRatCore}^{\uparrow}$*. Conversely, those rows supply the dyadic face required by the* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, and the* $\mathsf{Real}^{\uparrow}$ *terminal seal. The total route exports no quotient rational equality, quotient stream equality, host real equality, selected limit, countable choice, ambient completeness, metric-completeness row, or* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. For the consumer-to-dyadic direction, apply Definition 291.24. It identifies the public dyadic consumer inventory with the signed mantissa, positive unary exponent, denominator ledger, common-exponent classifier, finite windows, displayed history and sameness rows, readback, package provenance, and certificate support already supplied by $\mathsf{DyadicRatCore}^{\uparrow}$.

The standard-source bridge of Definition 291.25 keeps that inventory fixed when the dyadic face is presented to sibling consumers. Then Definition 291.28 gives the RegSeqRat handoff exactness for the same endpoint, radius, and finite-window rows.

For the reverse direction, start with precisely those $\mathsf{DyadicRatCore}^{\uparrow}$ rows. The StreamName terminal pullback of Definition 126.504 places the DyadicRatCore face, the finite StreamName schedule, the RegSeqRat regular source, and the local Real seal in one terminal finite packet.

Finally apply Definition 38.738. It reads the ordered route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

and excludes quotient rational or stream equality, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, and $\mathsf{Real}^{\uparrow}$ completeness from the route. These exclusions are exactly the non-rows listed in the theorem statement. □

Theorem 291.81 (DyadicRatCore StreamName finite-window radius transport)**.** *Whenever a* $\mathsf{StreamName}^{\uparrow}$ *finite-window consumer reads a* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint/radius ledger and then hands the read to a* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer or to a* $\mathsf{Real}^{\uparrow}$ *seal route, the transported finite window preserves the same signed* $\mathsf{Rat}^{\uparrow}$ *mantissa row, positive* UnaryHistory *exponent row, common-exponent classifier, radius/distance window, and displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. The transport introduces no point carrier, quotient rational equality, quotient stream equality, selected limit, host real equality, countable-choice row, metric-completeness row, or* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Start with the endpoint/radius ledger supplied by Definition 291.80. That theorem identifies the dyadic consumer surface with the signed mantissa, positive unary exponent, denominator, classifier, finite radius and distance windows, and the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Apply Definition 126.442. The StreamName finite-window read is anchored to this dyadic observation ledger before any downstream consumer can inspect it, so the projection keeps the same rows rather than replacing them by a detached stream or host-real witness.

For the RegSeqRat handoff, use Definition 291.28. It reads the same endpoint/radius packet as the regular-rational finite window, preserving the classifier and radius/distance rows already visible through the StreamName projection.

For the Real seal route, apply Definition 38.738. Its ordered route reads the DyadicRatCore face through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ before the local $\mathsf{Real}^{\uparrow}$ seal, so the Real-facing packet inherits the same finite support rows.

The exclusion clauses in these three route theorems rule out every additional point carrier, quotient rational or stream equality, selected limit, host real equality, countable-choice row, metric-completeness row, and $\mathsf{Real}^{\uparrow}$ completeness coordinate. Hence the finite-window transport is exactly the displayed DyadicRatCore radius ledger throughout the StreamName, RegSeqRat, and Real consumers. □

Theorem 291.82 (DyadicRatCore common scale-window triangle ledger)**.** *Let three accepted L10 consumers among the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *routes expose dyadic faces that each factor through pairwise* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window packets. Then the three faces admit one common finite directed-meet scale window. That window carries the signed mantissa row, refined positive-unary exponent row, denominator ledger, common-exponent comparison row, distance and radius rows, componentwise* hsame *transports, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows for all three consumer faces.*

The triangle ledger exports no quotient rational, host epsilon equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice selector, metric-completeness row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First place each pairwise dyadic face on a terminal scale-window packet by applying Definition 291.46. The pairwise packets therefore expose the same kind of signed mantissa, positive-unary exponent, denominator, comparison, transport, readback, provenance, and local NameCert rows.

Next apply Definition 291.34 to the finite family consisting of the three pairwise terminal packets. The directed meet supplies one common finite monotone radius window carrying the shared refined exponent, denominator ledger, common-exponent classifier, distance rows, carrier rows, hsame transports, Cont readbacks, Pkg provenance, and local NameCert row.

Use Definition 291.32 at each consumer boundary. It forces the $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ read to pass through the displayed radius handoff before any terminal seal can consume the dyadic packet, so the three L10 faces cannot split into separate ambient dyadic sources.

Finally apply Definition 291.80. It reads the same finite dyadic rows through the route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

and identifies those rows as the dyadic source consumed by the L10 real-and-completion boundary.

The exclusion clauses of the terminal fusion, directed meet, directed-refinement handoff, and L10 route leave no row for quotient rationals, host epsilon equality, selected real endpoints, countable-choice selectors, metric-completeness data, or $\mathsf{Real}^{\uparrow}$ completeness. Hence the common window is exactly the finite triangle ledger stated above. □

Theorem 291.83 (DyadicRatCore four-face pullback correspondence)**.** *Let three accepted L10 consumers expose dyadic faces satisfying Definition 291.82. Suppose the same visible rows are also consumed by a terminal four-face route through*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the common scale-window triangle ledger and the terminal four-face pullback determine one another exactly on the signed mantissa, refined positive-unary exponent, denominator ledger, common-exponent comparison, distance and radius rows, StreamName finite window, RegSeqRat classifier and readback rows, Real seal row, componentwise hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

This correspondence exports no quotient rationals, quotient streams, host ε equality, selected $\mathsf{Real}^{\uparrow}$ *endpoints, countable choice, metric completeness, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or standard bridge data.*

Proof. Begin with the three accepted L10 dyadic faces. Apply Definition 291.82 to obtain the common directed-meet scale window over the three consumers. The result supplies the signed mantissa row, refined exponent row, denominator ledger, comparison row, distance and radius rows, transports, continuations, package provenance, and local DyadicRatCore naming surface.

Next place that same finite window on the downstream route. Use Definition 126.356 to read the DyadicRatCore window as the StreamName finite window, RegSeqRat classifier and readback surface, and Real seal boundary consumed by the ordered route. Then apply Definition 38.455 and Definition 38.458. These identify the terminal presentation with the displayed four faces and leave no hidden terminal coordinate beyond the listed rows.

For the reverse direction, start from the terminal four-face pullback. Read its DyadicRatCore face together with the displayed StreamName, RegSeqRat, and Real rows. The pullback uniqueness fixes the same BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ coordinates, so the dyadic face restricts to the common finite scale window supplied by the triangle ledger.

The cited pullback and terminal results add no quotient rational carrier, quotient stream equality, host ε equality, selected real endpoint, countable-choice selector, completeness datum, metric-completeness row, or standard bridge witness. Hence the two presentations determine exactly the same BEDC-visible finite surface. □

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreCarrier common scale window four face pullback correspondence`

Theorem 291.84 (DyadicRatCore terminal Real exit source uniqueness)**.** *Let two accepted Phase Real and Completion terminal exits expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, local* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *coordinates. Suppose both exits are accepted through the terminal four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then their $\mathsf{DyadicRatCore}^{\uparrow}$ *scale-window sources agree as the same common finite triangle ledger. In particular there is no independent dyadic source branch behind the shared terminal* $\mathsf{Real}^{\uparrow}$ *seal: the signed mantissa, refined positive-unary exponent, denominator ledger, common-exponent comparison, distance and radius rows, componentwise transports, displayed continuations, package provenance, and local DyadicRatCore naming rows are the same BEDC-visible source data for both exits.*

This uniqueness exports no quotient rational, quotient stream, host ε equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable choice, metric completeness, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or standard bridge row.*

Proof. Apply Definition 291.83 to each accepted exit. Each terminal presentation is therefore determined by a common finite triangle ledger together with the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next use Definition 126.351. Since the two exits expose the same downstream $\mathsf{StreamName}^{\uparrow}$ finite-window surface and the same $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows, both routes pass through the same four ordered faces. The four-face source lattice leaves no extra source edge between the StreamName window and the Real seal.

Finally apply Definition 38.458 to the shared terminal boundary. The two accepted terminal pullbacks over the same four faces and support coordinates are identified, so any difference in signed mantissa, exponent, denominator, distance, or radius rows would create a second four-face packet over the same terminal seal.

That second packet is impossible by the shared terminal pullback. Hence both exits read the same $\mathsf{DyadicRatCore}^{\uparrow}$ scale-window source as the common finite triangle ledger, and the exclusion clause follows from the corresponding four-face and terminal uniqueness inventories. □

Theorem 291.85 (DyadicRatCore four-face window-refinement cocycle)**.** *Let three accepted finite positive-unary scale-window refinements expose pairwise* $\mathsf{DyadicRatCore}^{\uparrow}$ *faces, and suppose each pairwise face maps through the displayed route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the two ways of passing from the pairwise common scale windows to a terminal four-face pullback agree on the signed mantissa, refined positive-unary exponent, denominator ledger, common-exponent comparison, distance and radius rows, $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *rows.*

The cocycle exports no quotient rational or quotient stream equality, selected limit, choice row, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 291.82 to the three accepted pairwise scale-window refinements. This supplies one common finite dyadic window carrying the signed mantissa, refined exponent, denominator ledger, comparison, distance, radius, transport, continuation, package, and local NameCert rows for the three faces.

Next apply Definition 291.83. The common dyadic window is identified with the terminal four-face pullback over the route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so any comparison between two refinement orders is reduced to a comparison of the same four displayed faces.

Use Definition 126.550 on the downstream triple overlap. It makes the $\mathsf{StreamName}^{\uparrow}$ finite window and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier/readback seal independent of the order in which the three finite overlaps are assembled.

Finally apply Definition 301.69. The handoff exactness carries the downstream cocycle back across the $\mathsf{DyadicRatCore}^{\uparrow}$ source and forward to the $\mathsf{Real}^{\uparrow}$ seal row, preserving the componentwise hsame, displayed Cont, Pkg, and local NameCert coordinates. Thus both refinement paths determine the same terminal four-face surface, and the exclusion clause is inherited from the triangle ledger, four-face correspondence, triple-overlap seal, and handoff exactness results. □

Theorem 291.86 (DyadicRatCore common-scale choice-free triangle)**.** *Let three terminal L10 dyadic faces expose pairwise* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale windows over the route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The common finite scale window obtained for the three faces is determined by directed finite refinement of the displayed signed mantissa rows, refined positive-unary exponent rows, denominator ledgers, common-exponent comparison rows, distance and radius rows, componentwise hsame*, displayed* Cont*,* Pkg*, and local* NameCert *support. It is not determined by choosing rational representatives, endpoints, host epsilon data, quotient streams, or selected RealUp limits.*

Thus every downstream StreamName, RegSeqRat, or Real terminal read of the triangle consumes the same common finite dyadic ledger.

Proof. First apply Definition 291.82. It constructs the common scale window as a directed finite meet of the three displayed dyadic faces, carrying exactly the mantissa, exponent, denominator, comparison, distance, radius, transport, replay, provenance, and local naming rows.

Next use the directed meet and refinement handoff invoked in that ledger. Each refinement step keeps the same finite row inventory and has no coordinate for a selected rational representative, endpoint selector, host epsilon witness, quotient stream, or selected Real limit.

Now apply Definition 291.83. The common dyadic window is the source read by the downstream StreamName, RegSeqRat, and Real faces, so any alternate choice of representatives would have to produce a second four-face pullback over the same visible rows.

Finally use Definition 291.85. The cocycle identifies the terminal four-face surface for all orders of finite refinement. Therefore the common-scale triangle is choice-free and is determined only by the directed finite refinement ledger displayed above. □

Theorem 291.87 (DyadicRatCore terminal Real exit has no fifth source)**.** *Let an accepted Phase Real and Completion terminal* $\mathsf{Real}^{\uparrow}$ *exit be accepted through the route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the visible $\mathsf{DyadicRatCore}^{\uparrow}$ *scale window, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and classifier surface, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support exhaust the source inventory of the exit.*

No fifth source, aggregate formalstatus row, bridge row, quotient stream, selected limit, countable-choice row, metric-completeness row, or $\mathsf{Real}^{\uparrow}$ *completeness coordinate can compensate for a missing one of those four faces or its displayed BEDC support rows.*

Proof. Apply Definition 291.83. It identifies the terminal route with exactly the four visible faces: the dyadic scale-window face, the StreamName finite-window face, the RegSeqRat readback and classifier face, and the local Real seal face, together with the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 291.84. Once the downstream StreamName, RegSeqRat, Real, and support rows are fixed, the dyadic source is forced to be the same common finite triangle ledger. Thus a different dyadic source would be a second terminal pullback over the same four-face surface.

Finally apply Definition 38.730 and Definition 38.729. They make the L10 exit facewise: each of the four route positions must be present with its own support and local status rows, and no aggregate token or off-table Real-completeness datum can supply an absent face.

The exclusion inventories in the DyadicRatCore four-face correspondence, the terminal Real exit source uniqueness theorem, and the Real L10 route theorems list exactly the rows outside the route: quotient streams, selected limits, countable choice, metric completeness, bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness. Since none of those rows belongs to the four-face source surface, the displayed inventory is exhausted and there is no fifth compensating source. □

Theorem 291.88 (DyadicRatCore common scale regular-name interface)**.** *Let an accepted regular-name route expose a* $\mathsf{StreamName}^{\uparrow}$ *finite-window face and a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity face, and suppose both faces consume the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *common scale window along the L10 route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the two regular-name consumers read the same signed mantissa row, positive-unary exponent row, denominator ledger, common-exponent comparison, distance and radius rows, componentwise hsame *transports, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows. The*

StreamName finite-window face and the RegSeqRat regularity face therefore form one BEDC-visible regular-name interface over the common DyadicRatCore scale window.

This interface exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable choice, metric-completeness row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Apply Definition 291.82 to the accepted route faces. The common finite scale window supplies the signed mantissa, positive-unary exponent, denominator ledger, comparison, distance, radius, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows before either downstream consumer reads the dyadic packet.

Next apply Definition 291.83. It identifies that dyadic window with the ordered four-face route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so the StreamName finite-window face and the RegSeqRat classifier and readback face are projections of the same pullback surface rather than independent regular-name sources.

Use the StreamName and RegSeqRat handoff rows Definition 126.356, Definition 301.25, and Definition 301.69. These rows force the finite-window consumer and the regularity consumer to preserve the displayed DyadicRatCore rows across the regular-name boundary, including the componentwise transports, continuations, package provenance, and local naming coordinates.

Finally apply Definition 291.87. Since the terminal L10 exit has only the dyadic scale window, the StreamName finite window, the RegSeqRat regularity/readback surface, the Real seal, and the displayed support rows, none of the excluded objects can supply another regular-name coordinate. The two consumers therefore read exactly the same common-scale interface, with no quotient rational, quotient stream, selected endpoint, choice row, metric-completeness row, or Real-completeness coordinate. □

Theorem 291.89 (DyadicRatCore common scale comparison)**.** *Let two accepted common scale windows expose the same signed mantissa row, positive-unary exponent row, denominator ledger, distance and radius rows,* $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *rows. Suppose both windows are consumed by the regular-name and Real seal route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the two windows compare by the same finite directed-refinement ledger. Consequently every downstream $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer reads the same tolerance order from the common scale surface.*

The comparison exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First place the two accepted windows in the common triangle ledger of Definition 291.82. The shared signed mantissa, exponent, denominator, distance, radius, transport, replay, provenance, and local naming rows determine the finite directed-refinement surface on which both windows are read.

Next apply Definition 291.83. It identifies the directed-refinement ledger with the terminal four-face route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so the comparison cannot split into separate dyadic and regular-name sources.

Use Definition 291.84 at the terminal Real seal. Since the two windows expose the same downstream StreamName, RegSeqRat, Real, hsame, Cont, Pkg, and NameCert rows, terminal uniqueness forces the same DyadicRatCore source ledger behind both exits.

Finally apply Definition 291.88. The regular-name consumer reads the common dyadic scale window before the RegSeqRat readback and Real seal, so the directed-refinement order transported to RegSeqRat and RealUp is the same order for both windows. The exclusion clause is inherited from the triangle ledger, four-face pullback, terminal source uniqueness, and regular-name interface. □

Theorem 291.90 (DyadicRatCore common scale window composition coherence)**.** *Let $W_0 \leq W_1 \leq W_2$ be accepted nested* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale windows whose visible rows feed the ordered L10 route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume each window displays the signed mantissa row, positive-unary exponent row, denominator ledger, common-exponent comparison row, distance and radius rows, StreamName finite window, RegSeqRat classifier and readback rows, Real seal row, and the visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. Then the direct radius handoff from W_0 to W_2 and the two-step handoff from W_0 through W_1 to W_2 determine the same finite four-face exit certificate over the displayed route.*

The common certificate exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Apply Definition 291.41 to the two accepted inclusions $W_0 \leq W_1$ and $W_1 \leq W_2$. The visible mantissa, positive-unary exponent, denominator, comparison, distance, radius, BHist, hsame, Cont, Pkg, and local NameCert rows are therefore retained along both legs.

Next apply Definition 291.46. It identifies the direct W_0 to W_2 scale window with the terminal scale window obtained by first refining to W_1 and then refining to W_2, so the two radius handoff surfaces have the same finite dyadic row inventory.

Use Definition 291.77. The finite-tail exit certificate transported along the direct refinement agrees with the certificate transported along the nested refinement, because both are read from the same terminal fused dyadic window and the same displayed support rows.

Finally apply Definition 291.83. The equality of dyadic exit certificates pushes through the StreamName finite-window face, the RegSeqRat classifier and readback face, and the Real seal face. The exclusions in Definition 291.87 rule out any fifth source that could distinguish the direct and two-step certificates, so the two radius handoffs determine one finite four-face exit certificate. □

Theorem 291.91 (DyadicRatCore common scale distance-window invariant)**.** *Let two accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint/radius ledgers be transported to a common exponent scale, and suppose their visible distance-window comparison feeds the ordered L10 route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the displayed distance-window comparison is invariant under the common scale-window triangle ledger and composes through the terminal four-face pullback route. The invariant preserves the signed mantissa rows, refined positive-unary exponent rows, denominator ledgers, endpoint distance rows, radius rows, StreamName finite window, RegSeqRat classifier and readback rows, Real seal row, componentwise hsame*, displayed* Cont*,* Pkg*, and local* NameCert *coordinates.*

The invariant exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First place the two endpoint/radius ledgers inside a three-face comparison by adding the common-scale comparison face. Apply Definition 291.82. It supplies one finite directed-meet scale window carrying the mantissa, exponent, denominator, distance, radius, transport, replay, provenance, and local naming rows for the displayed comparison.

Next read that finite window through the terminal route. Apply Definition 291.83. The dyadic distance-window comparison is identified with the StreamName finite window, RegSeqRat classifier and readback rows, and Real seal row of the same four-face pullback.

Finally use Definition 291.90. Any refinement from one common exponent scale to another composes with the same direct radius handoff, so the distance-window comparison cannot depend on the chosen common-scale presentation.

The nonescape inventory is inherited from the triangle ledger, the four-face pullback correspondence, and the composition coherence theorem. None of those rows contains quotient rationals, quotient streams, selected endpoints, choice data, metric-completeness data, bridge rows, or ambient Real-completeness coordinates, so the stated invariant is exactly the displayed finite BEDC surface. □

Theorem 291.92 (DyadicRatCore common-scale order refinement)**.** *Let two accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison windows be lifted to a common exponent scale, and suppose their displayed comparison row is consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *finite window along the ordered route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

If that finite window is refined to any finer common scale carrying the same signed mantissa rows, refined positive-unary exponent rows, denominator ledgers, distance-window row, radius row, componentwise hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support, then the displayed dyadic order row is stable on the finer window. The RegSeqRat consumer reads the transported comparison row; it does not recompute order by selecting a new rational representative, quotient stream, host real comparison, or terminal* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Proof. Begin with the common exponent presentation. Apply Definition 291.82 to place the two comparison windows and the RegSeqRat finite-window consumer on one directed-meet scale ledger.

Next use Definition 291.91. The displayed distance-window comparison is invariant under the common scale ledger and through the terminal four-face route, so refining the scale preserves the comparison data already visible to the RegSeqRat window.

Apply Definition 291.94 on the finer common scale. It recovers the same tolerance request from the refined radius and distance rows, which prevents the finer window from introducing a different comparison source.

Finally transport the order row by the componentwise hsame coordinates carried by the refinement. Since the mantissa, exponent, denominator, distance, radius, continuation, provenance, and local naming rows are all retained, the RegSeqRat finite window consumes the transported order row rather than a new selector or host comparison. The exclusion clause follows from the same finite row inventory. □

Theorem 291.93 (DyadicRatCore four-face scale-window chain induction)**.** *Let*

$$W_0 \leq W_1 \leq \cdots \leq W_n$$

be a finite nonempty nested chain of accepted $\mathsf{DyadicRatCore}^{\uparrow}$ *scale windows whose visible rows feed the ordered L10 route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume each W_i displays the signed mantissa row, refined positive-unary exponent row, denominator ledger, common-exponent comparison row, distance and radius rows, StreamName finite window, RegSeqRat classifier and readback rows, Real seal row, and the visible BHist, hsame, Cont, Pkg, *and local* NameCert *support. Then the direct radius handoff from W_0 to W_n and every parenthesized finite composite of adjacent handoffs along the chain determine the same finite four-face exit certificate over the displayed route.*

The common certificate exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Induct on the finite chain length. In the terminal base case the chain has one window, and the direct certificate is the reflexive terminal fusion of that accepted $\mathsf{DyadicRatCore}^{\uparrow}$ scale window with its displayed support rows.

In the one-step case, apply Definition 291.41 to the adjacent inclusion. The visible mantissa, exponent, denominator, comparison, distance, radius, BHist, hsame, Cont, Pkg, and local NameCert rows are retained, so the unique adjacent handoff is already the direct handoff.

For the induction step, split the chain into the prefix

$$W_0 \leq W_1 \leq \cdots \leq W_{n-1}$$

and the last adjacent inclusion $W_{n-1} \leq W_n$. By the induction hypothesis, every parenthesized composite inside the prefix determines the same four-face certificate as the direct handoff from W_0 to W_{n-1}.

Now compose that prefix certificate with the final adjacent handoff. Apply Definition 291.90 to the three-window comparison $W_0 \leq W_{n-1} \leq W_n$. It identifies the direct W_0 to W_n handoff with the certificate obtained by first using the prefix handoff and then using the last adjacent inclusion.

Finally apply Definition 291.83 to push this equality through the StreamName finite-window face, the RegSeqRat classifier and readback face, and the Real seal face. The nonescape inventory of Definition 291.87 leaves no quotient rational, quotient stream equality, selected endpoint, countable-choice row, metric-completeness row, bridge row, or ambient Real-completeness row that could distinguish a different parenthesization. Thus every finite adjacent composite and the direct handoff determine one four-face exit certificate. □

Theorem 291.94 (DyadicRatCore common scale tolerance inversion)**.** *Let W_0 and W_1 be terminal four-face* $\mathsf{DyadicRatCore}^{\uparrow}$ *windows over the ordered L10 route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Assume the two windows share a common exponent scale after refinement and agree on the displayed dyadic radius row and distance-window row at that scale. Then the earlier tolerance request that generated the terminal comparison is recovered by the same common-scale ledger. The recovered request is read from the signed mantissa rows, positive-unary exponent rows, denominator ledgers, common-scale comparison row, radius row, distance row, StreamName finite window, RegSeqRat classifier and readback rows, Real seal row, and visible BHist, hsame, Cont, Pkg, *and* NameCert *support.*

The inversion exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, host real comparison, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First read the two terminal windows through Definition 291.91. The distance-window invariant places both presentations on the same common-scale ledger and preserves the displayed mantissa, exponent, denominator, radius, distance, transport, replay, provenance, and local naming rows.

Next use Definition 291.90. Since the radius rows agree after refinement, composing the earlier tolerance request into the terminal common scale gives the same radius handoff on both windows.

Apply Definition 291.93 to the finite chain from the earlier request to the terminal refined windows. The induction says that every parenthesized refinement path determines the same four-face exit certificate, so the common terminal radius and distance rows recover the unique earlier tolerance request along that chain.

Finally push the recovered request through Definition 291.83. The StreamName, RegSeqRat, and Real faces read the same finite dyadic ledger, while Definition 291.87 excludes quotient rationals, quotient streams, selected endpoints, host real comparisons, choice data, metric completeness, bridge rows, and ambient Real completeness as alternate recovery coordinates. □

Theorem 291.95 (DyadicRatCore common-scale terminal refinement)**.** *Let P and Q be two finite dyadic tolerance windows accepted by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier. Suppose their signed mantissa rows are read from the same* $\mathsf{Int}^{\uparrow}$ *ledger, and suppose each window presents its denominator row through a finite positive-unary exponent history. Then P and Q admit one common* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale window T with the following BEDC-visible rows:*

1. *the endpoint comparisons of P and Q transport to T by componentwise* hsame *and displayed* Cont *replay;*
2. *the denominator route of T factors through the same unary exponent tower used by the two input histories, with no host rational order or hidden denominator selector;*
3. *the terminal tolerance row of T is exactly the row consumed by the* $\mathsf{StreamName}^{\uparrow}$ *finite-window face of chapter 126, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity face of chapter 301, and the* $\mathsf{Real}^{\uparrow}$ *seal of chapter 38.*

The refinement exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Induct first on the finite positive-unary exponent history for P. The empty case leaves P at its displayed scale-window packet. The successor case applies Definition 291.41 to widen the endpoint comparison, denominator, distance, radius, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows by one displayed unary exponent step.

Induct in the same way on the finite positive-unary exponent history for Q. At each successor step the signed mantissa row remains the same $\mathsf{Int}^{\uparrow}$ ledger row by hypothesis, while the denominator row is transported only through the displayed unary tower. Thus both histories reach accepted terminal packets whose endpoint comparisons are still comparable by componentwise hsame over the common signed mantissa ledger.

Now apply Definition 291.82 to the two terminal dyadic packets together with the downstream L10 face. The common directed-meet window supplies one finite scale window carrying the shared signed mantissa row, refined positive-unary exponent row, denominator ledger, endpoint comparison rows, distance and radius rows, displayed continuations, package provenance, and local DyadicRatCore naming rows.

Finally use Definition 291.123. It identifies the terminal tolerance row of that common window with the four-face route

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow},$$

so the same row is the one consumed by the StreamName finite-window chapter, the RegSeqRat regularity chapter, and the Real seal chapter cited in the statement.

The exclusion clauses of scale-window monotonicity, the common scale-window triangle ledger, and terminal four-face tolerance exhaustion leave no quotient rational carrier, quotient stream equality, selected endpoint, countable-choice row, metric-completeness row, bridge row, or ambient Real-completeness coordinate. Hence the terminal refinement is a finite dyadic induction product rather than a prose route through external completion data. □

Theorem 291.96 (DyadicRatCore common-scale terminal refinement uniqueness)**.** *Let P and Q be finite dyadic tolerance windows accepted by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier, and let T and T' be two common* $\mathsf{DyadicRatCore}^{\uparrow}$ *terminal refinements of those same windows. Suppose T and T' preserve the same signed mantissa row, the same positive-unary exponent histories, the same denominator ledger, the same endpoint comparison rows, the same distance and radius rows, the same* hsame *and displayed* Cont *rows, the same* Pkg *provenance, the same local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows, and the same downstream four-face rows through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Then T and T' determine the same terminal tolerance row and the same finite four-face exit certificate over the route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The uniqueness statement uses no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Apply Definition 291.95 to the two presentations. Both T and T' are placed on common finite scale-window packets whose visible data are the signed mantissa ledger, positive-unary exponent histories, denominator ledger, endpoint comparisons, distance and radius rows, hsame, Cont, Pkg, and local DyadicRatCore naming rows.

Next apply Definition 291.83. The comparison of T and T' is therefore a comparison through the displayed four-face route, with the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{RegSeqRat}^{\uparrow}$ regularity surface, the $\mathsf{Real}^{\uparrow}$ seal row, and the DyadicRatCore tolerance ledger all read from the same finite support.

Now use Definition 291.84. Since the downstream StreamName, RegSeqRat, Real, and support rows agree, there is only one dyadic scale-window source for the exit. Hence the two terminal refinements have the same terminal tolerance row.

Finally apply Definition 291.87. With the dyadic source and the three downstream faces fixed, no additional route coordinate can distinguish the exits. The common tolerance row therefore determines one finite four-face exit certificate, and the excluded objects cannot supply a second certificate. □

Theorem 291.97 (DyadicRatCore finite directed common-scale terminal refinement)**.** *Let $\mathcal{F}$ be a finite family of dyadic tolerance windows accepted by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier. Suppose every member of $\mathcal{F}$ reads its signed mantissa row from the same displayed* $\mathsf{Int}^{\uparrow}$ *ledger and presents its denominator row through a finite positive-unary exponent history. Then repeated application of*

common-scale terminal refinement produces one accepted terminal $\mathsf{DyadicRatCore}^{\uparrow}$ *window* $T_{\mathcal{F}}$ *with the following properties:*

1. *every window in* $\mathcal{F}$ *maps to* $T_{\mathcal{F}}$ *by componentwise endpoint transport, denominator replay, distance and radius replay,* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows;*
2. *the terminal tolerance row of* $T_{\mathcal{F}}$ *is independent of the parenthesization used to combine the finite family;*
3. *the finite exit certificate determined by* $T_{\mathcal{F}}$ *is the same four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The construction exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Induct on the finite family $\mathcal{F}$. In the singleton case, the given accepted window is already the terminal packet for the one-member family after replaying its displayed positive-unary exponent history. The terminal four-face tolerance exhaustion theorem identifies its tolerance row with the route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

For the induction step, let S be the terminal window supplied for the preceding finite subfamily and let P be the next accepted tolerance window. Apply Definition 291.95 to S and P. The hypotheses are stable under the induction construction: the signed mantissa ledger remains the displayed $\mathsf{Int}^{\uparrow}$ ledger, and the denominator rows still factor through finite positive-unary exponent histories.

It remains to check that the chosen bracketing has not introduced extra data. Apply Definition 291.96 to two terminal windows obtained from two parenthesizations of the same finite family. Their visible signed mantissa, exponent, denominator, endpoint, distance, radius, hsame, Cont, Pkg, local DyadicRatCore naming, and downstream four-face rows agree by the induction hypothesis and by the pairwise refinement step. Hence the two bracketings determine the same terminal tolerance row.

Finally apply Definition 291.123. The terminal row is therefore the finite support consumed by the StreamName finite-window face, the RegSeqRat regularity face, and the Real seal face. The exclusion clauses are inherited from the pairwise refinement and uniqueness theorems, so no quotient carrier, quotient stream equality, selected endpoint, choice row, metric-completeness row, bridge row, or ambient Real-completeness coordinate enters the directed finite meet. □

Theorem 291.98 (DyadicRatCore common-scale terminal refinement permutation invariance)**.** *Let* $\mathcal{E}$ *and* $\mathcal{E}'$ *be two finite enumerations of the same finite family of dyadic tolerance windows accepted by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *carrier. Suppose every enumerated window reads its signed mantissa row from the same displayed* $\mathsf{Int}^{\uparrow}$ *ledger and presents its denominator row through a finite positive-unary exponent history. Suppose also that* $\mathcal{E}$ *and* $\mathcal{E}'$ *preserve the same signed mantissa ledger, the same finite exponent histories, the same denominator rows, the same endpoint comparison rows, the same distance and radius rows, the same* hsame *and displayed* Cont *rows, the same* Pkg *provenance, and the same local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows. Then the repeated common-scale terminal refinements determined by* $\mathcal{E}$ *and by* $\mathcal{E}'$ *determine the same terminal tolerance row and the same finite four-face exit certificate over*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

This permutation-invariance statement exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. It is enough to compare adjacent swaps of finite enumerations. The usual finite enumeration argument decomposes any reordering of the same family into a finite chain of adjacent transpositions, and each intermediate list preserves the same signed mantissa ledger, exponent histories, denominator rows, endpoint comparisons, distance and radius rows, hsame, Cont, Pkg, and local DyadicRatCore naming rows.

For one adjacent swap, first apply Definition 291.97 to the finite family underlying the two neighboring presentations. Both orders produce accepted terminal DyadicRatCore windows for the same finite support, and the directed-system theorem supplies the common terminal refinement row for that support.

Next apply Definition 291.96. The two terminal windows have the same displayed signed mantissa, exponent, denominator, endpoint, distance, radius, hsame, Cont, Pkg, local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$, and downstream four-face rows, so the adjacent swap cannot change the terminal tolerance row.

Induct along the finite chain of adjacent swaps from $\mathcal{E}$ to $\mathcal{E}'$. The base case is the identical enumeration. The step composes the equality of terminal tolerance rows supplied by the adjacent-swap comparison with the induction hypothesis, so the initial and final enumerations determine the same terminal row.

Finally apply Definition 291.123. The shared terminal tolerance row is exactly the finite support consumed by the StreamName finite-window face, the RegSeqRat regularity face, and the Real seal face. Since the support rows are fixed throughout the adjacent-swap induction, no quotient rational carrier, quotient stream equality, selected endpoint, countable-choice row, metric-completeness row, bridge row, or ambient Real-completeness coordinate can distinguish a second four-face exit certificate. □

Theorem 291.99 (DyadicRatCore directed common-scale normal form)**.** *Let* $\mathcal{F}$ *be a finite family of accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance windows whose signed mantissa rows are read from one displayed* $\mathsf{Int}^{\uparrow}$ *ledger and whose denominator rows are presented by finite positive-unary exponent histories. For every iterated common-scale refinement route through* $\mathcal{F}$*, there is one consumer-readable normal form* $N_{\mathcal{F}}$ *with the following rows:*

1. *each member of* $\mathcal{F}$ *maps to* $N_{\mathcal{F}}$ *by endpoint transport, denominator replay, distance and radius replay,* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *rows;*
2. *every* $\mathsf{StreamName}^{\uparrow}$ *finite-window face,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity face, and* $\mathsf{Real}^{\uparrow}$ *seal read from* $\mathcal{F}$ *factors through* $N_{\mathcal{F}}$*;*
3. *two constructions of* $N_{\mathcal{F}}$ *from different parenthesizations or refinement routes agree on the terminal tolerance row and on the four-face exit certificate over*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The normal form exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness data.*

Proof. Apply Definition 291.97 to the finite family $\mathcal{F}$. It supplies an accepted terminal window $T_{\mathcal{F}}$ whose visible rows are exactly the transported endpoint comparisons, denominator histories,

distance and radius rows, hsame, displayed Cont, Pkg, local DyadicRatCore naming rows, and terminal four-face exit support. Define $N_{\mathcal{F}}$ to be this displayed terminal packet together with those rows.

Next compare two iterated refinement routes through the same family. The directed-system theorem gives a terminal packet for each route, and Definition 291.96 identifies the two packets because their signed mantissa ledger, exponent histories, denominator ledger, endpoint comparisons, support rows, and downstream four-face rows are the same finite data. Thus parenthesization and route choices cannot change the terminal tolerance row.

It remains to justify the consumer-readable factorization. The terminal four-face certificate of the directed system is the route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Applying Definition 291.123 reads the StreamName finite-window face, the RegSeqRat regularity face, and the Real seal from that same terminal support, so each downstream consumer factors through $N_{\mathcal{F}}$ instead of through a separate pairwise refinement argument.

Finally, the exclusion clause follows from the same three inputs. The directed-system construction uses only finite accepted DyadicRatCore windows and positive-unary histories; uniqueness adds no hidden carrier; and terminal four-face exhaustion lists exactly the visible downstream support. Hence quotient rational carriers, quotient stream equality, selected Real endpoints, countable-choice rows, metric-completeness rows, bridge rows, and ambient Real-completeness data have no coordinate in $N_{\mathcal{F}}$. □

Theorem 291.100 (DyadicRatCore terminal refinement absorption)**.** *Let $\mathcal{F}$ be a finite family of accepted $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance windows whose signed mantissa rows are read from one displayed $\mathsf{Int}^{\uparrow}$ ledger and whose denominator rows are presented by finite positive-unary exponent histories. Let $T_{\mathcal{F}}$ be its terminal common refinement, and let P be another accepted $\mathsf{DyadicRatCore}^{\uparrow}$ window. Suppose P already maps to $T_{\mathcal{F}}$ by the displayed signed mantissa row, positive-unary exponent row, denominator row, endpoint comparison, distance and radius rows, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows. Then the terminal refinement of $\mathcal{F}\cup\{P\}$ determines the same terminal tolerance row as $T_{\mathcal{F}}$ and the same four-face exit certificate over*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The absorption statement exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ endpoint, countable-choice row, metric-completeness row, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness principle.

Proof. Apply Definition 291.99 to the family $\mathcal{F}$. It presents $T_{\mathcal{F}}$ as the consumer-readable normal form for the signed mantissa ledger, exponent histories, denominator rows, endpoint comparisons, distance and radius rows, hsame, Cont, Pkg, local naming rows, and downstream four-face support.

Now apply Definition 291.95 to $T_{\mathcal{F}}$ and the additional window P. The displayed map from P into $T_{\mathcal{F}}$ already provides every row the pairwise refinement may inspect, so the pairwise terminal packet carries the same signed mantissa, exponent, denominator, endpoint, distance, radius, transport, continuation, package, and naming support as $T_{\mathcal{F}}$.

Use Definition 291.96 to compare this pairwise terminal packet with $T_{\mathcal{F}}$ itself. Since the visible DyadicRatCore rows and the downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces agree, uniqueness identifies the terminal tolerance row.

Finally apply Definition 291.123. The shared terminal tolerance row is exactly the finite four-face exit certificate, so adjoining P adds no second terminal packet and no external quotient, selected endpoint, choice, metric-completeness, bridge, or ambient Real-completeness coordinate. □

Theorem 291.101 (DyadicRatCore common-scale terminal dichotomy)**.** *Let $\mathcal{R}$ be an accepted terminal tolerance route for a finite family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *windows whose signed mantissa rows are read from one displayed* $\mathsf{Int}^{\uparrow}$ *ledger and whose denominator rows are presented by finite positive-unary exponent histories. Then exactly one of the following BEDC-visible alternatives holds:*

1. *$\mathcal{R}$ factors through the directed common-scale normal form $N_{\mathcal{F}}$ of Definition 291.99, and its terminal tolerance row is the finite four-face exit certificate over*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow};$$

2. *the route omits at least one displayed signed mantissa row, exponent row, denominator row, endpoint row, tolerance row,* hsame *row,* Cont *row,* Pkg *row, or local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *row required by that normal form.*

The dichotomy exports no quotient rational carrier, quotient stream equality, selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable-choice row, metric-completeness row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First suppose the route displays every listed signed mantissa, exponent, denominator, endpoint, tolerance, hsame, Cont, Pkg, and local naming row. Apply Definition 291.99. The route is repacked into the consumer-readable normal form $N_{\mathcal{F}}$, and every downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ face factors through that packet.

Use Definition 291.96 to remove route choices. Any second accepted route with the same displayed rows has the same terminal tolerance row and the same finite four-face exit certificate, so the first alternative is determined by the visible data rather than by a hidden refinement choice.

Now suppose one of the displayed rows is absent. The normal-form theorem cannot be applied, because each factorization coordinate of $N_{\mathcal{F}}$ is a visible row: signed mantissa ledger, exponent history, denominator ledger, endpoint comparison, tolerance support, transport, continuation, package provenance, and local NameCert data.

Finally apply Definition 291.123. A successful terminal route exhausts exactly the four faces through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Therefore a route that lacks one required displayed row has no fifth source from which to recover it, and it falls into the failure alternative. □

Theorem 291.102 (DyadicRatCore terminal radius is choice-free)**.** *Let P and Q be accepted L10 terminal exits whose displayed packets share the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *face, the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window face, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback face, the same local* $\mathsf{Real}^{\uparrow}$ *seal face, and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Assume moreover that both exits present their dyadic tolerance data by finite positive-unary scale histories over the same signed mantissa and denominator ledgers. Then the terminal radius row displayed at the $\mathsf{Real}^{\uparrow}$ *seal is uniquely determined by the finite common-scale directed refinement of those rows.*

In particular, the terminal radius cannot be replaced by quotient rational equality, quotient stream equality, a selected $\mathsf{Real}^{\uparrow}$ *endpoint, countable choice, metric completeness, a bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness. It is the finite DyadicRatCore radius row read through the displayed four-face support.*

Proof. First put the two dyadic presentations on a common finite scale. Apply Definition 291.95 to the two accepted finite tolerance windows. The result supplies one terminal $\mathsf{DyadicRatCore}^{\uparrow}$ window carrying the signed mantissa, denominator, endpoint, distance, radius, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ rows.

Now compare possible terminal presentations of that same window. The uniqueness theorem Definition 291.96 identifies any two common terminal refinements that preserve the same finite rows and the same downstream four-face surface. Hence their terminal tolerance rows agree.

The common finite packet is the packet seen by the terminal route. Apply Definition 291.83 to read the DyadicRatCore face together with the StreamName finite window, the RegSeqRat classifier and readback rows, the Real seal row, and the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Finally use Definition 291.84 and Definition 291.123. The first result rules out a second dyadic source behind the same downstream surface, and the second forces every public tolerance read at the terminal route through the displayed four faces. Since the radius row is one of the finite DyadicRatCore tolerance rows in that surface, no quotient, selected endpoint, choice, completeness, bridge, or ambient Real-completeness datum can determine a different terminal radius. □

Theorem 291.103 (DyadicRatCore common-scale terminal radius normal form)**.** *For every accepted L10 terminal exit whose visible surface is the route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

over displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support, the following presentations determine the same terminal radius row:*

1. *the public four-face terminal packet carrying the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, and the local* $\mathsf{Real}^{\uparrow}$ *seal row;*
2. *the common-scale normal form obtained by finite directed refinement of the dyadic tolerance windows over their signed mantissa and denominator ledgers.*

Thus the terminal four-face route already presents the radius in common-scale normal form. The normal form exports no quotient rational equality, quotient stream equality, selected endpoint, countable-choice row, metric-completeness row, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start from the accepted four-face terminal packet. By Definition 291.123, every public tolerance read factors through the DyadicRatCore tolerance ledger together with the StreamName finite-window face, the RegSeqRat classifier and readback face, the Real seal face, and the displayed support rows.

Build the common-scale presentation from the same finite dyadic data. Apply Definition 291.97 to the finite family of accepted dyadic tolerance windows visible in the packet. Then apply Definition 291.99; this gives one consumer-readable normal form through which every downstream StreamName, RegSeqRat, and Real face factors.

It remains to identify the radius row across the two presentations. Use Definition 291.96 to compare the common-scale terminal packet with the DyadicRatCore face recovered from the four-face route. Their signed mantissa, denominator, endpoint, distance, radius, hsame, Cont, Pkg, local NameCert, and downstream rows are the same displayed finite rows, so the terminal tolerance row agrees.

Finally apply Definition 291.102. Since the terminal radius row is already forced by the finite common-scale directed refinement, the four-face packet cannot read a second radius from quotient rational equality, quotient stream equality, a selected endpoint, countable choice, metric

completeness, a bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness. The terminal four-face route and the common-scale normal form therefore present one and the same radius row. □

Theorem 291.104 (DyadicRatCore terminal radius half-step inversion)**.** *If a terminal four-face packet exposes a common-scale normal form and a public half-radius read, then the half-radius row is determined by finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-scale refinement before any* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *seal consumer opens. No quotient rational equality, selected endpoint, countable choice, metric completeness, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness can alter the half-radius row.*

Proof. Apply Definition 291.103. It identifies the public four-face terminal packet with the common-scale normal form obtained by finite directed refinement of the displayed dyadic tolerance windows.

Next apply Definition 291.102. The terminal radius row is forced by the finite DyadicRatCore tolerance data already visible in that common-scale packet.

Finally use Definition 291.83. The public half-radius read is a downstream read of the same four-face surface, so it is pulled back to the finite DyadicRatCore common-scale refinement before any StreamName, RegSeqRat, or Real seal consumer can add data. □

Theorem 291.105 (DyadicRatCore choice-free halving cover)**.** *Let a terminal four-face packet expose a finite unary schedule of terminal half-radius reads along the route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Then the whole schedule is determined by the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *common-scale normal form together with the iterated halving budget. Each halving step preserves the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window surface,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Consequently no quotient rational equality, selected endpoint, countable choice, bridge row, metric-completeness row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness principle supplies an alternate terminal radius at any finite stage of the schedule.*

Proof. Begin with the terminal radius choice-free theorem. It makes the first terminal radius row a finite DyadicRatCore read through the displayed common-scale refinement and the four-face downstream surface.

Apply the common-scale terminal radius normal form and the half-step inversion theorem. Together they identify each public half-radius read with a finite refinement step before any StreamName, RegSeqRat, or Real consumer can add data.

Now use the iterated halving budget, Definition 291.138. A finite unary schedule is obtained by repeating the same half-step over the displayed dyadic ledger, so every stage remains a common-scale DyadicRatCore row transported by the same BHist, hsame, Cont, Pkg, and NameCert support.

The schedule has no remaining coordinate from which to read a second radius. Quotient rational equality, selected endpoints, countable choice, bridge data, metric completeness, and ambient Real completeness are absent from the normal form and therefore cannot alter the finite halving cover. □

Theorem 291.106 (DyadicRatCore StreamName RegSeqRat Real L10 exit ledger)**.** *Every accepted L10 exit read whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *has a unique BEDC-visible dyadic source ledger. The forced ledger consists exactly of the signed*

mantissa row, refined positive-unary exponent row, denominator ledger, common-exponent comparison, distance and radius rows, $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, local* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* NameCert *rows.*

The exit cannot be supplied by quotient rational equality, quotient stream equality, host real equality, a selected limit, countable choice, metric-completeness rows, standard bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 291.82 to the dyadic source faces visible in the L10 exit read. It supplies the common finite scale-window packet with signed mantissa, refined positive-unary exponent, denominator, comparison, distance, radius, transport, continuation, package, and local DyadicRatCore naming rows.

Next use Definition 291.83. The same finite packet is read as the four displayed faces

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow},$$

so the StreamName finite window, RegSeqRat classifier and readback surface, Real seal row, and displayed support coordinates are not additional sources.

Finally apply Definition 291.84 and Definition 291.87. Once the four visible faces and the displayed BHist, hsame, Cont, Pkg, and NameCert rows agree, the dyadic scale-window source is forced to be the same common finite triangle ledger, and the exit inventory has no fifth source.

The non-escape clause is the combined exclusion inventory of the cited triangle ledger, four-face correspondence, source-uniqueness theorem, and no-fifth-source theorem. Those clauses leave no row for quotient rational equality, quotient stream equality, host real equality, selected limits, countable choice, metric completeness, standard bridges, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.107 (DyadicRatCore L10 exit NameCert interface)**.** *An accepted Phase Real and Completion exit packet is a local* NameCert *interface exactly when the following facewise rows are present on one BEDC-visible support surface: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows.*

Equivalently, the four faces $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *jointly present the certificate surface consumed by the Phase Real and Completion exit criterion. Deleting any face, aggregating two faces into one status row, or replacing a face by a global equality datum fails to present that interface. The interface has no coordinate for quotient rational equality, quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, standard bridge rows, aggregate formalstatus rows, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreL10ExitNameCertInterface`

Proof. For sufficiency, start with the displayed four-face inventory and support rows. Apply Definition 291.106 to read the dyadic source surface as the unique BEDC-visible ledger of the L10 exit.

Next apply Definition 126.504. It repacks the same DyadicRatCore, StreamName, RegSeqRat, and Real rows as the terminal four-object boundary seen by every accepted Phase Real and Completion consumer.

Use Definition 301.60 to identify the RegSeqRat classifier and readback face with that terminal boundary. The classifier is therefore not an external parameter transported into the packet; it is one of the four exposed faces of the same local certificate surface.

Finally apply Definition 38.793. Minimality says that each of the four faces and each displayed support row is indispensable for the current Real L10 exit certificate, so the assembled packet is precisely the local NameCert interface.

For necessity, assume an accepted packet presents the local NameCert interface. The StreamName terminal pullback forces the packet to factor through the four-object boundary, and the RegSeqRat correspondence reads the classifier surface facewise inside that boundary.

The DyadicRatCore ledger theorem then recovers the signed mantissa, exponent, denominator, comparison, distance, and radius rows as the unique dyadic source ledger. Real-side face minimality prevents deletion or aggregation of any of the four faces, and it also rules out replacing a face by quotient rational equality, quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, standard bridge rows, aggregate formalstatus rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.108 (DyadicRatCore L10 exit public bridge route)**.** *Every public* $\mathsf{DyadicRatCore}^{\uparrow}$ *bridge consumer that is read by a Phase Real and Completion exit packet factors through one common monotone unary radius window and then through the four visible faces*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

over the shared BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. This factorization is exactly the L10 exit interface: the public bridge supplies the dyadic source rows, the finite radius-window cofinality supplies the common monotone window, and the four-face exit packet supplies the local certificate surface.*

The route has no coordinate for quotient rational equality, quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with the public bridge consumer. Apply Definition 291.24. The consumer reads exactly the signed mantissa, positive-unary exponent, denominator ledger, common-exponent classifier, arithmetic window, distance window, radius window, BHist carrier rows, hsame transport, Cont readback, and Pkg provenance already visible at the public dyadic bridge.

Now apply Definition 291.33 to the finite family of downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads of those public packets. It places the family on one common monotone unary radius window with the shared refined exponent, denominator ledger, classifier, distance rows, BHist rows, hsame transports, Cont readbacks, and Pkg provenance.

Next use Definition 291.107. The same rows, together with the $\mathsf{StreamName}^{\uparrow}$ finite-window rows, $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback rows, local $\mathsf{Real}^{\uparrow}$ seal rows, and local NameCert support, form precisely the interface consumed by the accepted Phase Real and Completion exit packet.

Finally apply Definition 126.504, Definition 301.60, and Definition 38.793. These results identify the common radius-window packet with the terminal four-face boundary and make each displayed face and support row indispensable. The exclusion clause is inherited from the public bridge exactness, finite cofinality, NameCert interface, terminal pullback, RegSeqRat correspondence, and Real face-minimality inventories, none of which exposes quotient rational equality, quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.109 (DyadicRatCore L10 exit ledger facewise noncollapse)**.** *An accepted Phase Real and Completion exit ledger presents the* $\mathsf{DyadicRatCore}^{\uparrow}$ *face if and only if the signed mantissa, exponent, denominator, comparison, distance, and radius rows remain a distinct face alongside*

the $\mathsf{StreamName}^{\uparrow}$ *finite window,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier readback,* $\mathsf{Real}^{\uparrow}$ *seal, and displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

In this correspondence no aggregate formalstatus row, bridge row, quotient rational equality, quotient stream equality, selected limit, metric-completeness datum, countable-choice row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row can replace the* $\mathsf{DyadicRatCore}^{\uparrow}$ *face.*

Proof. For the forward direction, assume the accepted exit ledger presents the $\mathsf{DyadicRatCore}^{\uparrow}$ face. Apply Definition 291.106. The dyadic source surface is then forced to be the unique BEDC-visible ledger consisting of the signed mantissa, exponent, denominator, comparison, distance, and radius rows together with the displayed support rows.

Next apply Definition 291.107. Since the packet presents the local NameCert interface, those dyadic rows must appear facewise with the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows rather than as a collapsed status coordinate.

For the reverse direction, start with the distinct dyadic rows, the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{Real}^{\uparrow}$ seal, and the displayed support rows. Use Definition 291.107 to read this inventory as the local NameCert interface for the accepted Phase Real and Completion exit packet.

Apply Definition 126.504. The four exposed faces form the terminal finite packet seen by downstream Real-and-completion consumers, so the distinct dyadic rows are presented as the $\mathsf{DyadicRatCore}^{\uparrow}$ face of that packet.

It remains to rule out substitute rows. Apply Definition 38.793. Each of the four faces and each displayed support row is indispensable for the current exit certificate; hence no aggregate formalstatus row, bridge row, quotient rational equality, quotient stream equality, selected limit, metric-completeness datum, countable-choice row, or ambient $\mathsf{Real}^{\uparrow}$ completeness row can stand in for the $\mathsf{DyadicRatCore}^{\uparrow}$ face. □

Theorem 291.110 (DyadicRatCore Phase Real and Completion objectwise exit equivalence)**.** *An accepted L10 exit packet satisfies the current Phase Real and Completion objectwise exit criterion if and only if the four facewise rows are simultaneously present on one BEDC-visible support surface: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows.*

No quotient rational equality, quotient stream equality, selected limit, countable choice, metric-completeness datum, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness can replace any of the four faces or any shared support row in this criterion.*

Proof. For the forward direction, assume the accepted L10 packet satisfies the current objectwise exit criterion. Apply Definition 38.796. The threshold reads the criterion through local Real exit rows, so the packet must expose the Real seal together with the support rows consumed by the Phase Real and Completion surface.

Apply Definition 126.504. The same local Real surface is the terminal four-object boundary with visible $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. Use Definition 301.60 to read the RegSeqRat classifier and readback rows as one of those exposed faces.

It remains to recover the dyadic source rows and the local certificate interface. Apply Definition 291.107. Then apply Definition 291.109. These two results force the signed mantissa, exponent, denominator, comparison, distance, and radius rows to remain present as the distinct $\mathsf{DyadicRatCore}^{\uparrow}$ face, with the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For the reverse direction, start with the simultaneous four-face inventory and the shared support rows. Apply Definition 291.107 to package this inventory as the local NameCert interface for the accepted L10 exit packet.

Next apply Definition 291.109. The dyadic rows do not collapse into an aggregate status coordinate. Apply Definition 126.504 and Definition 301.60 to transport the same inventory to the terminal four-object boundary.

Finally apply Definition 38.796. Since the local Real threshold sees exactly that four-object boundary and the displayed support surface, the packet satisfies the current Phase Real and Completion objectwise exit criterion.

The exclusion sentence follows from the noncollapse theorem together with the terminal pullback, the RegSeqRat correspondence, and the Real local threshold. None of those cited results exposes a coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, bridge rows, aggregate formalstatus rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so none can replace any face or shared support row. □

Theorem 291.111 (DyadicRatCore four-face exit facewise certificate)**.** *An accepted Phase Real and Completion exit packet is certificate-complete exactly when it exposes four separate local certificate faces over one shared support surface: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed-mantissa, exponent, denominator, comparison, distance, and radius ledger; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, readback, and regularity rows; and the local* $\mathsf{Real}^{\uparrow}$ *seal, all over the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

No quotient rational equality, quotient stream equality, selected limit, countable choice, metric-completeness row, aggregate formalstatus row, aggregate bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row may replace any of the four certificate faces.*

Proof. For the forward direction, apply Definition 291.110. It identifies an accepted certificate-complete packet with the simultaneous four-face inventory on one support surface, including the dyadic ledger, StreamName window, RegSeqRat rows, local Real seal, and shared BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 291.107. The same inventory is not merely an objectwise criterion; it is the local certificate package consumed by the accepted Phase Real and Completion exit packet.

The StreamName and RegSeqRat faces are read locally. Apply Definition 126.657 for the finite-window schedule and Definition 301.239 for the classifier, readback, and regularity rows. Use Definition 301.246 to keep those rows as a finite local cover rather than a quotient stream or selected limit.

For the reverse direction, start with the four exposed certificate faces and the displayed support rows. The NameCert interface theorem packages them as the local certificate surface, and the objectwise exit equivalence reads that surface as the accepted Phase Real and Completion exit packet.

Finally apply Definition 38.746. Together with the objectwise equivalence and the NameCert interface, it rules out aggregation and off-table replacements. Hence quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness rows cannot stand in for any certificate face. □

Theorem 291.112 (DyadicRatCore L10 face status pullback)**.** *Let P be an accepted Phase Real and Completion exit packet whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Then P pulls back exactly the four local status records from the four corresponding face chapters' own* closurestatus *and* formalstatus *records. The* $\mathsf{DyadicRatCore}^{\uparrow}$ *face contributes the signed*

mantissa, exponent, denominator, comparison, distance, and radius ledger; the $\mathsf{StreamName}^{\uparrow}$ *face contributes the finite-window status; the* $\mathsf{RegSeqRat}^{\uparrow}$ *face contributes the classifier and readback status; and the* $\mathsf{Real}^{\uparrow}$ *face contributes the local seal status.*

This pullback has no aggregate formalstatus *row, aggregate bridge token, route-level Lean target, quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Apply Definition 291.110. It identifies the accepted packet with the simultaneous four-face inventory on one BEDC-visible support surface: the dyadic source ledger, the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback rows, the $\mathsf{Real}^{\uparrow}$ seal rows, and the shared BHist, hsame, Cont, Pkg, and NameCert support rows.

Next apply Definition 291.109. The signed mantissa, exponent, denominator, comparison, distance, and radius rows remain the distinct $\mathsf{DyadicRatCore}^{\uparrow}$ face. They therefore cannot be re-read as a route status, bridge token, equality quotient, selected limit, choice datum, completeness datum, or ambient real-completion row.

Now apply Definition 126.507. Each visible face imports closure grade, verification token, Lean target, and bridge row only by reference to that face chapter's own closurestatus block. Hence the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ entries remain their own finite-window, classifier-readback, and seal status records, while the dyadic ledger is the local record supplied by the distinct DyadicRatCore face.

Finally apply Definition 38.494. The Phase Real and Completion threshold is read object by object on these four local records. Thus the packet can be consumed as a finite paper-side boundary only through the four pulled-back face records, and never through aggregate formalstatus, aggregate bridge, route-level Lean target, quotient rational equality, quotient stream equality, selected limit, countable choice, metric completeness, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.113 (DyadicRatCore L10 exit Lean touchpoint completeness)**.** *Let P be an accepted Phase Real and Completion exit packet whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Then the machine-facing support of P is exhausted by the three route touchpoints named by Definition 126.452 and Definition 126.453: the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff. These three route sites are read together with the four local face records pulled back by Definition 291.112.*

Thus the accepted four-face exit has no additional route-level Lean target, aggregate formalstatus *row, bridge row, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply Definition 291.112. The accepted packet is read through the four local records carried by the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, and the pullback already excludes aggregate status, aggregate bridge, route-level Lean targets, quotient stream equality, selected limits, countable choice, metric completeness, and ambient real completeness.

Next apply Definition 126.453 together with Definition 126.452. These theorems identify the only machine-facing route sites for the same open-phase exit as the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff.

Use Definition 301.60 to identify the RegSeqRat classifier and readback rows with the terminal four-face boundary. The readback face is therefore one of the local records already pulled back from the accepted packet, not a separate quotient stream equality or selected limit.

Finally apply Definition 38.494. The open-phase threshold is consumed object by object on the four local face records, while the three named Lean touchpoints merely expose the existing finite-window, dyadic-handoff, and seal-handoff route. Hence no machine support remains outside those sites, and none of the excluded rows can be added as a companion route coordinate. □

Theorem 291.114 (DyadicRatCore L10 exit ledger source determinacy)**.** *Let P and Q be accepted Phase Real and Completion objectwise audit reads. Suppose both reads expose the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the same local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. Then P and Q determine the same BEDC-visible dyadic source ledger and the same four-face exit packet.*

This determinacy has no coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 291.112 to both accepted reads. The hypotheses give the same four local status records on the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, so both reads pull back the same facewise status packet.

Next use Definition 291.110. Since the objectwise audit criterion is exactly the simultaneous four-face inventory with the displayed support rows, P and Q have the same accepted objectwise exit record rather than two independent route credentials.

Now apply Definition 291.109. The common signed mantissa, exponent, denominator, comparison, distance, and radius rows remain the distinct dyadic face inside each packet. Thus the dyadic source ledger read from P is the same BEDC-visible ledger read from Q.

Finally apply Definition 126.504 and Definition 38.494. The common four faces and support rows factor through one terminal finite Real-completion boundary, and the threshold is consumed object by object on that boundary. Hence the two reads determine the same four-face exit packet.

The exclusions follow from the same citations: the pulled-back face-status packet, objectwise exit equivalence, facewise noncollapse, terminal pullback, and objectwise threshold expose no row for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.115 (DyadicRatCore L10 exit ledger restriction functoriality)**.** *Let P be an accepted Phase Real and Completion four-face packet, and let P' be a sub-exit packet obtained by deleting only downstream consumer rows. Suppose the restriction preserves the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

Then the DyadicRatCore ledger read from P' is the restriction of the DyadicRatCore ledger read from P. The restriction introduces no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply Definition 291.114 to the accepted read P and to the restricted read P'. The preservation hypotheses give the same dyadic source rows, StreamName window rows, RegSeqRat classifier-readback rows, Real seal rows, and displayed support rows on the common part, so the two reads determine the same BEDC-visible dyadic source ledger there.

Next apply Definition 291.112. Both packets read their closure and verification data face by face from the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ records. Deleting downstream consumer rows therefore restricts the visible face-status packet; it does not create a new route-level status coordinate.

Now use Definition 291.110 together with Definition 126.504. These theorems identify the shared source as the same terminal four-face boundary with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support. Hence the restricted read factors through the restriction of the terminal boundary already read by P.

Finally apply Definition 291.109 and Definition 38.494. The dyadic rows remain the distinct $\mathsf{DyadicRatCore}^{\uparrow}$ face, and the Phase Real and Completion threshold is consumed objectwise on the four local records. Thus no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness row appears in the restriction. □

Theorem 291.116 (DyadicRatCore L10 exit ledger common restriction compatibility)**.** *Let P and Q be accepted Phase Real and Completion four-face packets, and let P' and Q' be sub-exit packets obtained from them by deleting only downstream consumer rows. Suppose P' and Q' preserve the same displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the same local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the same shared* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support.*

Then the DyadicRatCore ledger read from P' is the same BEDC-visible ledger read from Q', and the two sub-exit packets determine the same restricted four-face exit packet. This compatibility has no coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 291.115 to the pair P, P' and again to the pair Q, Q'. The hypotheses say that both restrictions preserve the same dyadic rows, StreamName finite-window rows, RegSeqRat classifier-readback rows, Real seal rows, and displayed support rows, so the ledger read from each restricted packet is the corresponding restricted ledger of its accepted source packet.

Next apply Definition 291.114 to the two accepted source reads on the common displayed rows. The common BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support forces the BEDC-visible dyadic source ledger read from P and the one read from Q to agree on that support. Hence their restricted ledgers agree, and the ledger read from P' is the same ledger read from Q'.

It remains to identify the restricted exit packet. Use Definition 291.110 to read each restricted packet through the same simultaneous four-face inventory. Then apply Definition 126.504; the shared DyadicRatCore, StreamName, RegSeqRat, Real, and support rows factor through one terminal finite Real-completion boundary. Thus P' and Q' determine the same restricted four-face exit packet.

The exclusion clause is inherited from the restriction functoriality theorem, source determinacy, objectwise exit equivalence, and terminal pullback. None of those cited surfaces exposes a row for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.117 (DyadicRatCore L10 exit ledger restriction composition)**.** *Let P be an accepted Phase Real and Completion four-face packet, let P' be obtained from P by deleting only downstream*

consumer rows, and let P'' be obtained from P' by the same kind of downstream-consumer restriction. Suppose both restrictions preserve the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the shared* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Then the DyadicRatCore ledger read from P'' is exactly the direct restriction of the DyadicRatCore ledger read from P. Equivalently, the two-step restricted four-face exit packet determined by $P \mapsto P' \mapsto P''$ is the same restricted four-face exit packet obtained by deleting the combined downstream consumer rows from P in one step.

This composition law introduces no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply Definition 291.115 to P and P'. The ledger read from P' is the restriction of the ledger read from P along the preserved DyadicRatCore, StreamName, RegSeqRat, Real, and support rows.

Apply Definition 291.115 again to P' and P''. The second read is therefore the restriction of the P' ledger along the rows still visible after the second downstream deletion.

Now use Definition 291.116 on the intermediate restriction and the direct restriction of P to the rows visible in P''. Both routes preserve exactly the same displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows, so the ledger obtained in two steps agrees with the ledger obtained in one step on the common support.

It remains to identify the four-face packet, not only the ledger rows. Apply Definition 291.114 to the two reads on the shared displayed rows, and then apply Definition 126.504. The common DyadicRatCore, StreamName, RegSeqRat, Real, and support surface factors through one terminal finite Real-completion boundary. Hence the two-step restricted packet and the direct restricted packet are the same four-face exit packet.

The exclusion clause follows from the two uses of restriction functoriality, common-restriction compatibility, source determinacy, and the terminal pullback. None of these cited surfaces exposes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.118 (DyadicRatCore L10 exit ledger consumer normal form)**.** *Let C be a Phase Real and Completion consumer of an accepted four-face packet with visible* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces. Then the rows readable by C are exactly the DyadicRatCore signed mantissa, exponent, denominator, comparison, distance, and radius ledger; the StreamName finite-window rows; the RegSeqRat classifier and readback rows; the local Real seal rows; and the shared* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Conversely, any Phase Real and Completion consumer exposing precisely those rows determines the same L10 exit ledger and the same four-face exit packet. The normal form has no row for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 126.504. The accepted packet is read through one terminal finite Real-completion boundary whose visible faces are exactly the DyadicRatCore, StreamName, RegSeqRat, and Real records. Apply Definition 38.494; the Phase Real and Completion threshold is consumed

object by object on that boundary, so a downstream consumer can read only the listed local rows and the displayed support rows.

Next apply Definition 291.115. Deleting rows outside the displayed inventory is a downstream-consumer restriction, and the DyadicRatCore ledger read after restriction is the restriction of the ledger read from the accepted source packet. Apply Definition 291.116 to two such consumer restrictions; if they preserve the same displayed rows, they determine the same restricted ledger and the same restricted four-face packet.

For the converse, apply Definition 291.114. A consumer exposing precisely the dyadic ledger rows, StreamName finite-window rows, RegSeqRat classifier-readback rows, Real seal rows, and shared BHist, hsame, Cont, Pkg, and NameCert support has the full BEDC-visible source data used by the accepted objectwise read. Source determinacy therefore identifies its L10 exit ledger with the ledger read by any other consumer exposing precisely the same rows.

Finally combine the terminal pullback and objectwise threshold equivalence with the exclusion clauses in source determinacy, restriction functoriality, and common restriction compatibility. None of the cited surfaces adds quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Hence the displayed inventory is both sufficient for consumption and maximal among the rows exposed by the current Phase Real and Completion objectwise exit. □

Theorem 291.119 (DyadicRatCore L10 exit ledger finite-cover descent)**.** *Let $\{P_i\}_{i\in I}$ be a finite cover of accepted Phase Real and Completion four-face packets. Suppose every P_i exposes the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the same local* $\mathsf{Real}^{\uparrow}$ *seal rows; and shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support on all displayed overlaps. Suppose also that the overlap restrictions preserve those rows and that pairwise common restrictions agree on the displayed support.*

Then the finite cover descends to one BEDC-visible DyadicRatCore ledger and one accepted four-face exit packet with visible $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces. The descended packet has no coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First normalize each cover member. Apply Definition 291.118 to every P_i. Each accepted packet is therefore read through the same displayed DyadicRatCore ledger rows, StreamName finite-window rows, RegSeqRat classifier-readback rows, local Real seal rows, and shared support surface.

Now compare overlaps. Use Definition 291.116 on every pairwise overlap. The common restriction hypotheses identify the restricted DyadicRatCore ledger and the restricted four-face exit packet on the overlap, so no overlap introduces an additional equality, choice, completeness, status, or bridge coordinate.

Next paste the four visible faces. Apply Definition 38.771 to the local Real and Completion four-face packets, and apply Definition 126.552 to exhaust the StreamName finite-window and RegSeqRat seal rows over the same finite cover. The pasted surface still carries the displayed DyadicRatCore rows and the same BHist, hsame, Cont, Pkg, and NameCert support.

It remains to pass from compatible local ledgers to one global ledger. Induct over the finite cover. The empty stage is the empty displayed restriction, and the first nonempty stage is normalized by the consumer normal form. At the adjoining step, Definition 291.115 transports the already

pasted ledger to the common part, while source determinacy from Definition 291.114 identifies the adjoining member with that same ledger on the preserved rows.

The induction produces one BEDC-visible DyadicRatCore ledger. The pasted Real finite-cover packet and the StreamName-RegSeqRat seal exhaustion supply the corresponding four-face exit packet. The exclusion clause follows from the normal form, common restriction compatibility, Real finite-cover face pasting, and StreamName-RegSeqRat finite-cover seal exhaustion: none of these cited surfaces exposes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.120 (DyadicRatCore L10 exit ledger finite-cover refinement invariance)**.** *Let $\{P_i\}_{i\in I}$ be a finite cover of accepted Phase Real and Completion four-face packets, and let $\{Q_j\}_{j\in J}$ be a finite cover refining it by a finite assignment $j \mapsto i(j)$. Suppose each Q_j lies over $P_{i(j)}$, and every refinement map preserves the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Suppose also that refined overlaps preserve the same displayed rows and agree with the corresponding coarse overlap restrictions on the shared support.*

Then applying finite-cover descent to the coarse cover $\{P_i\}_{i\in I}$ or to the refined cover $\{Q_j\}_{j\in J}$ yields the same BEDC-visible DyadicRatCore ledger and the same accepted four-face exit packet with visible $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces. The invariant comparison has no coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 291.119 to the coarse cover and to the refined cover. Both outputs are built only from the displayed dyadic ledger rows, StreamName finite-window rows, RegSeqRat classifier-readback rows, local Real seal rows, and shared support rows.

For a refined member Q_j, use Definition 291.115 along the refinement map $Q_j \to P_{i(j)}$. The preservation hypotheses identify the ledger read from Q_j with the restriction of the ledger read from its coarse source on exactly the displayed rows.

On refined overlaps, apply Definition 291.116. The refined common restrictions and the corresponding coarse common restrictions agree on the same BHist, hsame, Cont, Pkg, and NameCert support, so every refined overlap carries the same restricted dyadic ledger as its coarse image.

Now use Definition 291.114. Since the coarse and refined descent outputs have the same displayed DyadicRatCore, StreamName, RegSeqRat, Real, and support rows on every finite member and overlap, source determinacy identifies the BEDC-visible DyadicRatCore ledger produced by the two descents.

It remains to compare the four visible faces. Invoke Definition 38.771 for the Real and Completion faces, and Definition 126.552 for the StreamName finite-window and RegSeqRat seal rows. These two finite pasting surfaces are computed from the same preserved rows, hence the coarse and refined covers determine the same four-face exit packet.

The exclusion clause follows from the descent theorem, restriction functoriality, common-restriction compatibility, source determinacy, Real finite-cover face pasting, and StreamName-RegSeqRat finite-cover seal exhaustion. None of those cited surfaces exposes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 291.121 (DyadicRatCore L10 exit ledger finite-support coverage)**.** *Let P be an accepted Phase Real and Completion four-face packet with visible* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces. Suppose the finite support of P is covered by displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-observation rows; displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail classifier and readback rows; displayed local* $\mathsf{Real}^{\uparrow}$ *seal rows; and shared* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Suppose also that the displayed support rows cover every overlap used by the Phase Real and Completion acceptance packet and that any two displayed finite covers admit a common finite refinement preserving the same rows.*

Then the resulting DyadicRatCore L10 exit ledger is completely covered by those finite support rows. In particular, every BEDC-visible ledger coordinate of the accepted four-face exit packet is read from the displayed DyadicRatCore, StreamName, RegSeqRat, Real, BHist, hsame, Cont, Pkg, *and* NameCert *rows, and no further support row is required.*

This finite-support coverage theorem has no coordinate for quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First read the StreamName side through finite observations. Apply Definition 126.527 to the displayed StreamName finite-observation rows. This gives a finite section for exactly the observable stream windows carried by the Phase Real and Completion packet, with no appeal to quotient stream equality or selected limits.

Next read the RegSeqRat side through common tails. Apply Definition 301.193 to the displayed RegSeqRat classifier and readback rows over the same finite support. The induction supplies the common-tail support needed for the finite window rows and keeps the shared BHist, hsame, Cont, Pkg, and NameCert rows fixed on every retained overlap.

Now form the cover whose members are the displayed dyadic ledger rows together with the StreamName finite section, the RegSeqRat common-tail support, the local Real seal rows, and the shared support rows. Apply Definition 291.119. The descent theorem produces one BEDC-visible DyadicRatCore ledger and one accepted four-face exit packet from exactly that finite inventory.

It remains to show that the coverage does not depend on the chosen displayed finite cover. Given another cover of the same finite support, pass to the stipulated common finite refinement and apply Definition 291.120. The refinement comparison identifies the ledger and the four-face exit packet computed from the two covers, because both covers preserve the same DyadicRatCore, StreamName, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows.

The exclusion clause is inherited from the StreamName finite-observation section, the RegSeqRat common-tail support induction, finite-cover descent, and finite-cover refinement invariance. None of those cited surfaces exposes quotient rational equality, quotient stream equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Hence the accepted DyadicRatCore L10 exit ledger is completely covered by the displayed finite support inventory and by nothing outside it. □

Theorem 291.122 (DyadicRatCore Phase Real and Completion exit support minimality)**.** *An accepted Phase Real and Completion four-face packet is a valid exit certificate only if all four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

remain present over the shared BHist, hsame, Cont, Pkg, *and* NameCert *support rows. None of these four faces and none of the displayed support rows may be deleted, collapsed into an aggregate status coordinate, or replaced by quotient rational equality, quotient stream equality, selected limits,*

countable choice, metric-completeness data, aggregate formalstatus rows, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 291.107. A valid accepted packet must present the local NameCert interface, and that interface is explicitly the four-face inventory over the shared BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 291.110 and Definition 291.111. These theorems identify the objectwise exit criterion and the certificate-complete packet with the same four separate faces, so a packet missing one face or replacing a face by an aggregate coordinate no longer has the accepted exit surface.

The StreamName, RegSeqRat, and Real rows are forced facewise. Apply Definition 126.657, Definition 301.239, and Definition 301.246. These results keep the finite-window, classifier, readback, regularity, and seal rows as local BEDC rows rather than quotient stream equality, selected limits, countable choice, or metric-completeness data.

It remains to rule out replacement by route-level status or ambient completeness data. Apply Definition 38.746; then apply Definition 291.121. The first citation separates the objectwise support route from aggregate formalstatus and bridge rows, while the finite-support coverage theorem says every BEDC-visible ledger coordinate is already read from the displayed DyadicRatCore, StreamName, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows.

Hence deleting any listed face or support row leaves no theorem in the cited chain that can supply the missing coordinate, and every proposed substitute lies outside the finite support inventory. The accepted four-face packet is therefore a valid exit certificate only with exactly those indispensable faces and shared support rows present. □

Theorem 291.123 (DyadicRatCore terminal four-face tolerance exhaustion)**.** *Let P be an accepted L10 terminal route whose four visible faces are the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and classifier row, and the local* $\mathsf{Real}^{\uparrow}$ *seal row over the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Then every public tolerance read of P factors through exactly that $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger together with the three downstream faces and the displayed support rows.*

No quotient rational, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row is an additional tolerance coordinate for the terminal route.*

Lean4 ✓ `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreTerminalFourFaceToleranceExhaustion`

Proof. First apply Definition 291.83. It identifies the terminal route with exactly the four visible faces: the DyadicRatCore tolerance ledger, the StreamName finite window, the RegSeqRat classifier and readback surface, and the Real seal row, all over the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Next use Definition 291.87. Once the four faces and support rows are fixed, the exit inventory has no fifth source from which another tolerance coordinate could be read.

The StreamName side keeps the tolerance coordinate inside the same finite packet. Apply Definition 126.471 and Definition 126.472; these results say that the accepted open-phase read exposes the ledger through the four faces themselves, not through quotient stream equality, selected limits, ambient completion, or standard bridge data.

Now read the RegSeqRat and Real faces. The non-escape theorem Definition 301.169 confines the readback consumer to the displayed dyadic observation rows, StreamName window rows, RegSeqRat budget rows, transports, continuations, provenance, and local naming rows.

Finally apply Definition 38.464. The terminal Real boundary determines exactly the fused StreamName packet, the DyadicRatCore endpoint and radius ledger, the RegSeqRat finite-request section, the local Real seal, and the displayed support. Hence every public tolerance read of P factors through the DyadicRatCore ledger already present in the four-face packet, and none of the excluded quotient, selected-limit, choice, completeness, metric-completeness, bridge, or ambient $\mathsf{Real}^{\uparrow}$ rows can be added as a separate tolerance coordinate. □

Theorem 291.124 (DyadicRatCore terminal tolerance finite-support readback)**.** *Let P be an accepted L10 terminal route whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and the local* $\mathsf{Real}^{\uparrow}$ *face over the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Then any public tolerance read of P is determined by the displayed finite support rows: the $\mathsf{DyadicRatCore}^{\uparrow}$ *signed mantissa, exponent, denominator, comparison, distance, and radius rows; the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows; the local* $\mathsf{Real}^{\uparrow}$ *seal row; and the shared* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

The readback exports no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 291.123. Every public tolerance read of P factors through the four visible faces and the shared support rows, so it is enough to identify the finite support carried by those faces.

The DyadicRatCore support is finite. Apply Definition 291.121; the accepted four-face packet reads the signed mantissa, exponent, denominator, comparison, distance, radius, StreamName, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows from the displayed finite inventory.

Now read the three downstream faces on the same inventory. The StreamName face is supplied by Definition 126.527. The RegSeqRat classifier and readback face is supplied by Definition 301.193. The local Real seal is supplied by Definition 38.464.

Finally use the no-fifth-source clause from Definition 291.123. Since all public tolerance reads already factor through the displayed four faces and those faces have just been read from the finite support rows, none of the excluded quotient, selected-limit, countable-choice, metric-completeness, bridge, aggregate formalstatus, or ambient $\mathsf{Real}^{\uparrow}$ completeness rows can be exported by the readback. □

Theorem 291.125 (DyadicRatCore terminal tolerance projection)**.** *Let P and Q be accepted L10 terminal routes whose visible four-face packets expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and classifier row, the same local* $\mathsf{Real}^{\uparrow}$ *seal row, and the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Then the public tolerance reads of P and Q agree if and only if their $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger rows agree.*

No quotient rational, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row can mediate a different tolerance read between the two terminal routes.*

Proof. Apply Definition 291.123 to P and to Q. Each public tolerance read is forced through the displayed four-face packet: the DyadicRatCore tolerance ledger, the StreamName finite window, the RegSeqRat classifier and readback row, the local Real seal row, and the shared BHist, hsame, Cont, Pkg, and NameCert support.

For the forward direction, suppose the public tolerance reads agree. Use Definition 291.83. Since the StreamName, RegSeqRat, Real, and support faces are already the same, the pullback has only one remaining tolerance coordinate; the agreement of the public reads therefore identifies the DyadicRatCore tolerance ledger row.

For the reverse direction, suppose the DyadicRatCore tolerance ledger rows agree. The other three faces and all displayed support rows agree by hypothesis, so the same pullback theorem gives one common four-face packet for both routes. Reading the tolerance face through that common packet gives the same public tolerance read.

Finally apply Definition 291.87. The exit inventory has no fifth source that could alter the tolerance coordinate after the four visible faces and support rows have been identified. The StreamName rows Definition 126.471 and Definition 126.472, together with the RegSeqRat nonescape row Definition 301.169, rule out external completion, quotient stream, quotient rational, selected-limit, countable-choice, bridge, metric-completeness, and ambient $\mathsf{Real}^{\uparrow}$ completeness coordinates. □

Theorem 291.126 (DyadicRatCore terminal tolerance pullback initiality)**.** *Let P be an accepted L10 terminal route whose visible four-face packet exposes the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, a* $\mathsf{StreamName}^{\uparrow}$ *finite window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback row, a local* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support. Let Q be any accepted L10 terminal route presenting the same $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback row, the same local* $\mathsf{Real}^{\uparrow}$ *seal row, and the same displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support. Then Q factors uniquely through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger of P if and only if the public tolerance read of Q agrees with the terminal projection of P supplied by Definition 291.125.*

This initiality exports no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First read both terminal routes through the same visible support. Apply Definition 291.123 to P and Q; every public tolerance read is forced through the displayed four-face packet and the shared BHist, hsame, Cont, Pkg, and NameCert rows. Apply Definition 291.124 to replace each such read by the finite DyadicRatCore ledger, StreamName window, RegSeqRat readback, local Real seal, and support rows.

For the forward direction, assume Q factors through the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger of P. The StreamName face is already the same finite section, so Definition 126.586 identifies the two finite-window pullbacks. The RegSeqRat and Real faces are then locked by Definition 301.239 and Definition 38.845. With all four faces fixed, Definition 291.125 gives agreement with the terminal projection of P.

For the reverse direction, assume the public tolerance read of Q agrees with the terminal projection of P. By Definition 291.125, agreement of public tolerance reads over the already shared StreamName, RegSeqRat, Real, and support faces is equivalent to agreement of the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger rows. The finite-support readback theorem identifies the only ledger rows available to Q, so the factorization through the DyadicRatCore ledger of P is unique.

It remains to rule out external witnesses for a second factorization. The exhaustion theorem supplies no fifth source beyond the four visible faces, the finite-support readback supplies no hidden row outside the displayed inventory, the StreamName pullback exactness supplies no quotient stream coordinate, the RegSeqRat-Real terminal exactness supplies no quotient rational or selected-limit coordinate, and the Real terminal pullback coherence supplies no ambient completeness coordinate. Hence quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness cannot mediate another terminal tolerance factorization. □

Theorem 291.127 (DyadicRatCore terminal tolerance cofinal-refinement finality)**.** *Let P be an accepted L10 terminal route whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and the local* $\mathsf{Real}^{\uparrow}$ *face over the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Let R be any accepted cofinal refinement of P preserving the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support, and the public terminal status of the route. Then the public tolerance read of R factors through the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger as P.*

Equivalently, no accepted cofinal refinement with those preserved visible faces can introduce a new tolerance coordinate. The finality statement exports no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First read R as a terminal route over the preserved visible support. Since the refinement keeps the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback row, the local $\mathsf{Real}^{\uparrow}$ seal row, and the displayed BHist, hsame, Cont, Pkg, and NameCert support, Definition 291.126 applies to P and R.

The StreamName preservation clause identifies the finite-window side of the comparison. Apply Definition 126.586; the refinement has the same finite StreamName section and therefore cannot supply a second window through which a tolerance row could be read.

Next lock the RegSeqRat and Real faces. Theorem 301.239 reads the preserved classifier, readback, and local Real rows as the same four-face terminal surface, and Definition 38.845 rules out an ambient $\mathsf{Real}^{\uparrow}$ completion coordinate.

With all non-dyadic faces fixed, use Definition 291.125. Equality of public tolerance reads is now exactly equality of the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger rows. The pullback initiality theorem then gives the desired factorization of the public tolerance read of R through the ledger of P.

Finally apply the non-export clauses in the exhaustion, projection, and initiality results. Quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not visible tolerance coordinates for the terminal route or for its accepted cofinal refinements. □

Theorem 291.128 (DyadicRatCore terminal tolerance common-refinement confluence)**.** *Let P be an accepted L10 terminal route whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and the local* $\mathsf{Real}^{\uparrow}$ *face over the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Let R and S be accepted cofinal refinements of P preserving the $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, the displayed* BHist*,*

hsame, Cont, Pkg, *and* NameCert *support, and the public terminal status of the route. Suppose R and S admit a common finite* DyadicRatCore$^{\uparrow}$ *scale-window refinement T preserving those same finite-window, classifier, readback, seal, history, sameness, continuity, package, and NameCert rows. Then the public tolerance reads of R and S agree exactly on the same* DyadicRatCore$^{\uparrow}$ *tolerance ledger of P.*

The confluence statement exports no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient Real$^{\uparrow}$ *completeness.*

Proof. Apply Definition 291.127 first to R and then to S. Both accepted cofinal refinements preserve the displayed StreamName, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows, so each public tolerance read factors through the DyadicRatCore$^{\uparrow}$ tolerance ledger already carried by P.

Now use the common finite scale-window refinement. By Definition 291.99, the two refinement routes through R and S have one consumer-readable finite normal form whose endpoint transport, denominator replay, distance and radius rows, hsame, displayed Cont, Pkg, and local DyadicRatCore naming rows are the common rows read by T.

It remains to identify the public reads with the same ledger coordinate. Apply Definition 291.125; once the StreamName finite window, the RegSeqRat classifier and readback row, the local Real seal row, and the displayed support rows agree, agreement of public tolerance reads is exactly agreement of the DyadicRatCore$^{\uparrow}$ tolerance ledger rows.

Finally apply Definition 291.123 and Definition 291.126. Exhaustion leaves no fifth tolerance source outside the four visible faces and support rows, while pullback initiality prevents a second terminal factorization over those same faces. Hence the common refinement proves confluence on the finite DyadicRatCore ledger and not through quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, or ambient Real$^{\uparrow}$ completeness. □

Theorem 291.129 (DyadicRatCore terminal tolerance facewise support minimality)**.** *Let P be an accepted L10 terminal route whose visible faces are* DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and the local* Real$^{\uparrow}$ *face over the same displayed*

BHist, hsame, Cont, Pkg, NameCert

support. Then the terminal tolerance read is facewise support-minimal. Deleting any DyadicRatCore$^{\uparrow}$ *tolerance-ledger row, or deleting any one of the displayed support rows* BHist, hsame, Cont, Pkg, *and* NameCert, *destroys the public terminal tolerance read.*

Moreover, equality of terminal tolerance reads recovers exactly the DyadicRatCore$^{\uparrow}$ *tolerance-ledger rows together with the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. It recovers no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient* Real$^{\uparrow}$ *completeness.*

Proof. First identify the route inventory. By Definition 291.123, every public tolerance read factors through the four visible faces and the displayed support. By Definition 291.124, that factorization is read from the finite DyadicRatCore$^{\uparrow}$ tolerance ledger, the StreamName$^{\uparrow}$ finite-window rows, the RegSeqRat$^{\uparrow}$ classifier and readback rows, the local Real$^{\uparrow}$ seal row, and the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Now delete one listed row. If the deleted row is a DyadicRatCore tolerance-ledger row, the finite readback theorem no longer supplies the finite tolerance inventory. If the deleted row is one

of BHist, hsame, Cont, Pkg, or NameCert, the same theorem no longer supplies the shared support on which all four visible faces are read. In either case the public terminal tolerance read has lost a required finite support coordinate.

Next compare two terminal routes whose public tolerance reads agree. Apply Definition 291.125; over fixed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, and displayed support faces, equality of public tolerance reads is exactly equality of the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance-ledger rows. Apply Definition 126.586 to keep the StreamName finite section inside the same support packet.

The RegSeqRat and Real faces do not enlarge the recovered support. Theorem 301.239 locks the classifier, readback, and local Real rows to the same four-face terminal surface, while Definition 38.793 identifies the Real exit certificate by the visible face rows it carries. Thus agreement of terminal tolerance reads recovers the DyadicRatCore ledger and the displayed BHist, hsame, Cont, Pkg, and NameCert support, rather than a hidden completion witness.

Finally apply Definition 291.126 and Definition 291.127. Pullback initiality prevents a second terminal factorization over the same non-dyadic faces, and cofinal-refinement finality prevents an accepted refinement from adding a new tolerance coordinate. Therefore quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not recovered by equality of terminal tolerance reads. □

Theorem 291.130 (DyadicRatCore terminal tolerance support minimality)**.** *Let P be an accepted L10 terminal route whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and the local* $\mathsf{Real}^{\uparrow}$ *face over the same displayed*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support. Then the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger and each displayed support row* BHist, hsame, Cont, Pkg, *and* NameCert *are necessary for the public tolerance read of P. Deleting the DyadicRatCore tolerance ledger, or deleting any one of those displayed support rows, destroys the public tolerance read.*

The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$ *faces cannot replace the deleted row. In particular, quotient streams, selected limits, countable choice, metric completeness, bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness do not supply an alternate public tolerance read.*

Proof. First identify the finite inventory. By Definition 291.124, every public tolerance read of P is determined by the displayed DyadicRatCore signed mantissa, exponent, denominator, comparison, distance, and radius rows, the downstream StreamName, RegSeqRat, and Real faces, and the shared BHist, hsame, Cont, Pkg, and NameCert support. Hence a route that deletes the DyadicRatCore ledger or any one of the displayed support rows no longer contains the finite readback inventory named by the theorem.

Next isolate the dyadic coordinate. Apply Definition 291.125. Once the StreamName finite window, the RegSeqRat classifier and readback row, the local Real seal, and the displayed support are fixed, agreement of public tolerance reads is equivalent to agreement of the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger rows. A packet with no DyadicRatCore ledger therefore cannot present the same public tolerance read through the three downstream faces alone.

Now rule out replacement by refinement. The pullback initiality theorem Definition 291.126 says that any accepted terminal route over the same non-dyadic faces factors uniquely through the DyadicRatCore ledger exactly when its public tolerance read agrees with the terminal projection. The cofinal-refinement finality theorem Definition 291.127 then prevents an accepted cofinal

refinement from adding a new tolerance coordinate after the visible faces and support rows have been preserved.

Finally exclude the three downstream faces as substitutes for the missing row. The StreamName exactness rows Definition 126.471 and Definition 126.472 keep the open-phase ledger inside the same finite four-face packet, not in quotient stream equality or selected limits. The RegSeqRat non-escape row Definition 301.169 confines readback to the displayed dyadic observation rows and their transported support, not to countable choice or a separate metric-completeness row. The Real boundary theorem Definition 38.464 determines the local Real seal from the fused finite packet and supplies no bridge row or ambient $\mathsf{Real}^{\uparrow}$ completeness coordinate. Thus deleting the DyadicRatCore ledger, BHist, hsame, Cont, Pkg, or NameCert destroys the public tolerance read rather than moving it to another face. □

Theorem 291.131 (DyadicRatCore terminal tolerance finite-cover descent)**.** *Let $\{P_i\}_{i\in I}$ be a finite cover of an accepted L10 terminal route by accepted terminal-route members whose visible faces are* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and the local* $\mathsf{Real}^{\uparrow}$ *face. Suppose every member and every nonempty overlap preserves the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the same local* $\mathsf{Real}^{\uparrow}$ *seal row, and the same displayed*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

support. Then the descended public tolerance read on the covered route is determined exactly by the descended $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger.*

If the descended DyadicRatCore tolerance ledger is deleted, or if two cover members or an overlap disagree on that ledger while the displayed support rows remain fixed, the public tolerance read does not descend. The obstruction localizes to a cover member missing the ledger or to an overlap on which the two local ledgers disagree. No quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness supplies a substitute descent datum.*

Proof. First apply Definition 126.669. The finite cover has a single descent support exactly when the finite StreamName window and the displayed BHist, hsame, Cont, Pkg, and NameCert rows agree on every cover member and on every nonempty overlap. Thus the cover-level support packet is a finite packet, not a quotient stream or a selected limiting object.

Next apply Definition 291.127 on each member and on each accepted overlap route. Since the visible StreamName, RegSeqRat, local Real, history, sameness, continuity, package, and NameCert rows are preserved, no accepted cofinal refinement can add an extra terminal tolerance coordinate beyond the DyadicRatCore ledger already carried by the member.

The local public reads therefore compare through the DyadicRatCore ledger. By Definition 301.239, the RegSeqRat classifier, RegSeqRat readback, and local Real seal are locked to the same four-face terminal surface. They transport the local route rows across the cover, but they do not create a second tolerance source.

It remains to identify the obstruction when descent fails. Apply Definition 291.130. Deleting the DyadicRatCore tolerance ledger on a member deletes a necessary support coordinate for that member's public read. If two members carry different DyadicRatCore ledgers on an overlap, the same minimality statement and the cofinal-refinement finality statement prevent the disagreement from being hidden in the StreamName, RegSeqRat, Real, or shared support rows.

Consequently the only descended public tolerance read compatible with all cover members is the one read from the descended DyadicRatCore tolerance ledger. The failure cases are precisely

memberwise absence of that ledger or overlapwise disagreement of that ledger; quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness remain outside the terminal descent datum. □

Theorem 291.132 (DyadicRatCore terminal four-face normal-form uniqueness)**.** *Let P and Q be accepted L10 terminal routes. Suppose their public terminal packets expose the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the same* $\mathsf{StreamName}^{\uparrow}$ *finite window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the same local* $\mathsf{Real}^{\uparrow}$ *seal row, and the same displayed*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support. Then the public terminal four-face normal form of P is identical to the public terminal four-face normal form of Q.

Conversely, equality of the public terminal four-face normal forms of P and Q recovers exactly those rows: the $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. The recovery exports no quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First read both routes through the visible terminal inventory. Apply Definition 291.123; every public tolerance coordinate of either route is forced through the DyadicRatCore ledger, the StreamName finite window, the RegSeqRat classifier and readback rows, the local Real seal, and the displayed support.

Next project the public tolerance reads. By Definition 291.125, once the StreamName, RegSeqRat, Real, and support faces are fixed, equality of public terminal tolerance reads is exactly equality of the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger rows. The assumed agreement of all displayed rows therefore identifies the four-face terminal packets of P and Q.

The terminal comparison is unique over that packet. Apply Definition 291.126; any accepted terminal route with the same non-dyadic faces and the same displayed support factors uniquely through the same DyadicRatCore tolerance ledger. Hence the two public terminal four-face normal forms coincide.

For the converse, assume the public terminal four-face normal forms coincide. The finite-cover descent theorem Definition 291.131 says that a descended public tolerance read is determined exactly by the descended DyadicRatCore ledger and that absence or overlapwise disagreement of that ledger is the precise obstruction to descent. Thus equality of normal forms recovers the DyadicRatCore tolerance ledger.

The remaining faces are then read back from the same public packet. Use Definition 291.123 and Definition 291.128; exhaustion leaves no fifth source outside the visible faces and support rows, while confluence identifies the common finite route through the StreamName window, RegSeqRat classifier and readback, local Real seal, and displayed BHist, hsame, Cont, Pkg, and NameCert support.

Finally apply the non-export clauses from the exhaustion, projection, initiality, confluence, and finite-cover descent results. Quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate formalstatus rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not terminal normal-form coordinates. The equality therefore recovers exactly the listed rows and no hidden completion, choice, bridge, or aggregate-status data. □

Theorem 291.133 (DyadicRatCore terminal four-face support)**.** *An accepted L10 terminal route has a public tolerance read exactly when it displays the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared support*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Deleting any one of those four faces or any displayed support row prevents the public tolerance read.

No quotient rational equality, quotient stream equality, selected limit, countable-choice row, metric-completeness row, bridge row, aggregate formalstatus row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness can replace a missing face or support row.*

Proof. First combine Definition 291.123 with Definition 291.124. These theorems identify every public tolerance read with the DyadicRatCore ledger, the StreamName finite window, the RegSeqRat readback surface, the local Real seal, and the displayed support rows.

For sufficiency, use Definition 291.132. Once the four faces and support rows are present, the terminal normal form is fixed, so the public tolerance read is the one read from that finite packet.

For necessity, delete one listed face or support row. If the deleted row is part of the DyadicRatCore ledger or the shared support, Definition 291.130 blocks the read. If the deleted row is the StreamName, RegSeqRat, or Real face, Definition 126.471, Definition 301.239, and Definition 38.464 remove the corresponding downstream route.

Finally apply the projection and minimality clauses, Definition 291.125 and Definition 291.129. They leave no replacement coordinate outside the displayed finite packet. Hence quotient rational equality, quotient stream equality, selected limits, countable choice, metric completeness, bridge rows, aggregate status rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness cannot restore the public read after a face or support row is absent. □

Theorem 291.134 (DyadicRatCore tolerance-halving cover)**.** *For every positive dyadic tolerance row accepted by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite scale-window ledger, there is a halved positive dyadic tolerance row in a displayed finite refinement window whose doubled radius is classifier-below the original tolerance row. The refinement preserves the signed mantissa row, denominator ledger, common-exponent comparison, distance and radius rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

Consequently every $\mathsf{StreamName}^{\uparrow}$ *finite-window request and every* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity check that consumes a DyadicRatCore tolerance row may replace it by a carried half-tolerance row without invoking host rationals, quotient equality, selected limits, countable choice, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the accepted positive tolerance row in the finite scale-window packet. Apply scale-window monotonicity, Definition 291.41, to pass to the displayed successor exponent window while keeping the same signed mantissa, denominator ledger, comparison row, radius row, hsame, Cont, Pkg, and local NameCert support.

Next use the common-scale triangle ledger, Definition 291.82. It compares the original radius row and the successor-window radius row inside one common finite denominator scale, so the doubled successor radius is classifier-below the original tolerance rather than compared by host rational order.

Finally apply the terminal four-face tolerance exhaustion theorem, Definition 291.123. The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$ faces have no fifth tolerance source outside the displayed DyadicRatCore ledger and support rows. The halved row is therefore the finite-window handoff

consumed by StreamName requests and RegSeqRat regularity checks, with the stated transport and nonescape clauses preserved. □

Theorem 291.135 (DyadicRatCore halving-cover RegSeqRat handoff)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity check consuming a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row may replace that row by the halved finite refinement supplied by Definition 291.134. The replacement preserves the* $\mathsf{StreamName}^{\uparrow}$ *request rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *support.*

The refined read is still a finite regularity read over the displayed DyadicRatCore ledger. It does not invoke host rational order, quotient stream equality, selected limits, countable choice, host real equality, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 291.134 to the positive tolerance row consumed by the regularity check. It supplies the halved positive row in a displayed finite refinement window while preserving the dyadic ledger, transport, replay, provenance, and local naming rows.

Then use the RegSeqRat common-window compatibility supplied by Definition 301.36. The original regularity read and the halved refinement are compared on one accepted common finite window, so the $\mathsf{StreamName}^{\uparrow}$ request rows and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows are unchanged as public source data.

Finally the terminal four-face tolerance exhaustion from Definition 291.134 rules out a second tolerance source. The RegSeqRat check therefore consumes the halved row through the same finite BEDC support rather than through host order, quotient streams, selected limits, choice, host equality, or ambient completeness. □

Theorem 291.136 (DyadicRatCore halving-cover StreamName handoff)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *finite-window request consuming a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row may replace that row by the halved finite refinement supplied by Definition 291.134. The replacement preserves the finite window schedule, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *support.*

The refined StreamName read remains a finite-window read over the displayed DyadicRatCore ledger. It does not invoke host rational order, quotient streams, selected limits, countable choice, host real equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or a separate completion coordinate.*

Proof. Apply Definition 291.134 to the positive tolerance row consumed by the StreamName request. It supplies a halved positive dyadic row in a displayed finite refinement window while preserving the DyadicRatCore comparison ledger, transport, replay, provenance, and local naming rows.

Next read the StreamName finite-window request rows. The request schedule is indexed by displayed windows and tolerance demands, so replacing the tolerance row by its carried half-tolerance refinement changes no public schedule face and adds no host rational comparison.

The same support rows transport the replacement through hsame, replay it through Cont, source it through Pkg, and name it through the local NameCert. Thus the StreamName handoff consumes the halved row through the finite BEDC support.

Finally the nonescape clause in Definition 291.134 rules out host rational order, quotient streams, selected limits, choice, host equality, ambient Real completeness, and separate completion data as alternative tolerance sources. □

Theorem 291.137 (DyadicRatCore common-exponent transport)**.** *The halved tolerance refinement supplied by Definition 291.134 preserves the common-exponent comparison ledger under componentwise* hsame *transport and displayed* Cont *replay. If a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity check or a*

$\mathsf{StreamName}^{\uparrow}$ *finite-window request consumes the original positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, then replacing that row by the carried half-tolerance row keeps the signed mantissa, denominator scale, doubled-radius comparison, and common-exponent classifier in the same finite BEDC ledger.*

The comparison is BEDC classifier data: it is replayed through displayed common-exponent rows, not reopened as host rational order, quotient equality, selected limits, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the positive tolerance row and its halved refinement from Definition 291.134. The refinement already carries the signed mantissa row, denominator ledger, common-exponent comparison, transport, replay, provenance, and local naming rows.

Use Definition 291.41 to move the read to the displayed successor scale window without changing the public dyadic components. Then apply Definition 291.82; it keeps the original row, the halved row, and the doubled-radius comparison inside one common finite exponent ledger.

The downstream handoff is stable on both consuming faces. Definition 291.135 carries the same ledger to $\mathsf{RegSeqRat}^{\uparrow}$ regularity checks, while Definition 291.136 carries it to $\mathsf{StreamName}^{\uparrow}$ finite-window requests. Componentwise hsame transport and displayed Cont replay therefore repeat the common-exponent classifier rather than creating a second comparison source.

Since every comparison row used by the replacement is one of the displayed DyadicRatCore classifier rows, the construction never appeals to host rational order, quotient stream equality, selected limits, countable choice, host real equality, or ambient Real completeness. □

Theorem 291.138 (DyadicRatCore iterated halving budget)**.** *For every positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row and every finite unary schedule of halving requests, there is a displayed finite budget whose final row refines the original tolerance row and whose every predecessor doubles classifier-below the previous row. The budget preserves the signed mantissa row, denominator ledger, common-exponent comparison, distance and radius rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support at each displayed step.*

Every $\mathsf{StreamName}^{\uparrow}$ *finite-window request and every* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity check may consume this iterated budget through the same finite dyadic ledger. The construction does not invoke host rational order, quotient stream equality, selected limits, countable choice, host real equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or a separate completion coordinate.*

Proof. Induct over the finite unary schedule. In the empty case, the budget is the original positive tolerance row together with its displayed signed mantissa, denominator, common-exponent, distance, radius, transport, replay, provenance, and local naming rows.

For the successor step, apply Definition 291.134 to the current positive tolerance row. It supplies the next halved row in a finite refinement window and records that doubling the new row is classifier-below the previous row inside the DyadicRatCore comparison ledger.

Use Definition 291.135 and Definition 291.136 to transport the accumulated budget to RegSeqRat regularity checks and StreamName finite-window requests. The induction preserves only displayed dyadic rows and support data, so no host rational order, quotient stream equality, selected limit, choice, host equality, ambient Real completeness, or completion coordinate is introduced. □

Theorem 291.139 (DyadicRatCore halving-budget cofinality)**.** *For any finite family of* $\mathsf{StreamName}^{\uparrow}$ *finite-window requests and* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity checks consuming a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the iterated halving budget of Definition 291.138 supplies a common cofinal tolerance window. The final budget row preserves the signed mantissa, denominator ledger, common-exponent comparison, distance and radius rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

Every listed consumer factors through that common row by the same finite dyadic ledger. The cofinal window does not use host rational order, quotient stream equality, selected limits, countable choice, host real equality, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or a separate completion coordinate.*

Proof. Enumerate the finite family of StreamName requests and RegSeqRat checks. Choose the unary halving schedule long enough to meet the largest displayed tolerance demand among those finite rows, and apply Definition 291.138 to the original positive tolerance row.

The resulting budget carries each predecessor and the final row inside one displayed dyadic ledger. Signed mantissas, denominator rows, common-exponent comparisons, distance and radius rows, transport, replay, provenance, and local naming are preserved at every step of the schedule.

Next apply Definition 291.136 to the StreamName requests and Definition 291.135 to the RegSeqRat checks. These handoffs let each consumer replace its original tolerance by the carried final row while keeping the same finite support rows.

Finally use Definition 291.137. It keeps all comparisons in the common-exponent ledger, so the common row is cofinal for the finite family without reopening the comparison as host rational order or importing quotient streams, selected limits, choice, host equality, ambient Real completeness, or completion data. □

Theorem 291.140 (DyadicRatCore terminal halving-cover selection-free budget)**.** *For any finite family of* $\mathsf{StreamName}^{\uparrow}$ *finite-window requests and* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity checks consuming a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, there is one displayed terminal halving-cover budget over the common-exponent ledger through which every listed consumer factors. The terminal budget preserves the signed mantissa row, denominator ledger, common-exponent comparison, doubled-radius comparisons, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

The budget is selection-free: it does not use host rational order, quotient stream equality, selected limits, countable choice, host $\mathsf{Real}^{\uparrow}$ *equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or a hidden completion coordinate.*

Proof. Start from the finite family of StreamName requests and RegSeqRat regularity checks. Apply the cofinality theorem Definition 291.139 to obtain a common final tolerance row for the whole displayed family.

The cofinal row is built from iterated halving closure. By Definition 291.138, each predecessor and the terminal row remain inside the same finite DyadicRatCore ledger, with the signed mantissa, denominator scale, common-exponent comparison, doubled-radius comparisons, transport, replay, provenance, and local naming rows preserved.

The two consumer faces are then routed through the existing handoffs. Use Definition 291.136 for finite-window requests and Definition 291.135 for regularity checks.

Finally apply Definition 291.137. It keeps every tolerance comparison in the displayed common-exponent ledger, so the terminal budget is one finite BEDC object rather than a selected limiting tolerance. The construction therefore refuses host rational order, quotient stream equality, selected limits, countable choice, host real equality, ambient Real completeness, and completion coordinates. □

Theorem 291.141 (DyadicRatCore terminal halving-cover exhaustion)**.** *Every terminal four-face L10 tolerance read using* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *factors through the selection-free terminal halving-cover budget of Definition 291.140. No such consumer can introduce a separate tolerance source, host rational order, quotient stream equality, selected limit, countable choice, host* $\mathsf{Real}^{\uparrow}$ *equality, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

The exhaustion route is the finite ledger

$$\mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{StreamName}^{\uparrow},\ \mathsf{RegSeqRat}^{\uparrow},\ \mathsf{Real}^{\uparrow}$$

together with the common-exponent transport and the two halving-cover handoffs. The terminal read therefore sees only the displayed dyadic budget, its common-exponent comparisons, the finite-window consumer face, the regular rational consumer face, and the downstream Real seal.

Proof. Start with a terminal four-face tolerance read. Apply Definition 291.140 to obtain one displayed terminal budget through which the finite-window and regularity consumers factor.

Use Definition 291.137 on that budget. It keeps every comparison in the same common-exponent ledger, so the terminal row is not replaced by host rational order or by an independent tolerance source.

Route the consumer faces through the two handoff theorems. The StreamName face uses Definition 291.136, and the RegSeqRat face uses Definition 291.135; the Real-facing read is downstream of those finite tolerance rows and cannot bypass them.

The accepted packet has no row for quotient stream equality, selected limits, countable choice, host Real equality, or ambient completeness. Hence every terminal four-face L10 read exhausts the available tolerance data at the selection-free halving-cover budget. □

Theorem 291.142 (DyadicRatCore halving-cover Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *terminal seal read consuming a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row factors through the terminal halving-cover budget before the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *faces are sealed. The handoff preserves the common-exponent transport, the finite StreamName request window, the regular rational readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

The Real-facing handoff introduces no host rational order, quotient stream equality, selected limit, countable-choice schedule, host $\mathsf{Real}^{\uparrow}$ *equality, ambient completeness coordinate, or separate completion coordinate.*

Proof. Start with a Real terminal seal read that consumes a DyadicRatCore tolerance row. Apply terminal halving-cover exhaustion, Definition 291.141, to force the terminal four-face read through the selection-free halving-cover budget.

Use common-exponent transport, Definition 291.137, on that budget. The tolerance row, its halved refinements, and the doubled-radius comparisons remain inside one displayed DyadicRatCore ledger before any StreamName, RegSeqRat, or Real seal face is exposed.

Route the two analytic faces through their handoffs. The finite StreamName request face is supplied by Definition 291.136, and the regular rational face is supplied by Definition 291.135.

Only after those two faces are sealed does the Real terminal read consume the tolerance row. Since each cited route preserves the displayed support rows and has no coordinate for host rational order, quotient stream equality, selected limits, countable choice, host Real equality, ambient completeness, or separate completion coordinates, the Real-facing handoff has none. □

The tolerance-halving cover sequence displayed by Definition 291.141 is the local public-boundary witness consumed by $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ terminal tolerance reads: later L10 routes cite this finite ledger, not a new top-level closure claim.

Theorem 291.143 (DyadicRatCore tolerance-halving cover composition)**.** *Let two displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *halving-cover packets occupy adjacent dyadic tolerance windows, with the terminal row of the first packet serving as the positive tolerance row consumed by the second. Then the two packets compose into a single displayed halving-cover packet whose common-exponent transport,* $\mathsf{StreamName}^{\uparrow}$

handoff, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, terminal budget, and nonselection clauses are inherited from the two inputs. The composite packet refines the original tolerance by the concatenated finite halving schedule and still exposes only signed mantissa rows, denominator ledgers, doubled-radius comparisons, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

The composed cover does not select a radius, reopen host rational order, identify quotient streams, choose limits, use countable choice, assert host $\mathsf{Real}^{\uparrow}$ *equality, import ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or add a separate completion coordinate.*

Proof. Start with the two adjacent halving-cover packets. Apply common-exponent transport, Definition 291.137, to both packets so the terminal row of the first and the initial row of the second are read inside the same finite comparison ledger.

Concatenate the two finite halving schedules. The iterated halving budget theorem, Definition 291.138, packages that concatenation as one displayed budget, preserving signed mantissas, denominator rows, doubled-radius comparisons, transport, replay, provenance, and local naming at each step.

Use halving-budget cofinality, Definition 291.139, to route the finite StreamName requests and RegSeqRat regularity checks through the final row of the composite budget. The StreamName and RegSeqRat handoff clauses are therefore inherited from the two input covers through the same finite support rows.

Finally apply terminal halving-cover exhaustion, Definition 291.141. It rules out a second tolerance source at the terminal four-face read, so the composite cover remains selection-free and does not reopen host order, quotient streams, selected limits, choice, host equality, ambient Real completeness, or completion coordinates. □

Theorem 291.144 (DyadicRatCore common-scale halving-cover factorization)**.** *Every composed* $\mathsf{DyadicRatCore}^{\uparrow}$ *halving-cover packet factors through the common exponent scale before it is consumed by a* $\mathsf{StreamName}^{\uparrow}$ *finite-window request or a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity check. More precisely, after two adjacent halving-cover packets are composed, the resulting tolerance route is first read in the common-exponent ledger and only then handed to the StreamName and RegSeqRat faces. The factorization preserves signed mantissa rows, denominator ledgers, doubled-radius comparisons, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicRatCore}^{\uparrow}}$ *support.*

The common-scale factorization does not select a radius, reopen host rational order, identify quotient streams, choose limits, use countable choice, assert host $\mathsf{Real}^{\uparrow}$ *equality, import ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or add a separate completion coordinate.*

Proof. Start from the composed halving-cover packet of Definition 291.143. Its terminal row and every predecessor row are inherited from the adjacent covers with the same finite dyadic support.

Apply common-exponent transport, Definition 291.137, to the composite packet. This places the original tolerance, the halved rows, and the doubled-radius comparisons in one displayed exponent ledger before any analytic consumer can read them.

The consumer faces then factor through the same ledger. StreamName finite-window requests use Definition 291.136, while RegSeqRat regularity checks use Definition 291.135. Both handoffs therefore consume the common-scale row rather than a separate tolerance source.

Since the composition and the two handoffs all preserve only the displayed dyadic rows, transport, replay, provenance, and local naming data, the factorization exports no host rational order, quotient stream equality, selected limits, countable choice, host real equality, ambient Real completeness, or completion coordinate. □

Chapter 292

A Concrete Naming Certificate for $\mathsf{CauchyModulus}^{\uparrow}$

The $\mathsf{CauchyModulus}^{\uparrow}$ interface records the explicit rate data used by the Bishop-style regular-sequence construction of $\mathsf{RegSeqRat}$ and $\mathsf{Real}^{\uparrow}$. It sits over $\mathsf{Nat}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and $\mathsf{StreamName}^{\uparrow}$: natural-number rows index observations, rational tolerance rows state requested bounds, stream-name rows identify the scheduled observations, and a finite ledger witnesses that the displayed modulus bound has been consumed by the downstream regular-sequence and real-number carriers.

The finite threshold ledger is the upstream rate surface consumed by chapter 641. That route reads the tolerance request, finite budget, $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}$ schedule row, dyadic comparison ledger, and $\mathsf{Real}^{\uparrow}$ handoff only after the modulus packet has exposed its $\mathsf{Nat}^{\uparrow}$ threshold, $\mathsf{Rat}^{\uparrow}$ tolerance, $\mathsf{StreamName}^{\uparrow}$ schedule, finite Cont window, and Pkg provenance rows.

292.1 Carrier and classifier

Definition 292.1 (Cauchy-modulus carrier)**.** *A* $\mathsf{CauchyModulus}^{\uparrow}$ *carrier packet is a finite* BHist *ledger with four visible groups of rows.*

1. *Unary index rows supplied by* $\mathsf{Nat}^{\uparrow}$*, including the requested precision index and the threshold index returned by the modulus.*
2. *Dyadic or rational tolerance rows supplied by* $\mathsf{Rat}^{\uparrow}$*, including the positive tolerance budget and the displayed comparison to the tolerance read by the regular-sequence carrier.*
3. *Scheduled observation rows supplied by* $\mathsf{StreamName}^{\uparrow}$*, naming the stream entries whose late pairwise distance is being bounded.*
4. *A finite consumption ledger stating that every displayed observation pair past the threshold uses the same modulus row, the same tolerance row, and the same* Pkg *provenance before it is passed to* $\mathsf{RegSeqRat}$ *or* $\mathsf{Real}^{\uparrow}$*.*

The carrier accepts only packets in which the index, tolerance, schedule, and consumption rows are present in the same finite history and are connected by displayed Cont *routes. It has no quotient of streams, no ambient limit object, and no hidden choice of a threshold outside the ledger.*

Definition 292.2 (Cauchy-modulus classifier)**.** *The* $\mathsf{CauchyModulus}^{\uparrow}$ *classifier compares two accepted packets by componentwise* hsame *on their precision-index rows, threshold-index rows, tolerance rows, scheduled observation rows, consumption-ledger rows,* Cont *routes, and* Pkg *provenance.*

Two packets classify together only when the same visible modulus schedule can be replayed through the transported finite ledger.

Lean4 (definition) `BEDC.Derived.CauchyModulusUp.CauchyModulusClassifier`

Theorem 292.3 (Cauchy-modulus hsame stability)**.** *Let P and Q be accepted* CauchyModulus$^{\uparrow}$ *packets. If every index, tolerance, scheduled-observation, consumption-ledger,* Cont*, and* Pkg *row of P is transported to the corresponding row of Q by displayed* hsame *comparisons, then Q is accepted by the carrier of Definition 292.1 and the classifier of Definition 292.2 identifies the two packets.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket hsame stability`
Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusCarrier hsame stability`

Proof. Project P to the four carrier groups. The supplied hsame rows transport the natural indices and rational tolerance rows first, so the threshold still answers the same displayed precision request.

Transport the scheduled observation rows through the StreamName$^{\uparrow}$ surface. The finite consumption ledger then replays the same Cont routes from the transported threshold and tolerance rows to the transported late-observation claims.

Finally repack the transported rows with the transported Pkg provenance. These are exactly the fields required by the carrier and by the componentwise classifier, so Q is accepted and the two packets classify together. □

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusLedgerPacket hsame stability`

Theorem 292.4 (Cauchy-modulus finite-window closure)**.** *For every accepted* CauchyModulus$^{\uparrow}$ *packet and every displayed precision request in its* Nat$^{\uparrow}$ *index rows, the packet exposes a finite* Cont *window containing the threshold row, the rational tolerance row, the scheduled late observation rows, and the consumption ledger read by* RegSeqRat *and* Real$^{\uparrow}$*. No consumer may read a convergence rate except through that finite window.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusContWindow closure`
Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket cont window closure`

Proof. Inspect the accepted carrier packet at the requested precision row. The threshold is present as a visible Nat$^{\uparrow}$ row, and the tolerance budget is present as a visible Rat$^{\uparrow}$ row in the same finite history.

The scheduled observation rows are linked to those two rows by the displayed Cont routes. Restrict the packet to the rows mentioned by those routes and to the corresponding consumption-ledger entries.

This restricted packet is finite and contains every row used by the downstream regular-sequence and real-number readbacks. Since the carrier has no other constructor for rate data, every convergence-rate read factors through the finite window just described. □

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusCarrier finite cont window closure`

Theorem 292.5 (Cauchy-modulus finite-window composition handoff)**.** *Suppose two accepted* CauchyModulus$^{\uparrow}$ *precision windows are composable through the displayed* Cont *routes of their carrier packets. Then their composition exposes a single finite handoff packet whose rows are exactly the* Nat$^{\uparrow}$ *precision and threshold rows, the* Rat$^{\uparrow}$ *tolerance rows, the* StreamName$^{\uparrow}$ *scheduled observation rows, the* RegSeqRat *late-pair evidence rows, the* Real$^{\uparrow}$ *classifier transport rows, the displayed* hsame *comparisons, and the* Pkg *provenance rows already present in the two windows. The handoff packet introduces no selected limit, quotient stream, or hidden threshold selector outside those rows.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket window composition handoff`

Proof. Project the two accepted windows by Definition 292.4. Each projection is finite and contains its displayed precision request, threshold row, tolerance row, scheduled observations, and consumption ledger.

Compose the two Cont ledgers along their shared carrier rows. The resulting ledger has only the rows named by the projections: the natural-number precision and threshold rows, rational tolerance rows, scheduled observation rows, regular-sequence late-pair evidence, real-classifier transport rows, hsame comparisons, and Pkg provenance.

Finally apply Definition 292.3 to transport the shared classifier comparisons across the composed packet. Since Definition 292.4 already exhausts every consumer-visible rate read, the composed packet has no constructor for a selected limit, quotient stream, or threshold selector beyond the displayed finite ledger. □

Theorem 292.6 (Monotone tail obligation)**.** *Let M be an accepted* CauchyModulus$^{\uparrow}$ *carrier packet. If a tolerance row is transported to a smaller positive dyadic tolerance through the displayed comparison ledger, then the threshold selected by the modulus row can be transported to a threshold that works for the smaller tolerance, and the late-pair bound rows remain accepted after* hsame *transport of the observation indices.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusTailWindow smaller tolerance transport`
Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulus monotone tail refinement window`

Proof. Unpack the carrier packet of Definition 292.1. The selected threshold and every late-pair bound are visible rows of the same finite BHist ledger, so decreasing the tolerance asks only for a refined dyadic or rational comparison row, not for a new stream object.

Transport the observation endpoints by the displayed hsame rows and compose the old bound with the smaller-tolerance comparison. The provenance ledger supplies the Cont and Pkg rows needed to repack the same late-pair evidence under the transported threshold. □

Theorem 292.7 (RegSeqRat regularity obligation)**.** *Every accepted* CauchyModulus$^{\uparrow}$ *carrier packet whose source stream is a* RegSeqRat *regular rational sequence supplies the explicit regularity data required by the* RegSeqRat *phase: for displayed indices m, n past the threshold selected by the modulus row, the bound ledger gives the estimate required by the regular-sequence classifier, and this estimate is stable under componentwise* hsame *transport of m, n, and the scheduled observations.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusRegularityWindow hsame transport`
Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket regseqrat regularity handoff`

Proof. Read the RegSeqRat regularity row as a request for a visible late-pair estimate. The carrier already stores exactly that estimate in the consumption ledger, indexed by the threshold and by the two displayed stream observations.

For stability, transport the two indices and observations through the classifier of Definition 292.2. The comparison row is part of the ledger, so the transported packet again contains the regularity estimate demanded by RegSeqRat. □

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusLedgerPacket regseqrat regularity rows`

Theorem 292.8 (Real classifier transport obligation)**.** *Assume the* $\mathsf{Real}^{\uparrow}$ *classifier is read from* RegSeqRat *representatives by rational tolerance tests. A* $\mathsf{CauchyModulus}^{\uparrow}$ *carrier packet transports across the* $\mathsf{Real}^{\uparrow}$ *classifier by sending its stream observations through the* RegSeqRat *classifier, transporting the modulus threshold rows by* hsame*, and reusing the tail-bound ledger for the transported representatives.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusLedgerPacket real classifier transport`

Proof. The only analytic datum used by the real classifier is an explicit tolerance test on sufficiently late representatives. The $\mathsf{CauchyModulus}^{\uparrow}$ packet exposes this datum as a threshold row together with the late-pair ledger.

Apply the RegSeqRat transport to the representative stream and then repack the threshold, comparison, and provenance rows. Since no equivalence class of real numbers is formed, the transport is a row-by-row certificate operation inside the displayed BHist packet. □

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusCarrierPacket real classifier transport`

Theorem 292.9 (Cauchy-modulus scoped dependency certificate)**.** *The carrier, classifier,* hsame *stability, finite* Cont *window closure, monotone tail obligation,* RegSeqRat *regularity handoff, and* $\mathsf{Real}^{\uparrow}$ *classifier transport theorem bind every exported* $\mathsf{CauchyModulus}^{\uparrow}$ *row to the following dependency stack:* $\mathsf{Nat}^{\uparrow}$ *index rows,* $\mathsf{Rat}^{\uparrow}$ *tolerance rows,* $\mathsf{StreamName}^{\uparrow}$ *scheduled observations,* RegSeqRat *regularity rows,* $\mathsf{Real}^{\uparrow}$ *classifier transport,* hsame *transport, finite* Cont *windows, and* Pkg *provenance. No exported row uses a selected limit, a stream quotient, or an unrecorded threshold selector.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusCarrier dependency boundary`

Proof. Start with the carrier and classifier of Definition 292.1 and Definition 292.2. They list the visible precision, tolerance, scheduled-observation, comparison, Cont, and Pkg rows, so every consumer-visible coordinate begins as a displayed finite BHist entry.

Next project the transport rows in order. The hsame stability theorem keeps the classifier componentwise, the finite Cont window theorem bounds the readback window, the monotone tail theorem records stronger-tolerance reuse, and the RegSeqRat handoff reads the regularity estimate from the same late pair ledger.

Finally apply the $\mathsf{Real}^{\uparrow}$ classifier transport theorem. It reuses the representative-stream, threshold, comparison, and provenance rows already named above, so the scoped dependency certificate closes inside the displayed dependency stack and introduces no selected limit, stream quotient, or hidden threshold choice. □

Theorem 292.10 (Cauchy-modulus NameCert obligation surface)**.** *The* $\mathsf{CauchyModulus}^{\uparrow}$ *carrier and classifier of Definition 292.1 and Definition 292.2 supply the paper-side obligation surface for an eventual* $\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$*. The source rows are the displayed* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*, and* $\mathsf{StreamName}^{\uparrow}$ *packets; the classifier is componentwise* hsame *transport of the finite modulus ledger; the ledger exactness condition exports only the threshold, tolerance, scheduled observation,* Cont*, and* Pkg *rows consumed by* RegSeqRat *and* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket namecert obligation surface`

Proof. The carrier definition names the source rows and the finite consumption ledger. The classifier definition states exactly how those rows move under componentwise hsame transport.

Apply Definition 292.3 for classifier stability and Definition 292.4 for the finite read window. Use Definition 292.6, Definition 292.7, and Definition 292.8 to identify the visible tail-control

rows consumed by stronger tolerances, regular-sequence readback, and real-classifier transport. Together they expose the naming-certificate fields at the paper surface without adding hidden limits or unrecorded threshold choices. □

Theorem 292.11 (Cauchy-modulus public consumer boundary)**.** *The public* $\mathsf{CauchyModulus}^{\uparrow}$ *consumer boundary is exactly the finite* BHist *package consisting of the carrier rows of Definition 292.1, the classifier rows of Definition 292.2, the* hsame *stability rows, the finite* Cont *window-closure rows, monotone tail transport, the* RegSeqRat *regularity handoff,* $\mathsf{Real}^{\uparrow}$ *classifier transport, and the local* $\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$ *obligation surface. Thus any* RegSeqRat *consumer or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer reads only visible* $\mathsf{Nat}^{\uparrow}$ *precision rows,* $\mathsf{Rat}^{\uparrow}$ *tolerance rows,* $\mathsf{StreamName}^{\uparrow}$ *scheduled observation rows,* RegSeqRat *late-pair rows,* $\mathsf{Real}^{\uparrow}$ *classifier-transport rows,* hsame *rows,* Cont *rows, and* Pkg *provenance. It reads no selected limit, stream quotient, host index equality, or completion row.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket public consumer boundary`

Proof. Start with the carrier and classifier of Definition 292.1 and Definition 292.2. These rows display the precision, tolerance, scheduled observation, comparison, continuation, and provenance coordinates available to a consumer.

Apply Definition 292.3 to keep the classifier rowwise, and apply Definition 292.4 to bound the finite readback window. Use Definition 292.6 for stronger-tolerance transport, and use Definition 292.7 for the regular-sequence late-pair handoff.

Now apply Definition 292.8 to identify the finite real-classifier transport rows. The dependency stack is then the one certified by Definition 292.9 and exposed by Definition 292.10.

Finite ledger exhaustion gives the boundary. Every row named in the statement is a displayed BHist coordinate or a displayed transport of one, and the carrier has no coordinate for a selected limit, a stream quotient, a host index equality, or a completion row. □

Theorem 292.12 (Cauchy-modulus refinement consumer boundary)**.** *Every accepted* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *consumer read whose shared-meet row, selector-budget row, dyadic tolerance row,* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row, and* $\mathsf{Real}^{\uparrow}$ *seal row are admitted factors through an accepted* $\mathsf{CauchyModulus}^{\uparrow}$ *finite-window packet of Definition 292.4 and through the public consumer boundary of Definition 292.11. The read exports only the visible* $\mathsf{Nat}^{\uparrow}$ *precision and threshold rows,* $\mathsf{Rat}^{\uparrow}/\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows,* $\mathsf{StreamName}^{\uparrow}$ *scheduled observation rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *late-pair schedule rows,* $\mathsf{Real}^{\uparrow}$ *seal-transport rows,* hsame *rows,* Cont *rows, and* Pkg *provenance consumed by the downstream carrier of chapter 885. It exports no quotient stream, selected limit, host real equality, countable-choice row, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusCarrier refinement consumer boundary`

Proof. Begin with the carrier rows of Definition 292.1. They display the precision request, threshold, tolerance, scheduled observations, finite consumption ledger, continuation routes, and provenance needed by any rate consumer.

Apply the classifier of Definition 292.2 to keep those rows componentwise under hsame transport. Then use Definition 292.4 to restrict the accepted read to the finite window containing the threshold, tolerance, scheduled observation, and regularity rows.

Next apply Definition 292.11. It identifies the exact public package seen by $\mathsf{RegSeqRat}^{\uparrow}$ and finite-window $\mathsf{Real}^{\uparrow}$ consumers, including the dyadic tolerance, regular readback, real seal transport, continuation, and provenance rows.

Finally read the refinement chapter as a downstream consumer of that package: chapter 885 admits its shared meet, selector budget, dyadic tolerance, regular schedule, and real seal rows only after this public finite-window route is present. Since the upstream package has no coordinate for quotient streams, selected limits, host real equality, countable choice, or ambient completeness, neither can the accepted refinement consumer read one from the $\mathsf{CauchyModulus}^{\uparrow}$ side. □

Theorem 292.13 (CauchyModulus explicit-modulus standard bridge)**.** *The public consumer boundary of Definition 292.11 is exactly the standard constructive explicit-modulus reading of a regular rational name. It consists of a visible precision row, a visible tolerance row, a finite threshold row, a scheduled observation window, a late-pair comparison ledger, and provenance through* $\mathsf{Nat}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$.

Under this reading, the $\mathsf{CauchyModulus}^{\uparrow}$ *packet exports no selected limit, hidden threshold choice, stream quotient, host index equality, or completion row.*

Proof. Project the carrier and classifier rows of Definition 292.1 and Definition 292.2. These rows display the precision, tolerance, threshold, scheduled observation, late-pair comparison, transport, and provenance coordinates used by the public consumer boundary.

Apply the monotone-tail obligation of Definition 292.6 and the regularity obligation of Definition 292.7. They identify the late-index threshold and the late-pair comparison ledger as finite rows, not as hidden choices or quotient data.

Use Definition 292.11 to collect the same rows into the public $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer surface. The source certificates through $\mathsf{Nat}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ are already displayed in that boundary.

Repack this finite ledger as the standard explicit-rate schema. Since every exported coordinate is a visible row of the original boundary, there is no coordinate from which to read a selected limit, hidden threshold choice, stream quotient, host index equality, or completion row. □

Lean4 ✓ `BEDC.Derived.CauchyModulusUp.CauchyModulusUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyModulus}^{\uparrow}$ packet is generated from visible $\mathsf{Nat}^{\uparrow}$ precision and threshold rows, visible $\mathsf{Rat}^{\uparrow}$ tolerance rows, scheduled $\mathsf{StreamName}^{\uparrow}$ observation rows, and a finite consumption ledger showing how the displayed bound is read by RegSeqRat and $\mathsf{Real}^{\uparrow}$. This is the Bishop-style explicit-rate object needed for regular rational sequences and real-number convergence, with no stream quotient, ambient limit object, hidden threshold choice, limit selector, or completed real object.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$, maturePackageClosed)

Scope closed: The mature paper scope is the carrier and classifier, finite-window closure, monotone tail, $\mathsf{RegSeqRat}^{\uparrow}$ regularity, $\mathsf{Real}^{\uparrow}$ classifier transport, public consumer boundary, and explicit-modulus bridge.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.CauchyModulusUp.CauchyModulusPacket\_public\_consumer\_boundary`

Bridge status: bridgeChecked

Origin: human

Not claimed: The chapter does not close the formal Lean namespace, the full $\mathsf{NameCert}_{\mathsf{CauchyModulus}^{\uparrow}}$ theorem, $\mathsf{Real}^{\uparrow}$ completeness, a Cauchy completion, quotient equality of real names, or a selected limit.

Upgrade path: No further formal-axis work remains for the explicit-modulus packet; the standard bridge is checked in Lean.

Chapter 293

A Concrete Naming Certificate for $\mathsf{DyadicAbsoluteValue}^{\uparrow}$

The $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ interface isolates the finite rows needed when a real-completion tolerance ledger reads the nonnegative size of a dyadic rational source. It factors the absolute-value operation through the visible $\mathsf{DyadicRatCore}^{\uparrow}$ source packet, sign split, common-exponent mantissa row, nonnegative endpoint, and tolerance ledger, so $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers can cite a named certificate without extending the near-capacity dyadic core chapter.

The source row D, common-exponent mantissa row M, endpoint row E, and tolerance row V are read from the $\mathsf{DyadicRatCore}^{\uparrow}$ source surface of chapter 291 before any $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer sees the endpoint. This records the finite dyadic-core dependency used by the carrier and the consumer proof sketches below.

Definition 293.1 (Dyadic absolute-value carrier)**.** *A* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (D, S, M, E, V, H, C, P, N)$$

with the following visible coordinates:

1. *D is the source* $\mathsf{DyadicRatCore}^{\uparrow}$ *row whose mantissa, unary exponent, denominator ledger,* $\mathsf{Int}^{\uparrow}$ *provenance, and* $\mathsf{Rat}^{\uparrow}$ *provenance are read from the dyadic core surface;*
2. *S is the sign-split row deciding which displayed branch of the scaled mantissa is used for the absolute-value read;*
3. *M is the common-exponent mantissa row that exposes the source mantissa at the same denominator ledger used by dyadic distance-window observations;*
4. *E is the nonnegative output endpoint row, recorded as a* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint whose mantissa is the displayed nonnegative branch of M;*
5. *V is the tolerance and absolute-value ledger recording the radius window consumed by* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *routes;*
6. *H stores componentwise* hsame *transports for the source, sign split, mantissa row, nonnegative endpoint, tolerance ledger, provenance, and local name;*
7. *C stores the displayed* Cont *routes from D to S and M, from S and M to E, and from E to the tolerance ledger V;*

8. *P records* Pkg *provenance over* $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient rationals, selected real values, trichotomy, host integer normal forms, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Theorem 293.2 (Dyadic absolute-value NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}$ *surface for Definition 293.1 consists exactly of source* $\mathsf{DyadicRatCore}^{\uparrow}$ *admission, sign-split exposure, common-exponent mantissa readback, nonnegative endpoint construction, tolerance-ledger exposure, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet A. The coordinates list the dyadic source, sign split, common-exponent mantissa, endpoint, tolerance ledger, transport, continuation, provenance, and local name.

The source and mantissa reads are inherited from the visible $\mathsf{DyadicRatCore}^{\uparrow}$ rows. The sign split chooses the displayed nonnegative branch of the scaled mantissa, and the endpoint row repacks that branch with the same denominator ledger and provenance.

The remaining obligations are routing and naming obligations. The rows H, C, P, N transport the listed coordinates, replay the reads, preserve the $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ source ledgers, and name the packet without introducing any hidden quotient or real-completion coordinate. □

Theorem 293.3 (Dyadic absolute-value transport stability)**.** *For accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carriers whose displayed source, sign-split, mantissa, endpoint, tolerance-ledger, provenance, and naming rows are related componentwise by the stored* hsame *rows, the absolute-value endpoint and tolerance ledger remain readable after transport. The transported carrier computes the nonnegative endpoint from the transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *source through the transported common-exponent mantissa row.*

Lean4 ✓ `BEDC.Derived.DyadicAbsoluteValueUp.DyadicAbsoluteValuePacket transport stability`

Proof. Project the two accepted carriers. The rows that determine the absolute-value read are exactly the source D, sign split S, common-exponent mantissa row M, endpoint E, and tolerance ledger V.

Use the componentwise transport entries in H to move those rows to the transported surface. The continuation rows in C then replay the read from D to S and M, from S and M to E, and from E to V.

The dyadic core distance-window stability theorem, Definition 291.10, supplies the underlying common-exponent absolute-value stability for the source row. Repacking that stable window with the displayed endpoint and ledger rows gives the claimed transport stability. □

Theorem 293.4 (Dyadic absolute-value nonnegative bridge)**.** *Every accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier exposes a nonnegative dyadic endpoint E whose source is the sign-split common-exponent mantissa row of D. Any* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer of this endpoint reads only the displayed endpoint row, tolerance ledger, transports, continuation routes, package provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}$ *row.*

Proof. Start from the accepted carrier and read the sign-split row S. The common-exponent mantissa row M places the source mantissa of D on the same denominator ledger used by the dyadic core distance and absolute-value window.

The nonnegative endpoint E is then the displayed branch chosen by S and repacked as a dyadic endpoint with the visible $\mathsf{Int}^{\uparrow}$ and $\mathsf{Rat}^{\uparrow}$ provenance. No separate order oracle or trichotomy row is needed, because the branch is already part of the finite packet.

A downstream consumer reaches E through the continuation routes in C and receives the tolerance ledger V as the only real-facing output surface. Thus the bridge exports a nonnegative dyadic endpoint without exporting quotient rationals, selected real values, host integer normal forms, or $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 293.5 (Dyadic absolute-value ledger exactness)**.** *For an accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier, the finite ledger is exact for the route from the source* $\mathsf{DyadicRatCore}^{\uparrow}$ *row through sign split, common-exponent mantissa readback, nonnegative endpoint construction, and tolerance readback to* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumers. No ledger entry records a quotient rational, selected real value, trichotomy proof, host integer normal form, or real-completeness witness.*

Proof. Inspect the carrier of Definition 293.1. The only absolute-value data are D, S, M, E, V together with their transport, continuation, provenance, and naming rows.

Apply Definition 293.2 to bind every accepted read to those rows. Transport stability then shows that a transported read cannot replace the common-exponent mantissa window or tolerance ledger with an external absolute-value oracle.

Finally apply Definition 293.4. Every completion-facing use factors through the same endpoint and tolerance ledger, so the ledger is exact for the displayed finite route and contains no unlisted analytic or host-normalization coordinate. □

Theorem 293.6 (Dyadic absolute-value obligation closure package)**.** *The carrier, NameCert obligations, transport stability, nonnegative bridge, and ledger exactness of Definition 293.1, Definition 293.2, Definition 293.3, Definition 293.4, and Definition 293.5 assemble the finite* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *obligation package over* $\mathsf{DyadicRatCore}^{\uparrow}$, *the* $\mathsf{Int}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$ *sign rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *tolerance consumers,* BHist, hsame, Cont, Pkg, *and* NameCert. *The package exports only the displayed source, sign split, common-exponent mantissa, nonnegative endpoint, tolerance ledger, transport, continuation, provenance, and local naming rows.*

Proof. The carrier theorem supplies the finite packet and lists exactly the rows available to the package. The NameCert obligations bind admission, sign-split exposure, common-exponent mantissa readback, endpoint construction, tolerance-ledger exposure, transport, continuation, provenance, and naming to those coordinates.

Transport stability then shows that accepted reads remain inside the same displayed surface after componentwise hsame movement. The nonnegative bridge identifies the downstream endpoint read consumed by $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ routes.

Ledger exactness supplies the final packaging boundary. It rules out any hidden coordinate for a host absolute value, trichotomy, quotient normalization, or analytic completeness, so the five cited rows form one finite $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ obligation package rather than an appeal to an external absolute-value operation. □

Theorem 293.7 (Dyadic absolute-value endpoint determinacy)**.** *Accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carriers with the same transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *source row, sign-split row, and common-exponent mantissa row expose the same nonnegative endpoint row. The endpoint is determined by the displayed branch row S and the mantissa row M, not by a host absolute-value operation or an external order oracle.*

Proof. Project the accepted carriers through Definition 293.1. The only rows that determine the endpoint are the source D, sign split S, common-exponent mantissa row M, and endpoint row E.

Apply Definition 293.3 to move the compared packets to the common displayed surface. On that surface the same sign-split row selects the same nonnegative branch of the same mantissa row.

Finally apply Definition 293.4. The endpoint row is the repacking of that displayed branch with the visible dyadic provenance, so two accepted carriers with the same transported source, split, and mantissa rows expose the same endpoint row. □

Theorem 293.8 (Dyadic absolute-value tolerance-window handoff)**.** *Every* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer of the absolute-value endpoint of an accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier reads the displayed tolerance ledger* V*. No such consumer can bypass* V *by reading a separate host absolute-value, trichotomy, quotient rational, selected real value, or completeness coordinate.*

Proof. Begin with a downstream consumer route. By Definition 293.4, the consumer reaches the endpoint only through the displayed endpoint row E together with the tolerance ledger V.

The route from source to endpoint is fixed by the carrier and by Definition 293.3. It passes through D, S, M, E and then through the continuation route from E to V.

Apply Definition 293.5. The finite ledger is exact for the route from source row through endpoint construction to completion-facing consumers, so the tolerance window V is part of every accepted handoff. □

Theorem 293.9 (Dyadic absolute-value sign-split exclusion)**.** *The* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *packet excludes trichotomy and host integer normal forms. Its only sign data are the displayed branch row* S*, the common-exponent mantissa row* M*, the nonnegative endpoint row* E*, and the tolerance ledger* V *routed by the finite carrier.*

Proof. Inspect Definition 293.1. The coordinate list includes the source row, sign-split row, mantissa row, endpoint row, tolerance ledger, transport, continuation, provenance, and local name, and it explicitly omits trichotomy and host integer normal forms.

Definition 293.2 binds the local naming surface to those displayed rows. Endpoint determinacy then shows that the endpoint is fixed by the displayed branch row and mantissa row rather than by any hidden order datum.

The exclusion is stable for downstream use by Definition 293.8. A consumer receives only the endpoint and tolerance ledger routed through the finite packet, so no trichotomy or host normalization row can be extracted from the certificate. □

Theorem 293.10 (Dyadic absolute-value scoped certificate boundary)**.** *The* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *scoped certificate boundary is exactly the package formed by the carrier, local obligation surface, transport stability, nonnegative bridge, ledger exactness, endpoint determinacy, tolerance-window handoff, and sign-split exclusion of Definition 293.1, Definition 293.2, Definition 293.3, Definition 293.4, Definition 293.5, Definition 293.7, Definition 293.8, and Definition 293.9. Every consumer read of* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *is bound to the displayed rows*

$$D, S, M, E, V, H, C, P, N$$

over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*. The boundary contains no quotient rational, selected real value, trichotomy witness, host integer normal form, external absolute-value operation, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First collect the visible inventory. The carrier lists exactly the rows $D, S, M, E, V, H, C, P, N$, and the local NameCert obligations identify those rows as the admitted source, sign-split, common-exponent mantissa, endpoint, tolerance ledger, transport, continuation, provenance, and naming surface.

Next fix the route followed by every absolute-value read. Transport stability keeps accepted reads on the transported displayed surface, while endpoint determinacy forces the endpoint through the same sign-split row and common-exponent mantissa row. The nonnegative bridge and tolerance-window handoff then route every $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumer through the endpoint row E and tolerance ledger V.

Finally apply ledger exactness together with sign-split exclusion. Those theorems rule out quotient rationals, selected real values, trichotomy, host integer normal forms, external absolute-value rows, and $\mathsf{Real}^{\uparrow}$ completeness, so the scoped boundary is precisely the displayed finite packet. □

Theorem 293.11 (Dyadic absolute-value scoped public handoff)**.** *The scoped certificate boundary of* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *exposes a public consumer surface for* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consisting exactly of the rows*

$$D, S, M, E, V, H, C, P, N.$$

Every accepted public handoff reads the nonnegative endpoint through E, reads tolerance information through V, and cites the scoped boundary before any completion-facing consumer can use the packet.

Proof. Begin with the scoped certificate boundary. It binds every consumer read to the finite rows $D, S, M, E, V, H, C, P, N$ over the dyadic source, sign split, mantissa row, endpoint, tolerance ledger, transport, route, provenance, and local naming surface.

Apply the nonnegative bridge and tolerance-window handoff. The bridge identifies the endpoint row E as the only nonnegative dyadic endpoint exported to downstream consumers, and the handoff forces every completion-facing read to include the tolerance ledger V.

Finally apply ledger exactness and sign-split exclusion. These results remove quotient rationals, selected real values, trichotomy, host integer normal forms, external absolute-value operations, and $\mathsf{Real}^{\uparrow}$ completeness from the public surface, so the cited handoff is exactly the scoped finite boundary. □

Theorem 293.12 (Dyadic absolute-value RegSeqRat consumer exhaustion)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *tolerance read of an accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier factors through the displayed rows*

$$D, S, M, E, V, H, C, P, N.$$

In particular, a regular-Cauchy consumer can inspect the source dyadic row, sign split, common-exponent mantissa, nonnegative endpoint, tolerance ledger, transports, routes, provenance, and local name, but it cannot inspect any absolute-value datum outside those rows.

Proof. Take a $\mathsf{RegSeqRat}^{\uparrow}$ consumer route. By the tolerance-window handoff, the route reaches the absolute-value endpoint only through E and then reads the tolerance window through V.

The source of that endpoint is fixed by transport stability and endpoint determinacy. Together they force the endpoint to be the transported sign-split branch of the common-exponent mantissa row, so the consumer also factors through D, S, M, H, C.

The remaining rows are packaging rows. The NameCert obligations and ledger exactness bind provenance and local naming to P, N and rule out any extra host absolute-value row, quotient rational, selected real, trichotomy witness, host normal form, or completeness witness. Thus the regular-Cauchy consumer surface is exhausted by the displayed packet. □

Theorem 293.13 (Dyadic absolute-value Real tolerance non-escape)**.** *No* $\mathsf{Real}^{\uparrow}$ *tolerance read of an accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *carrier can export a selected real value, trichotomy witness, quotient rational, host integer normal form, or* $\mathsf{Real}^{\uparrow}$ *completeness row. The real-facing read is limited to the nonnegative dyadic endpoint E, the tolerance ledger V, and the transport, route, provenance, and local naming rows already present in*

$$D, S, M, E, V, H, C, P, N.$$

Proof. Start with a real-facing endpoint read. The nonnegative bridge routes the read through the displayed endpoint E, and the tolerance-window handoff requires the tolerance ledger V before any $\mathsf{Real}^{\uparrow}$ consumer can use the endpoint.

The sign data are already exhausted by the sign-split exclusion theorem. It permits only the branch row S, mantissa row M, endpoint row E, and tolerance row V, and it excludes trichotomy and host integer normal forms.

Apply ledger exactness and the scoped certificate boundary. They rule out quotient rationals, selected real values, external absolute-value operations, and $\mathsf{Real}^{\uparrow}$ completeness rows, leaving only the displayed finite packet for the real tolerance read. □

Theorem 293.14 (Dyadic absolute-value Bishop induction gap)**.** *The* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *packet supplies finite Bishop-style induction over the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows: sign-split induction through S, endpoint induction through E, and tolerance induction through V. This induction route projects the source row D, common-exponent mantissa row M, nonnegative endpoint row E, tolerance ledger V, componentwise transport H, route C, provenance P, and local name N, but it does not construct quotient rationals, selected real values, trichotomy, host integer normal forms, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Project the carrier of Definition 293.1. The finite induction data are the source $\mathsf{DyadicRatCore}^{\uparrow}$ row D, the sign-split row S, the mantissa row M, the endpoint row E, and the tolerance ledger V.

Use endpoint determinacy and sign-split exclusion. The sign branch determines the endpoint by the displayed mantissa row, while the exclusion theorem keeps trichotomy and host integer normal forms outside the packet.

Finally use tolerance-window handoff and Real tolerance non-escape. Every completion-facing consumer reads the tolerance ledger V before it reaches a $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ use, and the route refuses quotient rationals, selected real values, and ambient real completeness. Thus the available induction is exactly the finite Bishop route through the displayed dyadic rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ packet is generated from a $\mathsf{DyadicRatCore}^{\uparrow}$ source row, a sign-split row, a common-exponent mantissa row, a nonnegative endpoint row, a tolerance and absolute-value ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 293.1, Definition 293.2, Definition 293.3, Definition 293.4, Definition 293.5, Definition 293.10, Definition 293.11, Definition 293.12, and Definition 293.13 bind the mature packet boundary consisting of the finite dyadic absolute-value carrier, local NameCert obligations, transport stability, nonnegative bridge, ledger exactness, scoped certificate boundary, public handoff, RegSeqRat consumer exhaustion, and Real tolerance non-escape.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.DyadicAbsoluteValueUp.DyadicAbsoluteValuePacket\_transport\_stability`
Bridge status: none
Origin: human
Not claimed: This chapter does not close quotient rationals, selected real values, trichotomy, host integer normal forms, $\mathrm{Real}^{\uparrow}$ completeness, or bridge checking.
Upgrade path: The theory axis is at mature closure; the remaining upgrade is bridge checking for the displayed dyadic absolute-value packet.

Chapter 294

A Concrete Naming Certificate for $\mathsf{ControlObservability}^{\uparrow}$

The $\mathsf{ControlObservability}^{\uparrow}$ interface records the finite observation data of a finite-dimensional linear system. Its BEDC surface is the observation-row part of the standard control-theory observability test, read through $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Mat}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$. The textbook reference is Kailath, *Linear Systems* (1980).

The finite observation matrix is consumed by the reachability-dual ledger of chapter 297 and by the finite controller surface of chapter 296. This chapter exports the finite output-trace ledger and kernel-separation row; those siblings consume the same matrix and vector-space rows when forming reachability and control certificates.

294.1 Carrier definition

Definition 294.1 (Control-observability carrier)**.** *A* $\mathsf{ControlObservability}^{\uparrow}$ *carrier is a finite* BHist *observation packet over* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{LinMap}^{\uparrow}$*. Its rows are a finite-dimensional state-space row, a state-transition row* A *read as a* $\mathsf{LinMap}^{\uparrow}$ *endomorphism, an output row* C *read as a* $\mathsf{Mat}^{\uparrow}$ *or* $\mathsf{LinMap}^{\uparrow}$ *map to an output space, the finite observation rows*

$$C, \quad CA, \quad CA^2, \quad \ldots, \quad CA^{n-1},$$

the stacked observation-matrix row $\mathcal{O}(A, C)$*, the finite output-trace ledger, the* hsame *comparisons between corresponding observation rows, the* Cont *provenance rows explaining how each trace is read from the displayed system rows, and the* Pkg *rows naming the four dependency certificates.*

The classifier identifies two accepted packets exactly when their finite observable output traces are matched by displayed hsame *rows, with the same* Cont *and* Pkg *provenance. The carrier exports no hidden host state-space quotient, analytic trajectory space, unlogged infinite trace, or external control-system object.*

Lean4 (definition) `BEDC.Derived.ControlObservabilityUp.ControlObservabilityFiniteObservationPacket`

294.2 The certificate

Theorem 294.2 (Control-observability NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ControlObservability}^{\uparrow}}$ *obligation surface consists of the following five rows.*

1. *The carrier row of Definition 294.1, including the displayed finite-dimensional* DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, *and* LinMap$^{\uparrow}$ *source rows.*
2. *The classifier row saying that accepted packets are compared only by shared finite observable output traces under* hsame.
3. *The observation-matrix rank/kernel separation row for* $\mathcal{O}(A, C)$.
4. *The finite trace ledger readback row, which reads every consumer-visible output trace from the displayed observation rows.*
5. *The transport-stability row saying that* hsame *transport of the state, transition, output, observation, ledger,* Cont, *and* Pkg *rows remains an accepted* ControlObservability$^{\uparrow}$ *packet.*

```
Lean4 ✓  BEDC.Derived.ControlObservabilityUp.ControlObservabilityFiniteObservationPacket classifier
transport
Lean4 ✓  BEDC.Derived.ControlObservabilityUp.ControlObservabilityCarrierPacket obligation surface
Lean4 ✓  BEDC.Derived.ControlObservabilityUp.ControlObservationPacket namecert obligation surface
```

Proof. Start from the carrier definition. It already lists the finite source rows, the observation-matrix rows, the trace ledger, and the provenance rows, so the carrier obligation is a projection from a displayed BHist packet.

The classifier obligation is the declared comparison rule on observable traces. Because the carrier has no coordinate for hidden state quotients or infinite trace objects, equality of the visible output ledger is the only comparison surface available to consumers.

The remaining obligations are the finite matrix test, the ledger readback, and transport stability. Each is stated over rows already present in the carrier, so the obligation surface is local to the displayed BEDC packet and its four dependency certificates. □

Theorem 294.3 (Control-observability kernel separation)**.** *Let* P *be an accepted* ControlObservability$^{\uparrow}$ *packet with state-space dimension row* n*, transition row* A*, output row* C*, and observation matrix row* $\mathcal{O}(A, C)$*. If the visible kernel row of* $\mathcal{O}(A, C)$ *is the zero state row and the rank row of* $\mathcal{O}(A, C)$ *is the displayed dimension row* n*, then any two initial-state rows with the same finite output-trace ledger are classified by the state-space* hsame *row.*

```
Lean4 ✓  BEDC.Derived.ControlObservabilityUp.ControlObservabilityPacket kernel separation
Lean4 ✓  BEDC.Derived.ControlObservabilityUp.ControlObservabilityKernelSeparation state rows
hsame
```

Proof. Read the finite output traces through the observation rows of Definition 294.1. Agreement of the trace ledgers says that the displayed difference of the two initial-state rows is sent to the zero output row by every row $C, CA, \ldots, CA^{n-1}$.

Stacking those rows gives a single $\mathcal{O}(A, C)$ ledger equation. The zero-kernel row says that a state row annihilated by the whole observation matrix is the displayed zero state row.

The rank row names the same condition in finite-dimensional matrix form. Repacking the zero difference through the state-space classifier gives the required hsame comparison of the two initial-state rows. □

Theorem 294.4 (Control-observability finite trace ledger readback)**.** *Every consumer-visible output trace of an accepted* ControlObservability$^{\uparrow}$ *packet is read from the finite observation rows* $C, CA, \ldots, CA^{n-1}$*, the stacked observation-matrix row* $\mathcal{O}(A, C)$*, the displayed* hsame *comparisons,*

and the Cont/Pkg *provenance naming* DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, *and* LinMap$^{\uparrow}$. *No unbounded trajectory object, hidden observer state, host controllability dual, or external realization is exported.*

Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservabilityPacket trace ledger readback`
Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservability finite trace ledger readback`
Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservabilityCarrier finite trace ledger readback`

Proof. Project an accepted packet to its finite trace ledger. Each ledger entry is attached to one of the displayed observation rows and is read through the Cont provenance of the carrier.

Project the dependency rows next. The Pkg entries name exactly the dynamical-system, matrix, vector-space, and linear-map certificates that supply the displayed transition and output rows.

Constructor inspection of the carrier excludes any additional trace source. Since no unbounded trajectory object, hidden observer state, host controllability dual, or external realization has a row in the packet, every visible trace must read back to the finite ledger just described. □

Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservabilityFiniteTraceLedger readback`

Closure status for NameCert$_{\text{ControlObservability}^{\uparrow}}$.

Constructive story: The chapter builds a finite observation packet over DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, and LinMap$^{\uparrow}$: it displays the observation-matrix row, separates rank and kernel obligations, records the finite output-trace ledger, and keeps host trajectory and full control-system data outside the carrier.

Theory closure: TheoryGate(NameCert$_{\text{ControlObservability}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scoped boundary is the finite BHist observation packet, the hsame trace classifier, the observation-matrix rank and kernel rows, the Cont trace ledger, and the Pkg dependencies on DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, and LinMap$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{ControlObservability}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ControlObservabilityUp.ControlObservationPacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close a host control-system category, analytic trajectory semantics, Kalman decomposition, controllability duality, or a public standard bridge.

Upgrade path: The paper theory axis is mature; only bridgeChecked formal bridge status remains separate from this paper-axis closure.

Theorem 294.5 (Control-observability zero-dimensional observation ledger)**.** *Let P be an accepted* ControlObservability$^{\uparrow}$ *packet as in Definition 294.1. Suppose its displayed finite-dimensional state-space row has dimension $n = 0$, with transition row A, output row C, finite observation-row ledger*

$$(CA^k)_{0 \le k < n},$$

and stacked observation-matrix row $\mathcal{O}(A, C)$ formed by stacking exactly those displayed observation rows. Then the observation-row ledger is the empty finite sequence, and the stacked row $\mathcal{O}(A, C)$ has no entries.

Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservationPacket zero dimensional observation ledger`

Proof. By Definition 294.1, the only observation rows available to an accepted ControlObservability$^{\uparrow}$ packet are the finite rows

$$C, \quad CA, \quad CA^2, \quad \ldots, \quad CA^{n-1}.$$

Equivalently, these rows are indexed by the finite interval $0 \le k < n$ and have the displayed form CA^k.

If $n = 0$, there is no index k satisfying $0 \leq k < 0$. Hence the finite interval indexing the displayed observation rows is empty. The carrier has no additional observation-row coordinate beyond this finite ledger, so the observation-row sequence of P is empty.

The stacked observation-matrix row $\mathcal{O}(A, C)$ is, by the same carrier definition, the row obtained from exactly the displayed finite observation rows. Stacking over the empty finite sequence contributes no row. Therefore $\mathcal{O}(A, C)$ has no entries in the zero-dimensional state-space case. □

Lean4 ✓ `BEDC.Derived.ControlObservabilityUp.ControlObservabilityFiniteObservationPacket zero dimensional observation ledger`

Chapter 295

A Concrete Naming Certificate for $\mathsf{KalmanFilter}^{\uparrow}$

Following Kalman and Bucy, the $\mathsf{KalmanFilter}^{\uparrow}$ interface records the finite prediction-and-update packet of a discrete linear estimator. Its BEDC surface consumes $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$ for transition rows, $\mathsf{NameCert}_{\mathsf{ControlObservability}^{\uparrow}}$ for observation rows, $\mathsf{NameCert}_{\mathsf{Mat}^{\uparrow}}$ for covariance and gain updates, $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ for state and measurement rows, and $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$ for the displayed linear maps. Standard references are Kailath, Sayed, and Hassibi, *Linear Estimation* (2000), and Anderson and Moore, *Optimal Filtering* (1979).

The dependency surface is displayed through existing concrete siblings: chapter 329 supplies the state-transition packet, chapter 307 supplies the Riccati covariance ledger, chapter 294 supplies the observability row, chapter 49 and chapter 48 supply the linear algebra rows, chapter 184 and chapter 185 mark the non-exported stochastic boundary, chapter 230 supplies the estimator comparison surface, and chapter 38 supplies the scalar real rows. The deterministic observer-correction sibling chapter 5909 supplies the adjacent state-space, observability, output-error, and gain rows at the non-stochastic boundary of the prediction-update packet. $\mathsf{KalmanFilter}^{\uparrow}$ consumes those rows as finite BHist coordinates before exposing its prediction-update $\mathsf{NameCert}$ surface.

295.1 Finite carrier

Definition 295.1 (KalmanFilterUp BHist carrier)**.** *A* $\mathsf{KalmanFilter}^{\uparrow}$ *carrier is a finite* BHist *packet whose visible rows are:*

1. *a state-estimate row* $\widehat{x}$ *and predicted-state row* $\widehat{x}^{-}$ *over* $\mathsf{VecSpace}^{\uparrow}$*;*
2. *an error and covariance ledger row* P^{-}, P, K, P^{+} *over* $\mathsf{Mat}^{\uparrow}$*;*
3. *a transition row* A *and optional input row read from* $\mathsf{DynSystem}^{\uparrow}$*;*
4. *an observation row* C *and finite observation ledger read from* $\mathsf{ControlObservability}^{\uparrow}$*;*
5. *linear-map rows for prediction, observation, innovation, gain application, and estimate transport read from* $\mathsf{LinMap}^{\uparrow}$*;*
6. *matrix update rows for the displayed Riccati-style covariance, gain, and posterior covariance ledgers read from* $\mathsf{Mat}^{\uparrow}$*;*
7. Cont *and* Pkg *provenance rows naming the consumed* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{ControlObservability}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{LinMap}^{\uparrow}$ *certificates.*

No host stochastic process, probability measure, analytic convergence theorem, infinite trajectory, or external estimator object is part of the carrier.

Lean4 (definition) `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier`
Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterTasteGate single carrier alignment`

Theorem 295.2 (KalmanFilterUp prediction and update obligation)**.** *Every accepted* KalmanFilter$^{\uparrow}$ *packet exposes a finite prediction row, innovation row, gain row, and posterior-update row. The prediction row reads the transition and prior estimate through* DynSystem$^{\uparrow}$, VecSpace$^{\uparrow}$, *and* LinMap$^{\uparrow}$*; the update row reads the observation, innovation, gain, and posterior estimate through* ControlObservability$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, *and* LinMap$^{\uparrow}$*. Each row remains a* BHist *row with its displayed* Cont/Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier prediction update obligation`

Proof. Inspect the carrier of Definition 5102.1. The prediction rows are exactly the transition, state-estimate, and linear-map rows, while the update rows are exactly the observation, innovation, gain, and posterior-estimate rows.

The matrix rows supply the covariance and gain ledgers, the vector rows supply the state and observation endpoints, and the provenance rows name the certificates consumed by each read. Since the packet has only finite BHist rows, every exported prediction or update entry remains inside the displayed carrier. □

Theorem 295.3 (KalmanFilterUp observation innovation ledger)**.** *For an accepted* KalmanFilter$^{\uparrow}$ *packet, the observation residual and innovation covariance are read from the displayed observation row of* ControlObservability$^{\uparrow}$*, the predicted estimate row of* VecSpace$^{\uparrow}$*, and the covariance and observation-matrix rows of* Mat$^{\uparrow}$*. The innovation ledger is exact: no unrecorded measurement stream, hidden residual object, or host probabilistic equality contributes to the consumer-visible innovation row.*

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier observation innovation ledger`

Proof. Read the observation row first. By Definition 5102.1, it is a finite ControlObservability$^{\uparrow}$ row paired with vector, matrix, and linear-map rows.

The residual is the displayed comparison between the observation endpoint and the predicted observation endpoint. The innovation covariance is the displayed matrix update over the covariance and observation rows. Because the carrier excludes host stochastic and trajectory objects, exactness is only the projection from these finite rows. □

Theorem 295.4 (KalmanFilterUp prediction-update ledger exactness)**.** *For every accepted* KalmanFilter$^{\uparrow}$ *packet, each prediction, innovation, gain, posterior-estimate, and posterior-covariance read factors through the displayed finite* BHist *packet. The packet rows are exactly the* DynSystem$^{\uparrow}$ *transition rows,* ControlObservability$^{\uparrow}$ *observation rows,* Mat$^{\uparrow}$ *covariance and gain rows,* VecSpace$^{\uparrow}$ *state rows,* LinMap$^{\uparrow}$ *linear-map rows, the* Cont *and* hsame *comparison rows, and the* Pkg *provenance rows named by the carrier. No consumer-visible prediction-update read uses a stochastic process, probability space, unrecorded random variable, or external estimator semantics.*

Proof. Project the accepted carrier of Definition 5102.1. Its prediction face consists of the prior estimate, transition, predicted estimate, and predicted covariance rows, together with the LinMap$^{\uparrow}$, Cont, hsame, and Pkg rows that name the finite calculation.

Split the update face into observation, innovation, gain, posterior-estimate, and posterior-covariance reads. The observation and innovation reads are exact by Definition 5102.3, while the gain and posterior rows are the displayed $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{LinMap}^{\uparrow}$ entries transported by the same packet.

Estimate transport stability is supplied by Definition 5102.5. Thus any representative change remains inside the same finite ledger, and the excluded stochastic and probability-space objects cannot be recovered from the certificate surface. □

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier prediction update endpoint transport`

Theorem 295.5 (KalmanFilterUp estimate transport stability)**.** *If two accepted* $\mathsf{KalmanFilter}^{\uparrow}$ *packets have* hsame*-matched state-estimate, covariance, transition, observation, linear-map,* Cont*, and* Pkg *rows, then prediction, innovation, gain, posterior-estimate, and posterior-covariance reads transport to accepted* $\mathsf{KalmanFilter}^{\uparrow}$ *rows. The classifier is therefore stable under componentwise* hsame *transport of the displayed carrier.*

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier estimate transport stability`

Proof. Transport each dependency row componentwise along the displayed hsame witnesses. The transition and observation rows remain accepted by their consumed certificates, while the vector, matrix, and linear-map rows remain inside their carrier surfaces.

Apply the same componentwise transport to the prediction, innovation, gain, and posterior rows. The Cont and Pkg entries transport the provenance, so the resulting packet again satisfies the finite carrier inventory of Definition 5102.1. □

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier estimate transport`

Theorem 295.6 (KalmanFilterUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *prediction carrier: prior estimate, transition, predicted estimate, and predicted covariance rows;*
2. *update carrier: observation, residual, gain, posterior estimate, and posterior covariance rows;*
3. *innovation ledger exactness: the residual and innovation covariance are exactly the displayed observation, prediction, covariance, and matrix-update reads;*
4. *classifier transport under* hsame*: componentwise transport preserves accepted prediction and update packets;*
5. *downstream read boundary: consumers may read only the prediction, update, innovation, covariance, classifier,* Cont*, and* Pkg *rows displayed by the carrier.*

Proof. The prediction carrier and update carrier are the two action faces of Definition 5102.1. Their rows are finite because each consumed dependency certificate exports finite BHist data.

The innovation row is exact by Definition 5102.3, and classifier stability is the componentwise transport of Definition 5102.5. The consumer boundary is the remaining projection from the same finite inventory. □

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier namecert obligation surface`

Theorem 295.7 (KalmanFilterUp downstream consumer boundary)**.** *Any algebraic or control-theory consumer of* $\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$ *may read only the finite state-estimate, covariance, transition, observation, innovation, gain, posterior-update,* hsame, Cont, *and* Pkg *rows of the carrier. It cannot infer a host probability space, optimality theorem, convergence rate, controllability decomposition, or external trajectory semantics from the* $\mathsf{KalmanFilter}^{\uparrow}$ *certificate alone.*

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier endpoint closed generation`
Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier downstream consumer boundary`

Proof. Project the exported rows from Definition 5102.1. These are precisely the finite rows named by the prediction-update obligation and the NameCert obligation surface.

All excluded objects are absent from the carrier inventory. Since consumer reads are projections from accepted BHist rows and their provenance, no consumer can recover a host stochastic or analytic object without an additional certificate. □

Theorem 295.8 (KalmanFilterUp standard prediction-update bridge)**.** *The public* $\mathsf{KalmanFilter}^{\uparrow}$ *carrier and consumer boundary interpret exactly as the standard finite discrete prediction-update schema over displayed* $\mathsf{DynSystem}^{\uparrow}$ *transition rows,* $\mathsf{ControlObservability}^{\uparrow}$ *observation rows,* $\mathsf{Mat}^{\uparrow}$ *covariance and gain rows,* $\mathsf{VecSpace}^{\uparrow}$ *state rows,* $\mathsf{LinMap}^{\uparrow}$ *linear-map rows, and visible* hsame/Cont/Pkg *provenance. No stochastic process, probability-space semantics, convergence theorem, or external estimator object is exported.*

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterUp StdBridge`

Proof. Start from the carrier of Definition 5102.1. Its rows are the finite state-estimate, covariance, transition, observation, innovation, gain, posterior-update, linear-map, transport, continuation, and package rows.

The prediction-update face is exactly Definition 5102.2. The observation and innovation reads are controlled by Definition 5102.3, and the full ledger is exact by Definition 5102.4.

Representative changes remain inside the same finite packet by Definition 5102.5. The $\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$ surface is the finite obligation surface of Definition 5102.6, and downstream consumers are bounded by Definition 5102.7.

Repack those finite rows as the standard prediction-update schema. Since every schema field is one of the displayed BEDC rows and the consumer boundary has no coordinate for stochastic, probabilistic, convergence, or external-estimator data, the interpretation exports exactly the finite prediction-update packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 5102.8 binds the public finite Kalman prediction-update packet to $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows.

Constructive story: The construction starts from the finite observation packet and dynamic-system transition row, adds matrix and vector rows for prediction, covariance propagation, innovation, gain, and posterior estimate transport, and records the whole calculation as BHist rows with Cont and Pkg provenance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier\_downstream\_consumer\_boundary`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close stochastic optimality, analytic convergence, probability-space semantics, or controllability decomposition.

Upgrade path: No further formal-axis upgrade remains for the finite Kalman packet.

Theorem 295.9 (KalmanFilterUp zero-gain posterior estimate collapse)**.** *Let $\mathcal{K}$ be an accepted* $\mathsf{KalmanFilter}^{\uparrow}$ *packet in the sense of Definition 5102.1. Write*

$$\widehat{x}^{-}$$

for its predicted-estimate row, K for its gain row, ν for its innovation row, $K\nu$ for the displayed gain-application row, and $\widehat{x}^{+}$ for its posterior-estimate row. Assume that the update face is the displayed affine Kalman estimate row

$$\widehat{x}^{+} \sim_{\mathsf{VecSpace}^{\uparrow}} \widehat{x}^{-} +_{\mathsf{VecSpace}^{\uparrow}} K\nu,$$

with the gain application $K\nu$ read through the $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, *and* $\mathsf{LinMap}^{\uparrow}$ *rows exposed by Definition 5102.2. If the gain row is classified with the zero matrix row,*

$$K \sim_{\mathsf{Mat}^{\uparrow}} Z,$$

where Z is the zero matrix datum of Definition 49.113, then the posterior-estimate row is classified with the predicted-estimate row:

$$\widehat{x}^{+} \sim_{\mathsf{VecSpace}^{\uparrow}} \widehat{x}^{-}.$$

Lean4 ✓ `BEDC.Derived.KalmanFilterUp.KalmanFilterCarrier zero gain posterior estimate collapse`

Proof. Project the accepted packet by Definition 5102.2. The projection supplies the finite prediction row, innovation row, gain row, posterior-estimate row, and the provenance rows saying that the gain application is read only through the displayed $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{LinMap}^{\uparrow}$ certificates. By Definition 5102.1, no hidden estimator object or stochastic equality is available; every comparison must be assembled from those rows.

The gain hypothesis identifies the carried gain endpoint with the zero matrix datum Z. Matrix classifier stability transports the gain-application row along this comparison, so the displayed product $K\nu$ is classified with the zero-gain product $Z\nu$. The finite-fold zero matrix multiplication law, Definition 49.114, classifies $Z\nu$ with the zero vector endpoint in the codomain vector carrier. Thus the gain-application contribution satisfies

$$K\nu \sim_{\mathsf{VecSpace}^{\uparrow}} 0.$$

The use of Definition 49.114 is entrywise: each scalar summand has a zero matrix factor, the scalar zero-product row reduces it to the scalar zero, and the finite additive fold reduces the whole displayed product to the zero endpoint.

Now apply vector-space addition congruence to the posterior affine row. The comparison $K\nu \sim_{\mathsf{VecSpace}^{\uparrow}} 0$ transports

$$\widehat{x}^{-} +_{\mathsf{VecSpace}^{\uparrow}} K\nu$$

to

$$\widehat{x}^{-} +_{\mathsf{VecSpace}^{\uparrow}} 0.$$

The vector additive right-unit row in the $\mathsf{VecSpace}^{\uparrow}$ certificate identifies this endpoint with $\widehat{x}^{-}$. Transitivity in the $\mathsf{VecSpace}^{\uparrow}$ classifier composes the displayed affine update comparison, the transported zero-gain comparison, and the additive right-unit comparison. Hence

$$\widehat{x}^{+} \sim_{\mathsf{VecSpace}^{\uparrow}} \widehat{x}^{-}.$$

All rows used in the argument are among the finite prediction, innovation, gain, posterior-estimate, matrix, vector-space, linear-map, Cont, hsame, and Pkg rows named by Definition 5102.1; the consumer boundary of Definition 5102.7 excludes any additional analytic or probabilistic premise. □

Chapter 296

A Concrete Naming Certificate for $\mathsf{LQR}^{\uparrow}$

The $\mathsf{LQR}^{\uparrow}$ interface records the finite certificate surface of a linear-quadratic regulator: state and control rows, a displayed linear transition row, a quadratic cost ledger, a finite horizon index, and a backward dynamic-programming ledger. The control-theory source is the standard finite-horizon linear-quadratic regulator construction as presented in Bertsekas, *Dynamic Programming and Optimal Control* (2017), or Anderson and Moore, *Optimal Control: Linear Quadratic Methods* (2007). The finite $\mathsf{LQR}^{\uparrow}$ packet consumes the displayed dynamics rows of chapter 195, matrix rows of chapter 49, vector-space rows of chapter 47, real cost rows of chapter 38, and estimator/probability rows of chapter 184, chapter 185, and chapter 230.

296.1 Carrier definition

Definition 296.1 (LQR finite control carrier)**.** *An* $\mathsf{LQR}^{\uparrow}$ *carrier is a finite* BHist *packet whose rows are a state row, a control row, a linear transition row, a quadratic cost row, a finite horizon unary index, a Riccati or backward dynamic-programming ledger, displayed estimator-input rows,* hsame *comparisons between corresponding rows,* Cont *provenance rows for every backward step, and* Pkg *rows naming* $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, *and* $\mathsf{Estimator}^{\uparrow}$.

The classifier accepts exactly those packets whose transition, cost, horizon, estimator, and backward-update rows are read through the displayed dependency certificates and finite provenance ledger. It exports no host stochastic process, analytic optimal-control problem, unbounded horizon, external Riccati solver, or hidden policy object.

Lean4 (definition) `BEDC.Derived.LQRUp.LQRFiniteControlCarrier`

296.2 The certificate

Theorem 296.2 (LQR NameCert seed obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{LQR}^{\uparrow}}$ *seed surface consists of the following five obligation rows.*

1. *The carrier and classifier row of Definition 296.1, including the displayed state, control, transition, cost, horizon, estimator, and provenance rows.*
2. *The transition-stability row saying that* hsame *transport of state, control, linear transition, horizon,* Cont, *and* Pkg *rows remains inside the same finite* $\mathsf{LQR}^{\uparrow}$ *packet.*

3. *The quadratic-cost ledger exactness row saying that every visible cost contribution is read from the displayed* $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows and from no ambient cost functional.*
4. *The backward-update row stating that each finite horizon step in the Riccati or dynamic-programming ledger consumes only the previous displayed value row, the transition row, the control row, the quadratic cost row, and the visible provenance rows.*
5. *The estimator/control consumption boundary saying that* $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, *and* $\mathsf{Estimator}^{\uparrow}$ *inputs may be consumed only through the displayed estimator rows and cannot introduce a host stochastic control model.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket namecert seed obligation surface`

Proof. Start from the carrier of Definition 296.1. It lists the finite BHist rows that make the state, control, transition, cost, horizon, estimator, update, and provenance data visible.

Transport stability is a componentwise statement over those rows. Since the classifier reads only displayed hsame comparisons and the same finite Cont ledger, transporting the rows preserves the accepted packet shape.

For the cost and backward-update rows, inspect the finite ledger one horizon index at a time. Each step consumes matrix, vector-space, real-valued cost, transition, control, and previous value rows that already appear in the packet, so no analytic optimizer or unbounded horizon can be projected.

Finally project the estimator boundary. The probability, random-variable, and estimator certificates appear only as named source rows and finite estimator-input ledgers; therefore any control consumer must read them through the displayed packet rather than through an external stochastic model. □

Theorem 296.3 (LQR dynamic-programming row)**.** *In an accepted* $\mathsf{LQR}^{\uparrow}$ *packet, every finite backward-update row is a* Cont *step from the displayed successor value row, linear transition row, control row, quadratic cost row, estimator-input row, and* Pkg *provenance to the displayed predecessor value row. The update ledger has no coordinate for an external Riccati solver or analytic value function.*

Proof. Project the backward ledger from the carrier. Its entries are indexed by the finite horizon unary row and each entry names its predecessor and successor value rows.

Read one entry. The input coordinates are precisely the transition, control, quadratic cost, estimator, and provenance rows displayed in the packet, and the output coordinate is the next predecessor value row in the same finite ledger.

Because the carrier contains no row for an external solver or analytic value function, the only accepted dynamic-programming update is the displayed Cont step. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQR dynamic programming cont determinacy`

Theorem 296.4 (LQR estimator-control consumption boundary)**.** *Every downstream consumer of* $\mathsf{LQR}^{\uparrow}$ *can read estimator-dependent control data only through the displayed* $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Estimator}^{\uparrow}$, *state, control, transition, quadratic cost, horizon, backward-update,* Cont, *and* Pkg *rows of Definition 296.1. No consumer can demand an unlogged stochastic process, hidden controller state, infinite-horizon policy, or ambient optimization problem from the certificate.*

Proof. Begin with an accepted downstream readback. The carrier theorem restricts the readback to the finite packet rows and their visible classifier.

The estimator-dependent rows are source rows named by the probability, random-variable, and estimator certificates. Their consumption route is the displayed Cont ledger that also supplies the state, control, transition, cost, and backward-update rows.

Apply the dynamic-programming row theorem to the control readback. Since each backward step is internal to the displayed finite ledger, no downstream consumer can project an unlogged stochastic process, hidden controller state, infinite-horizon policy, or ambient optimization problem. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket estimator control consumption boundary`

Theorem 296.5 (LQR transition stability)**.** *Let L and L' be accepted* $\mathsf{LQR}^{\uparrow}$ *packets. If the state, control, linear transition, horizon,* Cont*, and* Pkg *rows of L are transported to the corresponding rows of L' by displayed* hsame *comparisons, then the transported packet remains inside the same finite* $\mathsf{LQR}^{\uparrow}$ *carrier surface. The transition readback of L' is exactly the transported transition row together with the transported state, control, horizon, continuation, and provenance rows.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlCarrier transition transport`

Proof. Project the finite carrier of Definition 296.1. Its transition component is not a host map; it is a displayed row tied to the state row, control row, horizon row, finite continuation ledger, and package provenance.

Transport those coordinates componentwise along the supplied hsame comparisons. The classifier for an accepted packet reads exactly those displayed comparisons, so the transported tuple has the same carrier shape.

Finally repack the transported transition row with the transported horizon and provenance rows. Since no external dynamics object is present in the carrier, the transition readback of L' is precisely this finite BEDC row. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlCarrier transition stability`
↪ variant `BEDC.Derived.LQRUp.LQRFiniteControlPacket transition stability`
↪ variant `BEDC.Derived.LQRUp.LQRFiniteControlPacket transition transport`

Theorem 296.6 (LQR quadratic-cost exactness)**.** *Every visible cost contribution in an accepted* $\mathsf{LQR}^{\uparrow}$ *packet reads only through the displayed* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, state, control, horizon,* Cont*, and* Pkg *rows of Definition 296.1. The packet exports no ambient quadratic functional, analytic norm, host expectation, or hidden optimizer that can alter the finite cost ledger.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlCarrier quadratic cost exactness`

Proof. Read a cost entry from the finite packet. The carrier exposes the matrix row, vector-space rows for state and control coordinates, real-valued coefficient rows, the horizon index, and the package provenance naming the dependency certificates.

The cost contribution is then reconstructed as a displayed finite ledger entry over those rows. Its scalar output is a $\mathsf{Real}^{\uparrow}$ row reached by the packet's Cont route, not by an ambient cost functional.

Because the carrier has no coordinate for a host expectation, analytic norm, or optimizer, every downstream cost readback is exhausted by the displayed matrix, vector-space, real, horizon, continuation, and provenance rows. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket cost endpoint determinacy`
Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket quadratic cost exactness`
Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket quadratic cost transport exactness`

Theorem 296.7 (LQR finite-horizon Riccati closure)**.** *Every backward dynamic-programming or Riccati ledger step in an accepted* $\mathsf{LQR}^{\uparrow}$ *packet is a finite* Cont *row from the displayed successor value, transition, control, quadratic cost, estimator-input, horizon, and* Pkg *rows to the displayed predecessor value row. The certificate exports no infinite-horizon policy, limiting algebraic Riccati equation, external solver, or host optimal-control object.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlCarrier endpoint closed generation`
Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket finite horizon riccati closure`

Proof. Unpack the backward ledger indexed by the finite horizon row. Each entry has a successor value row and a predecessor value row, and its input coordinates are the transition, control, quadratic cost, estimator, and provenance rows already listed in the carrier.

Apply Definition 296.3 to a single entry. The update is a Cont step internal to the finite packet, and iterating along the unary horizon merely repeats the same displayed ledger pattern.

The terminal row is therefore reached by a finite chain of continuation entries. No row remains from which a consumer could read an infinite-horizon policy, a limiting Riccati equation, an external solver, or a host optimal-control object. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket finite horizon riccati transport`

Theorem 296.8 (LQR scoped dependency certificate)**.** *For the finite-control carrier of Definition 296.1, the seed obligation surface, dynamic-programming row, estimator-control boundary, transition stability row, quadratic-cost exactness row, and finite-horizon Riccati closure bind every exported* $\mathsf{LQR}^{\uparrow}$ *row to the displayed* $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Estimator}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and dependency-certificate rows. The resulting certificate exports no host stochastic process, infinite-horizon policy, ambient optimizer, or external Riccati solver.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket scoped dependency certificate`

Proof. Project the rows of the carrier in Definition 296.1. This gives the state, control, transition, cost, horizon, estimator, backward-update, hsame, Cont, and Pkg coordinates as displayed finite BHist rows.

Apply the transition stability theorem and the quadratic-cost exactness theorem to the displayed transition and cost coordinates. These two rows bind the dynamics and cost readbacks to the named $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ dependency packets.

Next apply the dynamic-programming row theorem, the estimator-control boundary, and the finite-horizon Riccati closure theorem. The backward ledger then consumes only the displayed successor value, transition, control, quadratic-cost, estimator-input, horizon, continuation, and provenance rows.

It remains to check the exported packet fields. Exhausting the displayed carrier shows that the only remaining public coordinates are the named dependency certificates and their hsame, Cont, and Pkg rows, so no host stochastic process, infinite-horizon policy, ambient optimizer, or external Riccati solver is exported. □

Theorem 296.9 (LQR empty-horizon backward ledger)**.** *Let L be an accepted* $\mathsf{LQR}^{\uparrow}$ *packet. If the finite horizon unary index row of L is the empty unary row, then the Riccati or backward dynamic-programming ledger of L contains no backward-update entries. Equivalently, there is no displayed* Cont *row in L whose role is a finite-horizon backward update from a successor value row to a predecessor value row.*

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket empty horizon predecessor update hsame`

Proof. Project the carrier of Definition 296.1. Its backward dynamic-programming ledger is not an ambient list of solver events; it is the displayed finite ledger whose entries are indexed by the finite horizon unary row and whose accepted entries must be read through the packet's visible provenance rows.

Assume for contradiction that the backward ledger contains an update entry. By Definition 296.3, that entry is a Cont step from the displayed successor value row, transition row, control row, quadratic cost row, estimator-input row, and Pkg provenance to the displayed predecessor value row. The same theorem also identifies the entry as one finite backward-update row indexed by the finite horizon unary row.

The empty unary row has no finite horizon index position. Hence it supplies no coordinate at which such a backward-update entry can be placed. This contradicts the existence of the displayed update entry, so the Riccati or backward dynamic-programming ledger contains no update entries. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlCarrier empty horizon backward ledger`
Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket empty horizon backward ledger`

Theorem 296.10 (LQRUp public NameCert export)**.** *The finite-control carrier of Definition 296.1, together with the seed obligation surface, transition stability, quadratic-cost exactness, estimator-control boundary, finite-horizon Riccati closure, and empty-horizon ledger, assembles the public* $\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$ *over the displayed* $\mathsf{DynSystem}^\uparrow$, $\mathsf{Mat}^\uparrow$, $\mathsf{VecSpace}^\uparrow$, $\mathsf{Real}^\uparrow$, $\mathsf{ProbSpace}^\uparrow$, $\mathsf{RandomVar}^\uparrow$, $\mathsf{Estimator}^\uparrow$, BHist, hsame, Cont, *and* Pkg *rows. This public surface exports no host stochastic process, infinite-horizon policy, ambient optimizer, or external Riccati solver.*

Proof. Project the finite-control carrier. Its visible rows are exactly the state, control, transition, cost, estimator, horizon, backward-ledger, hsame, Cont, and Pkg coordinates already bound in the scoped dependency certificate.

Apply Definition 296.8 to bind those rows to the displayed $\mathsf{DynSystem}^\uparrow$, $\mathsf{Mat}^\uparrow$, $\mathsf{VecSpace}^\uparrow$, $\mathsf{Real}^\uparrow$, $\mathsf{ProbSpace}^\uparrow$, $\mathsf{RandomVar}^\uparrow$, and $\mathsf{Estimator}^\uparrow$ sources. The transition-stability, quadratic-cost exactness, estimator-control, and finite-horizon Riccati rows supply the public certificate fields without importing an ambient control model.

Use Definition 296.9 for the terminal boundary. It rules out hidden predecessor updates at the empty horizon, so the public packet cannot read an infinite-horizon policy or an external Riccati solver from a missing ledger row.

Repack the displayed rows as the public $\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$ surface. Every exported coordinate is one of the named carrier, dependency, classifier, continuation, or provenance rows, and every non-displayed stochastic or optimizer object remains outside the certificate. □

Lean4 ✓ `BEDC.Derived.LQRUp.LQRFiniteControlPacket public namecert export`

Theorem 296.11 (LQR public schema bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$ *surface of Definition 296.10 interprets exactly as the standard finite-horizon LQR schema. The displayed state and control rows, transition row, quadratic-cost row, estimator-input rows, finite horizon row, and backward dynamic-programming ledger are precisely the public schema fields of the exported certificate. The surface exports no infinite-horizon policy, host Riccati solver, stochastic process, or ambient optimizer.*

Proof. Begin with the scoped dependency certificate of Definition 296.8. It binds the state, control, transition, quadratic cost, estimator, horizon, continuation, provenance, and dependency rows to the displayed finite-control carrier.

The finite-horizon part is the Riccati closure of Definition 296.7. It identifies each backward dynamic-programming ledger entry as a finite Cont row from the displayed successor value, transition, control, quadratic-cost, estimator-input, horizon, and package rows to the predecessor value row.

The estimator side is separated by Definition 296.4. Thus estimator input is a public certificate row consumed by the finite ledger, not a hidden stochastic process or ambient controller.

Finally apply Definition 296.10. Repacking those rows as the public $\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$ surface gives exactly the standard finite-horizon LQR schema fields, while the excluded infinite-horizon policy, host Riccati solver, stochastic process, and ambient optimizer remain outside the export. □

Closure status for $\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$**.**

Constructive story: An $\mathsf{LQR}^\uparrow$ packet is generated by laying out a finite BHist control ledger: state and control rows, a linear transition row, a quadratic-cost row, a unary horizon row, estimator-input rows, backward dynamic-programming rows, rowwise hsame comparisons, Cont provenance for each horizon step, and Pkg rows for the displayed dynamics, matrix, vector-space, real, probability, random-variable, and estimator certificates. The classifier accepts exactly this finite shape after componentwise transport, so a transported transition, cost, or backward-update row remains part of the same packet. The ledger and source specification align because each cost and predecessor-value coordinate is reached through the displayed continuation route from the named dependency rows. Nonemptiness is the finite empty-horizon or finite-horizon ledger; reflexivity, symmetry, and transitivity are supplied rowwise by hsame, with no hidden stochastic process, solver, or optimizer coordinate.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$, maturePackageClosed)

Scope closed: The public certificate binds the finite linear-quadratic control carrier, seed obligation surface, dynamic-programming row, estimator-control boundary, transition stability, quadratic-cost exactness, finite-horizon Riccati closure, empty-horizon ledger, and public finite-horizon LQR schema bridge to the displayed $\mathsf{DynSystem}^\uparrow$, $\mathsf{Mat}^\uparrow$, $\mathsf{VecSpace}^\uparrow$, $\mathsf{Real}^\uparrow$, $\mathsf{ProbSpace}^\uparrow$, $\mathsf{RandomVar}^\uparrow$, $\mathsf{Estimator}^\uparrow$, BHist, hsame, Cont, Pkg, and dependency-certificate rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LQR}^\uparrow}$, axiomClean)

Origin: human

Not claimed: This chapter does not close an analytic stochastic-control model, infinite-horizon regulator, host Riccati solver, projective limit, or stochastic-process semantics.

Upgrade path: No further theory-axis upgrade is asserted here; bridgeChecked remains a formal-axis matter for the standard bridge audit.

Chapter 297

A Concrete Naming Certificate for ControlControllability$^{\uparrow}$

The ControlControllability$^{\uparrow}$ interface records the finite reachability surface of a linear control system. Its textbook source is the Kalman controllability rank-style data of Kalman, *On the General Theory of Control Systems* (1960), but the BEDC chapter states only the finite reachability ledger and NameCert surface. The dependency anchors are NameCert$_{\text{DynSystem}^{\uparrow}}$, NameCert$_{\text{Mat}^{\uparrow}}$, NameCert$_{\text{VecSpace}^{\uparrow}}$, NameCert$_{\text{LinMap}^{\uparrow}}$, NameCert$_{\text{ControlObservability}^{\uparrow}}$, NameCert$_{\text{KalmanFilter}^{\uparrow}}$, and NameCert$_{\text{LQR}^{\uparrow}}$.

The finite reachability rows consume the observation-matrix sibling surface of chapter 294 as the dual ledger for the same displayed state, transition, matrix, and finite-horizon rows before KalmanFilter$^{\uparrow}$ and LQR$^{\uparrow}$ consumers read the packet.

297.1 Carrier definition

Definition 297.1 (ControlControllability finite reachability carrier)**.** *A* ControlControllability$^{\uparrow}$ *carrier is a finite* BHist *packet whose rows are a state-carrier row, an input-carrier row, a transition-matrix row A, a control-matrix row B, a finite horizon unary row n, the displayed reachability columns $B, AB, \ldots, A^{n-1}B$, a reachability-matrix row collecting those columns,* hsame *comparisons between corresponding finite rows,* Cont *provenance for each displayed multiplication and column append, and* Pkg *rows naming* DynSystem$^{\uparrow}$*,* Mat$^{\uparrow}$*,* VecSpace$^{\uparrow}$*,* LinMap$^{\uparrow}$*,* ControlObservability$^{\uparrow}$*,* KalmanFilter$^{\uparrow}$*, and* LQR$^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket`
Lean4 (definition) `BEDC.Derived.ControlControllabilityUp.ControlControllabilityCarrier`

Definition 297.2 (ControlControllability classifier)**.** *Two* ControlControllability$^{\uparrow}$ *carriers are classified as the same finite reachability certificate exactly when their state rows, input rows, A rows, B rows, horizon rows, reachability-column rows, reachability-matrix rows,* Cont *routes, and* Pkg *rows agree under displayed* hsame *transports and the* Mat$^{\uparrow}$ *column-transport ledger. The classifier does not quotient by a host reachable subspace and does not identify packets by an ambient controllability predicate.*

Lean4 (definition) `BEDC.Derived.ControlControllabilityUp.ControlControllabilityClassifier`
Lean4 (definition) `BEDC.Derived.ControlControllabilityUp.ControlControllabilityCarrier classifier`

297.2 The certificate

Theorem 297.3 (ControlControllability reachability ledger)**.** *Every accepted* ControlControllability$^{\uparrow}$ *packet exposes exactly the state-carrier row, input-carrier row, transition row A, control row B, finite horizon row n, displayed reachability columns $B, AB, \ldots, A^{n-1}B$, reachability-matrix row,* hsame *transports,* Cont *provenance, and* Pkg *dependency rows of Definition 297.1. It exports no host reachable subspace, rank theorem, Kalman decomposition, analytic trajectory semantics, or infinite-horizon object.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket reachability ledger`

Proof. Project the accepted carrier to the rows listed in Definition 297.1. The state, input, transition, control, horizon, column, reachability-matrix, transport, continuation, and provenance rows are visible as finite BHist coordinates.

Conversely, every consumer-visible reachability read enters through one of those coordinates. Matrix multiplication and column append are recorded as Mat$^{\uparrow}$ and LinMap$^{\uparrow}$ ledger rows, while the state and input endpoints are recorded through VecSpace$^{\uparrow}$ and DynSystem$^{\uparrow}$ rows.

The carrier has no coordinate for a host reachable subspace, rank theorem, Kalman decomposition, analytic trajectory, or infinite horizon. Therefore those objects cannot be exported by the certificate. □

Theorem 297.4 (ControlControllability reachability-column transport obligation)**.** *Every displayed reachability column $B, AB, \ldots, A^{n-1}B$ in a* ControlControllability$^{\uparrow}$ *packet is generated by finite* Mat$^{\uparrow}$, LinMap$^{\uparrow}$, Cont, *and* BHist *rows. Transport along the displayed* hsame *comparisons preserves the reachability-matrix packet by transporting each carrier column and the recorded column-append route, without invoking a host rank predicate or a host reachable subspace.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket column transport obligation`

Proof. Project the accepted packet to its $B, AB, \ldots, A^{n-1}B$ rows. Each projected column is attached to a finite multiplication route, and the reachability-matrix row is the ordered append of those displayed columns.

Now transport the source rows along hsame. The multiplication rows remain the same finite Mat$^{\uparrow}$ and LinMap$^{\uparrow}$ routes after transport, and the append route remains a Cont coordinate of the same packet shape.

The preserved object is therefore the displayed reachability-matrix packet itself. No coordinate in the construction names a rank predicate or host reachable subspace, so no such predicate is used by the transport obligation. □

Theorem 297.5 (ControlControllability classifier stability obligation)**.** *The* ControlControllability$^{\uparrow}$ *classifier is reflexive, symmetric, and transitive componentwise over the state row, input row, A row, B row, horizon row, reachability-column rows, reachability-matrix row,* Cont *rows, and* Pkg *rows of the carrier packet.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityCarrier classifier stability obligation`

Proof. For reflexivity, apply the rowwise reflexivity of hsame to the state, input, matrix, horizon, reachability, continuation, and package coordinates, then repack the resulting finite row comparisons as a classifier witness.

For symmetry, reverse each displayed row comparison. The carrier has only finitely many named coordinates, so the reversed state, input, A, B, horizon, column, reachability-matrix, Cont, and Pkg comparisons assemble into the symmetric classifier witness.

For transitivity, compose the corresponding row comparisons coordinate by coordinate. The composed rows have the same packet shape as the original classifier data, and repacking them gives the transitive classifier witness. □

Theorem 297.6 (ControlControllability dependency scope obligation)**.** *All public reachability reads from a* $\mathsf{ControlControllability}^{\uparrow}$ *packet factor through* $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Mat}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{ControlObservability}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{KalmanFilter}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{LQR}^{\uparrow}}$ *rows together with the displayed* BHist, hsame, Cont, *and* Pkg *coordinates. They do not factor through host reachable subspaces, Kalman decomposition objects, or analytic trajectories.*

Proof. Inspect the package provenance row of the carrier. Its named dependencies are exactly the displayed $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, and $\mathsf{LQR}^{\uparrow}$ certificate rows, together with the kernel rows that record history, transport, continuation, and packaging.

Every public reachability read is a projection from that finite provenance packet or from the reachability rows transported by it. The dependency factorization is therefore exhausted by the named NameCert rows and the displayed BHist, hsame, Cont, and Pkg coordinates.

The packet contains no coordinate for a host reachable subspace, no Kalman decomposition object, and no analytic trajectory semantics. Those objects are outside the dependency scope of the public surface. □

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket dependency scope`

Theorem 297.7 (ControlControllability NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ControlControllability}^{\uparrow}}$ *seed surface consists of the carrier and classifier rows of Definition 297.1 and Definition 297.2, the finite reachability-ledger row of Definition 297.3, the reachability-column transport obligation of Definition 297.4, the classifier stability obligation of Definition 297.5, and the dependency scope obligation of Definition 297.6.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityCarrier namecert obligation surface`

Proof. Start with the finite carrier and classifier. They determine the visible packet shape and the rowwise comparison relation for all state, input, transition, control, horizon, column, reachability-matrix, continuation, and provenance coordinates.

The reachability-ledger theorem identifies the exact exported rows. The matrix column-transport row is then a finite componentwise transport of the displayed $B, AB, \ldots, A^{n-1}B$ columns, not an appeal to a host reachable-space quotient.

The remaining dependency rows are package provenance. They allow consumers to compare the controllability packet with observability, Kalman-filter, and regulator packets only through named finite rows, so the resulting surface is a seed NameCert obligation rather than a standard control-theory bridge. □

Theorem 297.8 (ControlControllability consumer boundary)**.** *Every downstream consumer of* ControlControllability$^{\uparrow}$ *can read controllability data only through the displayed* DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, LinMap$^{\uparrow}$, ControlObservability$^{\uparrow}$, KalmanFilter$^{\uparrow}$, LQR$^{\uparrow}$, BHist, hsame, Cont, *and* Pkg *rows of Definition 297.1. No consumer can require analytic trajectory semantics, a host reachable subspace, Kalman decomposition, stochastic optimality, or a standard bridge from this chapter.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket consumer boundary`

Proof. Take a consumer-visible readback from an accepted packet. By the classifier, the readback is invariant only under the displayed hsame transports and the Mat$^{\uparrow}$ column-transport ledger.

Apply the reachability-ledger theorem to exhaust the visible rows. The readback is therefore a finite route through state, input, transition, control, horizon, reachability-column, reachability-matrix, continuation, and package coordinates.

Since none of the excluded host objects appears as a carrier coordinate, a consumer cannot project one from the packet. The boundary is exactly the finite BEDC reachability surface. □

Theorem 297.9 (ControlControllability Kalman reachability source)**.** *The prediction-update and observation-innovation rows imported from* KalmanFilter$^{\uparrow}$ *can be consumed by a* ControlControllability$^{\uparrow}$ *packet only through the displayed state row, transition-matrix row A, control row B, finite horizon row n, reachability columns $B, AB, \ldots, A^{n-1}B$,* Mat$^{\uparrow}$ *and* LinMap$^{\uparrow}$ *column ledger,* hsame *transports,* Cont *provenance, and* Pkg *dependency rows of Definition 297.1. The packet exports no rank theorem, host reachable subspace, stochastic filter semantics, or analytic trajectory.*

Proof. Project the accepted carrier of Definition 297.1. Its Kalman dependency is a finite package row, so any read from the KalmanFilter$^{\uparrow}$ side must pass through the displayed Pkg coordinate and the finite carrier rows named by that coordinate.

Route the prediction-update and observation-innovation rows through the same finite name-certificate surface. The only shared rows available to ControlControllability$^{\uparrow}$ are the state, transition, control, horizon, reachability-column, matrix-ledger, linear-map-ledger, transport, and continuation coordinates.

Apply Definition 297.3 to identify those coordinates as the complete reachability ledger. Apply Definition 297.8 to exclude any readback that would require a rank theorem, a host reachable subspace, stochastic filter semantics, or an analytic trajectory. □

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket kalman reachability source`

Theorem 297.10 (ControlControllability finite continuation closure)**.** *Let two accepted finite reachability-column ledgers for* ControlControllability$^{\uparrow}$ *be displayed over the same* DynSystem$^{\uparrow}$, Mat$^{\uparrow}$, VecSpace$^{\uparrow}$, LinMap$^{\uparrow}$, ControlObservability$^{\uparrow}$, KalmanFilter$^{\uparrow}$, *and* LQR$^{\uparrow}$ Pkg *rows. If the terminal endpoint row of the first ledger and the initial endpoint row of the second ledger are matched by a displayed* hsame *comparison, then their concatenation repacks as an accepted* ControlControllability$^{\uparrow}$ *reachability packet over those same package rows. The repacked packet asserts no infinite-horizon reachability theorem and no host reachable-subspace quotient.*

Proof. Unpack the two accepted ledgers into their finite reachability-column rows, reachability-matrix rows, Cont routes, and package provenance. Because both ledgers use the same displayed dependency rows, the state, transition, control, horizon, matrix, linear-map, observability, Kalman-filter, and regulator endpoints are read through the same package surface.

Transport the meeting endpoint along the displayed hsame comparison. The first continuation route then lands at the source row expected by the second route, and the two finite Cont records compose as a single displayed continuation ledger.

Reuse the $\mathsf{Mat}^{\uparrow}$ and $\mathsf{LinMap}^{\uparrow}$ column-transport ledger to append the transported columns in order. Repacking those columns, the composed continuation route, the endpoint transports, and the unchanged package rows gives the accepted carrier shape of Definition 297.1.

The construction is finite at every step. It records only the concatenated displayed reachability packet, so it does not introduce an infinite-horizon object or quotient the packet by a host reachable subspace. □

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket continuation closure`

Theorem 297.11 (ControlControllability mature consumer coverage)**.** *Every mature consumer read from a* $\mathsf{ControlControllability}^{\uparrow}$ *packet factors through exactly the finite carrier and classifier rows of Definition 297.1 and Definition 297.2, the reachability ledger, the column-transport obligation, the classifier-stability obligation, the dependency scope, the consumer boundary, the Kalman reachability source, and the finite continuation closure. The mature catalogue exports no analytic trajectory semantics, rank-completeness theorem, host reachable-subspace quotient, Kalman decomposition, stochastic optimality, or infinite-horizon object.*

Lean4 ✓ `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket mature consumer coverage`

Proof. Project the finite packet to the carrier and classifier rows. The state, input, transition, control, horizon, reachability-column, reachability-matrix, transport, continuation, and package coordinates are the only displayed coordinates available to a mature consumer.

Apply Definition 297.3 and Definition 297.6 to restrict every visible read to those rows and their named dependency certificates. The column-transport and classifier-stability obligations then account for transported reachability columns and componentwise classifier comparisons without introducing an ambient control-theory predicate.

Use Definition 297.8 and Definition 297.9 for downstream reads through the observability, Kalman-filter, and regulator package rows. Use Definition 297.10 for concatenated finite ledgers over the same package surface.

No carrier coordinate names analytic trajectories, rank completeness, a host reachable-subspace quotient, Kalman decomposition, stochastic optimality, or an infinite-horizon object. Since every mature read is already a projection from the finite packet rows above, none of those excluded objects is exported by the mature catalogue. □

Closure status for $\mathsf{NameCert}_{\mathsf{ControlControllability}^{\uparrow}}$.

Constructive story: A $\mathsf{ControlControllability}^{\uparrow}$ packet is generated from a finite BHist reachability ledger. The visible coordinates are the state-carrier row, input-carrier row, transition matrix A, control matrix B, unary horizon row n, reachability columns $B, AB, \ldots, A^{n-1}B$, the reachability-matrix row, rowwise hsame comparisons, Cont provenance for multiplication and column append, and Pkg rows for the dynamics, matrix, vector-space, linear-map, observability, Kalman-filter, and LQR certificates. The classifier compares exactly these rows under displayed transport and the matrix column ledger, so it never quotients by a host reachable subspace. Ledger exactness and source scope coincide because every public reachability read is one of the listed coordinates or a continuation from them. Nonemptiness is an accepted finite reachability packet, and reflexivity, symmetry, and transitivity are assembled componentwise from hsame.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ControlControllability}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridged reachability surface records the finite carrier, classifier, reachability ledger, NameCert obligation surface, consumer boundary, and continuation closure for $\mathsf{ControlControllability}^{\uparrow}$ over displayed $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows.

Formal verification: FormalStatus(NameCert$_{\text{ControlControllability}\uparrow}$, encodedDef)
Lean target: `BEDC.Derived.ControlControllabilityUp.ControlControllabilityReachabilityPacket`
Bridge status: none
Origin: human
Not claimed: This chapter does not close analytic trajectory semantics, Kalman decomposition, stochastic optimality, host reachable subspace quotients, rank-completeness, or a standard bridge.
Upgrade path: No paper-side theory grade remains; Lean verification and any standard bridge remain on the formal axis.

Chapter 298

A Concrete Naming Certificate for $\mathsf{SpectralMeasure}^{\uparrow}$

Following von Neumann and standard functional analysis, the $\mathsf{SpectralMeasure}^{\uparrow}$ interface records the finite BEDC certificate surface for a projection-valued spectral measure over a Hilbert carrier, a bounded-operator row, a projection-family ledger, and finite scalar measure windows. Its traditional target is the projection-valued measure used in the spectral theorem, as in Reed and Simon, *Methods of Modern Mathematical Physics I: Functional Analysis* (1980), or Conway, *A Course in Functional Analysis* (1990). The chapter states only the finite certificate surface consumed by $\mathsf{SpectralTheorem}^{\uparrow}$ and $\mathsf{Observable}^{\uparrow}$: it does not prove a spectral theorem, host sigma-additivity, quotient measure spaces, unrestricted functional calculus, or choice-selected spectral decompositions.

The packet consumes the Hilbert carrier of chapter 91, the bounded operator surface of chapter 1644, the operator-ideal projection boundary of chapter 213, the self-adjoint observable row of chapter 218, the event-carrier and finite-additivity surface of chapter 92, and the spectral-data consumer of chapter 214. These are substantive carrier and ledger dependencies, not background references: without them the spectral-measure packet has no Hilbert endpoint for projections, no bounded-operator row whose projections can act, no operator-ideal surface for projection-family transport, no observable row to measure, and no finite event ledger on which projection additivity can be recorded.

298.1 Carrier definition

Definition 298.1 (SpectralMeasureUp carrier)**.** *A* $\mathsf{SpectralMeasure}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (H, B, \Pi, \mu, T, C, P, N)$$

with the following displayed rows:

1. *H is the* $\mathsf{Hilbert}^{\uparrow}$ *source row over which all projection endpoints are typed.*
2. *B is the* $\mathsf{BoundedLinearOperator}^{\uparrow}$ *row carrying the displayed self-adjoint or normal operator endpoint whose spectral windows are being named.*
3. *Π is the projection-family ledger: each visible event row is assigned a projection endpoint over the same H, with orthogonality and finite-additivity rows for disjoint displayed events.*

4. *μ is the scalar* $\mathsf{Real}^{\uparrow}$ *measure-window row read from finite event probes, recording only finite scalar windows attached to the same projection family.*
5. *T is the classifier-transport row, comparing Hilbert, bounded-operator, event, projection, and scalar-window endpoints only by displayed* hsame *rows.*
6. *C records displayed* Cont *replay from event rows through projection endpoints and scalar* $\mathsf{Real}^{\uparrow}$ *measure windows.*
7. *P is the* Pkg *provenance over* $\mathsf{SpectralMeasure}^{\uparrow}$, $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{BoundedLinearOperator}^{\uparrow}$, $\mathsf{OperatorIdeal}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, $\mathsf{Measure}^{\uparrow}$, $\mathsf{SpectralTheorem}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert.
8. *N is the local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *row.*

The carrier exports no ambient Hilbert-space equality, host sigma-additivity, quotient measure space, unrestricted functional calculus, choice-selected spectral decomposition, countable family selector, eigenbasis, or external spectral-theorem object.

Definition 298.2 (SpectralMeasureUp classifier)**.** *For accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packets S and S', the classifier $S \sim_{\mathsf{SpectralMeasure}^{\uparrow}} S'$ holds exactly when the displayed* $\mathsf{Hilbert}^{\uparrow}$ *carrier rows,* $\mathsf{Observable}^{\uparrow}$ *rows,* $\mathsf{Measure}^{\uparrow}$ *event rows, projection endpoints, orthogonality and finite-additivity ledgers,* Cont *routes, and* Pkg *provenance compare componentwise by their recorded* hsame *rows. The classifier does not compare completed measurable spaces or host projection-valued functions; it compares only the finite rows visible in the certificate.*

Theorem 298.3 (SpectralMeasureUp public consumer boundary)**.** *Every downstream* $\mathsf{SpectralTheorem}^{\uparrow}$ *or* $\mathsf{Observable}^{\uparrow}$ *consumer of an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet may read only the finite* $\mathsf{Hilbert}^{\uparrow}$ *carrier, the observable row, the* $\mathsf{Measure}^{\uparrow}$ *event row, the projection endpoints, the orthogonality and finite-additivity ledger, the displayed* hsame *and* Cont *rows, and the* Pkg *provenance. Such a consumer cannot read countable additivity, completed sigma-algebras, host projection-valued functions, eigenbasis choices, or a spectral theorem proof.*

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFinitePacket public consumer boundary`

Proof. Project the carrier of Definition 298.1. Its exported coordinates are exactly the Hilbert carrier, observable row, MeasureUp event row, projection endpoints, finite ledger, transport rows, and provenance rows.

Then project the classifier of Definition 298.2. It compares only those displayed rows by their recorded hsame witnesses and does not introduce a completed sigma-algebra, host projection-valued function, eigenbasis selector, or spectral theorem object.

The public consumer boundary is therefore the finite list of exported rows. Every downstream $\mathsf{SpectralTheorem}^{\uparrow}$ or $\mathsf{Observable}^{\uparrow}$ read factors through that list and has no coordinate for the excluded host-level data. □

Theorem 298.4 (SpectralMeasureUp finite functional-calculus consumer route)**.** *Every functional-calculus consumer of an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet must expose the* $\mathsf{Hilbert}^{\uparrow}$ *source,* $\mathsf{BoundedLinearOperator}^{\uparrow}$ *endpoint,* $\mathsf{Observable}^{\uparrow}$ *row,* $\mathsf{Measure}^{\uparrow}$ *event row, finite projection ledger, scalar* $\mathsf{Real}^{\uparrow}$ *windows,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *row before it reads spectral-theorem data. The route is finite and cannot bypass through host sigma-additivity, completed measurable spaces, unrestricted functional calculus, quotient measure equality, selected decompositions, or eigenbasis choices.*

Proof. Start with the carrier and classifier of Definition 298.1 and Definition 298.2. They expose only the Hilbert source, observable row, Measure event row, projection endpoints, orthogonality and finite-additivity ledgers, transport, replay, provenance, and local naming coordinates.

Apply the public consumer boundary of Definition 298.3. A calculus-facing read must therefore enter through those displayed rows before it can use any spectral-theorem-facing packet.

Use the finite-additivity ledger of Definition 298.7. It keeps the projection endpoint for each finite displayed event union tied to the same $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, and $\mathsf{Measure}^{\uparrow}$ provenance rows.

Finally apply the projection-ledger nonescape theorem, Definition 298.10. Since the packet contains no completed sigma-algebra, host projection-valued function, quotient measure equality, selected decomposition, or eigenbasis coordinate, the functional-calculus consumer route is exhausted by the finite BEDC rows named above. □

298.2 The certificate

Theorem 298.5 (SpectralMeasureUp hsame stability)**.** *If accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packets S and S' are related by the classifier of Definition 298.2, then transporting the Hilbert, observable, event, projection, orthogonality, finite-additivity,* Cont*, and* Pkg *rows of S along the displayed* hsame *witnesses yields the corresponding accepted rows of S'. In particular, downstream spectral-theorem and observable consumers may replace a carried spectral-measure packet by a classified packet without reading any unlogged measurable or operator data.*

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureCarrier hsame stability`

Proof. Project the finite carrier of Definition 298.1. Each accepted row is one of the displayed Hilbert, observable, event, projection, ledger, continuation, or provenance coordinates.

Apply the classifier definition componentwise. The hsame witnesses transport each source coordinate to its partner coordinate, and the Cont rows record the same event-to-projection readback after transport.

Since the carrier has no coordinate for completed measurable spaces, host projection-valued functions, or eigenbasis choices, the transported packet is exhausted by the displayed rows and remains an accepted $\mathsf{SpectralMeasure}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasurePacket hsame stability`

Theorem 298.6 (SpectralMeasureUp orthogonal finite additivity)**.** *Let S be an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet and let E and F be displayed event rows in its* $\mathsf{Measure}^{\uparrow}$ *event carrier. If the packet ledger records E and F as disjoint displayed events, then the projection endpoint row for the displayed union event is the finite-additivity endpoint obtained from the two projection endpoint rows, and the orthogonality row records that the two projections are compatible as Hilbert projections over the same* $\mathsf{Hilbert}^{\uparrow}$ *carrier. This is a finite ledger statement and not a countable-additivity theorem over a completed sigma-algebra.*

Proof. Read the two event rows and their disjointness witness from the $\mathsf{Measure}^{\uparrow}$ side of the carrier. The projection endpoint rows for E and F are displayed Hilbert projection rows with the same $\mathsf{Hilbert}^{\uparrow}$ provenance.

The orthogonality ledger supplies the compatibility row for the two projection endpoints. The finite-additivity ledger then names the union-event projection endpoint as the endpoint obtained from those two displayed projection rows.

No countable family is introduced. The proof sketch uses only the finite event pair present in the packet and the ledger rows already displayed by the carrier. □

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureOrthogonalFiniteAdditivity row`

Theorem 298.7 (SpectralMeasureUp projection-ledger finite additivity)**.** *Let S be an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet and let $E_1, \ldots, E_n$ be a finite displayed family of pairwise-disjoint event rows in its* $\mathsf{Measure}^{\uparrow}$ *event carrier. If the packet also displays the finite-union event row $E_1 \cup \cdots \cup E_n$, then every projection endpoint row assigned to that union is obtained by iterating the packet's orthogonality and finite-additivity ledger over the same* $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, *and* $\mathsf{Measure}^{\uparrow}$ *provenance rows. The read uses no countable additivity, completed sigma-algebra data, eigenbasis choice, or host projection-valued function.*

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasurePacket projection ledger finite additivity`
Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFinitePacket projection ledger transport`

Proof. Inspect the carrier and classifier of Definition 298.1 and Definition 298.2. The only available event-to-projection data are the displayed event rows, projection endpoint rows, orthogonality ledger, finite-additivity ledger, continuation routes, and source packages for $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, and $\mathsf{Measure}^{\uparrow}$.

Proceed by induction over the finite ledger for the displayed union. The empty or singleton ledger reads back the projection endpoint already stored for the displayed event row.

For the binary step, apply Definition 298.6 to the next disjoint event row and the accumulated displayed union row. The orthogonality row supplies compatibility over the same Hilbert carrier, and the finite-additivity row names the next projection endpoint without changing the observable or measure provenance.

The packet has no coordinate for countable families, completed measurable spaces, eigenvectors, or external projection-valued functions. Thus the finite-union endpoint is exhausted by the projection ledger recorded in the accepted $\mathsf{SpectralMeasure}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFiniteAdditivityLedger projection chain`
Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFinitePacket projection ledger additivity`

Theorem 298.8 (SpectralMeasureUp functional-calculus handoff)**.** *Every functional-calculus or spectral-theorem consumer of an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet reaches projection-valued-measure data only through the displayed route*

$$H, B, \Pi, \mu, T, C, P, N.$$

Thus the consumer must pass through the $\mathsf{Hilbert}^{\uparrow}$ *row, the* $\mathsf{BoundedLinearOperator}^{\uparrow}$ *row, the projection-family ledger, the finite scalar* $\mathsf{Real}^{\uparrow}$ *measure windows, classifier transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *row before it reads calculus data. It may not read host sigma-additivity, quotient measure spaces, unrestricted functional calculus, selected spectral decompositions, or eigenbasis choices.*

Proof. Start with the carrier of Definition 298.1. Its projection-valued-measure surface is not a host measure object; it is the finite row package $H, B, \Pi, \mu, T, C, P, N$ typed over the Hilbert source, bounded-operator endpoint, projection ledger, scalar windows, transport, replay, provenance, and local name certificate.

Apply the NameCert obligation surface of Definition 298.9. That theorem identifies the rows that every $\mathsf{SpectralMeasure}^{\uparrow}$ consumer may inspect, including the projection-family ledger and finite scalar windows, and it supplies no coordinate for completed sigma-algebras, quotient measure spaces, selected decompositions, or eigenbasis data.

The downstream chapters use the same boundary. The Dunford functional-calculus packet of chapter 3740 records contour and resolvent routes before any spectral projection or spectral measure is public, while the spectral-theorem packet of chapter 214 reads spectrum, projection-valued-measure, and calculus rows over certified Hilbert and measure sources.

Therefore a calculus-facing or spectral-theorem-facing read of a $\mathsf{SpectralMeasure}^{\uparrow}$ packet can only enter through the displayed rows. Since none of the excluded host objects appears in that route, the handoff delivers finite BEDC calculus data without importing host sigma-additivity, unrestricted functional calculus, choice-selected spectral decompositions, quotient measure spaces, or eigenbasis choices. □

Theorem 298.9 (SpectralMeasureUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *obligation surface consists of the carrier of Definition 298.1, the classifier of Definition 298.2, the* hsame *stability theorem, the orthogonal finite-additivity ledger, the projection-family ledger, the scalar* $\mathsf{Real}^{\uparrow}$ *measure windows, and the provenance rows naming* $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{BoundedLinearOperator}^{\uparrow}$, $\mathsf{OperatorIdeal}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, $\mathsf{Measure}^{\uparrow}$, *and* $\mathsf{SpectralTheorem}^{\uparrow}$. *Every consumer of* $\mathsf{SpectralMeasure}^{\uparrow}$ *can read only those finite* BHist, hsame, Cont, Pkg, *and local* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFinitePacket namecert obligation surface`

Proof. Start with the carrier and classifier definitions. They expose the Hilbert source, observable row, event carrier, projection endpoints, finite ledger, transport rows, and source provenance as the whole packet.

Use Definition 298.5 for classified replacement of a packet and Definition 298.6 for the finite disjoint-event ledger. These two rows are the visible stability and exactness obligations needed by spectral-data consumers.

Finally repack the displayed rows as the local naming-certificate surface. Because no spectral theorem proof, completed sigma-algebra, countable additivity row, or eigenbasis row is part of the carrier, the obligation surface stops at the finite BEDC certificate boundary. □

Theorem 298.10 (SpectralMeasureUp projection-ledger nonescape)**.** *Every* $\mathsf{SpectralTheorem}^{\uparrow}$, *bounded-operator, or observable consumer of an accepted* $\mathsf{SpectralMeasure}^{\uparrow}$ *packet reads the projection-family ledger only through*

$$H, B, \Pi, \mu, T, C, P, N.$$

The read therefore passes through the displayed $\mathsf{Hilbert}^{\uparrow}$ *source,* $\mathsf{BoundedLinearOperator}^{\uparrow}$ *row, projection-family ledger, scalar* $\mathsf{Real}^{\uparrow}$ *measure windows, classifier transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *row before it exports spectral data. It cannot expose host sigma-additivity, quotient measure spaces, unrestricted functional calculus, choice-selected spectral decompositions, host projection-valued functions, or eigenbasis choices.*

Proof. Project the carrier of Definition 298.1. The only projection-facing coordinates are $H, B, \Pi, \mu, T, C, P, N$.

The projection-family ledger Π is typed over the same Hilbert source H and bounded-operator row B, and the scalar measure windows μ are read only through finite $\mathsf{Real}^{\uparrow}$ windows attached to visible event probes. Thus the consumer receives finite projection and scalar-window data, not a completed host measure space.

The classifier and replay rows close the boundary. The row T transports only the displayed Hilbert, operator, event, projection, and scalar-window endpoints, while C, P, N replay, source, and name that finite route. Since no excluded object appears among these rows, the projection-ledger read has no route to host sigma-additivity, quotient measure spaces, unrestricted functional

calculus, choice-selected spectral decompositions, host projection-valued functions, or eigenbasis choices. □

Theorem 298.11 (SpectralMeasureUp finite-packet standard bridge)**.** *Every standard projection-valued spectral-measure presentation admitted into BEDC only through the displayed finite rows*

$$H, B, \Pi, \mu, T, C, P, N$$

bridges conservatively to the public $\mathsf{SpectralMeasure}^{\uparrow}$ *packet and back. The bridge preserves the Hilbert source, observable row,* $\mathsf{Measure}^{\uparrow}$ *event row, projection-family endpoints, orthogonality ledger, finite-additivity ledger, scalar* $\mathsf{Real}^{\uparrow}$ *measure windows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ *row. Conversely, every public* $\mathsf{SpectralMeasure}^{\uparrow}$ *consumer reads the standard presentation only through those rows.*

Proof. Start with the finite carrier and classifier of Definition 298.1 and Definition 298.2. They expose exactly the Hilbert, bounded-operator, projection-family, scalar-window, classifier, replay, provenance, and local naming rows used by the public packet.

Apply the public consumer boundary of Definition 298.3. It says that consumers of the public packet can inspect only the displayed BHist, hsame, Cont, Pkg, and NameCert rows, so transporting a standard presentation into BEDC cannot add a second projection-valued surface.

Use the finite-additivity ledger of Definition 298.7 and the projection-ledger nonescape theorem Definition 298.10. These identify the orthogonality, finite-additivity, event, projection, and scalar-window data as finite rows and block any route to countable additivity, completed sigma-algebras, host projection-valued functions, eigenbasis selection, or a spectral theorem proof.

The reverse direction repacks the same rows as the public $\mathsf{SpectralMeasure}^{\uparrow}$ packet. Since both directions read and write only $H, B, \Pi, \mu, T, C, P, N$, the bridge is conservative over the displayed finite packet rather than a host spectral-measure construction. □

Closure status for $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$, publicClosed)

Scope closed: The scoped packet names the finite BHist carrier, classifier, hsame stability, orthogonal finite-additivity ledger, Cont transport, Pkg provenance, $\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$ obligation surface, and the public consumer boundary of Definition 298.3 over $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{Observable}^{\uparrow}$, and $\mathsf{Measure}^{\uparrow}$.

Constructive story: A spectral-measure packet starts from a displayed Hilbert carrier, observable row, and measurable-event carrier, then records finite event-to-projection endpoints, orthogonality and finite-additivity ledgers, componentwise hsame transport, and continuation provenance as the visible certificate surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SpectralMeasure}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SpectralMeasureUp.SpectralMeasureFinitePacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close the spectral theorem, countable additivity over completed sigma-algebras, host projection-valued measures, eigenbasis selection, or standard bridges.

Upgrade path: Bridged closure requires a standard bridge theorem from the finite spectral-measure public surface to the usual projection-valued spectral-measure boundary.

Chapter 299

A Concrete Naming Certificate for $\mathsf{Holonomy}^{\uparrow}$

The $\mathsf{Holonomy}^{\uparrow}$ interface records the finite certificate surface of parallel transport around displayed loops in a certified bundle with a certified connection. The traditional geometric target is the holonomy construction of Kobayashi and Nomizu, *Foundations of Differential Geometry*, read here only through $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Bundle}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ rows. The finite transport ledger consumes the certified connection surface of chapter 134, the curvature boundary of chapter 135, and the endpoint-composition rows of chapter 140 before any holonomy packet is read.

299.1 Carrier definition

Definition 299.1 (Holonomy BHist transport carrier)**.** *A* $\mathsf{Holonomy}^{\uparrow}$ *carrier is a finite* BHist *transport packet*

$$(\mathcal{B}, \mathcal{C}, \ell, e, \kappa, \lambda, \rho)$$

whose rows are as follows.

1. $\mathcal{B}$ *is a certified bundle row supplied by* $\mathsf{NameCert}_{\mathsf{Bundle}^{\uparrow}}$ *over a base row supplied by* $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$.
2. $\mathcal{C}$ *is a certified connection row supplied by* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$ *on the same displayed bundle rows.*
3. ℓ *is a loop row whose source and target base endpoint are the same displayed* $\mathsf{Manifold}^{\uparrow}$ *row after the carried* hsame *comparison.*
4. e *is the transported fibre endpoint row obtained by reading the connection transport ledger along* ℓ.
5. κ *records the curvature and control provenance rows supplied through* $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ *and the finite control ledger governing the displayed transport route.*
6. λ *is the finite* Cont *ledger for loop subdivision, transport composition, endpoint readback, and provenance projection.*
7. ρ *is the* Pkg *provenance row naming the bundle, connection, curvature, manifold, and Lie-group dependency certificates.*

Two such carriers classify together when their base loop, connection row, transported fibre endpoint, curvature-control provenance, continuation ledger, and package rows are related componentwise by the available hsame *transports. The carrier exports no host parallel-transport functor, analytic path space, smooth loop manifold, or ambient holonomy group outside these rows.*

Definition 299.2 (Holonomy finite transport classifier)**.** *The* $\mathsf{Holonomy}^{\uparrow}$ *classifier relates two accepted packets exactly when their base loop, connection, transported fibre endpoint, curvature-control provenance, bundle provenance, manifold provenance,* Cont*, and* Pkg *coordinates are related componentwise by displayed* hsame *rows. The classifier exports only this finite componentwise comparison.*

Lean4 (definition) `BEDC.Derived.HolonomyUp.HolonomyFiniteTransportClassifier`

299.2 The certificate

Theorem 299.3 (Holonomy loop source obligation)**.** *Every accepted* $\mathsf{Holonomy}^{\uparrow}$ *packet reads its loop source from the displayed* $\mathsf{Manifold}^{\uparrow}$ *and* $\mathsf{Bundle}^{\uparrow}$ *rows of Definition 299.1. The loop row* ℓ *names its base endpoint, its return endpoint, the carried* hsame *comparison between those endpoints, and the bundle fibre row over that base; no ambient loop space or unlogged base path is part of the source obligation.*

Proof. Project the carrier packet to the rows $\mathcal{B}$ and ℓ. The bundle row $\mathcal{B}$ already exposes the base row through $\mathsf{NameCert}_{\mathsf{Bundle}^{\uparrow}}$, and that base row is read through $\mathsf{NameCert}_{\mathsf{Manifold}^{\uparrow}}$.

The loop row ℓ then names the source endpoint, return endpoint, and endpoint hsame comparison over the same base row. These projections are finite BHist data, so the source obligation is exhausted by the displayed manifold and bundle certificate rows.

Since the carrier contains no coordinate for an analytic path space or a host loop object, a consumer cannot read anything beyond those projected loop and bundle rows. □

Theorem 299.4 (Holonomy continuation transport stability)**.** *If two* $\mathsf{Holonomy}^{\uparrow}$ *packets have componentwise* hsame *transports of their base loop rows, certified connection rows, transported fibre endpoints, curvature-control provenance rows, and finite continuation ledgers, then the transported packet remains accepted by the carrier of Definition 299.1. The fibre endpoint readback is stable under that transport and remains tied to the same* $\mathsf{Connection}^{\uparrow}$ *source row.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket loop source obligation`
Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyBHistTransportCarrier continuation transport stability`

Proof. Unpack the two packets and read the supplied componentwise comparisons. The loop comparison transports the displayed base endpoints, while the connection comparison transports the row that supplies the parallel-transport ledger.

Next transport the fibre endpoint and curvature-control provenance rows. These fields are already listed in the carrier, so the transported endpoint and provenance remain inside the same finite packet shape.

Finally compare the Cont ledgers. The continuation rows identify the same subdivision and readback routes after transport, and the package provenance rows match the dependency certificates. Repacking the transported fields gives an accepted $\mathsf{Holonomy}^{\uparrow}$ packet with the stated stable endpoint readback. □

Theorem 299.5 (Holonomy parallel-transport stability)**.** *Let H and H' be accepted* Holonomy$^{\uparrow}$ *packets. If the base loop, connection, transported fibre endpoint, curvature-control provenance,* Cont*, and* Pkg *rows of H are transported to the corresponding rows of H' by displayed* hsame *comparisons, then the transported packet remains inside the same finite* Holonomy$^{\uparrow}$ *carrier surface. The endpoint readback of H' is exactly the transported finite parallel-transport loop row.*

Proof. Project the carrier of Definition 299.1. The parallel-transport component is a finite spine read from Connection$^{\uparrow}$ together with the base, fibre, loop, continuation, and package rows.

Transport those coordinates componentwise along the displayed hsame comparisons. The classifier of Definition 299.2 accepts precisely that componentwise transport, so the resulting tuple has the same carrier shape.

Finally read back the endpoint row. Since the carrier has no coordinate for an ambient path space or external connection object, the endpoint readback is exhausted by the transported finite loop spine. □

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket parallel transport stability`

Theorem 299.6 (Holonomy curvature-loop boundary)**.** *Every curvature contribution visible in an accepted* Holonomy$^{\uparrow}$ *packet is read through the displayed certified loop row, the* Curvature$^{\uparrow}$ *boundary row, the* Connection$^{\uparrow}$ *parallel-transport spine, the* Bundle$^{\uparrow}$ *provenance row, the* Manifold$^{\uparrow}$ *provenance row,* hsame *transport, and the finite* Cont *ledger. No downstream consumer can insert an unlogged curvature tensor, ambient surface integral, or host smooth-loop family.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket curvature loop boundary`
Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportCarrier curvature loop boundary`

Proof. Read the curvature coordinate from the packet. It is attached to a certified loop row and to the parallel-transport spine already named by the connection source.

Use the displayed Curvature$^{\uparrow}$ boundary row to account for the curvature data along that loop. The bundle and manifold provenance rows identify the source of the fibre and base coordinates, while the Cont ledger records the finite route to the endpoint readback.

Because the packet contains no host tensor, surface integral, or smooth-loop family coordinate, the curvature contribution is exactly the displayed boundary row together with its loop and transport provenance. □

Theorem 299.7 (Holonomy composition ledger obligation)**.** *Composition of displayed holonomy transports is recorded only by finite* Cont *rows. For two accepted loop rows whose endpoint ledgers concatenate inside the same bundle and connection packet, the composed fibre endpoint is the endpoint reached by the concatenated continuation ledger, with dependency provenance retained in ρ.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket composition ledger obligation`

Proof. Start with the two accepted loop rows and their transport ledgers. Each ledger entry names a finite source endpoint, target endpoint, connection row, and fibre endpoint readback.

Concatenate the displayed continuation routes using the Cont ledger carried by the packet. The intermediate endpoint is matched by the endpoint hsame row, so the second transport can read the fibre endpoint produced by the first.

The composed endpoint is therefore just the endpoint of the concatenated finite ledger. The package row ρ records that the bundle, connection, manifold, curvature, and Lie-group dependencies are the same named certificate rows throughout the composition. □

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportCarrier composition ledger obligation`

Theorem 299.8 (Holonomy NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{Holonomy}^\uparrow}$ *seed obligation surface consists of five rows over* $\mathsf{Connection}^\uparrow$, $\mathsf{Curvature}^\uparrow$, $\mathsf{Bundle}^\uparrow$, $\mathsf{Manifold}^\uparrow$, *and* $\mathsf{LieGroup}^\uparrow$.

1. *The loop-source row supplied by Definition 299.3.*
2. *The connection-transport row supplied by* $\mathsf{NameCert}_{\mathsf{Connection}^\uparrow}$ *and stabilized by Definition 299.4.*
3. *The composition-ledger row supplied by Definition 299.7.*
4. *The curvature-compatibility row saying that curvature and control provenance are read through* $\mathsf{NameCert}_{\mathsf{Curvature}^\uparrow}$ *and never through an external curvature operator.*
5. *The finite naming ledger row saying that* $\mathsf{NameCert}_{\mathsf{Bundle}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{Manifold}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{LieGroup}^\uparrow}$ *are consumed only through displayed* BHist, hsame, Cont, *and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket namecert obligation surface`

Proof. Read the carrier packet of Definition 299.1. Its fields list the bundle, connection, loop, transported endpoint, curvature-control provenance, continuation, and package rows.

Apply Definition 299.3 to bind the loop source to the displayed manifold and bundle rows. Apply Definition 299.4 to bind transport and endpoint readback to the connection row.

Apply Definition 299.7 to record composition as a finite continuation route. The curvature-compatibility and naming rows are then projections from κ, λ, and ρ: every curvature, control, Lie-group, bundle, and manifold dependency appears as a named row in the packet.

These five rows exhaust the public seed surface. No host parallel-transport functor, analytic path space, ambient holonomy group, or unrecorded curvature operator has a projection from the carrier. □

Theorem 299.9 (Holonomy certificate boundary)**.** *The seed* $\mathsf{NameCert}_{\mathsf{Holonomy}^\uparrow}$ *obligation surface consists of five finite rows: carrier inhabitation for Definition 299.1, reflexivity, symmetry, and transitivity for the classifier of Definition 299.2, transport stability of finite parallel-transport loops, exactness of the curvature-boundary ledger, and a downstream readback boundary restricting consumers to the displayed loop, transport, curvature, bundle, manifold,* hsame, Cont, *and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyBHistTransportCarrier certificate boundary`

Proof. Carrier inhabitation is the constructor that assembles the base, fibre, loop, transport, curvature, provenance, and continuation rows into one finite BHist packet.

The classifier laws are componentwise. Reflexivity uses the displayed row identities, symmetry reverses each hsame comparison, and transitivity composes the corresponding comparisons while preserving the same finite continuation ledger.

The transport and curvature obligations are supplied by the preceding transport and curvature-boundary theorems. The final readback boundary follows by projecting the carrier coordinates: no accepted packet exposes an ambient holonomy group, host smooth-loop space, external transport solver, or extra curvature source. □

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket certificate boundary`

Theorem 299.10 (Holonomy standard boundary scope)**.** *The standard geometric boundary of* $\mathsf{Holonomy}^{\uparrow}$ *is limited in this chapter to the displayed loop, connection-transport, fibre endpoint, curvature-control, composition, and dependency-provenance rows of the carrier. A classical holonomy group may motivate the target name, but the BEDC packet exposes only a finite NameCert ledger and does not claim a host Lie subgroup, smooth parallel-transport action, or analytic path-space quotient.*

Lean4 ✓ `BEDC.Derived.HolonomyUp.HolonomyTransportPacket standard boundary scope`

Proof. Project a consumer-visible holonomy readback from the carrier. The available fields are exactly the loop row, connection row, transported endpoint, curvature-control provenance, continuation ledger, and package provenance.

The Lie-group dependency is present only through the named $\mathsf{NameCert}_{\mathsf{LieGroup}^{\uparrow}}$ row in ρ. It can classify displayed endpoint-composition data, but it does not create an ambient group of all loops or a smooth action on a host fibre.

Thus the standard boundary remains a scope statement about which classical rows can be consumed from the finite packet. Anything requiring a host path space, host parallel transport, or Lie-subgroup theorem lies outside this seed chapter. □

Closure status for $\mathsf{NameCert}_{\mathsf{Holonomy}^{\uparrow}}$**.**

Constructive story: The holonomy packet is a finite BHist transport ledger over certified bundle, connection, loop, transported fibre endpoint, curvature-control, continuation, and package rows. Classification transports the loop, connection, endpoint, curvature-control provenance, and ledger rows componentwise by hsame, while composition is a finite Cont route rather than a host path operation.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Holonomy}^{\uparrow}}$, maturePackageClosed)

Scope closed: The obligation scope names only the displayed $\mathsf{Connection}^{\uparrow}$, $\mathsf{Curvature}^{\uparrow}$, $\mathsf{Bundle}^{\uparrow}$, $\mathsf{Manifold}^{\uparrow}$, $\mathsf{LieGroup}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows of the transport packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Holonomy}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.HolonomyUp.HolonomyTransportPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Not claimed: This chapter does not close host parallel transport, analytic path spaces, a holonomy Lie subgroup theorem, or a standard bridge.

Upgrade path: No paper-axis theory grade remains; bridgeChecked verification is a separate formal-axis upgrade.

Chapter 300

A Concrete Naming Certificate for $\mathsf{KKT}^{\uparrow}$

The $\mathsf{KKT}^{\uparrow}$ interface records the finite certificate surface of Karush–Kuhn–Tucker optimality data for a displayed constrained convex program. Its standard optimization source is Boyd and Vandenberghe, *Convex Optimization* (2004). The BEDC dependencies are $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ for the feasible-region row, $\mathsf{NameCert}_{\mathsf{LPDuality}^{\uparrow}}$ for primal-dual comparison rows, $\mathsf{NameCert}_{\mathsf{Mat}^{\uparrow}}$ and $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ for stationarity and residual rows, and $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$ for scalar slack and objective rows. It consumes the feasible-region carrier of chapter 208 and the primal-dual comparison ledger of chapter 235 before packaging stationarity, feasibility, and complementary-slackness rows.

300.1 Carrier definition

Definition 300.1 (KKTUp BHist carrier)**.** *A* $\mathsf{KKT}^{\uparrow}$ *carrier is a finite* BHist *packet whose visible rows are a primal variable row, a dual multiplier row, a constraint residual row, a stationarity row, feasibility rows, a complementary-slackness ledger,* hsame *comparison rows between corresponding displayed entries,* Cont *provenance rows for the stationarity and ledger readbacks,* Pkg *rows naming* $\mathsf{ConvexSet}^{\uparrow}$*,* $\mathsf{LPDuality}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and a* NameCert *provenance row for the accepted packet.*

The classifier accepts exactly those packets whose primal, dual, residual, stationarity, feasibility, slackness, comparison, continuation, and package rows are read through the displayed dependency certificates. It exports no nonlinear optimizer, differentiability oracle, Slater witness, analytic duality theorem, or host real-valued minimization semantics.

Lean4 (definition) `BEDC.Derived.KKTUp.KKTCarrierPacket`

300.2 The certificate

Theorem 300.2 (KKTUp primal-dual row obligations)**.** *Every accepted* $\mathsf{KKT}^{\uparrow}$ *packet exposes a finite primal row, dual multiplier row, constraint residual row, stationarity row, and feasibility row. The primal and feasibility rows are read through* $\mathsf{ConvexSet}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$*; the dual and residual rows are read through* $\mathsf{LPDuality}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*; and every row carries its displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualCarrier primal dual row obligations`

Proof. Project the carrier of Definition 300.1. Its accepted packet lists exactly the primal, multiplier, residual, stationarity, feasibility, comparison, continuation, package, and naming rows.

Read each row through its named dependency certificate. The feasible-region row supplies the convex-set face, the linear and vector rows supply the displayed stationarity and residual endpoints, the real rows supply scalar slack and objective endpoints, and the duality row supplies the primal-dual comparison.

No other row is present in the packet. The accepted primal-dual surface is therefore exhausted by the finite BHist rows and their visible provenance. □

Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualPacket row obligations`

Theorem 300.3 (KKTUp stationarity and feasibility hsame transport)**.** *Let K and K' be finite* $\mathsf{KKT}^{\uparrow}$ *packets whose primal variable, dual multiplier, residual, stationarity, feasibility, and slackness rows are related componentwise by the displayed* hsame, Cont, Pkg, *and* NameCert *rows of the* $\mathsf{KKT}^{\uparrow}$ *classifier. Suppose the same transport also respects the dependency rows over* $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *If K is accepted, then K' is accepted on the same stationarity and feasibility surface, and the complementary-slackness ledger remains confined to the finite boundary of Definition 300.5.*

The transported packet introduces no analytic differentiability row, Slater data, host minimization predicate, or solver semantics beyond the displayed BEDC rows.

Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualCarrier stationarity feasibility hsame transport`
Lean4 ✓ `BEDC.Derived.KKTUp.KKTCarrierPacket stationarity feasibility hsame transport`

Proof. Unfold Definition 300.1. The carrier names exactly the primal, dual multiplier, residual, stationarity, feasibility, slackness, comparison, continuation, package, and naming rows that can participate in the classifier.

Apply Definition 300.2. The primal and feasibility rows are read through $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{VecSpace}^{\uparrow}$, while the multiplier, residual, stationarity, slackness, and scalar rows are read through $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Transport each displayed row through the given componentwise hsame, Cont, Pkg, and NameCert data, then repack the resulting finite rows in the same carrier positions. Since the dependency rows are transported with the visible packet, the stationarity and feasibility surface of K' is accepted by the same classifier shape.

Finally apply Definition 300.5. The slackness ledger remains only the displayed residual, multiplier, scalar slack, comparison, continuation, and package rows, so the transport cannot add analytic differentiability, Slater data, host minimization semantics, or solver evidence. □

Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualPacket stationarity feasibility hsame transport`

Theorem 300.4 (KKTUp stationarity and feasibility stability)**.** *Let K and K' be accepted* $\mathsf{KKT}^{\uparrow}$ *packets whose displayed primal variable, dual multiplier, residual, matrix and vector stationarity rows, real scalar rows, finite* Cont *routes, and* Pkg *provenance compare componentwise by the* hsame *rows of the* $\mathsf{KKT}^{\uparrow}$ *classifier. Transporting along those rows preserves the accepted stationarity and feasibility rows of the packet. The transport introduces no analytic differentiability oracle, Slater witness, nonlinear optimizer, or host minimization semantics.*

Lean4 ✓ `BEDC.Derived.KKTUp.KKTCarrierPacket stationarity feasibility stability`

Proof. Unpack the carrier of Definition 300.1. The stationarity and feasibility coordinates are displayed rows in the same finite BHist packet as the primal variable, multiplier, residual, scalar, continuation, package, and naming rows.

Apply Definition 300.2 to read the dependency provenance of those coordinates. The primal and feasibility rows are routed through the convex-set and vector-space certificates, while the dual, residual, stationarity, and scalar rows are routed through the displayed linear, vector, real, and duality certificates.

Componentwise hsame transport replaces each displayed row by its classified partner and keeps the finite Cont routes and Pkg provenance fixed at the readback boundary. Therefore the stationarity and feasibility rows remain accepted rows of K'.

The carrier has no field for a differentiability oracle, Slater witness, nonlinear optimizer, or host real minimization semantics. The stability claim is therefore confined to the displayed BEDC packet rows. □

Theorem 300.5 (KKTUp complementarity ledger exactness)**.** *In an accepted* $\mathsf{KKT}^{\uparrow}$ *packet, the complementary-slackness ledger is exactly the finite list of displayed residual, multiplier, scalar slack,* hsame*,* Cont*, and* Pkg *rows carried by Definition 300.1. A downstream read of complementarity cannot use an unrecorded inequality family, host multiplication law, analytic limit, or external optimality predicate.*

Lean4 ✓ `BEDC.Derived.KKTUp.KKTComplementarityLedger exactness`

Proof. Inspect the complementary-slackness coordinate of the carrier. It is a finite ledger, and each entry points to the displayed residual row, multiplier row, scalar row, comparison row, continuation row, and package row.

The ledger readback is obtained by following those entries and no ambient arithmetic table is introduced. The real-valued component is the named $\mathsf{Real}^{\uparrow}$ endpoint already present in the packet.

Since the carrier has no coordinate for an external inequality family, analytic limit, or host optimality predicate, complementarity is exact at the displayed ledger boundary. □

Theorem 300.6 (KKTUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{KKT}^{\uparrow}}$ *obligation surface consists of five finite rows: the carrier and classifier row of Definition 300.1; the primal-dual dependency row over* $\mathsf{ConvexSet}^{\uparrow}$*,* $\mathsf{LPDuality}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*; the stationarity and feasibility stability row under componentwise* hsame *transport; the complementary-slackness ledger exactness row; and the downstream consumer boundary that restricts all reads to the displayed* BHist*,* Cont*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.KKTUp.KKTPrimalDualPacket namecert obligation surface`

Proof. Start from the finite carrier and classifier. These give the packet inventory and the accepted readback relation for every visible row.

Apply Definition 300.2 to bind the primal, dual, residual, stationarity, and feasibility rows to their dependency certificates. Componentwise hsame transport preserves the same row inventory because the classifier reads only those displayed comparisons and the same provenance rows.

Apply Definition 300.5 for the slackness face. Repacking the dependency rows, transport rows, ledger row, and consumer restriction gives exactly the five local $\mathsf{NameCert}_{\mathsf{KKT}^{\uparrow}}$ obligations. □

Theorem 300.7 (KKTUp downstream consumer boundary)**.** *Any optimization, algebraic, or control consumer of* $\mathsf{NameCert}_{\mathsf{KKT}^\uparrow}$ *may read only the finite primal, multiplier, residual, stationarity, feasibility, slackness,* hsame, Cont, Pkg, *and* NameCert *rows of the carrier. It cannot infer full nonlinear optimization semantics, Slater existence, analytic differentiability, host real minimization, or a solver certificate from the* $\mathsf{KKT}^\uparrow$ *packet alone.*

Lean4 ✓ `BEDC.Derived.KKTUp.KKTCarrierPacket downstream consumer boundary`

Proof. Take an arbitrary downstream read of the certificate. By the local obligation surface, the read must factor through the displayed carrier and its finite provenance rows.

The only optimization-facing rows in that carrier are the primal, multiplier, residual, stationarity, feasibility, and complementary-slackness entries. Each is already tied to a dependency certificate and to a visible continuation route.

All excluded analytic objects require rows absent from the carrier. The downstream boundary therefore stops at the finite BEDC packet and cannot project host optimization semantics or solver evidence. □

Theorem 300.8 (KKTUp public finite-packet export)**.** *The public export for* $\mathsf{KKT}^\uparrow$ *is exactly the finite primal, multiplier, residual, stationarity, feasibility, complementary-slackness,* hsame, Cont, Pkg, *and* NameCert *rows of Definition 300.1. Its dependency reads pass only through* $\mathsf{ConvexSet}^\uparrow$, $\mathsf{LPDuality}^\uparrow$, $\mathsf{Mat}^\uparrow$, $\mathsf{VecSpace}^\uparrow$, *and* $\mathsf{Real}^\uparrow$ *rows already recorded in the carrier and its local certificate surface.*

The export contains no full nonlinear optimization semantics, Slater existence, analytic differentiability, host minimization predicate, or solver certificate.

Lean4 ✓ `BEDC.Derived.KKTUp.KKTTasteGate single carrier alignment`

Proof. Start with Definition 300.2. It binds the primal, multiplier, residual, stationarity, and feasibility rows to the displayed $\mathsf{ConvexSet}^\uparrow$, $\mathsf{LPDuality}^\uparrow$, $\mathsf{Mat}^\uparrow$, $\mathsf{VecSpace}^\uparrow$, and $\mathsf{Real}^\uparrow$ dependency reads.

Use Definition 300.3 for the componentwise hsame routes. These routes preserve the public row inventory because they transport only the displayed stationarity and feasibility certificates.

Apply Definition 300.5 for the complementary-slackness ledger. Then use Definition 300.7 to restrict every downstream read to the finite carrier rows, Cont routes, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{KKT}^\uparrow}$ surface.

The carrier has no coordinate for nonlinear optimization semantics, Slater existence, analytic differentiability, host minimization, or solver evidence. The listed finite rows are therefore the whole public packet export. □

Closure status for $\mathsf{NameCert}_{\mathsf{KKT}^\uparrow}$**.**

Constructive story: The construction starts from a finite constrained-convex-program packet, records primal, dual, residual, stationarity, feasibility, and complementary-slackness rows, and routes every read through displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KKT}^\uparrow}$, maturePackageClosed)

Scope closed: By Definition 300.7, Definition 300.8, Definition 300.9, and Definition 300.10, the scoped boundary binds the primal, dual, residual, stationarity, feasibility, slackness, hsame, Cont, Pkg, and NameCert rows of the finite KKT packet and its standard finite-packet bridge.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{KKT}^\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.KKTUp.KKTCarrierPacket\_downstream\_consumer\_boundary`

Bridge status: paperBridge

Not claimed: This chapter does not close full nonlinear optimization, Slater existence, analytic differentiability, host real optimization semantics, or checked bridge status.

Upgrade path: The paper-side finite KKT packet is mature; the remaining obligation is Lean bridge checking without adding analytic solver semantics.

Definition 300.9 (Standard finite KKT packet presentation)**.** *A standard finite KKT packet presentation for* $\mathsf{KKT}^{\uparrow}$ *is a displayed finite table whose entries are exactly a primal variable row, a dual multiplier row, a constraint residual row, a stationarity row, feasibility rows, a complementary-slackness row, componentwise* hsame *rows between the displayed entries,* Cont *rows for stationarity and slackness readback,* Pkg *rows naming* $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *a* $\mathsf{NameCert}_{\mathsf{KKT}^{\uparrow}}$ *row, and the dependency rows through those five named certificates. Its standard reading is only this finite KKT table: primal data, multipliers, residuals, stationarity, feasibility, and complementary slackness as displayed rows.*

Theorem 300.10 (KKTUp finite-packet standard bridge)**.** *Let* S *be a standard finite KKT packet presentation in the sense of Definition 300.9. If* S *is admitted solely through the primal, multiplier, residual, stationarity, feasibility, complementary-slackness,* hsame, Cont, Pkg, NameCert, *and dependency rows exported by* $\mathsf{KKT}^{\uparrow}$, *then* S *has a conservative standard bridge through the public* $\mathsf{KKT}^{\uparrow}$ *finite packet. The forward read sends* S *to the public export of Definition 300.8. The reverse read sends that public export back to the same displayed finite KKT presentation, up to the componentwise* hsame *rows already present in* S*. Both composites preserve the primal, multiplier, residual, stationarity, feasibility, complementary-slackness, continuation, package, naming, and dependency rows.*

The bridge adds no Slater condition, differentiability oracle, solver certificate, analytic duality theorem, nonlinear optimizer, host minimization predicate, or host real-valued optimization semantics.

Lean4 ✓ `BEDC.Derived.KKTUp.KKTUp finite packet standard bridge`

Proof. Read S through Definition 300.9. Its entries are exactly the finite KKT rows listed there, together with the dependency rows over $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

By Definition 300.1, these are precisely the visible carrier rows accepted by $\mathsf{KKT}^{\uparrow}$. The classifier therefore admits S only by placing its primal, multiplier, residual, stationarity, feasibility, slackness, comparison, continuation, package, naming, and dependency entries in the corresponding finite BHist packet positions.

Apply Definition 300.2. The primal, multiplier, residual, stationarity, and feasibility entries of S are read through the displayed dependency certificates, and every such entry carries its visible hsame, Cont, Pkg, and NameCert provenance. Apply Definition 300.5 to the slackness entry. The complementary-slackness row is exactly the finite ledger over the displayed residual, multiplier, scalar slack, comparison, continuation, and package rows.

The forward standard read is now forced: it forgets no row and adds no row, but regards this accepted finite packet as the standard finite KKT table consisting of the displayed primal data, multipliers, residuals, stationarity, feasibility, and complementary slackness. This is the public export described in Definition 300.8, because that theorem identifies the whole public $\mathsf{KKT}^{\uparrow}$ surface with exactly these finite rows and their five dependency reads.

For the reverse read, start from the public export just obtained. Definition 300.8 says that the export contains only the listed finite rows of Definition 300.1. Reinsert those rows into the table positions of Definition 300.9. The stationarity and feasibility entries are stable under the componentwise comparisons by Definition 300.3, and the slackness entry is fixed at the ledger boundary by Definition 300.5. Hence the returned table is the same displayed finite KKT presentation, with equality understood through the hsame rows already carried by S.

The two composites therefore preserve every visible row of the presentation: primal, multiplier, residual, stationarity, feasibility, complementary slackness, hsame, Cont, Pkg, NameCert, and the named dependency rows. Finally, Definition 300.7 rules out every downstream read not present in that finite carrier. Since there is no carrier coordinate for Slater data, differentiability, solver evidence, analytic duality, nonlinear optimization, host minimization, or host real-valued optimizer semantics, the bridge is conservative at exactly the finite packet boundary. □

Theorem 300.11 (KKTUp finite slackness optimality extraction)**.** *Let K be an accepted* $\mathsf{KKT}^{\uparrow}$ *packet. Suppose the displayed primal variable row, dual multiplier row, feasibility rows, and complementary-slackness ledger of K instantiate a finite* $\mathsf{LPDuality}^{\uparrow}$ *ordered-field row as in Definition 235.1. Write the displayed primal and dual witnesses as $x : J \to F$ and $y : I \to F$. Suppose the projected feasibility rows give*

$$\mathsf{PrFeas}_{A,b}(x) \wedge \mathsf{DuFeas}_{A,b,c}(y),$$

and suppose the projected slackness ledger gives the two finite product families

$$\forall j \in J.\ c_j \cdot_F x_j \sim_F \beta_j(y) \cdot_F x_j, \qquad \forall i \in I.\ y_i \cdot_F \alpha_i(x) \sim_F y_i \cdot_F b_i.$$

Then the $\mathsf{KKT}^{\uparrow}$ *packet exports the* $\mathsf{LPDuality}^{\uparrow}$ *weak-duality slackness optimality packet for the displayed rows. In particular,*

$$\mathsf{PrObj}_{A,c}(x) \sim_F \mathsf{DuObj}_b(y),$$

$$\forall x'.\ \mathsf{PrFeas}_{A,b}(x') \Longrightarrow \mathsf{PrObj}_{A,c}(x') \preceq_F \mathsf{PrObj}_{A,c}(x),$$

and

$$\forall y'.\ \mathsf{DuFeas}_{A,b,c}(y') \Longrightarrow \mathsf{DuObj}_b(y) \preceq_F \mathsf{DuObj}_b(y').$$

With $\tau := \mathsf{PrObj}_{A,c}(x)$, every further feasible optimal primal witness and feasible optimal dual witness whose objective endpoints are classifier-equal to τ also enters the common objective-fiber sandwich supplied by Definition 235.16. The extraction uses only the finite carrier rows of K and adds no Slater condition, differentiability oracle, analytic strong-duality theorem, nonlinear optimizer, host minimization predicate, or solver certificate.

Proof. Project the accepted packet K through Definition 300.1. By Definition 300.2, the primal row, dual multiplier row, residual row, stationarity row, feasibility rows, comparison rows, continuation rows, package rows, and naming provenance are all visible finite rows. By hypothesis, the primal row and dual multiplier row are read through the same finite $\mathsf{LPDuality}^{\uparrow}$ ordered-field surface of Definition 235.1; hence they determine the displayed witnesses $x : J \to F$ and $y : I \to F$ together with the projected feasibility statement

$$\mathsf{PrFeas}_{A,b}(x) \wedge \mathsf{DuFeas}_{A,b,c}(y).$$

Apply Definition 300.5 to the slackness coordinate of K. The ledger is exhausted by the displayed residual, multiplier, scalar slack, hsame, Cont, and Pkg rows. Under the stated $\mathsf{LPDuality}^{\uparrow}$ instantiation, those displayed ledger rows are precisely the two product-family equalities

$$\forall j \in J.\ c_j \cdot_F x_j \sim_F \beta_j(y) \cdot_F x_j, \qquad \forall i \in I.\ y_i \cdot_F \alpha_i(x) \sim_F y_i \cdot_F b_i.$$

The stationarity row remains part of the accepted $\mathsf{KKT}^{\uparrow}$ provenance, but the present extraction does not use it to introduce any analytic optimality semantics.

The hypotheses are exactly the inputs of Definition 235.16. Applying that theorem to the projected $\mathsf{LPDuality}^{\uparrow}$ row gives the scalar objective equality, the primal optimality clause for x, the dual optimality clause for y, and the common objective-fiber sandwich at $\tau := \mathsf{PrObj}_{A,c}(x)$ for any further feasible optimal witnesses whose objective endpoints lie in that scalar fiber.

It remains only to identify the consumer boundary. By Definition 300.8, the public $\mathsf{KKT}^{\uparrow}$ export consists exactly of the finite primal, multiplier, residual, stationarity, feasibility, complementary-slackness, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows and their dependency reads through $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. By Definition 300.7, a downstream consumer cannot read any solver certificate, host minimization predicate, Slater witness, differentiability oracle, or full nonlinear optimization semantics from that packet. Therefore the optimality packet just obtained is a conservative finite-row export through the displayed $\mathsf{LPDuality}^{\uparrow}$ slackness theorem and no stronger optimization principle is introduced. □

The $\mathsf{RegSeqRat}^{\uparrow}$ hub reads its finite observation schedules through chapter 126, its dyadic tolerance ledger through chapter 291, and its terminal seal through chapter 38. The child files below keep those three sibling rows in the finite L10 four-face route and export no quotient stream equality, selected limit, host real equality, or ambient completeness coordinate.

Chapter 301

A Concrete Naming Certificate for $\mathsf{RegSeqRat}^{\uparrow}$

The $\mathsf{RegSeqRat}^{\uparrow}$ interface names Bishop-style regular rational streams over the dyadic observation layer. It sits between $\mathsf{DyadicRatCore}^{\uparrow}$, which supplies finite dyadic endpoints and radius ledgers, and $\mathsf{Real}^{\uparrow}$, which consumes accepted regular-sequence packets as the finite source surface of a real-name seal.

The carrier consumes the finite observation schedules supplied by $\mathsf{StreamName}^{\uparrow}$ in chapter 126 and the endpoint and radius rows supplied by $\mathsf{DyadicRatCore}^{\uparrow}$ in chapter 291. Its accepted packets are then consumed by the $\mathsf{Real}^{\uparrow}$ seal surface in chapter 38.

301.1 Carrier and classifier

Definition 301.1 (RegSeqRat stream carrier)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carrier is a finite* BHist *packet naming a stream* $x : \mathbb{N} \to \mathsf{BHist}$ *together with the visible observation schedule supplied by* $\mathsf{StreamName}^{\uparrow}$*. For every finite window requested by the schedule, the packet carries:*

1. *a unary index row naming the requested stream position;*
2. *a dyadic endpoint row accepted by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
3. *the dyadic radius row* 2^{-n} *attached to the requested precision;*
4. *a regularity ledger comparing any two displayed endpoints* x_n *and* x_m *by the bound* $2^{-n} + 2^{-m}$*;*
5. *the* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *provenance rows for the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *reads.*

The carrier stores only these scheduled finite observations. It contains no quotient carrier of Cauchy sequences, no ambient metric completion, and no host real endpoint.

Lean4 (definition) `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier`

Definition 301.2 (RegSeqRat dyadic-tolerance classifier)**.** *For accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carriers* x *and* y*, the predicate* $\mathsf{RegSeqRatClassifier}(x, y)$ *records dyadic tolerance agreement on scheduled finite windows. A classifier witness supplies, for each requested unary precision window, dyadic observation rows for* x_n *and* y_m*, a common finite refinement requested through* $\mathsf{StreamName}^{\uparrow}$*, and a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger proving that the displayed dyadic distance is bounded by the requested dyadic radius.*

The classifier is a predicate over finite dyadic ledgers and visible stream-name rows. It does not identify streams by a quotient relation and does not import any external real equality.

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatClassifier window pairing`

301.2 Certificate obligations

Theorem 301.3 (RegSeqRat regularity obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the scheduled stream carrier of Definition 301.1;*
2. *classifier: the dyadic-tolerance classifier of Definition 301.2;*
3. *regularity ledger: every displayed pair of endpoints* x_n, x_m *is accompanied by a* $\mathsf{DyadicRatCore}^{\uparrow}$ *bound row for* $2^{-n} + 2^{-m}$*;*
4. *dyadic-radius observation: each precision request exposes the radius row, endpoint row, and finite dyadic distance row consumed by the classifier;*
5. *finite-window transport: restricting, refining, or transporting a window through* hsame *and* Cont *repacks the same* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows without adding a quotient or completion object.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier regularity obligation surface`

Proof. Project the carrier definition. Its accepted packet already lists the scheduled unary index rows, dyadic endpoint rows, radius rows, regularity comparisons, continuation routes, package provenance, and naming rows.

The classifier definition supplies the second face: every comparison between two accepted packets is a finite dyadic-tolerance ledger over the same scheduled observation rows. The regularity and dyadic-radius faces are the two distinguished projections from that ledger.

For finite-window transport, follow the displayed hsame and Cont rows attached to the schedule. A restriction or refinement only changes which finite indices are read; each selected endpoint and radius remains a $\mathsf{DyadicRatCore}^{\uparrow}$ row with the same visible provenance. Repacking these projections gives exactly the five obligation rows and no additional carrier. □

Theorem 301.4 (RegSeqRat window regularity ledger)**.** *Every scheduled finite window in an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carrier carries the unary index rows requested by* $\mathsf{StreamName}^{\uparrow}$*, two* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows for the displayed endpoints* x_n *and* x_m*, the two dyadic radius rows* 2^{-n} *and* 2^{-m}*, and the regularity ledger row displaying the bound*

$$2^{-n} + 2^{-m}.$$

The window carries these rows together with their hsame, Cont, Pkg, *and* NameCert *provenance, and it carries no quotient sequence, metric-completion object, or host real endpoint.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier window regularity ledger`

Proof. Project the stream carrier of Definition 301.1. A scheduled window is generated by the visible $\mathsf{StreamName}^{\uparrow}$ request, so its finite rows include the unary indices selected by that request and the dyadic endpoint rows accepted by $\mathsf{DyadicRatCore}^{\uparrow}$.

The regularity row in Definition 301.3 is the distinguished comparison row for any displayed endpoint pair. Reading it at the selected indices gives the two radius rows and the displayed ledger bound $2^{-n} + 2^{-m}$.

The same carrier projection lists the hsame, Cont, Pkg, and NameCert provenance rows attached to those observations. Since the carrier has no coordinate for quotient sequences, completions, or host real endpoints, the window ledger is exhausted by the displayed finite rows. □

Theorem 301.5 (RegSeqRat dyadic-radius observation)**.** *Every classifier precision request in* RegSeqRatClassifier(x, y) *exposes only the* StreamName$^{\uparrow}$ *schedule rows,* DyadicRatCore$^{\uparrow}$ *endpoint rows, dyadic radius rows, finite dyadic distance rows, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and* NameCert *rows of the accepted* RegSeqRat$^{\uparrow}$ *packets.*

Proof. Unpack the classifier of Definition 301.2. A precision request first selects a finite stream-name window and then reads dyadic endpoints for the two accepted packets through DyadicRatCore$^{\uparrow}$.

The tolerance witness is a finite dyadic ledger. It records the requested radius and the displayed dyadic distance, together with the common refinement supplied by the same StreamName$^{\uparrow}$ schedule.

All comparison and routing data are the componentwise hsame rows, displayed Cont routes, package provenance, and naming rows already present in the packets. No external real equality, quotient carrier, or completion datum can be projected from the classifier definition. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatClassifier dyadic radius observation`

Theorem 301.6 (RegSeqRat finite-window transport obligation)**.** *Restricting, refining, or transporting a finite* RegSeqRat$^{\uparrow}$ *window preserves the carrier and classifier rows through componentwise* hsame *comparisons and the displayed* Cont *routes. The transported window retains the* StreamName$^{\uparrow}$ *schedule,* DyadicRatCore$^{\uparrow}$ *endpoint rows, dyadic radius rows, finite dyadic distance rows, regularity ledgers,* Pkg *provenance, and* NameCert *rows, and introduces no additional carrier.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier finite window transport obligation`

Proof. Start with the window ledger of Definition 301.4. It identifies the unary index rows, endpoint rows, radius rows, and regularity bound carried by the source window.

Use Definition 301.5 for the classifier side. Every precision request reads the same schedule, endpoint, radius, distance, comparison, continuation, package, and naming rows.

Now apply the transport statement of Definition 301.7. Its hypotheses are exactly componentwise hsame rows and displayed Cont routes preserving the schedule, endpoints, radius rows, and regularity ledgers. Repacking the transported rows gives the target finite window with the same carrier and classifier surface, and there is no coordinate from which an additional carrier could be introduced. □

Theorem 301.7 (RegSeqRat classifier transport)**.** *Let x, y, x', y' be accepted* RegSeqRat$^{\uparrow}$ *stream carriers. Suppose x is transported to x' and y is transported to y' by componentwise* hsame *rows and displayed* Cont *routes that preserve the* StreamName$^{\uparrow}$ *schedule, the* DyadicRatCore$^{\uparrow}$ *endpoint rows, the dyadic-radius rows, and the finite regularity ledgers. If* RegSeqRatClassifier(x, y) *holds, then* RegSeqRatClassifier(x', y') *holds on the transported finite windows.*

The transported classifier reads only the carried stream-name, dyadic endpoint, radius, distance, regularity, hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier classifier transport`
Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatClassifier transport`

Proof. Start with a finite classifier witness for x and y. It consists of scheduled observation indices, endpoint rows, radius rows, common finite refinements, and dyadic distance ledgers.

Transport the two endpoint families along the supplied componentwise hsame rows. The Cont routes preserve the schedule, so every requested finite window for x' and y' has the same shape as the source window and reads the corresponding transported $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows.

Transport the dyadic-radius and distance ledgers through the same provenance. Since the regularity rows are carried with the endpoints, the transported witness satisfies the dyadic-tolerance classifier for x' and y' on the selected windows. No quotient sequence or ambient real equality is introduced. □

Theorem 301.8 (RegSeqRat classifier symmetric finite-window)**.** *Let x and y be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carriers. Suppose a finite* $\mathsf{StreamName}^{\uparrow}$ *scheduled window witnesses* $\mathsf{RegSeqRatClassifier}(x, y)$ *by displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic-radius rows, finite dyadic distance ledgers, regularity ledgers, componentwise* hsame *comparisons, displayed* Cont *routes,* Pkg *provenance, and* NameCert *rows. Then the reversed scheduled window witnesses* $\mathsf{RegSeqRatClassifier}(y, x)$ *using the same finite rows with the endpoint-pair order swapped.*

Proof. Project the witness through the classifier definition of Definition 301.2. The only visible coordinates are the scheduled endpoint rows, radius rows, dyadic distance ledgers, regularity rows, comparison rows, continuation routes, package provenance, and naming rows.

Reverse the scheduled window by swapping the two endpoint rows in every displayed pair. The dyadic distance ledger is read symmetrically by Definition 301.13, so the same tolerance rows certify the reversed endpoint comparison.

Transport the swapped rows through the finite-window transport obligation of Definition 301.6. The componentwise hsame comparisons and displayed Cont routes preserve the schedule, endpoint rows, radii, distance rows, and regularity ledgers.

Apply classifier transport from Definition 301.7 to the repacked reversed window. The resulting finite packet has exactly the rows required for $\mathsf{RegSeqRatClassifier}(y, x)$, and no quotient stream equality or host real equality is introduced. □

Theorem 301.9 (RegSeqRat common-refinement classifier determinacy)**.** *Let x and y be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carriers. Suppose two finite* $\mathsf{StreamName}^{\uparrow}$ *schedules both refine to a common window and carry the same transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic-radius rows, regularity ledgers, classifier ledgers,* hsame *comparisons,* Cont *routes, and* Pkg *provenance. Then the two schedules determine the same* $\mathsf{RegSeqRatClassifier}(x, y)$ *read on that common window.*

The common read is the one exposed by the $\mathsf{Real}^{\uparrow}$ *seal handoff through the refined finite rows. It contains no quotient stream equality, host real equality, or metric-completion comparison.*

Proof. Project the carrier of Definition 301.1 and the classifier of Definition 301.2. Each schedule reads only unary index rows, dyadic endpoints, radius rows, regularity ledgers, dyadic distance ledgers, and the displayed provenance attached to those rows.

Move both schedules to the stated common window. The finite-window transport obligation of Definition 301.6 carries the endpoints, radii, regularity rows, and provenance to the same refined rows on that window.

Apply classifier transport from Definition 301.7 to both transported reads. Since the hypotheses identify the transported endpoint, radius, regularity, classifier, hsame, Cont, and Pkg rows, the two classifier witnesses have the same finite ledger on the common window.

Finally read the $\mathsf{Real}^{\uparrow}$ seal boundary through Definition 301.22. That handoff consumes only the refined finite rows just identified, so it cannot distinguish the two source schedules and yields the same RegSeqRatClassifier read. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier common refinement classifier determinacy`

Theorem 301.10 (RegSeqRat classifier common-refinement transitivity)**.** *Let x, y, and z be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets. Suppose one finite* $\mathsf{StreamName}^{\uparrow}$ *schedule witnesses* $\mathsf{RegSeqRatClassifier}(x, y)$ *and another finite* $\mathsf{StreamName}^{\uparrow}$ *schedule witnesses* $\mathsf{RegSeqRatClassifier}(y, z)$*. If the two witnesses admit a common refinement on which the middle y endpoint rows, dyadic-radius rows, regularity ledgers, classifier ledgers,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance agree, then the common refinement witnesses* $\mathsf{RegSeqRatClassifier}(x, z)$ *using only the displayed finite rows.*

Proof. Project both classifier witnesses to their finite scheduled windows. The finite-window transport obligation of Definition 301.6 moves the x–y and y–z endpoint families, radius rows, regularity ledgers, classifier ledgers, hsame rows, Cont routes, package rows, and naming rows to the stated common refinement.

On that common refinement, apply Definition 301.9 to the two transported reads of the middle y side. The agreement hypotheses identify the displayed y endpoint rows and all provenance rows that the classifier can inspect, so the two source schedules have one middle finite surface.

Read the two dyadic tolerance ledgers through Definition 301.13. Since the radius and distance data are displayed on the same refined finite window, the x endpoint rows and the z endpoint rows compose across the common y rows inside the dyadic ledger surface.

Finally use classifier transport from Definition 301.7 to repack the composed finite surface as a witness for $\mathsf{RegSeqRatClassifier}(x, z)$. The construction introduces no quotient stream equality, host real equality, metric-completion object, or $\mathsf{Real}^{\uparrow}$ completeness datum. □

Theorem 301.11 (RegSeqRat diagonal window extraction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S be a finite* $\mathsf{StreamName}^{\uparrow}$ *schedule whose two classifier witnesses for displayed reads of P admit a common refinement. At the shared unary index of that refinement, the diagonal observation is a displayed finite window consisting only of* BHist *rows, the* UnaryHistory *witness for the index, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, regularity ledgers,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance.*

The same diagonal row is exactly the finite source row consumed by the $\mathsf{Real}^{\uparrow}$ *seal handoff. Thus the extraction exports no quotient stream, host real equality, metric-completion point,* $\mathsf{Real}^{\uparrow}$ *completeness datum, or additional bridge coordinate.*

Proof. Project the two scheduled reads through Definition 301.12. This exposes the common-refinement schedule together with the displayed unary index, endpoint rows, radius rows, regularity ledgers, comparison rows, continuation routes, package provenance, and naming provenance.

Read the radius and distance components by Definition 301.13. The diagonal row at the shared unary index is therefore a finite $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint-and-radius observation inside the same displayed BHist packet.

Use Definition 301.9 to identify the two transported classifier reads on the common refinement. Since the classifier can inspect only the displayed rows already projected, both witnesses present the same diagonal finite-window row.

Finally apply Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal consumes exactly the finite regular-rational source surface exposed by that diagonal row, so the handoff reads the extracted finite window itself and not any quotient, host-real, completion, or bridge datum. □

Theorem 301.12 (RegSeqRat scheduled-window projection)**.** *For every accepted finite scheduled window of a* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carrier, projection exposes only the unary index row, the*

DyadicRatCore$^{\uparrow}$ *endpoint row, the dyadic-radius row, the regularity ledger rows, and the associated* hsame, Cont, Pkg, *and* NameCert *rows. No projected window contains a quotient sequence coordinate, a host real coordinate, or a completion object.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier scheduled window projection`

Proof. Project Definition 301.1. Each scheduled window is stored as a finite BHist packet, and the carrier list contains precisely the unary index, dyadic endpoint, radius, regularity, continuation, package, and naming rows.

Apply Definition 301.3 to read the same packet as a local obligation surface. The theorem identifies the carrier, regularity ledger, dyadic-radius observation, and finite-window transport faces as projections of those displayed rows.

Finally use Definition 301.2 and Definition 301.7 to check that classifier reads do not add further coordinates. They consume the projected dyadic ledgers and transport them along the displayed hsame and Cont rows. □

Theorem 301.13 (RegSeqRat dyadic-radius ledger readback)**.** *Every radius or distance comparison used by* RegSeqRatClassifier *is read back from displayed* DyadicRatCore$^{\uparrow}$ *radius and distance ledgers in the accepted finite window. The classifier never appeals to quotient equality of streams, host real equality, or an ambient metric-completion comparison.*

Proof. Unfold the classifier of Definition 301.2. A witness is a finite list of scheduled dyadic observations, a common refinement row, and a DyadicRatCore$^{\uparrow}$ tolerance ledger for the displayed distance against the requested radius.

The available radius and regularity rows are exactly the dyadic-radius observation and regularity faces of Definition 301.3. Thus every comparison used in a classifier witness has a displayed ledger source inside the finite packet.

Transport stability follows from Definition 301.7. When the window is carried through hsame and Cont, the radius and distance ledgers are carried as the same DyadicRatCore$^{\uparrow}$ rows, so no quotient or host-real equality can enter the readback. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier dyadic radius ledger readback`

Theorem 301.14 (RegSeqRat finite-window transport closure)**.** *Restriction, refinement, and componentwise* hsame *or* Cont *transport of an accepted finite* RegSeqRat$^{\uparrow}$ *window repack the same* StreamName$^{\uparrow}$ *schedule rows and* DyadicRatCore$^{\uparrow}$ *endpoint, radius, distance, and regularity rows. The repacked window remains within the displayed carrier and classifier surface of the same stream-name certificate.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier finite window transport closure`

Proof. Begin with the finite-window transport row singled out by Definition 301.3. Restriction selects fewer scheduled unary indices, while refinement requests a larger finite schedule through StreamName$^{\uparrow}$ and keeps each selected endpoint and radius as a displayed DyadicRatCore$^{\uparrow}$ row.

For componentwise transport, apply Definition 301.7. Its hypotheses preserve the stream schedule, endpoint rows, radius rows, and regularity ledgers, and its conclusion rebuilds the dyadic-tolerance classifier on the transported finite windows.

The carrier of Definition 301.1 and the classifier of Definition 301.2 therefore close under these finite operations by repacking existing rows. The resulting packet is still a RegSeqRat$^{\uparrow}$ source surface, not a quotient or completion object. □

Theorem 301.15 (RegSeqRat finite-window classifier reflexivity)**.** *Every accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *scheduled window over its displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius rows, regularity ledger,* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *row carries a* RegSeqRatClassifier *witness from that finite window to itself.*

The self-classifier uses the same schedule rows, endpoint rows, radius rows, dyadic distance ledgers, regularity ledgers, package provenance, and naming row as the input window. It introduces no quotient stream, host real equality, metric-completion datum, or $\mathsf{Real}^{\uparrow}$ *seal claim.*

Proof. Project the accepted window through Definition 301.3. This exposes the finite schedule, endpoint rows, radius rows, regularity ledger, displayed hsame comparisons, Cont routes, Pkg provenance, and NameCert row that already belong to the accepted packet.

Use identity hsame rows on each displayed coordinate and reuse the same Cont routes. With the source and target window equal, the endpoint, radius, distance, and regularity ledgers are exactly the rows already read by the dyadic-radius classifier surface.

Apply Definition 301.14 to the identity transport of this finite packet. The resulting repackaged surface is a RegSeqRatClassifier witness from the window to itself, built only from the displayed finite-window rows. □

Theorem 301.16 (RegSeqRat refined-window gluing)**.** *Let* W_0 *and* W_1 *be accepted finite scheduled windows of the same* $\mathsf{RegSeqRat}^{\uparrow}$ *stream carrier. Suppose* $\mathsf{StreamName}^{\uparrow}$ *supplies a finite common refinement schedule* $W_{\cup}$ *whose source rows restrict to the two input schedules, and suppose the overlapping unary index rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic radius rows, regularity ledgers, and classifier ledgers of* W_0 *and* W_1 *agree along the displayed* hsame *comparisons and* Cont *routes. Then the refined union repacks as an accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *window over* $W_{\cup}$*.*

The restrictions of this refined window back to W_0 *and* W_1 *recover the original classifier witnesses on the two input windows. The gluing operation introduces no quotient sequence, host real equality, metric-completion row, or additional* $\mathsf{Real}^{\uparrow}$ *seal datum.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier refined window gluing`

Proof. Project the two accepted windows by Definition 301.12. This exposes the two finite lists of unary indices, dyadic endpoints, radius rows, regularity ledgers, classifier ledgers, and their displayed hsame, Cont, Pkg, and NameCert provenance rows.

Use the common-refinement schedule supplied by $\mathsf{StreamName}^{\uparrow}$ to choose the joint finite source window. On rows that come from only one input window, keep the corresponding projected row. On overlapping rows, use the stated hsame comparisons and Cont routes to identify the unary index, endpoint, radius, regularity, and classifier ledger entries as the same displayed BEDC data.

The overlap classifier is stable by Definition 301.7. Thus the two classifier witnesses restrict to the same transported witness wherever the schedules meet, and the non-overlap rows remain the witnesses already accepted in the two input windows.

Apply Definition 301.14 to repack the joint schedule, transported overlap rows, and retained non-overlap rows as one finite $\mathsf{RegSeqRat}^{\uparrow}$ carrier and classifier surface. Restricting the repacked window back along either source schedule discards only the other side's rows, so it recovers the original classifier witness for that input window. Since every row used in the construction came from the two projected finite packets and their displayed refinement routes, no quotient sequence, host real equality, completion object, or $\mathsf{Real}^{\uparrow}$ seal row is created. □

Theorem 301.17 (RegSeqRat prefix-window monotonicity)**.** *Let* W *be an accepted finite scheduled* $\mathsf{RegSeqRat}^{\uparrow}$ *window over the dyadic-tolerance classifier of Definition 301.2. Suppose* W' *is a finite*

certified $\mathsf{StreamName}^{\uparrow}$ *prefix subwindow of* W*, obtained by restricting the displayed schedule to an initial certified prefix. Then* W' *repacks as an accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *window over the same dyadic-tolerance classifier.*

The endpoint, radius, regularity, classifier, hsame*,* Cont*,* Pkg*, and* NameCert *rows of the repacked prefix are exactly the projections of the corresponding rows of* W*. The prefix restriction introduces no quotient sequence, host real equality, completion object, or* $\mathsf{Real}^{\uparrow}$ *seal row.*

Proof. Project W by Definition 301.12. This exposes the visible finite schedule, endpoint rows, radius rows, regularity ledgers, classifier ledgers, hsame comparisons, Cont routes, Pkg provenance, and NameCert rows.

Use the certified $\mathsf{StreamName}^{\uparrow}$ prefix to select the initial sublist of scheduled rows. Since the subwindow is a prefix restriction, every endpoint, radius, regularity, classifier, hsame, Cont, Pkg, and NameCert row visible in W' is the corresponding projected row already visible in W.

Apply Definition 301.14 to repack those selected rows as a finite accepted $\mathsf{RegSeqRat}^{\uparrow}$ carrier and classifier surface over the original dyadic-tolerance classifier. No new coordinate is available in this restriction step, so quotient sequences, host real equality, completion objects, and $\mathsf{Real}^{\uparrow}$ seal rows cannot enter the prefix packet.

Finally, when the prefix is compared back with the larger window, use Definition 301.16 on the overlap consisting of the prefix rows. The gluing restriction recovers the same classifier witness on that overlap, because both sides read the same projected endpoint, radius, regularity, classifier, hsame, Cont, Pkg, and NameCert rows. □

Theorem 301.18 (RegSeqRat shifted-tail regularity closure)**.** *Let* P *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet whose stream carrier, dyadic-tolerance classifier, regularity ledger, scheduled windows, and dyadic-radius rows are those of Definition 301.1 and Definition 301.2. For every certified unary tail index* k*, shifting the schedule of* P *by* k *and then reading any finite* $\mathsf{StreamName}^{\uparrow}$ *window produces another accepted regular-rational packet over the same dyadic-tolerance classifier.*

The shifted packet exposes only the transported BHist *rows, componentwise* hsame *comparisons, visible* Cont *routes, the retained* Pkg *row, and the local* NameCert *provenance. It exports no quotient sequence, host real equality, ambient metric-completion object, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Use Definition 301.12 on the shifted finite tail window. The projection exposes exactly the unary tail indices, dyadic endpoint rows, regularity ledgers, radius rows, classifier ledgers, and the visible provenance already carried by P.

Read the transported radius and distance comparisons through Definition 301.13. Since the tail shift only selects later scheduled rows, each tolerance comparison is still a displayed $\mathsf{DyadicRatCore}^{\uparrow}$ ledger row in the same source packet.

Apply Definition 301.14 to repack the selected tail rows as a finite $\mathsf{RegSeqRat}^{\uparrow}$ window over the original dyadic-tolerance classifier. When two shifted finite windows overlap, use Definition 301.16 to identify the common tail rows and retain the same classifier witness on the common refinement.

All consumed coordinates are therefore finite BEDC rows of the original accepted packet. The tail construction has no coordinate from which to read quotient sequences, host real equality, metric completion, or a $\mathsf{Real}^{\uparrow}$ completeness row. □

Theorem 301.19 (RegSeqRat tail-shift classifier stability)**.** *Let* P *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet whose scheduled stream carrier, dyadic-tolerance classifier, regularity ledger, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius rows, and* $\mathsf{Real}^{\uparrow}$ *seal source are the displayed rows of Definition 301.1 and Definition 301.2. If a certified unary tail shift selects a later finite window and the shared tail window is transported by the recorded* hsame *comparisons and* Cont *routes, then*

the shifted packet preserves the same classifier route through the $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *seal.*

The shifted read exports no quotient sequence equality, host real equality, metric-completion object, selected limit, ambient completeness row, or additional seal datum.

Proof. Start with Definition 301.18. It repacks the shifted finite window as an accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet over the original dyadic-tolerance classifier, using only transported rows from the source packet.

Use Definition 301.15 on the shared tail window. The finite $\mathsf{StreamName}^{\uparrow}$ schedule, endpoint observations, $\mathsf{DyadicRatCore}^{\uparrow}$ radius rows, regularity ledgers, classifier ledgers, hsame comparisons, Cont routes, Pkg provenance, and NameCert rows are the same displayed finite surface before and after the tail shift.

Apply Definition 301.20. It keeps the shifted $\mathsf{Real}^{\uparrow}$ seal source attached to the same transported classifier and finite-window rows whenever the shared tail window agrees under the recorded transport and replay data.

Finally invoke Definition 301.22. The seal consumes exactly the finite regular-rational source surface already identified, so the classifier route through stream windows, dyadic radii, readback, and seal rows is stable under the tail shift and cannot acquire any hidden quotient, host-real, completion, or seal coordinate. □

Theorem 301.20 (RegSeqRat shifted-tail seal determinacy)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let k be a certified unary tail index for its* $\mathsf{StreamName}^{\uparrow}$ *schedule. For any finite* $\mathsf{StreamName}^{\uparrow}$ *window read after shifting P by k, the* $\mathsf{Real}^{\uparrow}$ *seal source read from that window is determined by the shifted scheduled window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic-radius rows, regularity ledgers, classifier ledgers, componentwise* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *rows already present in P.*

If two selected shifted windows admit a common finite refinement and agree there on those displayed rows, then the shifted $\mathsf{Real}^{\uparrow}$ *seal source read is invariant under restriction to that refinement. The invariant source surface exports no quotient sequence, host real equality, metric-completion object,* $\mathsf{Real}^{\uparrow}$ *completeness row, or seal datum beyond those finite rows.*

Proof. Apply Definition 301.18 to the certified tail shift and selected finite window. This repacks the shifted read as an accepted finite $\mathsf{RegSeqRat}^{\uparrow}$ window whose visible coordinates are precisely the scheduled tail rows, dyadic endpoints, dyadic-radius rows, regularity ledgers, classifier ledgers, hsame comparisons, Cont routes, Pkg provenance, and NameCert rows inherited from P.

For two selected windows with a common finite refinement, use Definition 301.16 to repack the refinement as one accepted finite window. The classifier witnesses on the overlap are fixed by Definition 301.9, so restriction back to either shifted window reads the same displayed classifier and regularity surface.

Finally apply Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal boundary consumes exactly the finite regular-rational source rows exposed above, so common refinement cannot create a new seal coordinate. The result is a determinacy statement for finite BEDC rows only, with no quotient sequence, host real equality, metric-completion object, completeness row, or further seal datum in the export surface. □

Theorem 301.21 (RegSeqRat tail-cofinal RealUp seal invariance)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Suppose T_0 and T_1 are two certified unary tail shifts of P whose finite* $\mathsf{StreamName}^{\uparrow}$ *windows admit a common cofinal refinement. Assume that, on the displayed refinement, the two*

shifted windows agree on the $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic radius rows, regularity ledgers, classifier witnesses,* hsame *comparisons,* Cont *routes, and* Pkg *provenance rows.*

Then the two tail reads determine the same $\mathsf{Real}^{\uparrow}$ *seal source surface: every row consumed by the* $\mathsf{Real}^{\uparrow}$ *seal from* T_0 *is the corresponding displayed row consumed from* T_1*, after restriction to the common cofinal refinement. This invariance is only a statement about finite BEDC source rows. It does not identify quotient streams, host real values, metric-completion points, or any* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Apply Definition 301.18 separately to the two certified tail shifts. Each shifted finite window is repacked as an accepted $\mathsf{RegSeqRat}^{\uparrow}$ window over the original dyadic-tolerance classifier, and each exposes only transported BHist rows, displayed hsame comparisons, visible Cont routes, the retained Pkg row, and local NameCert provenance.

Use the common cofinal refinement as the joint schedule. The hypotheses identify the endpoint, radius, regularity, classifier, hsame, Cont, and Pkg rows on the overlap, so Definition 301.16 repacks the two tail windows into one accepted finite refinement whose restrictions recover the two original tail classifier witnesses.

Finally apply Definition 301.22. A $\mathsf{Real}^{\uparrow}$ seal read of a regular rational stream consumes exactly the scheduled stream-carrier rows, dyadic-tolerance classifier rows, regularity ledger rows, dyadic-radius rows, finite-window transport rows, and their displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, hsame, Cont, Pkg, and NameCert provenance. Since both tail reads restrict to the same refined finite packet, their seal source surfaces are the same displayed BEDC surface, with no quotient stream, host real equality, completion object, or completeness row available. □

Theorem 301.22 (RegSeqRat RealUp seal handoff)**.** *An accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet is exactly the finite source surface consumed by the existing* $\mathsf{Real}^{\uparrow}$ *seal rows. The handoff surface consists of the scheduled stream carrier, the dyadic-tolerance classifier, the regularity ledger, the dyadic-radius observation rows, the finite-window transport rows, and their* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Thus a $\mathsf{Real}^{\uparrow}$ *seal may read a regular rational stream only through those finite source rows. The handoff does not provide RealUp completeness, quotient carriers, metric completeness, or standard bridge data.*

Proof. Read the accepted packet through Definition 301.3. The projection exposes precisely the carrier, classifier, regularity, dyadic-radius, and finite-window transport rows.

The existing $\mathsf{Real}^{\uparrow}$ seal rows consume regular rational-stream data by finite windows: a stream-name schedule selects dyadic endpoint observations, the classifier supplies dyadic tolerance agreement, and the regularity ledger supplies the source bounds needed at the seal boundary.

Conversely, any source read used by the seal is one of those finite rows, because the $\mathsf{RegSeqRat}^{\uparrow}$ carrier has no coordinate for quotient sequences, ambient metric completion, host real equality, or standard bridge data. The accepted packet and the seal source surface therefore coincide at the displayed finite boundary. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier real seal handoff`

Theorem 301.23 (RegSeqRat public source export)**.** *Any consumer of* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *may read exactly the scheduled stream carrier, the dyadic-tolerance classifier, the regularity ledger, dyadic-radius observations, finite-window transport and gluing rows, the* $\mathsf{Real}^{\uparrow}$ *seal handoff row, and their displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The exported surface contains no quotient sequences, host real equality, ambient metric completion, or extra seal data beyond those finite BEDC rows.

Proof. The regularity obligation surface of Definition 301.3 exposes the scheduled carrier, classifier, regularity ledger, dyadic-radius rows, and their displayed provenance. The finite-window transport theorem Definition 301.14 keeps reads inside the same finite source rows under restriction and refinement.

The refined-window gluing theorem Definition 301.16 adds only common-refinement rows and transported overlap witnesses, again using the visible BHist, hsame, Cont, Pkg, and NameCert provenance already present in the two windows.

Finally, Definition 301.22 identifies the $\mathsf{Real}^{\uparrow}$ seal boundary with that same regular-rational source surface. Since each cited theorem exposes only finite BEDC rows, their composition exhausts the public export surface and leaves no coordinate through which a consumer could read quotient sequences, host real equality, ambient metric completion, or additional seal data. □

Theorem 301.24 (RegSeqRat standard bridge boundary)**.** *An accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet determines the finite standard-bridge boundary consumed by the* $\mathsf{Real}^{\uparrow}$*-facing regular rational stream interface. The boundary consists exactly of the scheduled stream carrier, the dyadic-tolerance classifier, the regularity ledger, dyadic-radius observation rows, finite-window transport and gluing rows, the* $\mathsf{Real}^{\uparrow}$ *seal handoff, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The bridge boundary exports no quotient sequence, host real equality, ambient metric completion, or $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Start with the public source export of Definition 301.23. It names the scheduled carrier, classifier, regularity ledger, radius observations, finite-window operations, seal handoff, and provenance as the consumer-visible rows of an accepted packet.

The seal-facing part is supplied by Definition 301.22. The finite-window part is supplied by Definition 301.14, Definition 301.16, and Definition 301.12; the dyadic-radius readback is supplied by Definition 301.13.

Composing these rows gives the finite boundary read by the regular rational stream interface. Since the cited statements expose only the carrier, classifier, ledger, window, seal, and provenance coordinates just listed, there is no extra coordinate from which a quotient sequence, host real equality, ambient metric completion, or $\mathsf{Real}^{\uparrow}$ completeness datum could be exported. □

Theorem 301.25 (RegSeqRat StreamName Dyadic finite-window lock)**.** *Let P be an accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *scheduled window. The same finite packet simultaneously exposes the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger extracted by the dyadic-radius window theorem, and the exact* $\mathsf{Real}^{\uparrow}$ *seal source surface consumed by Definition 301.22.*

If two refinements of P agree on the displayed $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic-radius rows, regularity ledgers, classifier rows,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *rows, then they induce the same* $\mathsf{Real}^{\uparrow}$ *seal source surface. The lock exports no quotient stream, host real equality, ambient completion point,* $\mathsf{Real}^{\uparrow}$ *completeness datum, or additional standard-bridge coordinate.*

Proof. Project P by Definition 301.12. This exposes the finite $\mathsf{StreamName}^{\uparrow}$ schedule row together with the endpoint, regularity, classifier, transport, provenance, and local naming rows carried by the same accepted packet.

Next read the regularity and radius data through Definition 301.4 and Definition 301.13. These two facts identify the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows and radius ledger as rows of the same finite scheduled window.

For two refinements, apply Definition 301.16. Agreement on the displayed schedule, endpoint, radius, regularity, classifier, hsame, Cont, Pkg, and NameCert rows repacks the overlap as one accepted finite $\mathsf{RegSeqRat}^{\uparrow}$ window whose restrictions recover both refinements.

Finally use Definition 301.22. Since the seal reads only the finite regular-rational source rows just locked together, the two agreeing refinements present the same $\mathsf{Real}^{\uparrow}$ seal source surface and no hidden quotient, completion, equality, or bridge coordinate is available. □

Theorem 301.26 (RegSeqRat StreamName Dyadic seal refinement lock)**.** *Let W_0 and W_1 be accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *windows that refine to a common* $\mathsf{StreamName}^{\uparrow}$ *schedule. Suppose the two windows agree on the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, regularity ledgers, classifier witnesses,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *rows. Then their* $\mathsf{Real}^{\uparrow}$ *seal source reads are the same displayed finite BEDC surface.*

The refinement lock exports no quotient stream equality, host real equality, ambient completion point, $\mathsf{Real}^{\uparrow}$ *completeness row, or extra bridge coordinate.*

Proof. First glue the two windows along the common schedule using Definition 301.16. The hypotheses identify exactly the schedule, endpoint, radius, regularity, classifier, transport, provenance, and naming rows needed to repack the common refinement as one accepted finite $\mathsf{RegSeqRat}^{\uparrow}$ window.

Next apply Definition 301.21. It says that cofinal refinement does not change the finite source surface read by the $\mathsf{Real}^{\uparrow}$ seal, provided the displayed carrier, classifier, ledger, and provenance rows agree on the refinement.

Finally combine Definition 301.22 with Definition 301.25. These theorems identify the seal-facing read with the same StreamName schedule and DyadicRatCore ledger rows already locked by the common refinement, so the result is a finite BEDC surface equality and not a host-level equality or completion claim. □

Theorem 301.27 (RegSeqRat tail seal diagonal-window coherence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0 and T_1 be certified unary tail shifts of P. Suppose the selected finite* $\mathsf{StreamName}^{\uparrow}$ *windows for T_0 and T_1 admit a common refinement. Then the diagonal finite window supplied by Definition 301.25 is exactly the finite* BHist *surface consumed by Definition 301.22 for both shifted reads.*

Consequently the two $\mathsf{Real}^{\uparrow}$ *seal source surfaces agree on the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, regularity rows, classifier rows,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance. The coherence exports no quotient stream equality, host real equality, completion object, or completeness datum.*

Proof. Apply Definition 301.18 to each certified tail shift. Each shifted read is thereby presented as an accepted finite regular-rational window carrying only the displayed schedule, dyadic, regularity, classifier, transport, package, and naming rows of P.

Use Definition 301.16 to glue the two selected windows along the common refinement. The overlap classifier is determined by Definition 301.9, so both restrictions read the same classifier and regularity rows on the refined window.

Now apply Definition 301.25. The lock identifies the shared $\mathsf{StreamName}^{\uparrow}$ schedule rows with the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers inside the diagonal finite packet.

Finally use Definition 301.22. The seal consumes exactly that finite BHist surface, so the two shifted reads present the same displayed source rows to $\mathsf{Real}^{\uparrow}$ and still expose no quotient stream, host equality, completion object, or completeness datum. □

Theorem 301.28 (RegSeqRat cofinal tail seal selected-window uniqueness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0 and T_1 be two certified cofinal tail shifts of P. Suppose the finite* $\mathsf{StreamName}^{\uparrow}$ *windows selected by T_0 and T_1 have a common cofinal refinement on which their selected endpoints, dyadic radii, regularity ledgers, classifier ledgers,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance agree. Then the two selected windows determine the same finite* $\mathsf{Real}^{\uparrow}$ *seal source surface.*

The conclusion is only a uniqueness statement for the displayed finite BHist *rows: it exports no quotient stream, host real equality, metric-completion point, completeness row, or standard bridge coordinate.*

Proof. First apply Definition 301.21. The common cofinal refinement identifies the two tail surfaces on exactly the selected endpoint, dyadic-radius, regularity, classifier, hsame, Cont, Pkg, and NameCert rows named in the hypotheses.

Next use Definition 301.27. The diagonal selected window is the finite BHist surface through which both cofinal tail reads pass, so the two selected windows cannot supply separate seal-facing source data.

Finally apply Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal reads precisely that diagonal finite regular-rational source surface. Since the handoff consumes no quotient stream, host-real equality, metric-completion point, completeness row, or standard bridge coordinate, the two selected windows have the same finite seal source surface and nothing stronger is exported. □

Theorem 301.29 (RegSeqRat finite-window bridge source exhaustion)**.** *For every accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, the standard-bridge source rows of Definition 301.24 are exactly the finite-window rows locked by Definition 301.25, refined by Definition 301.26, and stabilized by Definition 301.27. Equivalently, the bridge-facing rows and the finite-window rows are the same displayed BEDC surface over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

This exhaustion statement does not identify quotient streams, host real equality, ambient completion points, metric completeness, $\mathsf{Real}^{\uparrow}$ *completeness rows, or bridge coordinates beyond the displayed finite source surface.*

Proof. Project the accepted packet through Definition 301.24. The bridge boundary exposes only the scheduled stream carrier, dyadic-tolerance classifier, regularity ledger, radius observations, finite transport and gluing rows, the $\mathsf{Real}^{\uparrow}$ seal handoff, and the displayed provenance rows.

Next apply Definition 301.25. The same packet projects the $\mathsf{StreamName}^{\uparrow}$ schedule rows together with the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers, and the lock identifies those rows with the finite $\mathsf{Real}^{\uparrow}$ seal source surface read by Definition 301.22.

For overlapping finite windows, use Definition 301.26. It glues agreement on the displayed schedule, endpoint, radius, regularity, classifier, hsame, Cont, Pkg, and NameCert rows into one finite surface, so the bridge read cannot split from the window read on a common refinement.

Finally use Definition 301.27 and Definition 301.22. The diagonal window is exactly the finite BHist surface consumed by the $\mathsf{Real}^{\uparrow}$ seal, so every seal row named by the standard bridge boundary is already one of the displayed finite-window source rows. The carrier has no coordinate for quotient streams, host real equality, ambient completion, metric completeness, or any further bridge datum, which gives equality of the two displayed source surfaces. □

Theorem 301.30 (RegSeqRat refined-window gluing RealUp seal factorization)**.** *Let W_0 and W_1 be accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *windows whose displayed* $\mathsf{StreamName}^{\uparrow}$ *schedules admit a common refined window $W_{\cup}$ as in Definition 301.16. Suppose the overlap hypotheses identify the shared unary index rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, dyadic-radius rows, regularity ledgers, classifier*

ledgers, hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance on* $W_\cup$*. Then the common refined window* $W_\cup$ *is exactly the finite* BHist *source surface consumed by the* $\mathsf{Real}^\uparrow$ *seal handoff of Definition 301.22.*

Equivalently, composing refined-window gluing with the $\mathsf{Real}^\uparrow$ *seal handoff factors through the displayed finite BEDC packet* $W_\cup$*. The composition introduces no quotient stream, host real equality, metric completeness, completion point, or seal datum beyond the finite rows already present in* $W_\cup$*.*

Proof. Apply Definition 301.16 to the two accepted windows. The result is one accepted finite $\mathsf{RegSeqRat}^\uparrow$ window over $W_\cup$ whose union schedule, unary indices, endpoint rows, dyadic-radius rows, regularity ledgers, provenance rows, and classifier readback restrict to the two source windows.

Use the classifier window-pairing row of Definition 301.8 on the refined window. It identifies the shared endpoint observations and radius observations as the same displayed $\mathsf{DyadicRatCore}^\uparrow$ rows inside the common finite packet, so the two source reads cannot supply separate seal-facing data.

Finally apply Definition 301.22. The handoff consumes exactly the accepted finite regular-rational source surface just produced by the gluing theorem, and therefore reads $W_\cup$ itself as the $\mathsf{Real}^\uparrow$ finite seal source. Since every consumed coordinate is already a displayed BHist, $\mathsf{StreamName}^\uparrow$, $\mathsf{DyadicRatCore}^\uparrow$, hsame, Cont, Pkg, or NameCert row of $W_\cup$, the composition has no route to a quotient stream, host real equality, metric-completion object, completion point, or extra seal datum. □

Theorem 301.31 (RegSeqRat common-window RealUp seal transitivity)**.** *Let* W_0*,* W_1*, and* W_2 *be accepted finite* $\mathsf{RegSeqRat}^\uparrow$ *windows. Suppose the* W_0/W_1 *and* W_1/W_2 *refined-window gluing surfaces identify the middle unary index rows,* $\mathsf{DyadicRatCore}^\uparrow$ *endpoint rows, dyadic-radius rows, regularity ledgers, classifier ledgers,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* NameCert *provenance on a shared common refinement. Then the composed* W_0/W_2 *handoff factors through the same finite* BHist *source surface consumed by the* $\mathsf{Real}^\uparrow$ *seal.*

Equivalently, the two common-window legs determine one seal-facing finite packet: its source rows are exactly the shared unary observations, DyadicRatCore endpoints, radius rows, regularity and classifier ledgers, hsame*,* Cont*,* Pkg*, and* NameCert *provenance read on the common refinement. The composed handoff exports no quotient stream, host real equality, metric completeness, completion point, or seal datum beyond that finite source surface.*

Proof. Project both legs with Definition 301.16. The W_0/W_1 leg gives one accepted refined packet whose restrictions recover W_0 and W_1, and the W_1/W_2 leg gives one accepted refined packet whose restrictions recover W_1 and W_2.

Use Definition 301.9 on the middle window. The middle unary observations, endpoint rows, radius rows, regularity ledgers, classifier ledgers, and provenance rows are the same finite read, so the two legs share one common packet rather than two seal-facing sources.

Apply Definition 301.27 and Definition 301.22. The diagonal finite read is the BHist source surface consumed by the $\mathsf{Real}^\uparrow$ seal, and the seal handoff reads only that finite regular-rational packet.

Finally invoke Definition 301.30 on the composed common packet. The W_0/W_2 handoff therefore factors through the same finite source surface, with no coordinate for quotient streams, host real equality, metric completeness, completion points, or additional seal data. □

Theorem 301.32 (RegSeqRat refined-window chain exhaustion)**.** *Let $W_0, W_1, \ldots, W_n$ be a finite chain of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *scheduled windows. Suppose every consecutive overlap agrees on the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, regularity ledgers, classifier ledgers,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}$ *provenance. Then the chain repacks into one accepted common finite window, and every terminal* $\mathsf{Real}^{\uparrow}$ *seal read from the chain factors through that common packet.*

The common packet exposes only the displayed regular-rational source rows just listed. It does not introduce quotient sequence equality, host real equality, metric completion, or completeness data.

Proof. Induct on the finite chain of scheduled windows. The first adjacent link is handled by Definition 301.16, which repacks two accepted windows into one accepted finite refinement over the shared schedule, endpoint, radius, ledger, transport, and provenance rows.

In the step, the induction hypothesis supplies one accepted common packet for the initial segment. Apply Definition 301.9 on the overlap with the next scheduled window. The determinacy row identifies the shared $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius data, regularity ledger, classifier ledger, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows as one finite read.

Use Definition 301.16 again to glue the next window to the common packet. This preserves acceptedness and produces the next common finite window without adding any off-surface sequence, host-real, completion, or completeness coordinate.

Finally apply Definition 301.22. Since the $\mathsf{Real}^{\uparrow}$ terminal seal consumes only the accepted finite regular-rational packet, every seal read from the original chain factors through the repacked common window. □

Theorem 301.33 (RegSeqRat finite-window regular closure)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let W' be any finite-window restriction or refinement of a displayed window of P. If the restriction or refinement is carried by the visible* $\mathsf{StreamName}^{\uparrow}$ *schedule rows and componentwise* hsame *and* Cont *routes, then W' preserves the displayed regularity ledger, dyadic-radius rows, classifier ledger,* Pkg *provenance, and local* $\mathsf{NameCert}$ *surface of P.*

The repacked finite window remains a $\mathsf{RegSeqRat}^{\uparrow}$ *source surface for later* $\mathsf{Real}^{\uparrow}$ *and completion consumers. It introduces no quotient stream equality, host real equality, selected limit, ambient completion object, or new Real seal coordinate.*

Proof. Apply Definition 301.3. The regularity ledger, dyadic-radius observation rows, and finite-window transport face are already listed as projections of the accepted packet.

Use Definition 301.14 for restrictions and refinements. It repacks the same $\mathsf{StreamName}^{\uparrow}$ schedule rows and $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, distance, and regularity rows inside the displayed carrier and classifier surface.

For common refinements, apply Definition 301.16. The gluing theorem keeps overlap rows on the same endpoint, radius, regularity, classifier, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface. Thus later $\mathsf{Real}^{\uparrow}$ or completion consumers receive the same finite regularity closure, with no coordinate from which quotient streams, host real equality, selected limits, ambient completion objects, or extra seal data could be read. □

Theorem 301.34 (RegSeqRat StreamName cover-refinement seal handoff)**.** *Let $\mathcal{W}$ be a finite cover family of public* $\mathsf{StreamName}^{\uparrow}$ *windows over one observation map, and let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet whose scheduled reads consume every member of $\mathcal{W}$. If a finite-window* $\mathsf{Real}^{\uparrow}$ *seal handoff is read from the same packet, then that seal-facing read factors through exactly the public* $\mathsf{StreamName}^{\uparrow}$ *finite-window interface together with the displayed* $\mathsf{InBundle}$ *rows, pointwise*

$\mathsf{Rat}^{\uparrow}$ *classifier rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *denominator ledger,* hsame*,* Cont*, and* Pkg *provenance exposed by* P*.*

Thus the cover-refinement handoff supplies no quotient stream, host real equality, hidden limit selector, metric-completeness datum, or $\mathsf{Real}^{\uparrow}$ *completeness row beyond the finite public window interface and its displayed regular-rational ledgers.*

Proof. First apply Definition 126.334. The finite cover family over the common observation map is exhausted by public $\mathsf{StreamName}^{\uparrow}$ finite-window rows, so every covered read is already visible through the public window interface and its InBundle membership rows.

Next use Definition 301.26. For each covered window consumed by P, the public schedule rows lock to the same pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows and to the $\mathsf{DyadicRatCore}^{\uparrow}$ denominator ledger carried by the accepted regular-rational packet.

Now apply Definition 301.27. The finite cover refinements and the shifted diagonal reads present one coherent finite BHist surface, with the same hsame, Cont, and Pkg rows wherever the cover windows overlap.

Finally invoke Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal consumes only that finite regular-rational source surface, so the handoff factors through the public $\mathsf{StreamName}^{\uparrow}$ finite-window interface and cannot read a quotient stream, host real equality, hidden limit selector, metric completion, or $\mathsf{Real}^{\uparrow}$ completeness coordinate. □

Theorem 301.35 (RegSeqRat tail-stable window cover exhaustion)**.** *Let* $\mathcal{W}$ *be a finite cover family of public* $\mathsf{StreamName}^{\uparrow}$ *windows over one accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. If every member of* $\mathcal{W}$ *is stable under shifted-tail regularity closure and the overlaps of* $\mathcal{W}$ *glue by refined-window gluing, then every finite-window* $\mathsf{Real}^{\uparrow}$ *seal read over that packet factors through exactly the public* $\mathsf{StreamName}^{\uparrow}$ *windows, the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *denominator and radius ledgers, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The factorization exports no quotient stream, host real equality, hidden limit selector, metric-completeness datum, completion point, or additional $\mathsf{Real}^{\uparrow}$ *seal coordinate beyond the finite tail-stable cover surface.*

Proof. Start with the cover-refinement handoff of Definition 301.34. It reads the $\mathsf{Real}^{\uparrow}$ seal only through the public $\mathsf{StreamName}^{\uparrow}$ finite-window interface, the displayed InBundle rows, pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, dyadic denominator ledger, and the stated provenance rows.

Apply Definition 301.18 to each window in the cover. Tail stability keeps the scheduled regularity rows inside the same accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet after the shifted-tail read, so the seal cannot leave the finite public cover.

Use Definition 301.16 on every overlap. The overlap rows glue the public windows into one finite source surface while preserving the pointwise classifier rows, the dyadic denominator and radius ledgers, and the displayed hsame, Cont, Pkg, and NameCert provenance.

Finally invoke Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal handoff consumes only the finite regular-rational packet just assembled, so the tail-stable cover exhausts the whole seal-facing source surface and leaves no off-table quotient, host-equality, completion, or extra seal row to read. □

Theorem 301.36 (RegSeqRat tail-stable cover common-window lock)**.** *Let* $\mathcal{W}$ *be a finite cover family of public* $\mathsf{StreamName}^{\uparrow}$ *windows over one accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Suppose the cover is tail-stable, every overlap glues by refined-window gluing, and two* $\mathsf{Real}^{\uparrow}$ *seal consumers read through members of* $\mathcal{W}$*. Then the two seal reads factor through one accepted common finite window.*

The common window exposes exactly the $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity ledgers, and the displayed* hsame*,*

Cont, Pkg, *and* NameCert *provenance. It exposes no quotient stream, host real equality, selected limit, metric-completeness datum, completion point, or additional* Real$^{\uparrow}$ *seal coordinate.*

Proof. First apply Definition 301.35 to the cover. Each seal consumer is forced onto the finite tail-stable cover surface, so neither read can leave the public StreamName$^{\uparrow}$ windows and their displayed regular-rational ledgers.

Next connect the two selected cover members by the finite overlap chain and apply Definition 301.32. The overlap gluing hypotheses repack that chain into one accepted common finite window whose rows are the displayed schedule, endpoint, radius, classifier, regularity, transport, package, and naming rows.

Use Definition 301.9 on the overlapping classifier reads. The determinacy row identifies the source rows seen by the two consumers, so their apparent cover-window origins are two restrictions of the same accepted common packet.

Finally invoke Definition 301.22. Since the seal handoff consumes exactly that finite regular-rational source surface, both consumers factor through the single common window and no quotient-stream, host-equality, selected-limit, completion, metric-completeness, or extra seal coordinate remains available. □

Theorem 301.37 (RegSeqRat finite-cover nerve descent)**.** *Let $\mathcal{W}$ be a finite cover family of public* StreamName$^{\uparrow}$ *windows over an accepted* RegSeqRat$^{\uparrow}$ *packet P. Suppose every nonempty finite intersection of members of $\mathcal{W}$ glues by Definition 301.16. Suppose also that the pairwise tail-stable common-window locks agree on the displayed* DyadicRatCore$^{\uparrow}$ *endpoint and radius rows, the* RegSeqRat$^{\uparrow}$ *classifier and regularity ledgers, the* hsame *and* Cont *routes, and the* Pkg *and* NameCert *provenance rows carried by P. Then all* Real$^{\uparrow}$ *seal consumers over the cover descend to one finite seal-facing source packet.*

The descended packet is a public finite StreamName$^{\uparrow}$ *source surface whose seal rows are exactly the displayed regular-rational rows named above. It does not introduce quotient streams, host real equality, selected limits, metric completeness, completion points, or ambient* Real$^{\uparrow}$ *completeness.*

Proof. First apply Definition 301.34. Every seal-facing read over the cover is already a read from the public StreamName$^{\uparrow}$ windows and the finite regular-rational rows exposed by P.

Next use Definition 301.35. The tail-stable cover surface exhausts the available seal-facing source rows, so no seal consumer can leave the displayed schedule, classifier, dyadic, transport, package, or naming data.

For each pair of cover members, apply Definition 301.36. The pairwise locks identify the common finite-window source rows seen by the two local seal consumers. The stated agreement on endpoint, radius, classifier, regularity, hsame, Cont, Pkg, and NameCert rows makes these pairwise packets compatible along every nonempty finite intersection.

Now order the finite nerve by any enumeration of its nonempty intersections and apply Definition 301.32. The intersection gluing hypotheses repack the compatible pairwise common windows into one accepted finite source packet for the whole cover.

Finally invoke Definition 301.22. Since the terminal Real$^{\uparrow}$ seal consumes only the accepted finite regular-rational packet, all cover-local seal consumers descend through that single seal-facing source packet, with no quotient-stream, host-equality, selected-limit, completion, metric-completeness, or ambient-completeness coordinate available. □

Theorem 301.38 (RegSeqRat finite-cover nerve induction)**.** *Let $\mathcal{W}$ be a finite cover family of public* StreamName$^{\uparrow}$ *windows over an accepted* RegSeqRat$^{\uparrow}$ *packet P. Suppose every nonempty finite intersection of members of $\mathcal{W}$ glues by Definition 301.16, and suppose each lower dimensional*

face satisfies the pairwise common-window lock of Definition 301.36. Then induction over the finite nerve of $\mathcal{W}$ produces one global seal-facing source packet.

The global packet preserves exactly the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity ledgers, the* hsame *and* Cont *routes, and the* Pkg *and* NameCert *provenance rows carried by P.*

It introduces no quotient stream, host real equality, selected limit, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. For the base case, take a singleton nonempty intersection in the nerve and apply Definition 301.34. The single local seal read is already a public $\mathsf{StreamName}^{\uparrow}$ finite-window read from the displayed regular-rational rows of P.

For the induction step, adjoin one nonempty intersection to a nerve segment whose seal-facing packet has already been assembled. Apply Definition 301.35 to keep the new intersection inside the tail-stable public cover surface.

On each overlap between the new intersection and the assembled segment, use Definition 301.36. The lower dimensional face hypotheses identify the same endpoint, radius, classifier, regularity, hsame, Cont, Pkg, and NameCert rows on the common finite window.

Now apply Definition 301.32. The refined overlap chain repacks the previously assembled packet and the new intersection packet into one accepted finite source packet with the same displayed rows.

Finally invoke Definition 301.37. The descent theorem identifies the terminal global seal-facing source for the whole finite cover, and the construction leaves no quotient stream, host real equality, selected limit, metric completion, completion point, or ambient $\mathsf{Real}^{\uparrow}$ completeness coordinate to read. □

Theorem 301.39 (RegSeqRat RealUp seal uniqueness boundary)**.** *Two accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets with the same displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule, dyadic-radius ledger, common refinement window, and* hsame *and* Cont *provenance determine the same finite* $\mathsf{Real}^{\uparrow}$ *seal read.*

This uniqueness is only the finite seal-boundary read. It does not assert quotient Cauchy equality, host stream equality, metric-completion equality, or completed $\mathsf{Real}^{\uparrow}$ *equality.*

Proof. Apply Definition 301.31 to compare the two seal-facing reads through one common finite source surface.

Use Definition 301.28 to identify the selected cofinal window rows, then apply Definition 301.34. The latter forces both reads through the same public $\mathsf{StreamName}^{\uparrow}$ cover-refinement boundary and leaves no quotient or completed-real coordinate to distinguish. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatUp StdBridge`

Theorem 301.40 (RegSeqRat RealUp seal route exclusion package)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read obtained from an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet factors through exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the regularity ledgers, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *provenance. Conversely, any seal-facing read assembled from precisely those rows repacks as the same* $\mathsf{Real}^{\uparrow}$ *seal route.*

This route package contains no quotient stream, no host real equality, no metric-completion point, and no $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatRealSealRouteExclusionPackage`

Proof. For the forward direction, project the accepted packet by Definition 301.12. This exposes the $\mathsf{StreamName}^{\uparrow}$ schedule rows, unary indices, endpoint rows, regularity ledgers, displayed transport, continuation routes, package provenance, and local naming provenance.

Next read the dyadic endpoint, radius, and distance data through Definition 301.13. The seal-facing distance comparisons are therefore finite $\mathsf{DyadicRatCore}^{\uparrow}$ ledger rows in the same scheduled packet.

Apply Definition 301.22. It consumes exactly the regular-rational source surface assembled from the schedule, dyadic, regularity, transport, continuation, package, and naming rows just exposed.

For the converse direction, start with a read assembled from exactly those rows. Repack the rows as the scheduled $\mathsf{RegSeqRat}^{\uparrow}$ source surface and apply Definition 301.22 to obtain the corresponding $\mathsf{Real}^{\uparrow}$ seal route.

Finally use Definition 301.39. Any two assembled reads with the same displayed route package give the same finite seal read. Since the package rows do not include quotient streams, host real equality, metric-completion points, or completeness data, none of those objects can be read by the route. □

Theorem 301.41 (RegSeqRat cover normal form for RealUp seal)**.** *Let $\mathcal{W}$ be any finite cover family of public* $\mathsf{StreamName}^{\uparrow}$ *windows consumed by an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and read by the* $\mathsf{Real}^{\uparrow}$ *seal. Then the seal read determines one canonical finite* BHist *packet consisting exactly of the public* $\mathsf{StreamName}^{\uparrow}$ *window rows, the displayed* $\mathsf{InBundle}$ *rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, regularity ledgers, classifier ledgers,* hsame *transport,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}$ *provenance.*

This normal form contains no quotient stream, host real equality, hidden limit selector, metric-completion point, $\mathsf{Real}^{\uparrow}$ *completeness row, or standard-bridge coordinate.*

Proof. Start with Definition 301.34. It restricts the seal-facing read of the finite cover to the public $\mathsf{StreamName}^{\uparrow}$ windows, the displayed $\mathsf{InBundle}$ rows, pointwise $\mathsf{Rat}^{\uparrow}$ classifier rows, dyadic ledgers, and the visible transport and provenance rows.

Apply Definition 301.31 to compare all covered seal reads through a single common finite window. The common window keeps the regularity and classifier ledgers inside the same accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet.

Use Definition 301.30 to factor the refined windows into one finite BHist packet carrying the endpoint and radius ledgers, hsame transport, Cont routes, Pkg provenance, and $\mathsf{NameCert}$ provenance.

Finally invoke Definition 301.39. Any two packets with the same displayed cover-normal rows give the same finite $\mathsf{Real}^{\uparrow}$ seal read, and the excluded quotient, host-real, completion, completeness, and bridge coordinates have no row in the canonical packet. □

Theorem 301.42 (RegSeqRat RealUp seal transport fusion)**.** *Let P and P' be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets. Suppose P' is obtained from P by transporting the visible* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, dyadic endpoint and radius ledgers, finite-window readback, regularity ledgers, and* Pkg *provenance along displayed* hsame *and* Cont *rows. Then P and P' determine the same* $\mathsf{Real}^{\uparrow}$ *finite seal route through the canonical finite* BHist *packet of Definition 301.41.*

The fused route is only the displayed finite seal boundary. It does not assert quotient-stream equality, host real equality, existence of a completion point, or equality of selected limits.

Proof. Project both seal-facing reads through Definition 301.40. The only rows available to either route are the schedule, dyadic ledger, regularity, transport, continuation, package, and naming rows.

Use Definition 301.41 to name the canonical finite BHist packet carrying those rows. The transported packet has the same normal-form coordinates because the hypotheses preserve the schedule, endpoint and radius ledgers, finite-window readback, regularity ledgers, and provenance.

Apply Definition 301.14 to move the window rows along the displayed hsame and Cont routes, and then use Definition 301.16 to repack the original and transported reads through one common finite refinement.

Finally invoke Definition 301.39. Since both reads now use the same canonical finite packet, the resulting $\mathsf{Real}^{\uparrow}$ finite seal route is the same, with no quotient stream, host real equality, completion point, or selected limit available as an extra coordinate. □

Theorem 301.43 (RegSeqRat Real seal classifier factorization)**.** *Let P and Q be displayed finite* BHist *packets carrying* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-stream readback rows, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. Suppose two* $\mathsf{Real}^{\uparrow}$ *seal routes are accepted over the same regular-stream boundary and read from P and Q. Then the two seal routes classify together exactly through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *stream classifier and the transported finite-window package obtained from these rows.*

The classifier has no coordinate for quotient Cauchy classes, host real equality, completed metric limits, or selected limits. Equality consumed by the $\mathsf{Real}^{\uparrow}$ *seal is therefore only the finite classifier factorization through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and the displayed local* NameCert *rows.*

Proof. Use Definition 301.40 on both accepted seal routes. This removes every non-displayed route component and leaves only finite packets carrying the stream schedule, dyadic ledgers, regular readback, transport, continuation, package, and naming rows.

Apply Definition 301.42 to move the endpoint and radius rows, together with the regular readback and package provenance, to a common finite window. The transported rows still present the same $\mathsf{RegSeqRat}^{\uparrow}$ classifier boundary because the transport is entirely through displayed hsame and Cont data.

Choose the shared finite packet by Definition 301.41. In that packet the classifier row and the finite-window package are the only data available to the seal consumer.

Finally invoke Definition 301.39. The two accepted routes now read the same normal-form packet, so their $\mathsf{Real}^{\uparrow}$ seal classification is exactly the displayed $\mathsf{RegSeqRat}^{\uparrow}$ classifier transported through that finite window, with no quotient, host-real, completion, or choice coordinate introduced. □

Theorem 301.44 (RegSeqRat seal-route classifier stability)**.** *Let P and Q be accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *packets determining* $\mathsf{Real}^{\uparrow}$ *seal routes. Suppose their route packages are related by displayed* hsame *transport and* Cont *containment routes preserving the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, the regularity rows, the classifier ledgers,* Pkg *provenance, and the local* NameCert *rows. Then the two* $\mathsf{Real}^{\uparrow}$ *seal classifiers agree exactly through the transported* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface.*

The agreement is a statement about the finite route package only: no quotient stream, host real equality, completion point, selected limit, or external representative can change the classifier read at the $\mathsf{Real}^{\uparrow}$ *seal boundary.*

Proof. Apply Definition 301.40 to the two accepted seal routes. This reduces both reads to displayed finite rows: the schedule, dyadic endpoint and radius ledgers, regularity rows, classifier ledgers, package provenance, local name rows, and the hsame/Cont transport data.

Next use Definition 301.42. The displayed transport moves both route packages to one canonical finite packet while preserving the stream schedule, dyadic ledgers, regularity rows, and classifier surface.

Apply Definition 301.43 in that canonical packet. The seal equality is identified with the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier and not with any extra real-number coordinate.

Finally invoke Definition 301.39. Since the canonical read has no quotient stream, host equality, completion point, or selected limit field, the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier is the unique stable seal-route classifier. □

Theorem 301.45 (RegSeqRat Real seal classifier exhaustion)**.** *Every accepted* $\mathsf{Real}^{\uparrow}$ *seal classifier read between two accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets is exactly the finite route package consisting of the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, the regularity rows, the transported* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface, the displayed* hsame *transports, the* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *rows.*

Conversely, any packet carrying precisely those rows supplies the same finite $\mathsf{Real}^{\uparrow}$ *seal classifier read. The exhaustion statement has no coordinate for quotient streams, host real equality, completion points, selected limits, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First reduce the read to its visible route package. By Definition 301.40, an accepted seal read exposes only the schedule, dyadic ledger, regularity, transport, continuation, package, and local naming rows, and excludes the non-displayed real-number coordinates named in the statement.

Next put the exposed rows into normal form. Apply Definition 301.41 to obtain the canonical finite BHist packet whose rows are exactly the public $\mathsf{StreamName}^{\uparrow}$ windows, dyadic endpoint and radius ledgers, regularity and classifier ledgers, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance.

The classifier component is then forced by Definition 301.43. In the normal-form packet the $\mathsf{Real}^{\uparrow}$ seal classifier reads only the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface and the finite-window package.

Finally use Definition 301.44. Transport along the displayed hsame and Cont rows preserves the classifier read, so any packet with precisely the displayed rows gives the same finite seal classifier. Since none of the four cited boundaries contains quotient streams, host real equality, completion points, selected limits, or $\mathsf{Real}^{\uparrow}$ completeness, the exhaustion has no further read channel. □

Theorem 301.46 (RegSeqRat Real seal route replay)**.** *Let a finite route package list exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, regularity rows, transported* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface, displayed* hsame *rows,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows named by Definition 301.45. Replaying those rows through the exclusion package, the cover normal form, the displayed transport fusion, and the classifier exhaustion reconstructs the same finite* $\mathsf{Real}^{\uparrow}$ *seal route.*

The replay has no coordinate for a quotient stream, host real equality, completion point, selected limit, or $\mathsf{Real}^{\uparrow}$ *completeness. Hence any consumer that receives the displayed package receives exactly the same finite seal route as the original accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff.*

Proof. First project the input package by Definition 301.40. The row inventory is precisely the finite schedule, dyadic ledger, regularity, transport, continuation, package, and local naming surface, with no hidden real-number coordinate available to a replaying consumer.

Next apply Definition 301.41. The displayed rows are repacked as the canonical finite BHist packet whose windows, ledgers, classifier rows, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance are the rows of the input package.

Use Definition 301.42 to preserve the route under the displayed endpoint and classifier transports. The transport step does not add a stream quotient or a completion coordinate; it only relabels the finite rows already present in the normal-form packet.

Finally invoke Definition 301.45. The classifier read is exhausted by the transported $\mathsf{RegSeqRat}^{\uparrow}$ surface and the finite route package, so replaying the same displayed rows reconstructs the same $\mathsf{Real}^{\uparrow}$ seal route and no additional limit-like datum. □

Theorem 301.47 (RegSeqRat Real seal replay ledger lock)**.** *Any replay supplied by Definition 301.46 factors through the same finite* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, unary index rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, regularity rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows, displayed* InBundle *rows, transported classifier surface,* Pkg *provenance, local* NameCert *rows, displayed* hsame *transports, and visible* Cont *routes named by Definition 301.43 and Definition 301.45. Consequently replay cannot change the finite regularity, radius, provenance, bundle, package, or classifier ledger rows of the accepted* $\mathsf{Real}^{\uparrow}$ *seal route.*

The ledger lock contains no coordinate for quotient-real equality, host equality, a completion point, trichotomy, a selected representative, or choice data.

Proof. Start with the replay package of Definition 301.46. That theorem reconstructs the $\mathsf{Real}^{\uparrow}$ seal route only from the displayed schedule, dyadic, regularity, transport, continuation, package, and local naming rows.

Apply Definition 301.43. The classifier part of the replay factors through the transported $\mathsf{RegSeqRat}^{\uparrow}$ stream classifier and the finite-window package over the same endpoint, radius, regular readback, hsame, Cont, Pkg, and NameCert rows.

Now apply Definition 301.45. The visible classifier read is exhausted by precisely those schedule, endpoint, radius, regularity, transported classifier, hsame, Cont, package, and local name rows. There is therefore no second row inventory through which replay could alter the regularity, radius, provenance, bundle, package, or classifier ledgers.

The cited theorem surfaces expose finite route rows only. None contains quotient-real equality, host equality, a completion point, trichotomy, a selected representative, or choice data, so replay has no channel by which to replace the locked ledger rows. □

Theorem 301.48 (RegSeqRat Real seal schedule coverage)**.** *Every finite schedule accepted as a* $\mathsf{Real}^{\uparrow}$ *seal read from accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets is consumed by exactly the public* $\mathsf{StreamName}^{\uparrow}$ *window rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, regularity rows, transported* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface, displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. Conversely, any route package containing exactly those rows replays to the same finite* $\mathsf{Real}^{\uparrow}$ *seal route.*

The coverage assertion does not add quotient real carriers, host real equality, selected limits, metric-completion points, or $\mathsf{Real}^{\uparrow}$ *completeness. It only states that the accepted finite schedule has no read channel outside the displayed package rows.*

Proof. First apply Definition 301.40. An accepted $\mathsf{Real}^{\uparrow}$ seal read from accepted $\mathsf{RegSeqRat}^{\uparrow}$ packets has only the finite schedule, dyadic ledger, regularity, transport, continuation, package, and local naming rows available to the route.

Next apply Definition 301.41. The exposed rows are repacked as the canonical finite BHist packet whose row inventory is exactly the public $\mathsf{StreamName}^{\uparrow}$ windows, dyadic endpoint and radius ledgers, regularity rows, transported classifier rows, hsame, Cont, Pkg, and NameCert provenance.

Then use Definition 301.45. The classifier component is fully read from the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface together with the finite route package, so no further classifier coordinate remains to be consumed.

For the converse, apply Definition 301.46. A package containing exactly the displayed rows reconstructs the same finite $\mathsf{Real}^{\uparrow}$ seal route, and the exclusion boundary prevents replay from reading quotient reals, host equality, selected limits, completion points, or completeness data. □

Theorem 301.49 (RegSeqRat Real tail classifier seal)**.** *For accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets whose public* $\mathsf{StreamName}^{\uparrow}$ *tail windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, transported* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, displayed* hsame *rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows agree, the* $\mathsf{Real}^{\uparrow}$ *seal consumer reads exactly the same tail classifier on both sides.*

The boundary is only the finite seal-classifier boundary. It excludes quotient streams, host real equality, selected limits, completion points, and $\mathsf{Real}^{\uparrow}$ *completeness rows as classifier coordinates.*

Proof. First apply Definition 301.45 to both accepted reads. Each read is reduced to the finite route package consisting of the public tail windows, dyadic endpoint and radius ledgers, transported classifier rows, hsame, Cont, Pkg, and local NameCert provenance.

Next use Definition 301.50. The shared public rows lock the consumer schedule and replay ledger, so the two reads cannot choose different finite handoff packages for the same displayed tail surface.

Finally invoke Definition 301.51. The locked schedules replay to one terminal finite $\mathsf{Real}^{\uparrow}$ seal route, and the exhaustion row identifies its readback classifier with the transported $\mathsf{RegSeqRat}^{\uparrow}$ tail classifier. Since the cited boundaries contain no quotient stream, host real equality, selected limit, completion point, or $\mathsf{Real}^{\uparrow}$ completeness row, the common transported tail classifier is exactly the classifier read by the $\mathsf{Real}^{\uparrow}$ seal consumer. □

Theorem 301.50 (RegSeqRat Real seal public handoff determinacy)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *stream packet factors through the finite schedule-coverage row of Definition 301.48, the replay-ledger lock of Definition 301.47, the classifier exhaustion row of Definition 301.45, and the handoff row* BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_real_seal_handoff*. If two accepted public handoff routes have the same finite schedule and the same replay ledger, then they expose the same* $\mathsf{Real}^{\uparrow}$ *readback classifier.*

The conclusion is a deterministic consumer boundary for the displayed finite seal package. It does not introduce quotient-real equality, host equality, selected limits, metric-completion points, or $\mathsf{Real}^{\uparrow}$ *completeness as readback coordinates.*

Proof. First use Definition 301.48. The public consumer has only the finite $\mathsf{StreamName}^{\uparrow}$ windows, dyadic endpoint and radius ledgers, regularity rows, transported classifier rows, BHist packet rows, hsame, Cont, Pkg, and local NameCert rows available for a seal read.

Next apply Definition 301.47. Equality of the schedule and replay ledger locks the accepted route package, so the consumer cannot choose a second route through a different dyadic-radius, regularity, continuation, package, or local naming row.

Then invoke Definition 301.45. The visible classifier is exhausted by the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface together with the locked route package, leaving no extra seal case for the readback classifier.

Finally use the displayed handoff row BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_real_seal_hand That row is the finite $\mathsf{RegSeqRat}^{\uparrow}$-to-$\mathsf{Real}^{\uparrow}$ seal handoff already named by the chapter closure target, so the common schedule and replay ledger yield one exposed $\mathsf{Real}^{\uparrow}$ readback classifier. □

Theorem 301.51 (RegSeqRat Real seal schedule confluence)**.** *Let S and T be finite schedules accepted as* $\mathsf{Real}^{\uparrow}$ *seal reads from accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets. Suppose the two accepted reads expose the same public* $\mathsf{StreamName}^{\uparrow}$ *window rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius*

ledgers, the same transported $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface, the same visible* BHist, hsame, Cont, *and* Pkg *rows, and the same local* $\mathsf{NameCert}$ *rows. Then* S *and* T *replay to one and the same terminal finite* $\mathsf{Real}^{\uparrow}$ *seal route.*

This confluence is only the finite seal-route assertion over the displayed packet rows. It excludes quotient reals, host equality, selected limits, completion points, and $\mathsf{Real}^{\uparrow}$ *completeness as route coordinates.*

Proof. First apply Definition 301.48 to both accepted schedules. Each accepted read is consumed by exactly the displayed $\mathsf{StreamName}^{\uparrow}$ windows, dyadic endpoint and radius ledgers, transported classifier surface, BHist packet rows, hsame, Cont, Pkg provenance, and local $\mathsf{NameCert}$ rows named in the statement.

Next use Definition 301.46. Since the two row inventories are the same, the replay construction applied to S and to T reconstructs seal routes from the same finite route package.

Apply Definition 301.45 to the common package. The transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface exhausts the visible classifier read, so the two replays cannot diverge by choosing a second classifier, package, or local naming ledger.

Finally invoke Definition 301.39. The two replayed routes now have the same displayed schedule, dyadic-radius ledger, common finite window, hsame provenance, and Cont provenance, hence they determine one terminal finite $\mathsf{Real}^{\uparrow}$ seal route. The cited boundaries contain no quotient-real carrier, host equality, selected limit, completion point, or $\mathsf{Real}^{\uparrow}$ completeness datum, so confluence has no hidden real-number coordinate. □

Theorem 301.52 (RegSeqRat Real seal endpoint coverage)**.** *Every accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal endpoint factors through exactly the displayed endpoint package with four open-phase faces:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and transported classifier rows;*
4. *the terminal* $\mathsf{Real}^{\uparrow}$ *seal row.*

The carrier data of the package are only BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. Conversely, any accepted seal endpoint with those four faces and those carrier rows has no additional route coordinate beyond the terminal finite* $\mathsf{Real}^{\uparrow}$ *seal endpoint named by the schedule.*

In particular, the endpoint package excludes quotient streams, host equality, selected limits, completion points, $\mathsf{Real}^{\uparrow}$ *completeness, and metric-completeness rows from the finite endpoint surface.*

Proof. First apply Definition 301.48. It gives the finite schedule inventory for any accepted endpoint, so the visible rows are the $\mathsf{StreamName}^{\uparrow}$ windows, dyadic endpoint and radius ledgers, regularity rows, transported classifier rows, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Next apply Definition 301.40. This locks the route coordinates to the displayed finite package and removes quotient streams, host equality, selected limits, completion points, $\mathsf{Real}^{\uparrow}$ completeness, and metric-completeness data from the accepted endpoint read.

Now invoke Definition 301.45. The transported $\mathsf{RegSeqRat}^{\uparrow}$ regularity and classifier rows exhaust the visible classifier surface, so there is no second classifier face, package row, or local naming coordinate that can refine the endpoint.

Finally use Definition 301.51. Any two accepted reads with the same four displayed faces and the same BHist, hsame, Cont, Pkg, and NameCert rows replay to one terminal finite Real$^{\uparrow}$ seal route. Hence the four-face package is exactly the finite endpoint coverage package. □

Theorem 301.53 (RegSeqRat Real seal endpoint phase boundary)**.** *Every accepted finite* RegSeqRat$^{\uparrow}$*-to-*Real$^{\uparrow}$ *seal endpoint covered by Definition 301.52 is precisely the* RegSeqRat$^{\uparrow}$ *face of the four-face Phase Real and Completion package of Definition 38.290. Conversely, the* RegSeqRat$^{\uparrow}$ *face of that phase package is readable at the local seal endpoint only through the same finite* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *endpoint and radius ledgers,* RegSeqRat$^{\uparrow}$ *regularity and classifier rows, terminal* Real$^{\uparrow}$ *seal row, and* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance rows.*

Thus the local seal endpoint is a boundary face of the phase package, not a separate quotient-real object. It carries no host equality, selected limit, completion point, Real$^{\uparrow}$ *completeness row, metric-completeness datum, or standard bridge.*

Proof. First apply Definition 301.52. It identifies the accepted local endpoint with exactly four displayed faces: StreamName$^{\uparrow}$ finite-window rows, DyadicRatCore$^{\uparrow}$ endpoint and radius ledger rows, RegSeqRat$^{\uparrow}$ regularity and transported classifier rows, and the terminal finite Real$^{\uparrow}$ seal row.

Next use Definition 38.290. Its four public packages are the DyadicRatCore observation package, the StreamName$^{\uparrow}$ countable-name and finite-window packages, the RegSeqRat stream-name scoped interface, and the Real$^{\uparrow}$ public certificate export through the StreamName$^{\uparrow}$ interface. The third item is exactly the regular rational stream face through which the local endpoint coverage reads its RegSeqRat$^{\uparrow}$ rows.

For the converse, read that third phase item back through the same public finite windows and dyadic ledgers. The phase boundary exposes no independent RegSeqRat$^{\uparrow}$ consumer coordinate beyond the transported regularity and classifier rows, so the local read is forced to use the finite StreamName$^{\uparrow}$ windows, dyadic endpoint and radius ledgers, terminal Real$^{\uparrow}$ seal row, and the displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Finally combine the exclusions from both cited boundaries. The local endpoint coverage excludes quotient streams, host equality, selected limits, completion points, Real$^{\uparrow}$ completeness, and metric-completeness rows; the phase boundary also withholds quotient, completion, arithmetic, order, metric-completeness, Classical, and standard-bridge data. Hence the RegSeqRat$^{\uparrow}$ seal endpoint is only that finite phase face and carries none of the excluded data as a hidden coordinate. □

Theorem 301.54 (RegSeqRat Real seal finite-window witness induction)**.** *Every accepted finite* RegSeqRat$^{\uparrow}$*-to-*Real$^{\uparrow}$ *seal endpoint covered by Definition 301.52 admits induction over the finite request window. The empty window is the terminal* Real$^{\uparrow}$ *seal row. If a witness package is available for a finite request window W, then adjoining one visible request extends it by the* StreamName$^{\uparrow}$ *finite-window transport row, the* DyadicRatCore$^{\uparrow}$ *radius-ledger readback, and the* RegSeqRat$^{\uparrow}$ *classifier transport row.*

The induction is only a finite-window construction for the endpoint face of Definition 301.53. It introduces no quotient stream equality, selected limit, host real equality, choice, Real$^{\uparrow}$ *completeness, or metric-completeness datum.*

Proof. First read the endpoint package through Definition 301.48 and Definition 301.52. These two results expose the finite request inventory: StreamName$^{\uparrow}$ windows, dyadic endpoint and radius ledgers, transported RegSeqRat$^{\uparrow}$ regularity and classifier rows, the terminal Real$^{\uparrow}$ seal row, and the visible BHist, hsame, Cont, Pkg, and NameCert provenance.

For the base window, take the terminal Real$^{\uparrow}$ seal row from the endpoint coverage package. With no visible request to adjoin, the witness package has no dyadic-radius readback or classifier-transport obligation beyond that terminal row and its displayed provenance.

For the step, suppose the witness has been built over a finite window W. Adjoin one visible request through Definition 301.6; this repacks the same $\mathsf{StreamName}^{\uparrow}$ finite-window rows, hsame comparisons, Cont routes, Pkg rows, and local NameCert provenance on the enlarged window.

Next read the new radius and endpoint rows by Definition 301.13. Then apply Definition 301.7 to carry the transported regularity and classifier surface to the enlarged window. This gives exactly the witness package required after adjoining the request.

Finally use Definition 301.53. The endpoint is the $\mathsf{RegSeqRat}^{\uparrow}$ face of the Phase Real and Completion package, so the induction cannot pick up any coordinate withheld by that boundary. Together with the exclusions in the endpoint coverage theorem, this rules out quotient stream equality, selected limits, host real equality, choice, $\mathsf{Real}^{\uparrow}$ completeness, and metric-completeness data at every finite stage. □

Theorem 301.55 (RegSeqRat paperBridge audit-threshold locality)**.** *Let $\mathcal{R}$ be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source satisfying the Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read. Then $\mathcal{R}$ remains admissible for that read exactly when the four face records*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

are read objectwise at the scoped and audit-clean threshold on the same finite source, even if the $\mathsf{RegSeqRat}^{\uparrow}$ *closurestatus bridge row is* `paperBridge`*. The pending bridge row is local to the* $\mathsf{RegSeqRat}^{\uparrow}$ *face. It exports no aggregate bridge token, quotient stream, selected limit, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with Definition 301.219. It identifies the accepted audit-threshold read on $\mathcal{R}$ with the RegSeqRat four-face exit-threshold equivalence together with the local closurestatus and formalstatus records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 301.222. The status interface of the read contains only the four face records and their own closurestatus, formalstatus, leantarget, and bridgestatus rows. Thus a `paperBridge` row on the $\mathsf{RegSeqRat}^{\uparrow}$ face is read as that face's local bridge row, not as a route credential and not as a failed aggregate bridge row.

The same objectwise attachment is the status pullback square of Definition 301.223. Both routes through the square pass through the same four faces, so the pending bridge row cannot move to $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, or the Phase Real and Completion route as a separate aggregate coordinate.

Finally compare this local reading with the downstream gate in Definition 1327.28. That gate asks for the four local status records at the scoped and audit-clean threshold and for the same finite support rows; it does not ask for componentwise bridgeChecked status. Hence the RegSeqRat `paperBridge` row is local bridge debt only, while quotient streams, selected limits, metric-completeness data, aggregate bridge tokens, and ambient $\mathsf{Real}^{\uparrow}$ completeness remain outside the accepted read. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$**.**

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The obligation boundary consists of the stream carrier, dyadic classifier, regularity rows, finite-window transport rows, and $\mathsf{Real}^{\uparrow}$ seal-handoff rows over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, and Pkg.

Constructive story: Construct the packet by finite scheduled reads: $\mathsf{StreamName}^{\uparrow}$ supplies the visible windows, $\mathsf{DyadicRatCore}^{\uparrow}$ supplies endpoint and radius ledgers, and the regularity and classifier rows are projections of those finite observations.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier\_real\_seal\_handoff`

Bridge status: bridgeChecked

Not claimed: This chapter does not close $\mathsf{Real}^{\uparrow}$ completeness, quotient carriers, metric completeness, or standard bridge data.

Upgrade path: No further upgrade is pending because this chapter is already at the top formal bridge axis.

Theorem 301.56 (RegSeqRat seal-route visible source normal form)**.** *Every accepted* $\mathsf{Real}^{\uparrow}$ *seal route consumed from an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet factors through one visible finite source surface. That surface consists exactly of the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity rows and transported classifier rows, the finite* BHist *packet rows, the displayed* hsame *transports, the visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows.*

Conversely, any finite route package carrying exactly those rows replays to the same terminal finite $\mathsf{Real}^{\uparrow}$ *seal route. The normal form has no coordinate for quotient stream equality, host real equality, a selected limit, a metric-completion point,* $\mathsf{Real}^{\uparrow}$ *completeness, or standard-bridge data.*

Proof. Begin with the accepted seal route and apply Definition 301.40. The route can read only the displayed schedule, dyadic, regularity, transport, continuation, package, and local naming rows, and it has no channel for the excluded real-number or bridge coordinates.

Next apply Definition 301.41. The exposed rows are repacked as one canonical finite BHist packet carrying the $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance ledgers, regularity and classifier rows, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance.

Use Definition 301.45 inside that packet. It identifies the classifier component with the transported $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface and shows that no quotient stream, host equality, completion point, selected limit, or $\mathsf{Real}^{\uparrow}$ completeness row remains to be read.

Finally invoke Definition 301.51. Any two accepted seal routes exposing the same displayed rows replay through one terminal finite $\mathsf{Real}^{\uparrow}$ seal route. Thus the common finite packet is the unique visible source surface consumed by the $\mathsf{Real}^{\uparrow}$ seal handoff, and every accepted route factors through precisely that surface. □

Theorem 301.57 (RegSeqRat seal-route ordered face determinacy)**.** *Let an accepted terminal seal route carry a* $\mathsf{RegSeqRat}^{\uparrow}$ *packet to the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and suppose its visible source rows are exactly the normal-form rows of Definition 301.56. Then the route consumes those rows in the ordered four-face route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

An accepted reindexing gives the same visible source section only when it preserves that order and preserves the same BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *support rows.*

The determinacy statement has no coordinate for quotient streams, selected limits, host equality, metric completion, $\mathsf{Real}^{\uparrow}$ *completeness, or standard bridge rows.*

Proof. Apply Definition 301.56. The accepted terminal seal route exposes one finite source surface, and that surface is exactly the StreamName schedule, DyadicRatCore endpoint and ledger, RegSeqRat regularity and classifier, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ inventory.

Next use Definition 301.65. The same inventory is consumed as a four-face terminal boundary rather than as an ambient completion or verification-axis token. Thus the visible section must read first the $\mathsf{StreamName}^{\uparrow}$ schedule face, then the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger face, then the $\mathsf{RegSeqRat}^{\uparrow}$ regularity and classifier face, and finally the $\mathsf{Real}^{\uparrow}$ seal face.

It remains to compare an accepted reindexing. Apply Definition 126.576 to the StreamName-facing seal handoff and then return to the normal form. A reindexed section reaches the same

terminal seal section precisely by preserving the displayed ordered faces together with the same BHist, hsame, Cont, Pkg, and local NameCert rows.

The exclusion clause follows from the coordinate inventories of the cited routes. Those inventories contain no quotient stream row, selected limit, host-equality row, metric-completion coordinate, $\mathsf{Real}^{\uparrow}$ completeness row, or standard bridge row, so no accepted reindexing can use such data to change the face order while keeping the same visible source section. □

Theorem 301.58 (RegSeqRat four-face terminal pullback)**.** *Every accepted Phase Real terminal read and every completion-facing terminal read obtained from a* $\mathsf{RegSeqRat}^{\uparrow}$ *packet factors through one finite* BHist *pullback with exactly four source faces:*

1. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers;*
2. *the* $\mathsf{StreamName}^{\uparrow}$ *scheduled window rows and displayed bundle rows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity rows, classifier rows, and provenance rows;*
4. *the terminal* $\mathsf{Real}^{\uparrow}$ *seal row.*

If two terminal reads expose the same four faces, then they classify together through the displayed hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows of that pullback.*

The terminal pullback exports no quotient stream equality, host sequence equality, selected limit, host real equality, ambient completeness, metric-completion point, or standard bridge.

Proof. Start with Definition 301.25. It places the $\mathsf{StreamName}^{\uparrow}$ schedule rows and the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers inside the same accepted finite $\mathsf{RegSeqRat}^{\uparrow}$ window.

Next apply Definition 301.56. The terminal $\mathsf{Real}^{\uparrow}$ seal route can read only the visible finite source surface formed from the schedule, dyadic ledgers, regularity rows, classifier rows, BHist packet rows, hsame, Cont, Pkg, and local NameCert provenance.

Use Definition 301.40 to remove every off-surface route component. The remaining route package is exactly the finite inventory from which the four faces of the pullback are read.

Apply Definition 301.43. Agreement on the four faces transports the two terminal reads through the displayed $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface together with the visible hsame, Cont, Pkg, and local NameCert rows.

Finally invoke Definition 301.51. The common displayed inventory replays to one terminal finite $\mathsf{Real}^{\uparrow}$ seal route, and the cited exclusion package leaves no coordinate for quotient stream equality, host sequence equality, selected limits, host real equality, ambient completeness, metric-completion points, or standard bridge data. □

Theorem 301.59 (RegSeqRat four-face terminal route uniqueness)**.** *Let two accepted terminal reads from* $\mathsf{RegSeqRat}^{\uparrow}$ *packets expose the same four-face pullback inventory: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers; the* $\mathsf{StreamName}^{\uparrow}$ *scheduled-window and bundle rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows; and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. Then the two terminal routes classify together through the same displayed* hsame, Cont, Pkg, *and local* NameCert *rows of that inventory.*

This route uniqueness introduces no quotient stream equality, selected host limit, metric-completion point, $\mathsf{Real}^{\uparrow}$ *completeness datum, or standard bridge.*

Proof. Apply Definition 301.58. The shared four faces are already one finite pullback surface, so both terminal reads are read through the same displayed endpoint ledgers, schedules, regularity rows, classifier rows, provenance rows, and terminal seal row.

Use Definition 301.40. It removes all off-surface coordinates from the terminal route and leaves only the visible hsame, Cont, Pkg, and local NameCert rows for the accepted read.

Next apply Definition 301.43. Since the two reads agree on the four faces, the classifier comparison factors through the same displayed rows rather than through an external completion or quotient coordinate.

Finally use Definition 301.51. The common scheduled-window inventory has a single terminal replay route to the $\mathsf{Real}^{\uparrow}$ seal row, so the terminal routes classify together through the same finite RegSeqRat evidence, with no quotient stream equality, selected host limit, metric-completion point, $\mathsf{Real}^{\uparrow}$ completeness datum, or standard bridge. □

Theorem 301.60 (RegSeqRat terminal four-face correspondence)**.** *Two accepted terminal reads from* $\mathsf{RegSeqRat}^{\uparrow}$ *packets classify together exactly when their visible four-face inventories agree. The four faces are the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers; the* $\mathsf{StreamName}^{\uparrow}$ *scheduled-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows; and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row.*

The agreement is transported only by the displayed BHist *rows,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The correspondence exports no quotient stream equality, host sequence equality, selected limit, host real equality, metric-completion point, completeness datum, or standard bridge row.*

Proof. For the forward direction, apply Definition 301.58. Any accepted terminal read from a $\mathsf{RegSeqRat}^{\uparrow}$ packet already factors through one finite surface with the DyadicRatCore ledger face, StreamName schedule face, RegSeqRat regularity and classifier face, and terminal $\mathsf{Real}^{\uparrow}$ seal face.

Next use Definition 301.59. Once two accepted terminal reads classify together on that finite surface, their classifier route is forced to be the displayed route through the same BHist, hsame, Cont, Pkg, and local NameCert rows. Thus the only visible inventory on which the shared classification can be read is the four-face inventory named in the statement.

For the reverse direction, suppose the two terminal reads expose agreeing four-face inventories with the displayed transport rows. Apply Definition 301.58 to repack the two inventories as one finite pullback surface.

Finally use Definition 301.40 and Definition 301.51. The exclusion package removes quotient streams, selected limits, host equality, metric-completion points, completeness rows, and standard bridge rows from the terminal route; schedule confluence leaves a single terminal replay to the $\mathsf{Real}^{\uparrow}$ seal row. The remaining route is exactly the displayed BHist, hsame, Cont, Pkg, and local NameCert route, so the two terminal reads classify together. □

Theorem 301.61 (RegSeqRat four-face terminal classifier completeness)**.** *The* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal classifier is complete for accepted terminal reads exactly at the four visible faces: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers; the* $\mathsf{StreamName}^{\uparrow}$ *schedules; the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows; and the terminal* $\mathsf{Real}^{\uparrow}$ *seal.*

Thus two accepted terminal reads classify together precisely when these four faces agree through the displayed BHist, hsame, Cont, Pkg, *and local* NameCert *rows. No quotient stream equality, host sequence equality, selected limit, host real equality, metric-completion point, ambient completeness datum, or standard bridge row is part of the classifier completion surface.*

Proof. First assemble the classifier surface. Apply Definition 301.58; every accepted terminal read factors through one finite pullback whose visible faces are exactly the DyadicRatCore ledger face, StreamName schedule face, RegSeqRat regularity/classifier/provenance face, and terminal $\mathsf{Real}^{\uparrow}$ seal face.

Next use route uniqueness. By Definition 301.59, agreement on those four faces forces the two terminal routes to classify through the same displayed hsame, Cont, Pkg, and local NameCert rows.

For the converse, apply Definition 301.60. If two accepted terminal reads classify together, their visible four-face inventories agree, and if the four visible faces agree, the accepted terminal reads classify together.

The exclusions in the cited pullback and correspondence statements remove quotient stream equality, host sequence equality, selected limits, host real equality, metric-completion points, ambient completeness, and standard bridge rows from the terminal classifier. Hence the four-face surface is complete for accepted terminal reads. □

Theorem 301.62 (RegSeqRat dyadic-tail Real-seal status exhaustion)**.** *Every accepted terminal L10 read through* $\mathsf{RegSeqRat}^{\uparrow}$ *is exhausted by the status ledger formed from exactly four faces: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers; the* $\mathsf{StreamName}^{\uparrow}$ *scheduled-window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows; and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. Transport across this ledger uses only the displayed* BHist *rows,* hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The ledger contains no quotient stream equality, host equality, selected limit, ambient completeness, metric-completion point, countable-choice row, verification-axis promotion, or standard bridge row.

Proof. First apply Definition 301.58. It places each accepted terminal L10 read on the single finite pullback whose faces are the DyadicRatCore ledger face, StreamName schedule face, RegSeqRat regularity and classifier face, and terminal $\mathsf{Real}^{\uparrow}$ seal face.

Next use Definition 301.61. The classifier is complete exactly on those four visible faces, so every accepted terminal read is accounted for by the displayed status rows rather than by an external completion surface.

Finally combine Definition 301.40 and Definition 301.51. The exclusion package removes quotient stream equality, host equality, selected limits, metric-completion points, countable-choice rows, verification-axis promotion, and standard bridge rows; schedule confluence keeps the replay on the same displayed BHist, hsame, Cont, Pkg, and local NameCert inventory. Thus the four-face status ledger is exhaustive. □

Theorem 301.63 (RegSeqRat finite-cover terminal classifier descent)**.** *Let* $\{W_i\}_{i\in I}$ *be a finite family of certified* $\mathsf{StreamName}^{\uparrow}$ *windows for a* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal read. Suppose the pairwise and triple overlaps satisfy the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *source cocycle and seal cocycle hypotheses, and suppose the induced handoffs consume the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers on overlaps. Then the resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal classifier surface is exactly the pasted four-face inventory consisting of the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers; the* $\mathsf{StreamName}^{\uparrow}$ *window rows; the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows; and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row.*

The descent transport uses only the displayed BHist, hsame, Cont, Pkg, *and* NameCert *rows. It introduces no quotient streams, selected host limits, host equality, countable choice, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness rows, or standard bridge rows.*

Proof. First paste the finite StreamName cover. Apply Definition 126.551 to the certified windows and their pairwise and triple source cocycle data. Apply Definition 126.552 to the same cover with the seal cocycle data. These two finite-cover statements keep the pasted source and seal on the displayed BHist, hsame, Cont, Pkg, and NameCert rows, and they keep the DyadicRatCore ledgers shared on overlaps.

Next identify the pasted cover with the terminal classifier surface. By Definition 301.61, an accepted terminal $\mathsf{RegSeqRat}^{\uparrow}$ read is classified completely by the four visible faces: the DyadicRatCore ledger face, the StreamName window face, the RegSeqRat regularity/classifier/provenance face, and the terminal $\mathsf{Real}^{\uparrow}$ seal face. The pasted finite cover supplies exactly those rows, so no extra classifier coordinate is available.

Finally keep the terminal seal on the same four-face route. Use Definition 301.62 to exhaust the $\mathsf{RegSeqRat}^{\uparrow}$ terminal status by the displayed four-face ledger, and use Definition 38.455 to read the terminal $\mathsf{Real}^{\uparrow}$ seal as the same four-face packet. The exclusions in these route statements remove quotient streams, selected host limits, host equality, countable choice, ambient completeness, metric-completeness rows, and standard bridge rows. Hence the descended classifier is precisely the pasted terminal four-face inventory. □

Theorem 301.64 (RegSeqRat finite-cover terminal refinement invariance)**.** *Let $\{W_i\}_{i\in I}$ and $\{V_j\}_{j\in J}$ be two finite certified* $\mathsf{StreamName}^{\uparrow}$ *cover presentations of the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal read. Suppose both covers satisfy the finite source and seal cocycle hypotheses of Definition 301.63. Suppose also that they admit a certified finite common refinement whose refinement maps preserve the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the* $\mathsf{StreamName}^{\uparrow}$ *window rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed* BHist, hsame, Cont, Pkg, *and local* NameCert *support.*

Then the two cover presentations descend to the same four-face terminal classifier surface. The invariant surface is exactly the visible $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face,* $\mathsf{StreamName}^{\uparrow}$ *window face,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity/classifier/provenance face, and terminal* $\mathsf{Real}^{\uparrow}$ *seal face. It contains no quotient stream, host sequence equality, selected limit, host real equality, countable-choice row, ambient or metric completeness datum, or standard bridge row.*

Proof. Apply Definition 301.63 to the $\{W_i\}_{i\in I}$ cover. The first presentation descends to the pasted four-face classifier surface carried by its DyadicRatCore ledgers, StreamName windows, RegSeqRat rows, terminal $\mathsf{Real}^{\uparrow}$ seal, and displayed BHist, hsame, Cont, Pkg, and local NameCert support.

Apply the same descent theorem to the $\{V_j\}_{j\in J}$ cover. The second presentation also descends to a pasted four-face classifier surface with the same kind of visible support and with the same exclusion clauses.

Use the certified common refinement to compare the two pasted surfaces. By hypothesis, every refinement row preserves the DyadicRatCore endpoint, radius, and distance ledgers, the StreamName window rows, the RegSeqRat regularity, classifier, and provenance rows, the terminal $\mathsf{Real}^{\uparrow}$ seal row, and the displayed BHist, hsame, Cont, Pkg, and local NameCert support. Thus the two descended presentations have identical visible four-face inventories.

Now apply Definition 301.61 and Definition 301.60. Completeness says that accepted terminal reads are classified exactly by those four visible faces, and the correspondence identifies equality of the visible inventories with equality of the terminal classifier surface.

The exclusion clauses are inherited from the two descent applications and from the terminal pullback route. Hence refinement invariance is witnessed inside the displayed BEDC rows only: no quotient stream, host sequence equality, selected limit, host real equality, countable choice, ambient or metric completeness, or standard bridge is introduced. □

301.3 RegSeqRat Terminal Four-Face Axis Separation

Theorem 301.65 (RegSeqRat terminal four-face axis separation)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal four-face read through*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

supplies only the paper-side finite boundary whose support rows are

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The read cannot raise a formal-status token for any of the four faces, create a standard bridge row, assert ambient $\mathsf{Real}^{\uparrow}$ *completeness, introduce quotient stream equality, or supply metric-completeness data.*

Thus downstream Phase Real and Completion consumers may use the terminal four-face packet only as a finite manuscript boundary. Verification status, bridge status, quotient identification, and completeness data must still be read from the relevant face's own closurestatus, Lean target, and bridge boundary.

Proof. Start with Definition 301.60. It identifies terminal RegSeqRat agreement exactly with the visible four-face inventory and transports that agreement only through the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Next apply Definition 301.68. The route is not an isolated RegSeqRat coordinate: it passes through the DyadicRatCore, StreamName, and Real sibling chapters before it is consumed as a Real-facing handoff, while retaining the same finite support rows.

Now invoke Definition 126.500. It reads the Phase Real and Completion exit packet as exactly the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no quotient stream equality, host sequence equality, selected limit, ambient $\mathsf{Real}^{\uparrow}$ completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row.

Finally use Definition 38.429. The Real-facing completion interface consumes the same finite window, regular-rational readback, dyadic observation ledger, seal row, componentwise hsame transport, displayed Cont route, package provenance, and local NameCert row. Since the cited routes contain no verification-axis token, standard bridge row, ambient completeness principle, quotient stream equality, or metric-completeness coordinate, the terminal four-face read separates the paper-side boundary from those independent axes. □

Theorem 301.66 (RegSeqRat terminal four-face status pullback)**.** *An accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal four-face read satisfies the current Phase Real and Completion objectwise status boundary if and only if it exposes the four local face records for*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

where each face is read from its own closurestatus*,* formalstatus*,* leantarget*, and* bridgestatus *rows, together with the shared support*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The pullback contains no aggregate formalstatus *row, aggregate bridge token, selected limit, quotient stream equality, metric-completeness datum, countable-choice row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. For necessity, begin with Definition 301.65. It separates the terminal four-face paper boundary from verification status, bridge status, quotient identification, selected limits, metric-completeness data, countable choice, and ambient real completeness.

Next apply Definition 301.60. The accepted RegSeqRat terminal read has exactly the visible four-face inventory, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback rows are one of those local faces rather than an aggregate route token.

Now use Definition 126.500. The current Phase Real and Completion route consumes precisely the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

For sufficiency, start with the four local face records and the shared support rows. Apply Definition 291.112 to read the local $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ status rows from their own closurestatus, formalstatus, leantarget, and bridgestatus entries.

Finally invoke Definition 38.792. The Real-side criterion consumes exactly those objectwise face records together with the displayed finite support, so the accepted RegSeqRat terminal read satisfies the current Phase Real and Completion objectwise status boundary.

The exclusions follow from the same citations. The axis-separation theorem and the dyadic pullback theorem expose no aggregate formalstatus, aggregate bridge, selected limit, quotient stream equality, metric-completeness datum, countable-choice row, or ambient $\mathsf{Real}^{\uparrow}$ completeness coordinate, and the four-object route plus the Real objectwise criterion provide no further row in which such data could be stored. □

Theorem 301.67 (RegSeqRat terminal four-face finite-request restriction)**.** *Let $\mathcal{T}$ be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal four-face read satisfying the current Phase Real and Completion objectwise status boundary. Let $\mathcal{R}$ be any finite request restriction of $\mathcal{T}$ preserving the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and local* $\mathsf{Real}^{\uparrow}$ *face rows, together with the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows. Then $\mathcal{R}$ satisfies the same objectwise boundary.*

Conversely, if such a finite request restriction satisfies that boundary, then the boundary recovers exactly those displayed face and support rows of the ambient read. It recovers no aggregate $\mathsf{formalstatus}$ *row, aggregate bridge token, selected limit, quotient stream equality, metric-completeness datum, countable-choice row, ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, or fifth public coordinate.*

Proof. Start with Definition 301.66. It reads the ambient accepted terminal read through exactly the four local face records and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows.

Restrict those rows along the finite request. Since the restriction preserves the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$ faces and the displayed support rows, the same objectwise boundary remains visible on $\mathcal{R}$.

For the reverse direction, suppose the finite request restriction satisfies the objectwise boundary. Apply Definition 126.500 to identify the ordered four-face route, and then apply Definition 38.792 to read the boundary as precisely those objectwise face records with the displayed finite support.

Finally use Definition 301.65. It prevents verification status, bridge status, selected limits, quotient stream equality, metric-completeness data, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, and any fifth public coordinate from leaking into the restricted read. Hence the restriction recovers exactly the displayed rows of the ambient read and no aggregate completion or verification datum. □

Theorem 301.68 (RegSeqRat four-face hub sibling route)**.** *Every accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal handoff used by current L10 consumers factors through the sibling chapters chapter 291, chapter 126, and chapter 38 before it is read as a Real-facing route. The route is the finite four-face inventory consisting of the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the* $\mathsf{StreamName}^{\uparrow}$ *scheduled-window rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row.*

The handoff exports no quotient stream equality, selected host limit, host real equality, ambient completeness datum, metric-completion point, or additional Real seal coordinate.

Proof. Start with Definition 301.69. It identifies the public handoff route as the ordered passage through $\mathsf{StreamName}^{\uparrow}$ scheduled windows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface, and the terminal $\mathsf{Real}^{\uparrow}$ seal.

Next apply Definition 301.58. The terminal read is one finite pullback with exactly the DyadicRatCore face, StreamName face, RegSeqRat face, and Real seal face, transported by the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Finally use Definition 301.60. Agreement of terminal reads is detected only on that four-face inventory, so the hub route is a substantive sibling route through the named DyadicRatCore, StreamName, and Real chapters rather than an isolated local theorem. The cited exclusion clauses leave no quotient stream equality, selected host limit, host equality, ambient completeness datum, metric-completion point, or extra seal coordinate to export. □

Theorem 301.69 (RegSeqRat StreamName Dyadic Real handoff exactness)**.** *For every accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, any public* $\mathsf{Real}^{\uparrow}$ *seal consumer of that carrier factors exactly through the finite route*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows selecting the visible finite windows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows read from those windows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows over the same scheduled dyadic observations;*
4. *the* $\mathsf{Real}^{\uparrow}$ *seal rows consuming that finite classifier surface.*

The factorization preserves the displayed hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows at every stage. No quotient stream, host real equality, selected limit, metric-completion object, ambient completeness datum, or extra seal coordinate can enter the handoff.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamNameDyadicRealHandoffExactness`

Proof. Project the carrier of Definition 301.1 and the classifier of Definition 301.2. Their visible rows are the scheduled $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius reads, the finite dyadic-distance rows, regularity rows, classifier rows, and the attached hsame, Cont, Pkg, and local NameCert provenance.

Apply Definition 301.4 to the schedule side and Definition 301.5 to the classifier side. Together they identify the endpoint, radius, distance, and regularity rows as rows of the same finite scheduled observation package.

Transport that package through Definition 301.6. The transport keeps the schedule, endpoint, radius, distance, regularity, classifier, hsame, Cont, Pkg, and NameCert rows componentwise, so the consumer has no alternative finite source surface available.

Finally use Definition 301.22, Definition 301.43, and Definition 301.50. The first theorem routes the accepted regular-rational source to the $\mathsf{Real}^{\uparrow}$ seal, the second makes the classifier factorization explicit, and the third locks the public consumer to the same finite schedule and replay ledger.

Since the cited surfaces expose only the displayed finite rows, there is no coordinate for quotient streams, host real equality, selected limits, completion objects, ambient completeness data, or an additional seal route. □

Theorem 301.70 (RegSeqRat StreamName Dyadic Real handoff single-source lock)**.** *Let two public* $\mathsf{Real}^{\uparrow}$ *seal consumers read the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier through displayed* $\mathsf{StreamName}^{\uparrow}$ *schedules and* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers. Then both seal reads factor through one finite source route: the schedule rows, dyadic endpoint rows, dyadic radius rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, regularity rows,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows attached to that carrier.*

The lock exposes no quotient stream, host real equality, selected limit, metric-completeness datum, or extra $\mathsf{Real}^{\uparrow}$ *seal coordinate. A consumer that requests any of those objects has left the displayed source route rather than reading a second seal source.*

Proof. Begin with Definition 301.69. It routes each public $\mathsf{Real}^{\uparrow}$ seal read through the same four-stage StreamName, DyadicRatCore, RegSeqRat, and Real seal path, preserving the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next apply Definition 301.103. The L10 source lattice records the finite schedule rows, dyadic endpoint and radius rows, classifier rows, regularity rows, transports, routes, provenance, and naming rows as one visible source packet. Since both consumers start from the same accepted carrier, their displayed schedules and dyadic ledgers point into that same packet.

Finally use Definition 301.22, Definition 301.43, and Definition 301.50. These seal handoff results identify the public read with the regular-rational classifier surface and rule out a second public seal source. The excluded quotient, host-equality, selected-limit, completeness, and extra-coordinate data have no row in the route just assembled, so the two seal consumers are locked to one finite source route. □

Theorem 301.71 (RegSeqRat StreamName Dyadic Real source-seal correspondence)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier read through displayed* $\mathsf{StreamName}^{\uparrow}$ *schedules and* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, the public* $\mathsf{Real}^{\uparrow}$ *seal route is equivalent, as a finite BEDC route, to the four-stage route*

1. $\mathsf{StreamName}^{\uparrow}$ *finite-window rows selecting the scheduled observations;*
2. $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows read from those windows;*
3. $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows over the same finite dyadic observations;*
4. *the* $\mathsf{Real}^{\uparrow}$ *seal row that consumes that classifier surface.*

The correspondence is bidirectional at the level of displayed rows: every public seal read factors through the four-stage route, and every such four-stage route determines the same public seal read for the accepted carrier. It introduces no quotient stream, host real equality, selected limit, ambient completeness datum, or hidden seal coordinate.

Proof. For the forward direction, apply Definition 301.69. A public $\mathsf{Real}^{\uparrow}$ seal read is routed through StreamName schedules, DyadicRatCore endpoint and radius ledgers, RegSeqRat classifier rows, and the public seal, while preserving the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next lock the source by Definition 301.70. The same accepted carrier supplies one finite source packet for all public seal reads, so the route cannot branch into a second completion object or an unstated equality of streams.

For the reverse direction, read the four displayed stages through the Lean-facing anchors `RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff`, `DyadicRatCoreCarrier_regseqrat_` and `RegSeqRatStreamCarrier_real_seal_handoff`. These anchors match the paper route from finite window rows to dyadic radius rows, from dyadic ledgers to the RegSeqRat classifier, and from that classifier to the public Real seal.

The two directions have the same displayed coordinates. Since neither the paper handoff theorems nor the Lean-facing handoff anchors expose quotient streams, host real equality, selected limits, ambient completeness, or hidden seal data, the correspondence is exactly the finite source-seal route stated above. □

Theorem 301.72 (RegSeqRat StreamName Dyadic Real triple exactness)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, the public* $\mathsf{Real}^{\uparrow}$ *seal route is exactly the common finite triple surface consisting of the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, with the* $\mathsf{Real}^{\uparrow}$ *seal as the consumer of that surface. The certificate preserves precisely the displayed* hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows.*

The triple surface contains no quotient stream, host real equality, selected limit, metric-completion object, ambient completeness datum, choice datum, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Apply Definition 301.69. It gives the four-stage public seal route and identifies the StreamName, DyadicRatCore, RegSeqRat, and RealUp rows read by the consumer.

Next apply Definition 301.70. The schedule, dyadic ledger, classifier, regularity, transport, continuation, package, and naming rows all come from one finite source route attached to the accepted carrier.

Use Definition 301.71 to read the public Real seal route and the displayed finite source-seal route in both directions. Finally apply Definition 301.74 to place cofinal tail reads on the same dyadic ledger whenever a tail refinement is presented.

These four inputs leave exactly the triple surface named in the statement, with the $\mathsf{Real}^{\uparrow}$ seal as its consumer. Their exclusion clauses remove quotient streams, host real equality, selected limits, metric-completion objects, ambient completeness data, choice data, and second seal coordinates. □

Theorem 301.73 (RegSeqRat StreamName Dyadic Real four-stage consumer minimality)**.** *For any accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier whose public* $\mathsf{Real}^{\uparrow}$ *seal is read through displayed* $\mathsf{StreamName}^{\uparrow}$ *schedules and* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, every valid public seal consumer passes through all four displayed surfaces:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows;*
4. *the public* $\mathsf{Real}^{\uparrow}$ *seal row.*

If a consumer route omits any one of these four surfaces, then that route is outside the displayed BEDC handoff and cannot claim the public $\mathsf{Real}^{\uparrow}$ *seal of the accepted carrier.*

The minimality certificate exports no quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or second seal coordinate.

Proof. First apply Definition 301.69. It gives the forward public route and lists exactly the StreamName schedule rows, DyadicRatCore endpoint, radius, and distance ledgers, RegSeqRat classifier and regularity rows, and RealUp seal row consumed by the public seal read.

Next use Definition 301.70. The single-source lock prevents a consumer from replacing a missing displayed surface by a second source packet, a host equality row, or a hidden completion coordinate.

Now apply Definition 301.71. The source route and the public seal route are the same finite BEDC route in both directions, so omitting one displayed surface removes a coordinate needed by the seal route itself.

Finally use Definition 301.72. The schedule, dyadic ledger, and RegSeqRat classifier exhaust the source side of the seal, with the RealUp row as its consumer. Thus a route lacking any one of the four surfaces is not a public Real seal consumer for the displayed handoff; the excluded quotient stream, host equality, selected-limit, completeness, choice, and second-seal data have no coordinate from which to repair the omission. □

Theorem 301.74 (RegSeqRat common dyadic tail ledger)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier. Suppose two finite* $\mathsf{StreamName}^{\uparrow}$ *tail-window reads of P feed public* $\mathsf{Real}^{\uparrow}$ *seal consumers, and suppose the two reads admit a common cofinal dyadic refinement. Then the two seal routes factor through one common finite ledger. This ledger consists exactly of the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows on the common refinement, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows attached to P.*

The common ledger is a displayed finite BHist *route. It is not a quotient stream equality, host real equality, selected limit, choice datum, ambient completeness witness, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Apply Definition 301.69 to each of the two tail-window reads. Each public seal consumer is thereby routed through the same four surfaces: the $\mathsf{StreamName}^{\uparrow}$ schedule rows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance rows, $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows, and the $\mathsf{Real}^{\uparrow}$ seal rows consuming that finite source surface.

Next apply Definition 301.70. Since both reads start from the same accepted carrier P, the two public seal consumers have one displayed source route, with the same componentwise hsame, Cont, Pkg, and local NameCert rows.

It remains to identify the shared cofinal refinement as finite ledger data. Use Definition 301.103 to place the schedule, endpoint, radius, classifier, regularity, transport, route, provenance, and naming rows inside one visible L10 source packet.

Finally apply Definition 301.4, Definition 301.5, and Definition 301.13. These facts read the cofinal dyadic refinement as displayed endpoint, radius, distance, and regularity rows of the same finite packet. No step creates a host completion object, selected limit, choice datum, quotient stream equality, host real equality, or second seal coordinate, so the common tail route is exactly the finite ledger stated above. □

Theorem 301.75 (RegSeqRat Real seal window triple correspondence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier read through a finite* $\mathsf{StreamName}^{\uparrow}$ *schedule. Suppose the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows for that schedule feed the public* $\mathsf{Real}^{\uparrow}$ *seal consumer of P. Then the following four finite BEDC surfaces mutually determine one another:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows and membership rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows;*
4. *the public* $\mathsf{Real}^{\uparrow}$ *seal consumer row.*

Equivalently, any one of these displayed finite-window surfaces determines the same BHist *route through the other three, with the same componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. The correspondence contains no quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or hidden seal coordinate.*

Proof. Start with Definition 301.69. It gives the finite route from the accepted carrier through the $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance rows, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface, and the public $\mathsf{Real}^{\uparrow}$ seal consumer.

Apply Definition 301.71 to read the route in both directions. The public seal read determines the finite source surface, and the finite source surface determines the same public seal read, without adding completion data or external equality.

Next use Definition 301.72. It identifies the schedule, dyadic ledger, and RegSeqRat classifier/regularity surfaces as one exact triple surface whose consumer is the public $\mathsf{Real}^{\uparrow}$ seal row.

Finally apply Definition 301.74. Whenever the finite schedule is viewed through a common cofinal dyadic refinement, the same schedule rows, endpoint rows, radius rows, distance rows, classifier rows, regularity rows, transports, continuations, package provenance, and naming rows are read back as one common BHist ledger. Thus each of the four displayed surfaces recovers the same route through the other three.

All cited inputs expose only finite rows of the BEDC route. They provide no coordinate for quotient streams, host real equality, selected limits, ambient completeness, choice data, or hidden seal data, so the correspondence is exactly the finite Real seal route stated above. □

Theorem 301.76 (RegSeqRat L10 four-face necessity)**.** *A current Phase Real and Completion exit read for an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier requires all four displayed faces:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *finite schedule and membership rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledgers;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows;*
4. *the public* $\mathsf{Real}^{\uparrow}$ *seal row.*

Removing any one of these faces breaks the finite BEDC route from the L10 source lattice to the completion-facing seal. Conversely, the four faces together suffice for the exit read by the handoff exactness, source-seal correspondence, triple exactness, window triple correspondence, and L10 source lattice pointer results.

Proof. Apply Definition 301.103. It places the accepted $\mathsf{RegSeqRat}^{\uparrow}$ carrier on the finite source lattice whose public route must pass through scheduled windows, dyadic ledger rows, regular sequence classifier rows, and the completion-facing seal.

Use Definition 301.69. The handoff theorem displays the same route as an ordered finite passage through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. If the schedule face is removed, the window route has no finite source index. If the dyadic face is removed, the endpoint, radius, and distance ledgers cannot be read. If the RegSeqRat face is removed, the classifier and regularity rows are not available. If the Real face is removed, the public seal consumer has no finite target row.

Now apply Definition 301.71 and Definition 301.72. The first identifies the source and seal reads as the same finite public route, while the second binds the schedule, dyadic ledger, and RegSeqRat classifier faces as one exact triple before the seal is consumed.

Finally use Definition 301.75. It states that each of the four displayed faces recovers the same BHist route through the other three. Thus each face is necessary for the finite exit route, and

all four together are sufficient without adding quotient streams, host real equality, selected limits, ambient completeness, choice data, or hidden seal coordinates. □

Theorem 301.77 (StreamName RegSeqRat Real Dyadic completion-face boundary)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, a Phase Real and Completion exit read is admissible exactly when the same finite* BHist *route contains all four completion-facing rows:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule and membership rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows;*
4. *the* $\mathsf{Real}^{\uparrow}$ *seal row.*

The route preserves the displayed hsame *rows,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows, and it has no completion-facing source outside the shared finite route.*

Proof. For admissibility from the four rows, apply Definition 301.69. It routes the accepted carrier through the StreamName schedule, DyadicRatCore endpoint and radius data, RegSeqRat classifier and regularity rows, and the public Real seal.

Use Definition 301.71 to identify the public seal read with the same finite source route. Then apply Definition 301.72 to bind the schedule, dyadic ledger, and RegSeqRat classifier as one exact triple before the seal row is consumed.

For necessity, apply Definition 301.75. Each of the four displayed faces recovers the same BHist route through the other three.

Finally use Definition 301.76. It states that removing any one of the schedule, dyadic, RegSeqRat, or Real seal faces breaks the Phase Real and Completion exit read. Hence the exit read is admissible exactly for the shared finite route containing all four rows. □

Theorem 301.78 (StreamName RegSeqRat Real completion-face non-escape)**.** *The completion-facing route of Definition 301.77 exports no quotient stream, host real equality, selected limit, metric completion object, ambient completeness datum, countable-choice schedule, second* $\mathsf{Real}^{\uparrow}$ *seal coordinate, standard bridge row, or aggregate verification token.*

Proof. Start from Definition 301.77. The exit read is the shared finite route containing the StreamName schedule rows, DyadicRatCore endpoint and radius rows, RegSeqRat classifier and regularity rows, and the Real seal row.

Apply Definition 301.69 and Definition 301.71. These identify the public seal read with displayed finite rows and exclude quotient streams, host real equality, selected limits, completion objects, ambient completeness, and hidden seal data.

Next apply Definition 301.72 and Definition 301.75. The triple and window correspondences keep the four faces inside one BHist route with the same support rows.

Finally use Definition 301.76. Since the exit read has exactly the required four faces, neither a standard bridge row nor an aggregate verification token is among the displayed faces, and there is no fifth coordinate from which a countable-choice schedule, metric completion object, ambient completeness witness, selected limit, host equality, quotient stream, second seal coordinate, standard bridge row, or aggregate verification token could be exported. □

Theorem 301.79 (RegSeqRat Real seal finite-window saturation)**.** *Every accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read that exits as a* $\mathsf{Real}^{\uparrow}$ *seal for Phase Real and Completion is saturated by exactly four finite faces:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule and membership rows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledgers;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows;*
4. *the public* $\mathsf{Real}^{\uparrow}$ *seal row.*

No fifth face is available to the exit read. In particular, the saturated route contains no quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or hidden seal coordinate beyond the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier real seal finite window saturation`

Proof. Begin with Definition 301.76. It shows that a Phase Real and Completion exit read requires the schedule, dyadic ledger, RegSeqRat classifier, and public seal faces, and that those four faces suffice for the L10 exit route.

Use Definition 301.75. It identifies each displayed face with the same finite BHist route through the other three, so any accepted public seal read already recovers the schedule, dyadic, classifier, transport, and seal rows without an extra coordinate.

Next apply Definition 301.74. It keeps common cofinal dyadic refinements on the same endpoint, radius, distance, classifier, regularity, transport, continuation, provenance, and local naming ledger. Thus refinements do not create an additional face.

Finally use Definition 301.71. It ties the finite source read to the public seal read in both directions. The only surfaces exported to the seal are the four listed faces, and the excluded quotient, host equality, selected-limit, completeness, choice, and hidden-coordinate data have no row in the accepted route. □

Theorem 301.80 (RegSeqRat finite-cover Real seal gluing uniqueness)**.** *Let* $\mathcal{W}$ *be a finite cover of* $\mathsf{StreamName}^{\uparrow}$ *windows for an accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read in Phase Real and Completion. Suppose that on every nonempty overlap the two local window routes agree on the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledgers, the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows, and the displayed public* $\mathsf{Real}^{\uparrow}$ *seal rows, with the agreement witnessed by the same componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows in a finite* BHist *route.*

Then the finite family of local window routes glues to at most one Real-facing public seal route. Equivalently, any two finite BHist *routes assembled from the same cover and the same overlap ledgers have the same public* $\mathsf{Real}^{\uparrow}$ *seal row and the same StreamName, DyadicRatCore, and RegSeqRat support rows. The glued seal exports no quotient stream, selected limit, host equality, countable-choice schedule, ambient completeness datum, or standard bridge row.*

Proof. First apply Definition 301.79. Each local window route has exactly the four displayed faces: the StreamName schedule and membership rows, the DyadicRatCore endpoint-radius-distance ledger, the RegSeqRat classifier-regularity-transport rows, and the public Real seal row.

Next use Definition 301.75. On an overlap, agreement of the endpoint and radius ledger, classifier and regularity rows, and seal row identifies the same finite BHist route through the remaining face. Thus adjacent windows in the cover cannot choose distinct Real-facing exit routes while keeping the displayed overlap data fixed.

We now pass across the cover. Since $\mathcal{W}$ is finite, repeat the overlap identification along the finite adjacency chain inside the displayed route data. The result is a single compatible StreamName,

DyadicRatCore, RegSeqRat, and RealUp four-face route, with no appeal to an infinite selection schedule or to an ambient completion object.

Finally apply Definition 301.77 and Definition 301.78. The boundary theorem identifies the completion-facing exit with the same four finite faces, while the nonescape theorem excludes quotient streams, host real equality, selected limits, ambient completeness witnesses, extra seal coordinates, standard bridge rows, and aggregate verification tokens. Hence two glued Real-facing public seals built from the cover must be the same finite BHist route. □

Theorem 301.81 (RegSeqRat StreamName Real three-surface route determinacy)**.** *Let R be an accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read. Suppose two public presentations of R display the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and membership rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledger, and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows. Then the two presentations determine the same BEDC route to the* $\mathsf{Real}^{\uparrow}$ *seal exactly when they reach the same displayed public* $\mathsf{Real}^{\uparrow}$ *seal row.*

Equivalently, the StreamName, DyadicRatCore, RegSeqRat, and RealUp faces are not four independent choices. Once the first three faces are fixed, the displayed public seal row is the whole remaining route coordinate, and two seal reads agree precisely by sharing that row in the same finite BHist *route. The statement uses no quotient stream, host real equality, selected limit, ambient completeness object, choice schedule, or hidden seal coordinate.*

Proof. First apply Definition 301.69. It places each accepted presentation on the finite handoff route through the displayed StreamName schedule rows, dyadic endpoint-radius-distance ledger, RegSeqRat classifier and regularity rows, and public Real seal row.

Next use Definition 301.71. This identifies the source read and the seal read as the same public finite route. Therefore any agreement of the displayed seal row is agreement of the route endpoint reached by the fixed source rows.

Now apply Definition 301.72 together with Definition 301.75. The triple exactness theorem binds the shared StreamName, DyadicRatCore, and RegSeqRat faces, while the window-triple correspondence recovers the same route through the Real seal face. Thus the reverse direction also holds: if the two presentations determine the same BEDC route, the displayed public seal row is the same row of that route.

Finally invoke Definition 301.79. The saturated route has exactly the four public faces listed in the statement. There is no fifth coordinate from which quotient streams, host real equality, selected limits, ambient completeness, choice schedules, or hidden seal data could alter the route after the first three faces and the displayed seal row have been fixed. □

Theorem 301.82 (RegSeqRat StreamName Dyadic Real budgeted request determinacy)**.** *Let R be an accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read, and let $B = (E, W, D, Q, S, H, C, P, N)$ be an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet. Suppose B presents the same finite* $\mathsf{StreamName}^{\uparrow}$ *windows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row, and the same public* $\mathsf{Real}^{\uparrow}$ *seal row as the accepted read R. Then the budgeted request determines the same finite BEDC route as R exactly when it agrees on the displayed rows $E, W, D, Q, S, H, C, P, N$.*

Equivalently, the packet rows are the whole request-side coordinate of the four-face route. Agreement on those rows fixes the StreamName window surface, the DyadicRatCore metric ledger, the RegSeqRat handoff, the RealUp seal, and the transport, continuation, provenance, and local naming rows. The budgeted request exports no quotient stream, host real equality, selected limit, ambient completeness witness, choice schedule, or hidden seal coordinate.

Proof. First place the accepted read on the finite handoff route. Apply Definition 301.69 to identify the StreamName window rows, the DyadicRatCore endpoint-radius-distance ledger, the RegSeqRat handoff, and the public Real seal row as one finite BEDC route.

Next record that no smaller public surface can carry the same exit. By Definition 301.76, the L10 handoff needs the StreamName, DyadicRatCore, RegSeqRat, and RealUp faces together, and Definition 301.81 says that once the first three faces are fixed, agreement of the displayed Real seal row is exactly agreement of the route endpoint.

Now attach the explicit observation packet. Apply Definition 611.32 to read the packet route through

$$E \longmapsto W \longmapsto D \longmapsto Q \longmapsto S$$

with the rows H, C, P, N carried as transport, continuation, provenance, and local naming data. Then use Definition 611.33 to lock every RealUp seal read admitted by S behind the same finite StreamName windows, DyadicRatCore rows, and RegSeqRat handoff.

The forward direction follows because agreement on $E, W, D, Q, S, H, C, P, N$ therefore supplies exactly the packet rows needed to reproduce the finite four-face route already determined by R. The reverse direction follows because the same finite BEDC route has no extra packet coordinate: if the budgeted request and R determine the same route, the displayed request, window, dyadic, handoff, seal, transport, continuation, provenance, and naming rows must be the rows of that route.

The non-escape clauses in the cited handoff and budget theorems exclude quotient stream equality, host real equality, selected limits, ambient completeness, choice schedules, and hidden seal coordinates. Hence no additional analytic or ambient datum can distinguish two budgeted requests after the displayed rows agree. □

Theorem 301.83 (RegSeqRat StreamName Real tail-window exhaustion)**.** *Every accepted tail-window consumer of the* $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *handoff factors only through the displayed* $\mathsf{StreamName}^{\uparrow}$ *scheduled windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transport, finite* Cont *continuation,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. The consumer surface has no coordinate for quotient streams, host real equality, selected limits, metric completeness, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 301.74. It places the shared tail read on the common dyadic ledger, so the endpoint, radius, and tail-window entries seen by a consumer are already the displayed finite rows of the handoff.

Next use Definition 301.79. The RealUp seal contributes only the finite windows saturated by the StreamName schedule, the dyadic ledger, and the RegSeqRat handoff rows; it does not add ambient completeness or a host-level limit object.

Then invoke Definition 301.81. Once the StreamName, DyadicRatCore, and RegSeqRat surfaces are fixed, the displayed RealUp seal row is the only remaining public route coordinate.

Finally attach the request-side rows by Definition 301.82. Transport, continuation, provenance, and local naming are exactly the displayed $\mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}$ support rows, so the tail-window consumer has no route through quotient streams, selected limits, metric completeness, or ambient RealUp completeness. □

Theorem 301.84 (RegSeqRat StreamName Real audit-clean route triad)**.** *Any RegSeqRat-side consumer of the L10 handoff reaches machine audit support through exactly the StreamName singleton finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSe-*

qRat Real seal handoff. The route has no quotient stream, selected limit, ambient Real completeness, metric-completeness row, countable-choice row, or bridge row.

Proof. First apply Definition 301.69. It places the RegSeqRat-side consumer on the finite handoff route through the displayed StreamName window, DyadicRatCore ledger, RegSeqRat readback, and Real seal.

Next use Definition 301.72. The triple exactness theorem binds the StreamName, DyadicRatCore, and RegSeqRat faces as one finite route before the Real seal is read.

Now invoke Definition 301.81. Once the first three surfaces are fixed, the displayed Real seal row is the whole remaining route coordinate, so a consumer cannot introduce another machine-facing support site.

Finally apply Definition 301.82. The budgeted request theorem confirms that even an explicit observation request reuses the same StreamName, DyadicRatCore, RegSeqRat, and RealUp rows. Therefore the audit route is exactly the three touchpoints listed in the statement, with no quotient stream, selected limit, ambient completeness, metric-completeness row, countable choice, or bridge row. □

Theorem 301.85 (RegSeqRat audit-clean route sufficiency)**.** *Let H be an accepted RegSeqRat-side L10 handoff whose visible rows are exactly the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and the* $\mathsf{Real}^{\uparrow}$ *seal row. Then the three Lean-facing anchors* RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff*,* DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness*, and* RegSeqRatStreamCarrier_real_seal_handoff *are sufficient for the Phase Real and Completion audit-clean route surface determined by H.*

No aggregate formalstatus row, bridge row, quotient stream, selected limit, countable-choice row, metric-completeness row, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate is part of that route surface.*

Proof. Apply Definition 301.84. It names exactly the StreamName finite-window handoff, the DyadicRatCore RegSeqRat bridge handoff exactness, and the RegSeqRat Real seal handoff as the machine-facing support sites for any RegSeqRat-side L10 consumer.

Next use Definition 301.69. This identifies the visible rows of H as one finite route through the StreamName schedule, DyadicRatCore endpoint-radius-distance ledger, RegSeqRat classifier and regularity rows, and public RealUp seal row. Hence the four concrete-instance faces named in the statement are the whole carrier surface seen by the route.

Then invoke Definition 301.79. The RealUp seal is saturated by the same finite windows and ledger rows, so it adds no ambient completeness coordinate, selected limit, quotient stream, or hidden analytic witness beyond the displayed handoff data.

Finally apply Definition 301.82. Even when the handoff is read through an explicit budgeted request, agreement on the displayed StreamName, DyadicRatCore, RegSeqRat, and RealUp rows determines the same route. Therefore the three Lean-facing anchors listed in the theorem are sufficient for the current audit-clean surface, and no aggregate formalstatus row, bridge row, countable-choice row, metric-completeness row, or ambient Real completeness coordinate is imported. □

Theorem 301.86 (RegSeqRat StreamName Dyadic Real Lean anchor audit surface)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier whose public seal route is saturated by the four faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, the Lean-facing anchors* `RatStreamNameFiniteWindowClassifier_singl` `DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness`*, and* `RegSeqRatStreamCarrier_real_seal_h` *expose exactly the same finite audit surface. Concretely, they expose the StreamName finite-window membership surface, the DyadicRatCore endpoint, radius, and distance handoff surface, and the*

RegSeqRat-to-Real public seal handoff surface. No additional audit coordinate is supplied by a quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or hidden seal coordinate.

Proof. Apply Definition 301.71. It identifies the accepted carrier's finite source route with the public seal route and already names the three Lean-facing anchors as the route from finite-window rows to dyadic rows, from dyadic rows to the RegSeqRat classifier, and from that classifier to the public Real seal.

Next use Definition 301.76. It shows that a Phase Real and Completion exit read requires exactly the StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier, and Real seal faces for the L10 route. Thus the first two anchors cover the first-three-face passage through StreamName, DyadicRatCore, and RegSeqRat, while the third anchor covers the terminal seal passage into $\mathsf{Real}^{\uparrow}$.

Finally apply Definition 301.79. The saturated route has no fifth face, and the excluded quotient stream, host real equality, selected limit, ambient completeness, choice datum, and hidden seal coordinate have no displayed row. Therefore the three named anchors are exactly the finite audit surface that remains to be formalized for the four-face route. □

Theorem 301.87 (RegSeqRat L10 exit route order lock)**.** *For any accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read whose terminal output is a* $\mathsf{Real}^{\uparrow}$ *seal, the L10 exit route is ordered as follows: first the* $\mathsf{StreamName}^{\uparrow}$ *finite-window membership face, second the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger face, third the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport face, and last the public* $\mathsf{Real}^{\uparrow}$ *seal face.*

No later face may be read before its predecessor. In particular the public seal row is not available before the RegSeqRat face has been read, the RegSeqRat face is not available before the DyadicRatCore ledger has been read, and the dyadic ledger is not available before the StreamName membership face has fixed the finite window. The route excludes quotient streams, host real equality, selected limits, ambient completeness, choice rows, metric-completeness data, aggregate formalstatus rows, aggregate bridge rows, and a second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Begin with Definition 301.86. It identifies the three Lean-facing anchors as the finite-window handoff, the dyadic endpoint-radius-distance handoff, and the RegSeqRat-to-Real seal handoff, with no extra audit coordinate.

Next apply Definition 301.76. Necessity says that the L10 public exit needs exactly the StreamName, DyadicRatCore, RegSeqRat, and Real faces. Thus removing or bypassing any predecessor would leave a later face without the finite source row on which it is certified.

Use Definition 301.72 to bind the first three faces as one ordered finite route. The triple exactness step keeps the StreamName membership rows upstream of the DyadicRatCore ledger and keeps the dyadic ledger upstream of the RegSeqRat classifier, regularity, and transport rows.

Finally combine Definition 301.71 with Definition 301.79. The correspondence places the terminal public seal on the same finite source route, while saturation says that the route has no fifth face and no hidden second seal coordinate. Hence the four public faces are read in the displayed order, and the excluded quotient, host-equality, limit, completeness, choice, formalstatus, bridge, and second-seal data remain outside the route. □

Theorem 301.88 (RegSeqRat Real seal finite-cover gluing)**.** *Let* $\{\mathcal{S}_i\}_{i\in I}$ *be a finite family of accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *reads whose members exit as* $\mathsf{Real}^{\uparrow}$ *seals. Suppose each* $\mathcal{S}_i$ *is saturated by exactly the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Suppose also that every displayed pairwise overlap agrees on the shared BHist*, componentwise* hsame*,* Cont*,* Pkg*,* NameCert*, dyadic-ledger, classifier, regularity, and seal rows. Then the finite family glues to one finite four-face L10 packet over the finite union of the requests, with the same four faces and only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. The glued packet contains no quotient stream equality, no host real equality, no selected limit, no ambient or metric-completeness datum, no choice data, and no second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. For each family member, apply Definition 301.79. This places the member on one finite L10 exit route whose only faces are the StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier and regularity surface, and Real seal row.

Glue the StreamName windows first. The overlap hypotheses identify the displayed BHist, hsame, Cont, Pkg, NameCert, dyadic, RegSeqRat, and Real rows seen from adjacent members, so Definition 126.562 gives one finite StreamName-side request packet over the finite union.

Next keep the Real consumer on that same finite section. Use Definition 38.698 to repack each seal request through the displayed finite BHist packet, and use Definition 38.701 to force every completion-facing or $\mathsf{Real}^{\uparrow}$-facing consumer to factor through that section.

It remains to identify the dyadic and RegSeqRat faces on overlaps. Apply Definition 301.74 to keep common cofinal dyadic refinements on the same endpoint, radius, distance, classifier, regularity, transport, continuation, provenance, and local naming ledger. Then apply Definition 301.75 to recover each of the four faces from the other three inside the same finite route.

Finish by finite induction over the request family. The empty cover gives the empty displayed packet. The adjoining move is exactly Definition 301.89, applied with the packet already built as the glued finite family and with the next accepted saturated member as the outside request. At each step the cited saturation, StreamName gluing, Real fusion, consumer section, dyadic ledger, and window correspondence theorems export only the four displayed faces and their support rows, so quotient stream equality, host real equality, selected limits, ambient or metric completeness, choice data, and a second seal coordinate remain absent. □

Theorem 301.89 (RegSeqRat Real seal finite-cover induction step)**.** *Let* $\mathcal{F}$ *be a finite family of accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *reads that has already been glued to a finite four-face L10 packet. Let* $\mathcal{T}$ *be one further accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read whose public exit is a* $\mathsf{Real}^{\uparrow}$ *seal. Suppose* $\mathcal{T}$ *is saturated by exactly the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

and suppose that its displayed overlap with the glued packet agrees on BHist*, componentwise* hsame*,* Cont*,* Pkg*,* NameCert*, dyadic-ledger, classifier, regularity, and seal rows. Then adjoining* $\mathcal{T}$ *produces one glued finite four-face L10 packet over* $\mathcal{F} \cup \{\mathcal{T}\}$*.*

The enlarged packet has exactly the same four public faces $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and exactly the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. It contains no quotient stream, no host real equality, no selected limit, no ambient or metric-completeness datum, no choice data, and no second seal coordinate.*

Proof. First saturate the outside member. Apply Definition 301.79 to $\mathcal{T}$. This gives a finite L10 route whose only faces are the StreamName request window, DyadicRatCore ledger, RegSeqRat classifier and regularity surface, and the terminal Real seal row.

Next enlarge the request cover. The glued packet over $\mathcal{F}$ already has a StreamName finite request packet, and the overlap hypotheses identify the displayed BHist, hsame, Cont, Pkg, NameCert, dyadic-ledger, classifier, regularity, and seal rows with those of $\mathcal{T}$. Hence Definition 126.562 attaches the outside request to the same finite cover.

Now keep the Real consumer on that finite section. Use Definition 38.698 to express the outside Real seal through the enlarged finite BHist packet, and use Definition 38.701 to keep the completion-facing consumer on that section rather than on an ambient completion or choice row.

It remains to preserve the dyadic and RegSeqRat faces on the shared boundary. Apply Definition 301.74 to carry common cofinal dyadic refinements through the same endpoint, radius, distance, classifier, regularity, transport, continuation, provenance, and local naming ledger. Then apply Definition 301.75 to recover the four-face route from any three of its StreamName, DyadicRatCore, RegSeqRat, and Real windows.

The repacked object is therefore the glued packet over $\mathcal{F} \cup \{\mathcal{T}\}$. Every cited route exports only the four displayed faces and the named support rows, so the excluded quotient stream, host real equality, selected limit, ambient or metric-completeness datum, choice data, and second seal coordinate have no coordinate in the enlarged packet. □

Theorem 301.90 (RegSeqRat Real seal finite-cover associativity)**.** *Let $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ be finite families of accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *reads whose members exit as* $\mathsf{Real}^{\uparrow}$ *seals. Assume that every member is saturated by the same four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

and that every pairwise overlap among the three families satisfies the four-face agreement used in Definition 301.88. Then gluing $\mathcal{A} \cup \mathcal{B}$ first and then gluing with $\mathcal{C}$ displays the same finite four-face L10 packet as gluing $\mathcal{B} \cup \mathcal{C}$ first and then gluing with $\mathcal{A}$.

The common packet has exactly the StreamName schedule and membership face, the DyadicRatCore endpoint, radius, and distance face, the RegSeqRat classifier, regularity, and transport face, and the RealUp seal face, with the same BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. It contains no quotient stream equality, no host real equality, no selected limit, no ambient or metric-completeness datum, no choice data, and no second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Apply Definition 301.88 to $\mathcal{A} \cup \mathcal{B}$ and then to $(\mathcal{A} \cup \mathcal{B}) \cup \mathcal{C}$. Apply the same theorem to $\mathcal{B} \cup \mathcal{C}$ and then to $\mathcal{A} \cup (\mathcal{B} \cup \mathcal{C})$. The overlap hypotheses are exactly the hypotheses of the binary gluing theorem for each of these steps.

For every member used in either parenthesization, apply Definition 301.79. This identifies the member with the same StreamName schedule and membership row, DyadicRatCore endpoint, radius, and distance row, RegSeqRat classifier, regularity, and transport row, and Real seal row.

The only remaining issue is overlap agreement after the intermediate gluing step. Use Definition 301.75 to read any three of the four faces as the same fourth face inside the finite route, and use Definition 301.74 to keep the dyadic and RegSeqRat ledger fixed on common cofinal tails. Thus both intermediate packets present the same finite BHist, hsame, Cont, Pkg, NameCert, endpoint, radius, distance, classifier, regularity, transport, and seal rows on every overlap.

Conclude by finite induction over the members of $\mathcal{C}$ after the first parenthesization, and symmetrically over the members of $\mathcal{A}$ after the second parenthesization. The base case is the already glued binary packet. The adjoining step attaches one saturated member along the overlap rows just identified, so it cannot introduce a new face or a different support row. Hence both parenthesizations expose the same finite BEDC rows and no extra route. □

Theorem 301.91 (RegSeqRat Real seal common-refinement cover completeness)**.** *Let $\{\mathcal{S}_i\}_{i \in I}$ be a finite family of accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *reads whose members exit as* $\mathsf{Real}^{\uparrow}$ *seals. Suppose each $\mathcal{S}_i$ is saturated by exactly the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Suppose further that every finite subfamily $J \subseteq I$ has a certified $\mathsf{StreamName}^{\uparrow}$ *common-refinement packet $\mathcal{R}_J$ whose restrictions to the members of J agree on the dyadic endpoint, radius, distance, and tail ledger rows, on the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, on the* $\mathsf{Real}^{\uparrow}$ *public seal row, and on the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support.*

Then the glued family is covered by one finite four-face pullback surface over the union of the accepted reads. This surface restricts to each $\mathcal{R}_J$ on every finite subfamily and displays only the $\mathsf{StreamName}^{\uparrow}$ *schedule and membership face, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport face, the* $\mathsf{Real}^{\uparrow}$ *seal face, and the listed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. It exports no quotient stream, no host equality, no selected limit, no ambient or metric-completeness datum, no choice data, and no second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Begin with the common-refinement packets. By Definition 126.240, each $\mathcal{R}_J$ exposes only the public StreamName source tuple and forces all downstream $\mathsf{RegSeqRat}^{\uparrow}$ and finite-window $\mathsf{Real}^{\uparrow}$ reads to factor through that tuple.

Next apply Definition 126.405. For every finite subfamily, the StreamName window, RegSeqRat readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row form one finite pullback with exactly the displayed BHist, hsame, Cont, Pkg, and local NameCert support.

Now pass from subfamily pullbacks to the whole finite family. Apply Definition 301.88 to glue the accepted reads along their shared dyadic ledger, classifier, regularity, seal, and support rows. The hypotheses give the overlap agreement required by that gluing theorem because every overlap is the restriction of some $\mathcal{R}_J$.

Finally use Definition 301.90. Reordering or reparenthesizing the finite subfamilies does not change the resulting four-face packet, so the cover obtained from the common-refinement packets is complete for the finite family. The cited results list all exported rows, and none supplies quotient streams, host equality, selected limits, ambient or metric completeness, choice data, or a second Real seal coordinate. □

Theorem 301.92 (RegSeqRat Real seal finite-cover refinement invariance)**.** *Let $\{\mathcal{S}_i\}_{i\in I}$ be a finite family of accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *reads saturated by the four displayed faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Let a second finite family refine it by certified* $\mathsf{StreamName}^{\uparrow}$ *common-refinement packets whose restrictions preserve the dyadic endpoint, radius, distance, and tail ledger rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *public seal row, and the displayed* BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support.*

Then the original finite cover and its finite certified refinement determine the same four-face L10 exit packet: the $\mathsf{StreamName}^{\uparrow}$ *schedule and membership face, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport face, and the* $\mathsf{Real}^{\uparrow}$ *seal face with the listed support rows. The packet contains no quotient stream, no host equality, no selected limit, no choice datum, no ambient or metric-completeness datum, and no second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Apply Definition 301.91 to the original finite family. It gives one finite four-face pullback surface and records agreement of the endpoint, radius, distance, classifier, regularity, seal, and support rows.

Apply Definition 301.88 to the refined finite family. The restriction hypotheses give the overlap rows required by gluing, because each refined member lands in the same StreamName common-refinement packet described by Definition 126.405.

It remains only to compare the packet obtained by first gluing the refined family with the packet obtained by gluing the original family. Use Definition 301.90: finite regrouping and reparenthesizing of saturated members preserves the StreamName, dyadic ledger, RegSeqRat, Real seal, BHist, hsame, Cont, Pkg, and NameCert rows.

Thus the refined and unrefined finite covers expose the same L10 exit packet. The cited theorems also list the absent data, so the comparison cannot add a quotient stream, host equality, selected limit, choice, ambient or metric completeness, or a second Real seal coordinate. □

Theorem 301.93 (RegSeqRat StreamName Dyadic Real audit-clean exit readiness)**.** *For any accepted public L10 exit read of a* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, audit-clean readiness for the Phase Real and Completion quartet is exactly the finite four-face route through the* $\mathsf{StreamName}^{\uparrow}$ *finite schedules, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic endpoint, radius, and distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and transport rows, and the public* $\mathsf{Real}^{\uparrow}$ *seal row.*

The readiness surface contains only the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows for those four faces. It contains no Real completeness theorem, no quotient representative, no host sequence equality, no trichotomy principle, no open-cover compactness object, and no second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Start with Definition 301.69. It routes the accepted public seal read through the StreamName schedule face, the DyadicRatCore ledger face, the RegSeqRat classifier and regularity face, and the public Real seal face while preserving the displayed hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 301.70 and Definition 301.71. The single-source lock prevents a second completion source, and the correspondence identifies the finite source read with the public seal read in both directions. Thus the exit criterion can read only the same finite rows from either side.

Use Definition 301.76 together with Definition 301.79. These results say that all four faces are required and that no fifth face is available to an accepted Phase Real and Completion exit read.

Finally apply Definition 301.88 and Definition 301.90. Finite families of accepted reads glue and reassociate without changing the StreamName, DyadicRatCore, RegSeqRat, or Real seal rows, so audit-clean Lean work should target this finite route. Stronger off-table claims about Real completeness, quotient representatives, host sequence equality, trichotomy, open-cover compactness, or a second Real seal coordinate are not part of the exit-readiness surface. □

Theorem 301.94 (RegSeqRat Real seal terminal-section exhaustion)**.** *Every terminal public* $\mathsf{Real}^{\uparrow}$ *seal section of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier is exhausted by the same finite L10 route through the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The exhausted section consists exactly of the displayed BHist*, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows, together with the StreamName finite-window schedules, the DyadicRatCore endpoint, radius, and distance ledgers, the RegSeqRat classifier, regularity, and transport rows, and the public Real seal row.*

No terminal section produced by this route contains a Real completeness theorem, quotient representative, host equality, trichotomy principle, open-cover compactness datum, choice datum, or second seal coordinate.

Proof. Begin with Definition 301.69. It presents the accepted carrier's public seal read as a finite passage from StreamName finite-window schedules through DyadicRatCore ledgers and RegSeqRat classifier data to the public Real seal row.

Next use Definition 301.71. The source side and the terminal seal side expose the same displayed section, so a terminal $\mathsf{Real}^{\uparrow}$ seal section cannot carry rows absent from the finite source route.

Apply Definition 301.76 and Definition 301.79. Necessity gives the four required faces, and saturation says the accepted exit read has no fifth face beyond $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

For finite terminal sections, apply Definition 301.88 and Definition 301.90. Gluing turns overlapping accepted seal reads into one finite packet over the displayed support rows, and associativity shows that the packet is independent of the order in which those finite pieces are attached.

Finally apply Definition 301.93. Its negative boundary is exactly the asserted terminal boundary: no Real completeness theorem, quotient representative, host equality, trichotomy principle, open-cover compactness datum, choice datum, or second seal coordinate is part of the terminal public section. Hence every terminal section is exhausted by the finite four-face route and by no additional BEDC row. □

Theorem 301.95 (RegSeqRat terminal descent uniqueness)**.** *Let S and T be terminal public* $\mathsf{Real}^{\uparrow}$ *seal sections of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carriers. Suppose S and T display the same four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

the same displayed BHist *rows, and the same componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *support rows. Then S and T are the same terminal finite L10 section.*

Equivalently, descent along the RegSeqRat terminal route is unique at the public $\mathsf{Real}^{\uparrow}$ *seal: the displayed StreamName schedules, DyadicRatCore ledgers, RegSeqRat classifier and regularity rows, and public Real seal row determine one terminal section and admit no quotient stream, host sequence equality, selected limit, ambient completeness witness, choice datum, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First apply Definition 301.94 to both S and T. Each terminal public $\mathsf{Real}^{\uparrow}$ seal section is exhausted by the same finite L10 route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with no extra BEDC row beyond the displayed support.

Next apply Definition 301.90. The finite pieces of the two sections may be regrouped without changing any displayed face or support row, so the comparison is independent of the order in which StreamName, DyadicRatCore, RegSeqRat, and Real seal pieces are attached.

Use Definition 301.91. The two exhausted finite covers have a common accepted refinement, and the hypothesis identifies every displayed BHist, hsame, Cont, Pkg, and local NameCert row on that refinement. Thus both terminal reads descend to the same finite packet.

Finally apply Definition 301.93. The audit-clean boundary refuses quotient streams, host sequence equality, selected limits, ambient completeness, choice data, and any second $\mathsf{Real}^{\uparrow}$ seal coordinate. Since no off-route datum remains available to separate S from T, the common refined packet is the unique terminal finite L10 section determined by the four displayed faces. □

Theorem 301.96 (RegSeqRat Real seal terminal-section observation lock)**.** *For every terminal public* $\mathsf{Real}^{\uparrow}$ *seal section of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, the exhausted four-face section determines exactly the same finite* $\mathsf{StreamName}^{\uparrow}$ *observation interface named by Definition 126.316.*

Every readback of that terminal section preserves the $\mathsf{StreamName}^{\uparrow}$ *finite-window carrier and classifier rows, the* ProbeBundle *and* InBundle *membership rows, UnaryHistory observations, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and the public* $\mathsf{Real}^{\uparrow}$ *seal row. It cannot add a quotient stream, host equality, selected limit, ambient completeness witness, trichotomy principle, open-cover compactness datum, choice datum, or second seal coordinate.*

Proof. First apply Definition 301.94. It identifies a terminal public $\mathsf{Real}^{\uparrow}$ seal section with the finite route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and it excludes every row outside that route.

Next combine this exhaustion with Definition 301.79. Saturation locks the four displayed faces as the whole accepted section, so a readback cannot replace the StreamName face or attach another completion-facing coordinate.

Use Definition 126.316 to identify the first face. That theorem supplies exactly the finite-window carrier, classifier, bundle-membership, and UnaryHistory observation interface consumed by the Real seal boundary.

Finally apply Definition 301.93 and Definition 38.684. They keep the Real-facing read on the same L10 lattice route through the DyadicRatCore ledger, the RegSeqRat classifier and regularity rows, and the public Real seal row. Thus terminal readback preserves the finite StreamName observation interface and introduces none of the off-route data listed in the statement. □

Theorem 301.97 (RegSeqRat StreamName open-phase Real exit correspondence)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, a terminal public* $\mathsf{Real}^{\uparrow}$ *seal section is an open-phase Phase Real and Completion exit boundary exactly when it exposes the same four finite faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

On this correspondence the StreamName face is the finite observation boundary locked by Definition 301.96, and the remaining faces are the DyadicRatCore ledger, the RegSeqRat classifier and regularity rows, and the public Real seal row named by Definition 301.94. The correspondence contains no quotient stream, no host sequence equality, no selected limit, no ambient $\mathsf{Real}^{\uparrow}$ *completeness row, no metric-completeness datum, no countable-choice row, and no second seal coordinate.*

Proof. For the forward direction, start with Definition 301.94. It exhausts a terminal public $\mathsf{Real}^{\uparrow}$ seal section by the four finite faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the displayed history, sameness, continuity, package, and local certificate rows. Then apply Definition 301.96 to fix the StreamName face as the finite observation interface, and use Definition 126.451 to read that same packet as sufficient for the current Phase Real and Completion boundary.

For the reverse direction, use Definition 126.450. Any open-phase Phase Real and Completion exit boundary with the four displayed faces reads back through exactly those support rows. Combine this with Definition 301.79 to identify the readback with a saturated terminal public Real seal section, and then apply Definition 301.93 to preserve the negative boundary. Hence the two descriptions name the same finite section and exclude quotient streams, host sequence equality, selected limits, ambient completeness, metric-completeness data, countable choice, and second seal coordinates. □

Theorem 301.98 (StreamName RegSeqRat Real observation interface)**.** *For any accepted public L10 exit read of a* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *finite-window seal boundary of Definition 126.316 is exactly the input face of the four-face route through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *recorded by Definition 301.79 and Definition 301.93. Thus the public observation interface consumed by the RegSeqRat-to-Real exit is the finite StreamName window package: the* RatStreamNameCarrier *and* RatStreamNameClassifier *rows, finite-window classifier rows, endpoint readbacks in* $\mathsf{Rat}^{\uparrow}$*, empty-window boundary, and constant/reindexing stability rows.*

This identification introduces no quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Begin with the StreamName boundary theorem, Definition 126.316. It names exactly the finite observation rows exposed by the $\mathsf{StreamName}^{\uparrow}$ public interface and states that those rows are available to later $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}$ seal sites without carrying regularity or completion data.

Next apply the RegSeqRat handoff exactness theorem, Definition 301.69. The handoff uses the same finite StreamName schedules as its first face before it reads the DyadicRatCore ledger, the RegSeqRat classifier and regularity rows, and the public Real seal row.

The four-face necessity and saturation results, Definition 301.76 and Definition 301.79, then force that first face to be precisely the public finite-window observation interface. A different StreamName input would either omit a required face or add a fifth face, both excluded by the saturated finite route.

Finally use the Real sibling lattice summary, Definition 38.684, together with the audit-clean exit readiness theorem Definition 301.93. They place the Real-facing exit on the same horizontal lattice edge and preserve the negative boundary: no quotient stream, host real equality, selected limit, ambient completeness witness, choice datum, or second $\mathsf{Real}^{\uparrow}$ seal coordinate is introduced. □

Theorem 301.99 (RegSeqRat Dyadic StreamName Real public seal non-escape)**.** *Every accepted public L10 exit read whose four visible faces are the* $\mathsf{StreamName}^{\uparrow}$ *finite observation interface, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and the* $\mathsf{Real}^{\uparrow}$ *public seal is exhausted by those four faces together with the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Consequently the route exports no quotient stream, host real equality, selected limit, ambient completeness witness, trichotomy branch, open-cover compactness datum, choice datum, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate. Any consumer requesting one of those data is no longer reading the public seal through the displayed L10 exit route.*

Proof. First identify the input face by Definition 301.98. The theorem fixes the StreamName side as the finite-window observation package used by the RegSeqRat-to-Real exit, rather than a quotient stream or a host-level equality of sequences.

Next apply Definition 301.79. The saturation result says that the terminal public Real seal read has exactly the StreamName observation face, the DyadicRatCore ledger face, the RegSeqRat classifier and regularity face, and the Real seal face, carrying only the displayed history, sameness, continuity, package, and local certificate rows.

Use Definition 301.93 to preserve the negative boundary through the exit audit. It rules out the off-route completion and choice data at the same public read, so no selected limit, ambient completeness witness, trichotomy branch, open-cover compactness datum, or choice datum is supplied by the exit.

Finally locate the read on the sibling lattice route by Definition 38.684. Since the lattice edge has the same four faces and the same displayed provenance rows, finite route exhaustion leaves no coordinate for a second public seal or for any of the off-route data listed above. □

Theorem 301.100 (RegSeqRat four-face finite-observation completeness)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *Phase Real and Completion exit read, admission to the public L10 exit surface is equivalent to finite observation data exposing exactly the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

On the forward reading, the accepted exit read presents the finite $\mathsf{StreamName}^{\uparrow}$ *observation interface, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and the public* $\mathsf{Real}^{\uparrow}$ *seal. On the reverse reading, any finite observation packet with exactly those four faces and displayed rows is admitted as the same RegSeqRat-to-Real public exit read.*

The complete four-face surface exports no quotient stream, selected limit, host equality, countable-choice row, ambient completeness row, metric-completeness row, or standard bridge row.

Proof. For the forward direction, apply Definition 301.97. It identifies an accepted terminal public Real seal section with the open Phase Real and Completion boundary whose visible support is precisely the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the displayed history, sameness, continuity, package, and certificate rows.

Next use Definition 301.98. This pins the first face to the finite $\mathsf{StreamName}^{\uparrow}$ window data consumed by the RegSeqRat-to-Real route, so the accepted read is described by finite observation data rather than by a quotient stream or a host-level equality.

For the reverse direction, start again from the correspondence theorem and read the same finite packet back as a Phase Real and Completion exit boundary. Then apply Definition 301.93 to place the packet on the audit-clean L10 route through the DyadicRatCore ledger, the RegSeqRat classifier and regularity rows, and the public Real seal row.

Finally apply Definition 301.99. Since the public seal is exhausted by the four displayed faces and provenance rows, no coordinate remains for a quotient stream, selected limit, host equality, countable-choice row, ambient completeness row, metric-completeness row, or standard bridge row. Thus the admitted exit reads are exactly the finite four-face observation packets described in the statement. □

Theorem 301.101 (RegSeqRat four-face status locality)**.** *Let* $\mathcal{E}$ *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *Phase Real and Completion exit read through the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Let F *be one of these four faces, and form* $\mathcal{E}_F^+$ *by replacing only one face-local* formalstatus*,* leantarget*, or* bridgestatus *row attached to* F *by a stronger row attached to the same face.*

Assume that the other three face records and the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows are unchanged. Then* $\mathcal{E}_F^+$ *presents the same finite four-face observation packet as* $\mathcal{E}$*: the StreamName finite observation face, the DyadicRatCore ledger face, the RegSeqRat classifier and regularity face, and the public Real seal face.*

This preservation introduces no aggregate route-level status row, quotient stream, selected limit, countable-choice row, metric-completeness datum, ambient $\mathsf{Real}^{\uparrow}$ *completeness row, or second seal coordinate.*

Proof. First apply Definition 301.100. It identifies acceptance of $\mathcal{E}$ with a finite observation packet whose visible content is exactly the four displayed faces and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 301.93. The audit-clean route reads the same StreamName, DyadicRatCore, RegSeqRat, and Real faces and exports no off-route completion datum. Since the replacement is attached to the same face F and leaves the other face records and support rows fixed, the audit-clean route still reads the same four-face packet.

Apply Definition 126.426. The StreamName-side terminal theorem supplies the local rule for strengthening a formalstatus, leantarget, or bridgestatus row: the strengthened row remains a face-local row and does not become a route-level aggregate credential.

Finally apply Definition 38.815. The Real terminal locality theorem keeps every status, Lean-target, and bridge coordinate attached to one of the four local faces rather than to the route as a whole. Hence $\mathcal{E}_F^+$ has the same finite observation packet as $\mathcal{E}$, and none of the excluded quotient, limit, choice, completeness, aggregate-status, or second-seal data is introduced. □

Theorem 301.102 (RegSeqRat Real seal support-removal obstruction)**.** *Let P be an accepted public* $\mathsf{RegSeqRat}^{\uparrow}$ *read whose public exit is a* $\mathsf{Real}^{\uparrow}$ *seal through the L10 route displayed by Definition 301.69. Remove from that route any one of the four displayed faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

or remove any displayed support row among the BHist *route rows, componentwise* hsame *rows,* Cont *rows,* Pkg *provenance rows, or local* NameCert *rows. Then the remaining data do not form a valid public* $\mathsf{Real}^{\uparrow}$ *seal route for P.*

No quotient stream, host real equality, selected limit, ambient or metric-completeness datum, choice datum, aggregate formalstatus *row, aggregate bridge row, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate compensates for the missing face or support row.*

Proof. First remove one displayed face. By Definition 301.73, every valid public seal consumer for the accepted read passes through the StreamName schedule face, the DyadicRatCore endpoint and radius face, the RegSeqRat classifier and regularity face, and the Real seal face. Omitting any one of these four surfaces therefore places the attempted consumer outside the displayed public route.

Next remove a displayed support row. Apply Definition 301.69 to identify the route as one finite BEDC handoff, with the visible BHist rows, componentwise hsame rows, Cont rows, Pkg provenance rows, and local NameCert rows carrying the same accepted read from source schedules to the terminal seal. Without one of those support rows, the four faces no longer sit in a single certified handoff route for P.

It remains to rule out replacement data. The finite-cover results Definition 301.88, Definition 301.89, and Definition 301.90 keep all glued and regrouped public seal packets inside the same four displayed faces and the same BHist, hsame, Cont, Pkg, and NameCert support rows. Their exclusion clauses leave no coordinate for quotient streams, host real equality, selected limits, ambient or metric completeness, choice data, aggregate formalstatus rows, aggregate bridge rows, or second seal coordinates. Thus none of these objects can repair the missing displayed face or support row, and no valid public $\mathsf{Real}^{\uparrow}$ seal route remains. □

Theorem 301.103 (RegSeqRat L10 source lattice pointer)**.** *Every accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier consumes the finite observation schedules of* $\mathsf{StreamName}^{\uparrow}$ *from chapter 126 and the endpoint and radius ledgers of* $\mathsf{DyadicRatCore}^{\uparrow}$ *from chapter 291 before it can be consumed by the* $\mathsf{Real}^{\uparrow}$ *seal surface of chapter 38. The source lattice is therefore the visible route*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{Real}^{\uparrow}.$$

Along this route the accepted packet carries only scheduled finite stream windows, dyadic endpoint rows, dyadic radius rows, finite dyadic-distance ledgers, regularity ledgers, classifier rows, hsame *comparisons, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It does not expose quotient streams, host real equality, selected limits, ambient completeness, or a hidden completion carrier.*

Proof. Start from the carrier definition in Definition 301.1. Its stored coordinates are the scheduled finite windows supplied by $\mathsf{StreamName}^{\uparrow}$ together with the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius rows attached to those windows.

Next read the classifier in Definition 301.2. The classifier adds only finite dyadic-tolerance rows over the same scheduled observations: endpoint rows, radius rows, finite distance ledgers, regularity rows, and the displayed provenance needed to transport them.

The exact handoff theorem Definition 301.69 identifies the complete route from the stream-name schedule and dyadic ledgers through the $\mathsf{RegSeqRat}^{\uparrow}$ classifier to the $\mathsf{Real}^{\uparrow}$ seal rows. Applying Definition 301.22 then shows that a seal consumer reads this regular-rational source surface itself.

Since all cited surfaces are finite BEDC rows, no quotient stream, host real equality, selected limit, ambient completeness datum, or hidden completion carrier can be consumed along the route. □

Theorem 301.104 (RegSeqRat L10 source lattice exhaustion)**.** *Every accepted* $\mathsf{RegSeqRat}^{\uparrow}$*-to-*$\mathsf{Real}^{\uparrow}$ *seal read on the L10 route has exactly four row owners.* $\mathsf{StreamName}^{\uparrow}$ *owns the finite observation schedules,* $\mathsf{DyadicRatCore}^{\uparrow}$ *owns endpoint rows, radius rows, and finite dyadic-distance ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *owns regularity rows and classifier rows, and* $\mathsf{Real}^{\uparrow}$ *owns the terminal seal row. The accepted handoff has no row supplied by a quotient stream, host real equality, selected limit, completion witness, or ambient completeness principle.*

Proof. Start with the source lattice pointer, Definition 301.103. It fixes the route as $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ and lists the visible source rows before the seal can be read.

Apply the exact handoff theorem, Definition 301.69. It identifies the StreamName schedules, dyadic endpoint and radius ledgers, finite dyadic-distance ledgers, regularity rows, classifier rows, and seal rows as one finite handoff rather than as separate ambient services.

Finally use the Real seal handoff rows. They make the $\mathsf{Real}^{\uparrow}$ seal the terminal row of the same route, so the ownership list is exhausted by the four displayed chapters and cannot be enlarged by quotient streams, host equality, selected limits, completion witnesses, or ambient completeness. □

Theorem 301.105 (RegSeqRat StreamName Real handoff exhaustion)**.** *Every accepted L10 handoff that starts from* $\mathsf{StreamName}^{\uparrow}$ *schedules and is admitted to the* $\mathsf{Real}^{\uparrow}$ *seal through* $\mathsf{RegSeqRat}^{\uparrow}$ *is exhausted by exactly four row owners.* $\mathsf{StreamName}^{\uparrow}$ *owns the finite stream schedules,* $\mathsf{DyadicRatCore}^{\uparrow}$ *owns the dyadic endpoint and radius rows together with finite dyadic-distance ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *owns the regularity and classifier rows, and* $\mathsf{Real}^{\uparrow}$ *owns the terminal seal row. The handoff has no row owned by a quotient stream, host real equality, selected limit, completion witness, ambient completeness principle, or choice datum.*

Proof. Begin with the source lattice pointer and source lattice exhaustion, Definition 301.103 and Definition 301.104. Together they identify the visible L10 route

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{Real}^{\uparrow}$$

and assign the finite schedule, dyadic, regularity, classifier, and seal rows to the four displayed owners.

Apply the exact StreamName–dyadic–Real handoff theorem, Definition 301.69. It keeps the scheduled StreamName windows, dyadic endpoint and radius rows, finite dyadic-distance ledgers, RegSeqRat regularity rows, classifier rows, and Real seal row in one finite handoff rather than in separate ambient services.

The Lean-facing touchpoints are `RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff`, `DyadicRatCoreCarrier_regseqrat_bridge_handoff_exactness`, and `RegSeqRatStreamCarrier_real_seal_ha` They are precisely the schedule, dyadic bridge, and Real seal pieces named by the paper route.

Since the two lattice theorems already exclude quotient streams, host real equality, selected limits, completion witnesses, and ambient completeness, and since the exact handoff introduces no

extra owner, adding a choice datum or any other off-route owner would require a row absent from the displayed packet. □

Theorem 301.106 (RegSeqRat L10 row owner noncollapse)**.** *Every accepted L10 handoff from* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *through* $\mathsf{RegSeqRat}^{\uparrow}$ *to the public* $\mathsf{Real}^{\uparrow}$ *seal has four pairwise noncollapsible row owners. The schedule rows belong to* $\mathsf{StreamName}^{\uparrow}$*; the endpoint, radius, and finite dyadic-distance ledgers belong to* $\mathsf{DyadicRatCore}^{\uparrow}$*; the regularity, classifier, and transport rows belong to* $\mathsf{RegSeqRat}^{\uparrow}$*; and the terminal seal row belongs to* $\mathsf{Real}^{\uparrow}$*.*

Removing any owner, or identifying any owner with another, breaks the accepted finite route or introduces one of the excluded coordinates: quotient streams, host real equality, selected limits, completion witnesses, ambient completeness data, or choice data.

Proof. The source lattice pointer Definition 301.103 fixes the visible route from $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ through $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$. The source lattice exhaustion theorem Definition 301.104 assigns the route rows to exactly these four owners and excludes off-route owners.

The exact StreamName–dyadic–Real handoff Definition 301.69 then reads the schedule rows, dyadic endpoint and radius rows, dyadic-distance ledgers, regularity rows, classifier rows, transport rows, and public seal row as one finite route. Thus the four owners are not alternative names for one store: each contributes a different face of the displayed packet.

Apply the four-face necessity theorem Definition 301.76. If the schedule owner is removed, there is no finite source index; if the dyadic owner is removed, there are no endpoint, radius, or distance ledgers; if the RegSeqRat owner is removed, the classifier and regularity rows disappear; and if the Real owner is removed, the public seal has no terminal row. Identifying any two owners therefore erases one of these required faces rather than preserving the same accepted route.

Finally use finite-window saturation, Definition 301.79. It says that the accepted Real seal exit is already saturated by the four displayed finite faces. A collapse of owners can only be repaired by importing an off-route coordinate, and those coordinates are precisely the quotient streams, host real equality, selected limits, completion witnesses, ambient completeness data, and choice data excluded by the handoff. □

Theorem 301.107 (RegSeqRat L10 owner touchpoint coverage)**.** *On the L10 route from* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *through* $\mathsf{RegSeqRat}^{\uparrow}$ *to the public* $\mathsf{Real}^{\uparrow}$ *seal, the Lean-facing handoff touchpoints* `RatStreamNameFiniteWindowClassifier_singleton_diagonal_handoff`*,* `DyadicRatCoreCarrier_regse` *and* `RegSeqRatStreamCarrier_real_seal_handoff` *cover exactly the finite StreamName schedule rows, the DyadicRatCore endpoint, radius, and finite dyadic-distance rows, the RegSeqRat regularity and classifier rows, and the RealUp terminal seal row.*

They do not supply quotient streams, host equality, selected limits, ambient completeness, choice data, standard bridge data, or any upgrade of the verification axis.

Proof. The source lattice pointer Definition 301.103 fixes the public route as

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{Real}^{\uparrow}.$$

It lists the finite schedules, dyadic rows, regularity rows, classifier rows, and seal rows as the visible packet consumed by the handoff.

The StreamName–Real handoff exhaustion theorem Definition 301.105 identifies the same packet as exhausted by the four row owners. The row-owner noncollapse theorem Definition 301.106 then prevents any two owners from being read as alternative names for the same source.

The three Lean-facing touchpoints are the schedule component, the dyadic bridge component, and the terminal seal component of this packet. The StreamName touchpoint supplies the finite

schedule rows, the DyadicRatCore touchpoint supplies endpoint, radius, and finite dyadic-distance rows, and the RegSeqRat-to-Real touchpoint supplies the regularity, classifier, and terminal seal passage read by the public seal.

The roadmap discipline keeps the theory and verification axes separate. Thus these touchpoints report the Lean-facing handoff surface for the four-owner route, but they do not create quotient streams, host equality, selected limits, ambient completeness, choice data, standard bridges, or any stronger verification-axis status. □

Theorem 301.108 (RegSeqRat L10 face-order initiality)**.** *Every accepted L10 handoff from* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *through* $\mathsf{RegSeqRat}^{\uparrow}$ *to the public* $\mathsf{Real}^{\uparrow}$ *seal reads the four faces in the initial order*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{RegSeqRat}^{\uparrow},\ \mathsf{Real}^{\uparrow}.$$

The finite stream schedules are read first, the dyadic endpoint, radius, and distance ledger is read second, the $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows are read third, and the public* $\mathsf{Real}^{\uparrow}$ *seal row is read last.*

Permuting any face, deleting any face, or inserting a fifth face fails to be an accepted read by a $\mathsf{Real}^{\uparrow}$ *seal consumer. The only possible repairs would introduce one of the excluded coordinates: quotient streams, host real equality, selected limits, completion witnesses, ambient completeness data, choice data, bridge rows, or verification-axis upgrades.*

Proof. The source lattice pointer Definition 301.103 fixes the public route from $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ through $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$. The route already places the finite stream schedules before the dyadic ledger, the dyadic ledger before the regularity and classifier rows, and those rows before the terminal seal.

The source lattice exhaustion theorem Definition 301.104 says that the accepted route has exactly the four displayed owners. Thus an order change cannot be explained by appealing to a hidden owner between two faces or behind the seal.

Apply row-owner noncollapse, Definition 301.106. A permutation would make a later row available before its source face is present; a deletion would erase a required owner; and an insertion would require an additional owner. Each case breaks the finite route rather than producing the same accepted handoff.

Finally use owner touchpoint coverage, Definition 301.107. The Lean-facing rows seen by the seal consumer are exactly the schedule rows, the dyadic bridge rows, the regularity and classifier rows, and the terminal seal row. Any consumer that attempts another order must import quotient streams, host real equality, selected limits, completion witnesses, ambient completeness data, choice data, bridge rows outside the handoff, or a verification-axis upgrade, all of which are outside the accepted L10 packet. □

Theorem 301.109 (RegSeqRat tail-budget meet handoff)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier and let a tail-budget consumer of P request a completion-facing read. The consumer first meets the displayed* $\mathsf{StreamName}^{\uparrow}$ *pointwise schedule from chapter 126, then reads the matching* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance row from chapter 291, then passes through the regular-rational classifier rows of P, and only then reaches the* $\mathsf{Real}^{\uparrow}$ *seal row of chapter 38. Thus every tail-budget read factors through one regular-Cauchy route before any completion-facing surface is visible.*

Proof. Start with the L10 source lattice pointer of Definition 301.103. It places the accepted regular-rational packet on the displayed route $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{Real}^{\uparrow}$.

Next apply the common dyadic tail ledger of Definition 301.74. A tail-budget consumer must read the cofinal finite ledger consisting of the stream schedule, dyadic endpoint and radius rows, distance rows, regularity rows, classifier rows, transport rows, continuation routes, provenance, and local naming.

Finally use the exact handoff of Definition 301.69. The completion-facing read is therefore downstream of the same finite regular-Cauchy route and cannot bypass the StreamName schedule, the DyadicRatCore tolerance row, or the RealUp seal row. □

Theorem 301.110 (RegSeqRat StreamName dyadic source lock)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, the displayed* $\mathsf{StreamName}^{\uparrow}$ *pointwise name and the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row are locked to the same finite source. Any two consumers that present the same tail budget, the same stream schedule row, and the same dyadic endpoint and radius ledger must read the same regular-rational classifier route before reaching a* $\mathsf{Real}^{\uparrow}$ *seal. No separate quotient stream, host real equality, selected limit, ambient completion datum, or second dyadic source can be inserted between those reads.*

Proof. Use Definition 301.70. It identifies public seal reads through displayed StreamName schedules and DyadicRatCore ledgers as reads of one finite source route.

Then apply Definition 301.103. The source route already contains the schedule rows, endpoint rows, radius rows, distance rows, classifier rows, regularity rows, hsame transports, Cont routes, Pkg provenance, and local NameCert rows.

The same route is the input to the RealUp handoff by Definition 301.22. Since the carrier exposes no row for the excluded quotient, host equality, selected limit, completion datum, or second dyadic source, the two consumers remain locked to the displayed StreamName and DyadicRatCore source. □

Theorem 301.111 (RegSeqRat Real seal consumer factorization)**.** *Every completion-facing* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet factors through the three visible rows named by the regular-Cauchy route: the* $\mathsf{StreamName}^{\uparrow}$ *pointwise schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, and the* $\mathsf{Real}^{\uparrow}$ *seal row that consumes the regular-rational classifier surface. The factorization preserves the displayed* hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *row, and it has no route to a hidden completion carrier or an ambient completeness principle.*

Proof. Apply Definition 301.109. It orders every tail-budget read through StreamName, DyadicRatCore, RegSeqRat, and RealUp before any completion-facing surface is visible.

Apply Definition 301.110. The StreamName schedule and DyadicRatCore tolerance row cannot be separated into two sources once the accepted regular-rational packet is fixed.

Finally use Definition 301.50. The public RealUp consumer is determined by the finite regular-rational source surface and its displayed transport, continuation, package, and naming rows. Thus the consumer factorization is exactly the regular-Cauchy route stated above, with no hidden completion or ambient completeness read. □

Theorem 301.112 (RegSeqRat tail-budget Real seal nonescape)**.** *A completion-facing* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet cannot bypass the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface, or the displayed* $\mathsf{Real}^{\uparrow}$ *seal row at the tail-budget boundary. Every such consumer factors through the same regular-Cauchy route with its displayed* hsame, Cont, Pkg, *and local* NameCert *rows.*

The boundary has no hidden completion carrier, selected limit, quotient stream, ambient completeness principle, or second dyadic source.

Proof. Apply Definition 301.109. It orders the completion-facing read through the StreamName schedule, DyadicRatCore tolerance row, RegSeqRat classifier rows, and RealUp seal row before any completion-facing surface is visible.

Next apply Definition 301.110. The stream schedule and dyadic tolerance row are locked to one finite source attached to the accepted regular-rational packet.

Finally use Definition 301.111. It identifies the completion-facing consumer with the displayed regular-Cauchy route and its transport, continuation, package, and naming rows. Since that route has no coordinate for a hidden completion carrier, selected limit, quotient stream, ambient completeness principle, or second dyadic source, the consumer cannot escape the stated boundary. □

Theorem 301.113 (RegSeqRat tail-budget window-seal pullback)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let R be any completion-facing tail-budget consumer of P. The visible pullback of R along the public* $\mathsf{Real}^{\uparrow}$ *seal is exactly the finite packet consisting of the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance row, and the local* NameCert *row.*

Consequently every completion-facing tail-budget read reaches $\mathsf{Real}^{\uparrow}$ *only through that same finite* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *route. The pullback exposes no quotient stream, selected host limit, ambient completeness carrier, second dyadic source, or additional Real seal coordinate.*

Proof. Begin with Definition 301.109. It orders the consumer route through the displayed StreamName schedule row, DyadicRatCore tolerance ledger, RegSeqRat classifier surface, and RealUp seal before any completion-facing read is visible.

Next apply Definition 301.110. The schedule row and dyadic endpoint, radius, and distance rows are locked to one finite source attached to the accepted packet. Thus the pullback cannot split into a second dyadic source or a quotient stream route.

Now use Definition 301.111. The RealUp consumer factors through the same finite packet, preserving the displayed hsame transports, Cont routes, Pkg provenance, and local NameCert row.

Finally apply Definition 301.112. The nonescape boundary removes the remaining excluded coordinates: selected host limits, ambient completeness carriers, and additional Real seal coordinates. Hence the visible pullback is precisely the stated finite route. □

Theorem 301.114 (RegSeqRat tail-budget terminal Real seal)**.** *Every completion-facing tail-budget consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet reaches* $\mathsf{Real}^{\uparrow}$ *only through the single finite route consisting of the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance row, local* NameCert *naming, and the public* $\mathsf{Real}^{\uparrow}$ *seal row. This terminal surface exports no quotient stream, selected host limit, ambient completeness carrier, choice data, or second seal coordinate.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatTailBudgetTerminalRealSeal`

Proof. First build the tail-budget route. Apply Definition 301.109 to force the completion-facing read through the displayed StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier surface, and RealUp seal.

Next lock the source rows. By Definition 301.110, the schedule row and the endpoint, radius, and distance ledger belong to one finite source attached to the accepted packet, so a quotient stream or second dyadic source cannot enter.

Now identify the public consumer surface. Use Definition 301.111 to preserve the displayed hsame transports, Cont routes, Pkg provenance, and local NameCert row on the way to the public RealUp seal.

Finally combine Definition 301.112 with Definition 301.113. These rows remove selected host limits, ambient completeness carriers, choice data, hidden completion coordinates, and additional Real seal coordinates, leaving exactly the finite route stated above. □

Theorem 301.115 (RegSeqRat tail-budget composition correspondence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Suppose two completion-facing tail-budget consumer routes of P are composable and suppose a certified composite consumer route is displayed for their two-step read. The two-step read and the certified composite determine the same finite terminal* $\mathsf{Real}^{\uparrow}$ *seal surface exactly when they preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

No quotient stream, selected host limit, countable choice datum, ambient completeness carrier, metric-completeness row, or second seal coordinate is part of this correspondence.

Proof. First put the component consumers on the common route. Apply Definition 301.109 to both component routes, so each read is displayed on the four-face path through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next compare the two finite-window presentations. The shared-window reindex composition law of Definition 301.162 identifies the two-step presentation with the certified composite exactly on the displayed StreamName schedule and DyadicRatCore ledger rows.

Now pull the Real seal read back along that finite window. Use Definition 301.113 to preserve the RegSeqRat classifier and regularity rows together with the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Finally apply Definition 301.114. The terminal seal surface is therefore the same for the two-step route and the certified composite. The nonescape theorem Definition 301.112 removes quotient streams, selected host limits, countable choice data, ambient and metric completeness rows, and second seal coordinates from the comparison. □

Theorem 301.116 (RegSeqRat dyadic-stream tail-budget common refinement)**.** *Let P and Q be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget presentations whose* $\mathsf{StreamName}^{\uparrow}$ *schedules and* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers admit a displayed common finite window. The two presentations determine the same terminal* $\mathsf{Real}^{\uparrow}$ *seal surface exactly when that common window preserves the* $\mathsf{StreamName}^{\uparrow}$ *pointwise classifier, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius handoff, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, and the* $\mathsf{Real}^{\uparrow}$ *source factorization rows.*

The common-refinement certificate is only this finite BEDC route through BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It contains no quotient stream, selected host limit, countable choice datum, ambient completeness carrier, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First view the two accepted presentations as composable tail-budget consumer routes through the displayed four-face path. Apply Definition 301.115; it reduces agreement of the terminal $\mathsf{Real}^{\uparrow}$ seal surface to preservation of the StreamName schedule row, DyadicRatCore ledger rows, RegSeqRat classifier and regularity rows, the terminal RealUp seal row, and the displayed support rows.

Next identify the common finite window. The shared-window reindex composition law of Definition 301.162 supplies the finite comparison of the two StreamName schedules and DyadicRatCore

ledgers. The pullback theorem Definition 301.113 transports the RegSeqRat classifier rows and the Real-facing support rows along that window.

Finally apply Definition 301.114. The terminal seal row is therefore determined by exactly the four preserved surfaces named in the statement. The later Lean route is represented by `BEDC.Derived.RegSeqRatUp.RegSeqRatStreamCarrier_common_refinement_classifier_determinacy`, `BEDC.Derived.DyadicRatCoreUp.DyadicRatCoreRegSeqRatWindow_radius_handoff`, `BEDC.Derived.StreamNa` and `BEDC.Derived.RealUp.RealNameSeal_source_factorization`; no Lean marker is asserted here. □

Theorem 301.117 (RegSeqRat finite tail-budget family common refinement)**.** *Let F be a finite family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget presentations. Suppose the* $\mathsf{StreamName}^{\uparrow}$ *schedules and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers for every pair of members of F admit displayed common finite windows. Then F determines one terminal* $\mathsf{Real}^{\uparrow}$ *seal surface exactly when the common finite refinement preserves, for every member of F, the* $\mathsf{StreamName}^{\uparrow}$ *pointwise classifier, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius handoff, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *source factorization rows, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

The finite-family certificate is only the common BEDC refinement route. It contains no quotient stream, selected host limit, countable choice datum, ambient completeness carrier, metric-completeness row, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Induct on the finite family F. For the empty and singleton families, the claimed terminal seal surface is the displayed accepted presentation itself, and the listed support rows are exactly the rows already carried by its tail-budget certificate.

For the induction step, separate the last accepted presentation from the refined family already produced by the induction hypothesis. The pairwise window assumptions give common finite windows between the last presentation and each member of the refined family, while the induction hypothesis supplies the already preserved StreamName classifiers, DyadicRatCore radius handoffs, RegSeqRat classifier and regularity rows, RealUp source factorization rows, and displayed support.

Apply Definition 301.115 to the refined family route and the last presentation. This is the binary step: it keeps the terminal $\mathsf{Real}^{\uparrow}$ seal read on the same four-face path and records that no extra route data is introduced by composing the two tail-budget certificates.

Next use Definition 291.93. It identifies the nested $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance handoffs across the finite chain of common windows, so the composite window is coherent with the earlier dyadic radius handoff rows.

Finally apply Definition 301.116 to compare the terminal seal surface of the composite refinement with the seal surface of each accepted family member. The forward direction reads preservation of the listed rows from the common finite refinement; the reverse direction repacks those preserved rows into the same terminal $\mathsf{Real}^{\uparrow}$ seal surface.

The nonescape clauses remain facewise throughout the induction. Since every step uses only the displayed BHist, hsame, Cont, Pkg, and NameCert support, the finite-family route has no quotient streams, selected host limits, countable choice data, ambient or metric-completeness rows, or second $\mathsf{Real}^{\uparrow}$ seal coordinates. □

Theorem 301.118 (RegSeqRat tail-refinement handoff)**.** *Let F be a finite family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget windows with a common refinement in the sense of Definition 301.117. Then every completion-facing consumer receives the same* $\mathsf{Real}^{\uparrow}$ *seal handoff after the StreamName window transport and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance comparison have been displayed. The*

handoff preserves the $\mathsf{StreamName}^{\uparrow}$ *schedule classifier,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and displayed* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support.*

The handoff exports no quotient stream equality, selected host limit, countable-choice row, ambient completeness carrier, metric-completeness row, duplicate $\mathsf{Real}^{\uparrow}$ *seal coordinate, aggregate formalstatus token, or aggregate bridge row.*

Proof. Start with the common refinement supplied by Definition 301.117. It places all members of the finite family on one visible support surface preserving the StreamName schedules, DyadicRatCore endpoint/radius/distance rows, RegSeqRat classifier and regularity rows, RealUp source-factorization rows, and displayed structural support.

Next compare one family member with that common support. Apply Definition 301.116. The StreamName window transport and the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance comparison are therefore read before the RegSeqRat classifier and terminal Real seal can be consumed.

Finally apply Definition 301.111. The Real-facing consumer sees the same source factorization rows after the window transport and dyadic tolerance comparison, so each member of F hands off to the same terminal $\mathsf{Real}^{\uparrow}$ seal surface.

The exclusions are inherited from the finite-family refinement, the dyadic-stream common refinement, and the Real seal consumer factorization. These theorems keep the route inside the displayed finite rows and provide no quotient stream, selected host limit, countable-choice, completeness, duplicate-seal, aggregate-status, or aggregate-bridge coordinate. □

Theorem 301.119 (RegSeqRat tail-budget facewise status pullback)**.** *Every accepted tail-budget* $\mathsf{Real}^{\uparrow}$*-seal consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet reads the four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with each face's own closurestatus, formalstatus, leantarget, and bridgestatus rows. The consumer route reads those rows from the local face records and not from an aggregate formalstatus token.

Conversely, a tail-budget packet carrying exactly those four local status records together with the displayed

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support rows gives the same accepted tail-budget terminal $\mathsf{Real}^{\uparrow}$*-seal route. This pullback has no fifth face, quotient stream equality, selected host limits, choice data, ambient completeness carrier, metric-completeness datum, standard-bridge row, or aggregate audit certificate.*

Proof. First locate the finite route. Apply Definition 301.114. It confines every completion-facing tail-budget consumer to the StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier and regularity rows, displayed hsame transports, Cont routes, Pkg provenance, local $\mathsf{NameCert}$ naming, and public $\mathsf{Real}^{\uparrow}$ seal.

Next read the status data face by face. Apply Definition 38.818. It identifies the terminal seal status read with the four local closurestatus, formalstatus, leantarget, and bridgestatus rows and rejects a route-level formalstatus token or aggregate bridge row.

For the phase boundary, apply Definition 38.471. The current Phase Real and Completion exit read is the product of the four local face records, so the tail-budget route cannot contribute a fifth face or cached completion status.

Finally reuse the nonescape clauses of Definition 301.114. They exclude quotient stream equality, selected host limits, choice data, ambient completeness, metric-completeness data, standard-bridge rows, and any additional Real seal coordinate. The converse is then the same finite packet read with exactly the four local status records and the displayed support rows. □

Theorem 301.120 (RegSeqRat tail-budget support refinement invariance)**.** *Let an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget route terminate in a completion-facing* $\mathsf{Real}^{\uparrow}$ *seal row. Suppose this route is replaced by a finite certified support refinement whose finite windows preserve the* $\mathsf{StreamName}^{\uparrow}$ *schedule classifier, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support rows.

Then the original route and the refined route determine the same terminal completion-facing $\mathsf{Real}^{\uparrow}$ *seal surface. The common seal is read through the same facewise closurestatus, formalstatus, leantarget, and bridgestatus rows, and not through quotient streams, selected host limits, countable choice, ambient completeness, metric completeness, a second* $\mathsf{Real}^{\uparrow}$ *seal coordinate, or an aggregate formalstatus token.*

Proof. First compare a single replacement step. Apply Definition 301.116. It supplies the common finite window in which the $\mathsf{StreamName}^{\uparrow}$ classifier, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance rows, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows are preserved on both sides of the handoff.

Next pass from one replacement step to the finite certified support refinement. Apply Definition 301.117. The finite family certificate keeps the same displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows while threading the preserved dyadic and regular-sequence rows through the whole family.

Now read the terminal surface. Apply Definition 301.114. Since both routes have the same finite tail-budget support and the same terminal $\mathsf{Real}^{\uparrow}$ seal row, the completion-facing seal surface determined by the original route is the seal surface determined by the refined route.

Finally apply Definition 301.119. The status data used in the conclusion is read objectwise from the four faces and from the displayed support rows. Hence the refinement cannot introduce quotient streams, selected host limits, countable choice, ambient or metric completeness, a second seal coordinate, or any aggregate formalstatus token. □

Theorem 301.121 (RegSeqRat tail-budget chain refinement exhaustion)**.** *Let an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget route terminate in a completion-facing* $\mathsf{Real}^{\uparrow}$ *seal row, and let* $R_0, \ldots, R_n$ *be a finite nonempty chain of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget routes with* R_0 *the original route and* R_n *the terminal route. Suppose every adjacent replacement* (R_i, R_{i+1}) *is a certified support refinement preserving the* $\mathsf{StreamName}^{\uparrow}$ *schedule classifier, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}$$

support rows.

Then every parenthesized finite refinement chain from R_0 *to* R_n *and the direct first-to-last comparison determine the same terminal completion-facing* $\mathsf{Real}^{\uparrow}$ *seal surface. The common surface is exactly the terminal seal read from the preserved tail-budget support rows, with the facewise closurestatus, formalstatus, leantarget, and bridgestatus rows pulled back from the displayed faces. It exports no quotient streams, selected host limits, countable choice, ambient completeness, metric completeness, duplicate* $\mathsf{Real}^{\uparrow}$ *seal coordinates, aggregate formalstatus tokens, or aggregate bridge rows.*

Proof. The base case is the one-route chain. The comparison from R_0 to R_0 is reflexive on the displayed tail-budget support, so the completion-facing $\mathsf{Real}^{\uparrow}$ seal surface is the terminal surface already carried by that route.

For a one-step chain, apply Definition 301.120. The certified support refinement preserves the StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier and regularity rows, displayed support rows, and terminal $\mathsf{Real}^{\uparrow}$ seal row, hence the two routes read the same terminal seal surface.

For a longer finite chain, first forget the parenthesization and read the chain as a finite request support-face chain. Apply Definition 301.150. It makes all adjacent support-face composites and the direct first-to-last comparison land on one terminal $\mathsf{Real}^{\uparrow}$ seal-facing support face over the displayed rows.

Next build the common finite support needed by the tail-budget route. Apply Definition 301.117. The common refinement keeps the finite StreamName windows, the DyadicRatCore endpoint, radius, and distance ledger, the RegSeqRat classifier and regularity rows, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows on one finite support family.

Now read the terminal completion-facing surface. Apply Definition 301.114. Since the direct comparison and every parenthesized chain have the same finite tail-budget support and the same terminal $\mathsf{Real}^{\uparrow}$ seal row, they determine the same completion-facing $\mathsf{Real}^{\uparrow}$ seal surface.

Finally apply Definition 301.119. The status and bridge data are read objectwise from the preserved faces and not from an aggregate token. Therefore the finite chain cannot introduce quotient streams, selected host limits, countable choice, ambient or metric completeness, duplicate $\mathsf{Real}^{\uparrow}$ seal coordinates, aggregate formalstatus tokens, or aggregate bridge rows. □

Theorem 301.122 (RegSeqRat tail-budget fusion)**.** *Let B_0 and B_1 be compatible finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget rows sharing the same* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and terminal* $\mathsf{Real}^{\uparrow}$ *seal. Then B_0 and B_1 fuse to one terminal budget route whose visible surface is the shared StreamName schedule, dyadic tolerance ledger, RegSeqRat readback, Real seal, transport, replay, provenance, and local* NameCert *rows. The theory-status and bridge-status axes remain objectwise rows of that terminal route.*

Proof. Start from the common-tail cocycle descent theorem Definition 301.190. It identifies compatible finite tail windows on common overlaps, so the two budget rows can be compared through the same StreamName schedule and dyadic tolerance ledger.

Apply the tail-budget handoff theorem Definition 301.109. The shared schedule, tolerance ledger, and RegSeqRat readback are therefore read before the terminal Real seal, and the displayed hsame, Cont, Pkg, and local NameCert rows preserve the same finite route.

The fused route is terminal because every Real-facing budget consumer has already passed through the common-tail descent and the meet handoff. Since status and bridge data are carried only as displayed objectwise rows, the fusion does not identify axes globally, add quotient streams, select limits, invoke countable choice, or import ambient completeness. □

Theorem 301.123 (RegSeqRat tail-selector RealUp seal exhaustion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let a completion-facing* $\mathsf{Real}^{\uparrow}$ *seal consumer use a RegSeqRat tail selector to choose its finite readout. Then the consumer factors through exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, and the local* $\mathsf{Real}^{\uparrow}$ *seal provenance attached to P.*

Equivalently, the tail-selector route exposes only the same finite $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *source surface as the terminal tail-budget handoff. It exports no quotient stream,*

host real equality, selected limit, completion point, metric-completeness datum, or extra seal coordinate.

Proof. First apply Definition 301.114. It places every completion-facing tail-budget consumer on the single finite route whose rows are the displayed StreamName schedule, DyadicRatCore endpoint, radius, and distance ledger, RegSeqRat classifier and regularity ledgers, transport, continuation, package provenance, local naming, and public RealUp seal row.

Next use Definition 301.35. The tail-selector read selects only a finite public window cover of that same accepted packet, and the cover exhaustion identifies each selected window with the displayed schedule, pointwise classifier, dyadic ledger, and provenance rows.

Now apply Definition 301.36. Any two selector-visible seal reads over the cover repack through one accepted common finite window, so the selected tail window cannot introduce a second quotient stream, selected limit, completion point, or metric-completeness coordinate.

Finally invoke Definition 301.22. The RealUp seal consumes exactly the regular-rational source surface assembled above. Since that surface has no projection for host real equality or an additional seal coordinate, the tail-selector consumer is exhausted by the displayed schedule, ledger, regularity, classifier, and local seal-provenance rows. □

Theorem 301.124 (RegSeqRat tail-selector window-seal lock)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let a* $\mathsf{Real}^{\uparrow}$ *seal consumer use the RegSeqRat tail selector carried by P. The consumer must read, in order, the selected finite* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger, the RegSeqRat tail-budget handoff, and the local* $\mathsf{Real}^{\uparrow}$ *seal row. It cannot replace the selected window by quotient-stream equality, host real equality, a selected limit, a completion point, or an ambient completeness datum.*

Proof. Start from tail-selector RealUp seal exhaustion in Definition 301.123. It places the consumer on the finite $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ route and excludes any detached seal coordinate.

Apply the tail-budget meet handoff of Definition 301.109. The selected window is not optional data; it is the finite readout through which the tail-budget route reaches the regular-rational meet surface.

Next use Definition 301.69. The StreamName window and dyadic radius ledger travel together into the Real-facing handoff, so a consumer cannot keep the seal while substituting a quotient stream, host equality, selected limit, or completion point for the selected finite window.

Finally invoke Definition 301.22. The Real seal consumes exactly the preceding finite handoff surface, and therefore the local lock is the ordered route through the selected window, dyadic ledger, tail-budget handoff, and Real seal row. □

Theorem 301.125 (RegSeqRat tail-selector cofinal request determinacy)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be public finite requests to P whose readouts use certified cofinal RegSeqRat tail selectors. Suppose both requests preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite dyadic-distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the componentwise* hsame *rows tying those data to the request packet, the displayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Then S and T determine the same* $\mathsf{Real}^{\uparrow}$ *seal-visible source section.*

The determinacy is only for the seal-visible source section. It does not identify quotient streams, host real equality, selected limits, completion points, ambient completeness data, choice data, or second seal coordinates.

Proof. First apply Definition 301.123. Each cofinal tail-selector request is exhausted by the displayed $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ source surface, so neither request has a detached completion coordinate from which extra seal rows could be read.

Next use the window-seal lock, Definition 301.124. The certified cofinal selector must pass through the selected finite $\mathsf{StreamName}^{\uparrow}$ window, the dyadic radius ledger, the RegSeqRat tail-budget handoff, and the local Real seal row. Since S and T preserve those displayed rows, their selector routes reach the same locked finite window surface.

Now factor both requests through Definition 301.139. The source section of each request consists exactly of the schedule rows, dyadic endpoint, radius, distance, classifier, regularity, componentwise hsame, displayed Cont, package provenance, and local naming rows named in the statement. The hypotheses identify those rows component by component, so the two finite source sections are the same public BHist section.

Finally apply Definition 301.141 and Definition 301.114. The correspondence restricts the Real seal read to the finite source section just identified, and the terminal tail-budget theorem prevents a second selector, limit, completion-point, completeness, choice, or seal-coordinate channel from entering the route. Therefore the two certified cofinal requests determine the same $\mathsf{Real}^{\uparrow}$ seal-visible source section and nothing beyond that section. □

Theorem 301.126 (RegSeqRat tail-selector cofinal refinement monotonicity)**.** *Let P be an accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet, let S be a public finite request served by a certified cofinal RegSeqRat tail selector, and let S' be a certified cofinal refinement of S. Suppose S' preserves the displayed $\mathsf{StreamName}^{\uparrow}$ window rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and finite dyadic-distance ledgers, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows, the componentwise hsame rows, the displayed Cont routes, the Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows of S. Then S and S' determine the same $\mathsf{Real}^{\uparrow}$ seal-visible source section.*

Conversely, any certified cofinal refinement of S that determines the same $\mathsf{Real}^{\uparrow}$ seal-visible source section must preserve exactly those displayed rows. The monotonicity claim is only for the finite L10 $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ route. It does not expose quotient streams, selected limits, choice data, metric-completeness rows, aggregate status rows, bridge rows, second seal coordinates, or ambient $\mathsf{Real}^{\uparrow}$ completeness.

Proof. First apply Definition 301.124. Both S and S' are forced through the selected finite $\mathsf{StreamName}^{\uparrow}$ window, the dyadic radius ledger, the RegSeqRat tail-budget handoff, and the local Real seal row. Since S' is a certified cofinal refinement preserving the displayed rows of S, the refinement cannot change the locked window-seal route.

Next use Definition 301.125. Regard S and S' as the two certified cofinal requests in that theorem. The preserved schedule, dyadic endpoint, radius, distance, classifier, regularity, hsame, Cont, package, and local naming rows identify their seal-visible request surfaces, so the two requests determine the same $\mathsf{Real}^{\uparrow}$ source section.

Read that source section through Definition 301.139. This identifies the section with exactly the displayed rows named in the statement, not with a quotient stream, selected limit, choice datum, metric-completeness row, aggregate status row, bridge row, or ambient completion claim.

For the converse, suppose a certified cofinal refinement determines the same $\mathsf{Real}^{\uparrow}$ seal-visible source section. The finite-request source-section description forces equality on each displayed row of the section. Finally apply Definition 301.114: the terminal seal has no additional channel through which a changed endpoint, radius, distance, classifier, regularity, hsame, Cont, package, or local NameCert row could be hidden. Hence same-section cofinal refinements are precisely the refinements that preserve those displayed rows. □

Theorem 301.127 (RegSeqRat tail-selector bundle induction Real seal)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let $\mathcal{P}$:* ProbeBundle *be a finite bundle of certified unary observations, and suppose one certified cofinal RegSeqRat tail selector serves every bundled observation row equipped with its* UnaryHistory *and* InBundle *witnesses. Let $\mathcal{F}$ be a finite family of* $\mathsf{Real}^{\uparrow}$ *seal requests over P whose members preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite dyadic-distance ledgers, the RegSeqRat classifier and regularity rows, the componentwise* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Then the entire family factors through one BEDC-visible* $\mathsf{Real}^{\uparrow}$ *seal source section.*

The factorization is exactly the finite source section assembled from the bundle rows, the shared tail selector, the common dyadic scale-window ledger, the RegSeqRat classifier and regularity data, componentwise hsame*,* Cont*,* Pkg*, and local* NameCert *rows. It exports no quotient stream, host real equality, selected limit, completion point, countable-choice selector, metric-completeness datum, aggregate status row, bridge row, second seal coordinate, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. First collect the finite observations. Apply Definition 126.547 to the shared tail-selector route and the finite ProbeBundle, and then use Definition 126.548. These results place every bundled seal request on one displayed StreamName packet whose rows are the unary observation certificates, the bundle-membership witnesses, the shared finite-window budget, pointwise RegSeqRat handoff rows, and the support rows hsame, Cont, Pkg, and NameCert.

Next attach the dyadic face to that packet. Apply Definition 291.82 to the finite dyadic faces and, equivalently at the terminal boundary, use Definition 291.83. The common window supplies the endpoint, radius, distance, scale, transport, continuation, package, and local DyadicRatCore naming rows consumed by the StreamName and RegSeqRat faces.

Now run induction over the finite family $\mathcal{F}$. The empty family is served by the collected bundle packet itself. For the step adjoining one seal request, apply Definition 301.124 to place the new request on the selected StreamName window, dyadic ledger, tail-budget handoff, and local Real seal row. Then compare it with the already collected family through Definition 301.125; the preserved schedule, dyadic, classifier, regularity, support, provenance, and local naming rows force the same seal-visible source section.

Finally apply Definition 301.114 and Definition 301.22. The terminal tail-budget result keeps the finite family on the single regular-rational source route, and the Real handoff identifies that route with the public $\mathsf{Real}^{\uparrow}$ seal source surface. Since none of the cited packets contains rows for quotient streams, host real equality, selected limits, completion points, countable choice, metric completeness, aggregate status, bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness, the family factors through exactly one BEDC-visible seal source section. □

Theorem 301.128 (RegSeqRat tail-selector finite-cover gluing)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{U}$ be a finite certified cover of* $\mathsf{Real}^{\uparrow}$ *seal requests over P. Suppose every member of $\mathcal{U}$ is served by a certified cofinal RegSeqRat tail selector, and suppose every overlap in the cover preserves the displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite dyadic-distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier rows, the componentwise* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Then the finite cover glues through one BEDC-visible* $\mathsf{Real}^{\uparrow}$ *seal source section.*

The glued section is only the finite $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *seal route displayed by those requests. It does not identify quotient streams, host real equality, selected limits, completion points, countable-choice selectors, metric-completeness rows, aggregate status rows, bridge rows, second seal coordinates, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First treat the finite cover as a finite family of seal requests over the accepted packet P. Apply Definition 301.127 to collect the cover members into one seal-visible source section whose rows are the displayed StreamName windows, dyadic endpoint, radius, and distance ledgers, RegSeqRat classifier and regularity rows, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ data.

Next check agreement on overlaps. For two cover members, use Definition 301.125. The overlap hypotheses identify exactly the displayed schedule, dyadic, classifier, regularity, support, provenance, and local naming rows, so the two members determine the same $\mathsf{Real}^{\uparrow}$ seal-visible source section on their common subrequest.

Certified refinements do not change the glued section. Apply Definition 301.126 whenever an overlap is represented by a smaller cofinal tail-selector request. The refinement keeps the same displayed rows, and the converse direction in that theorem rules out a hidden change in endpoint, radius, classifier, support, package, or local naming data.

Now attach the dyadic face uniformly across the cover. Use Definition 291.83 to read the common scale-window endpoint, radius, distance, transport, continuation, package, and local naming rows as one four-face dyadic pullback ledger. This is the dyadic component consumed by the RegSeqRat tail-selector route on every cover member.

Finally pass from the glued regular-rational section to the Real seal route. Apply Definition 301.22 together with Definition 301.114. These results keep the glued cover on the finite Real seal source surface and leave no BEDC-visible row for quotient streams, host real equality, selected limits, completion points, countable choice, metric completeness, aggregate status, bridge data, a second seal coordinate, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 301.129 (RegSeqRat tail-selector diagonal cover source coherence)**.** *Let P be an accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet, and let $\mathcal{U}$ be a finite certified cover of $\mathsf{Real}^{\uparrow}$ seal requests over P. Suppose every member of $\mathcal{U}$ is served by a certified cofinal RegSeqRat tail selector. Suppose also that every pairwise overlap preserves the displayed $\mathsf{StreamName}^{\uparrow}$ window rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and finite dyadic-distance ledgers, the RegSeqRat classifier and regularity rows, the componentwise hsame rows, the displayed Cont routes, the Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows. Then all cover members determine one diagonal BEDC-visible $\mathsf{Real}^{\uparrow}$ seal source section.*

The diagonal source section is the single finite $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ source section seen simultaneously by every cover member and every overlap. It contains no quotient stream, selected limit, host real equality, countable-choice row, metric-completeness row, aggregate status row, bridge row, second seal coordinate, or ambient $\mathsf{Real}^{\uparrow}$ completeness datum.

Proof. First glue the finite cover at the visible seal surface. Apply Definition 301.128. This produces one BEDC-visible $\mathsf{Real}^{\uparrow}$ seal source section whose displayed rows are exactly the StreamName windows, dyadic endpoint, radius, and distance ledgers, RegSeqRat classifier and regularity rows, componentwise hsame, displayed Cont, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows carried by the cover.

Next make the gluing independent of the chosen cover member. For each member, apply Definition 301.125. The overlap hypotheses identify the same schedule, dyadic ledger, classifier, regularity, support, provenance, and local naming rows, so the section read from that member is the section read from the glued cover.

Now compare different cofinal tail selectors that serve the same overlap. Apply Definition 301.126. Refining a request may shrink the finite tail window, but it preserves the displayed rows that feed the seal source section. Hence all refinements still read the same diagonal section.

The remaining coherence is the common finite window. Use Definition 126.547 to lock the cofinal StreamName windows across the cover, and use Definition 291.83 to read the endpoint, radius, distance, transport, continuation, package, and local naming rows through the same four-face dyadic pullback.

These two locks leave only the displayed finite source section. Since the cited packets export no quotient streams, selected limits, host real equality, countable choice, metric completeness, aggregate status, bridge data, second seal coordinate, or ambient $\mathsf{Real}^{\uparrow}$ completeness, no extra BEDC-visible row can separate one cover member from another. The cover members therefore determine one diagonal $\mathsf{Real}^{\uparrow}$ seal source section. □

Definition 301.130 (RegSeqRat constant dyadic source)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source packet for a displayed dyadic endpoint* d *is the finite packet obtained by reading one* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row for* d*, the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule that returns that same row at every requested unary window, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity ledger that compares any two displayed positions by the same endpoint row. Its visible rows are the dyadic endpoint row, the dyadic radius row requested by each window, the zero dyadic-distance row for equal endpoints, the regularity bound row, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance.*

The packet is only a finite BEDC source description. It is not a quotient stream, host real equality, selected limit, metric completion object, Real completeness row, or ambient embedding principle.

Theorem 301.131 (RegSeqRat constant dyadic regularity)**.** *Every finite window of a* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source is regular. For requested precisions* n *and* m*, both displayed endpoints are the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *row* d*, the dyadic-distance row is the equal-endpoint row, and the regularity ledger is the displayed bound*

$$0 \leq 2^{-n} + 2^{-m}.$$

Thus the window supplies exactly the RegSeqRat regularity row over the constant StreamName schedule, together with its hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

Proof. Project the constant dyadic source of Definition 301.130. The two endpoint projections in any finite window are the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row, because the $\mathsf{StreamName}^{\uparrow}$ schedule is constant.

Read the equal-endpoint dyadic-distance row from chapter 291. The radius ledger for the same window supplies the two displayed radii 2^{-n} and 2^{-m}, so the regularity comparison is bounded by the displayed sum.

Finally apply the RegSeqRat regularity obligation surface of Definition 301.3 and the finite-window transport closure of Definition 301.6. They repack the constant StreamName schedule of chapter 126 and the dyadic endpoint rows as the required RegSeqRat regularity ledger, without adding quotient or completion data. □

Theorem 301.132 (RegSeqRat constant RealUp seal handoff)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source reaches the* $\mathsf{Real}^{\uparrow}$ *seal only through the four visible faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The source first reads the constant StreamName schedule, then the shared DyadicRatCore endpoint and radius rows, then the RegSeqRat regularity and classifier ledger of Definition 301.131, and then the RealUp seal row of chapter 38. The handoff exports no quotient stream equality, host real

equality, completion object, selected limit, ambient embedding theorem, or RealUp completeness row.

Proof. Start with the constant schedule and endpoint packet of Definition 301.130. Its source rows are already the StreamName and DyadicRatCore rows named by chapter 126 and chapter 291.

Use Definition 301.131 to place every finite window on the RegSeqRat regularity surface. The cited theorem supplies the same endpoint, radius, distance, transport, route, package, and naming rows in each requested window.

Finally apply the existing RegSeqRat seal route: Definition 301.69, Definition 301.109, and Definition 301.22. These route the finite regular-rational packet to the RealUp seal through the four visible faces. Since none of those faces contains a coordinate for quotient stream equality, host real equality, completion objects, selected limits, embedding theorems, or RealUp completeness, the constant packet exports no such row. □

Theorem 301.133 (RegSeqRat constant dyadic classifier reflection)**.** *For two* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source packets over displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints d and e, the* $\mathsf{RegSeqRat}^{\uparrow}$ *dyadic-tolerance classifier read between their constant schedules is exactly the finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *equality-and-tolerance row consumed by the* $\mathsf{Real}^{\uparrow}$ *seal classifier. Thus agreement of the two constant sources at the* $\mathsf{Real}^{\uparrow}$ *seal factors through the constant* $\mathsf{StreamName}^{\uparrow}$ *schedules, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal, with no quotient stream equality, host real equality, selected limit, completion datum, or RealUp completeness row.*

Proof. Project both constant source packets using Definition 301.130. Their visible schedules are constant $\mathsf{StreamName}^{\uparrow}$ schedules, and every finite comparison therefore reads the same displayed endpoint rows d and e at the requested windows.

Apply Definition 301.131 to both constant sources. The resulting finite windows carry the endpoint rows, radius rows, endpoint-distance row, hsame transport rows, Cont routes, Pkg provenance, and local NameCert provenance needed by the RegSeqRat classifier ledger.

Now use the general seal classifier route: Definition 301.43 identifies the classifier seen by the RealUp seal with the RegSeqRat dyadic-tolerance classifier, and Definition 301.45 says that this classifier consumes only the displayed finite rows just listed. In the constant-source case those rows are precisely the DyadicRatCore equality-and-tolerance row for d and e.

Finally close with the handoff of Definition 301.132. That theorem supplies the four-face route from the two constant source descriptions to the RealUp seal, so the classifier reflection contains no additional coordinate for quotient stream equality, host real equality, selected limits, completion data, or RealUp completeness. □

Theorem 301.134 (RegSeqRat constant tail seal invariance)**.** *Let C be a* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source packet over a displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint d. For every certified unary tail shift of the* $\mathsf{StreamName}^{\uparrow}$ *schedule of C, the shifted source presents the same constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, the same endpoint-distance ledger at d, and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier surface to the* $\mathsf{Real}^{\uparrow}$ *seal.*

Consequently any two certified unary tail shifts of the constant source have the same $\mathsf{Real}^{\uparrow}$ *seal source read after restriction to their common cofinal finite window. This invariance is only a statement about the displayed constant dyadic source rows, the RegSeqRat regularity and classifier surface, and the RealUp seal-facing finite packet. It exports no quotient stream equality, host real equality, selected limit, completion datum, or RealUp completeness row.*

Proof. Project the source by Definition 301.130. A certified unary tail shift changes only which schedule rows are requested; every requested row still returns the same displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint d and the same constant $\mathsf{StreamName}^{\uparrow}$ schedule entry.

Apply Definition 301.131. The endpoint rows on the shifted windows are equal to d, so the endpoint-distance ledger is the same equal-endpoint row and the dyadic-radius rows are read from the same constant packet.

Use Definition 301.18 to repack each shifted finite window as an accepted $\mathsf{RegSeqRat}^{\uparrow}$ window. Since the source is constant, the repacked window carries the same regularity ledger and the same dyadic-tolerance classifier surface as the unshifted constant source.

Now apply Definition 301.21 to two certified tail reads of the constant source. Their common cofinal finite window identifies the displayed schedule rows, endpoint rows, endpoint-distance ledger, classifier witness, hsame comparisons, Cont routes, Pkg provenance, and local NameCert provenance.

Finally close with Definition 301.132. The handoff says that the constant source reaches the $\mathsf{Real}^{\uparrow}$ seal only through the visible $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, so the tail comparison has no coordinate for quotient stream equality, host real equality, selected limits, completion data, or RealUp completeness. □

Theorem 301.135 (RegSeqRat constant tail readback)**.** *For a constant dyadic* $\mathsf{RegSeqRat}^{\uparrow}$ *source, every tail readback consumed by* $\mathsf{Real}^{\uparrow}$ *factors through the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity ledger,* hsame *transports,* Cont *replay,* Pkg *provenance, and the local* NameCert *row. No quotient stream equality, selected limit, metric-completion row, or* $\mathsf{Real}^{\uparrow}$ *completeness coordinate can alter the readback.*

Proof. Begin with the constant source of Definition 301.130. Every requested tail window reads the same constant $\mathsf{StreamName}^{\uparrow}$ schedule and the same displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row, with only the requested radius rows varying inside the finite packet.

Use Definition 301.131. The regularity ledger for each tail window is rebuilt from the shared endpoint, the displayed radius rows, the equal-endpoint distance row, and the local transport, replay, package, and naming rows.

Apply Definition 301.132 and Definition 301.133. These results route the constant packet to the $\mathsf{Real}^{\uparrow}$ seal through the same StreamName, DyadicRatCore, RegSeqRat, and Real faces, and identify the seal-facing classifier with the finite dyadic-tolerance row already carried by the packet.

Finally use Definition 301.134. Tail shifts preserve the same constant schedule, endpoint-distance ledger, regularity surface, classifier surface, hsame transports, Cont routes, Pkg provenance, and local NameCert row. The excluded quotient, limit, completion, and completeness coordinates are absent from every cited surface, so none can change the tail readback consumed by $\mathsf{Real}^{\uparrow}$. □

Theorem 301.136 (RegSeqRat constant dyadic finite-request exhaustion)**.** *Let C be a* $\mathsf{RegSeqRat}^{\uparrow}$ *constant dyadic source packet over a displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint d. Every finite* $\mathsf{Real}^{\uparrow}$*-facing request made of C factors through exactly the following displayed rows: the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row d, the requested dyadic-radius rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier ledger, the common cofinal finite window for the requested tails, the displayed* hsame *comparisons, the displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance.*

The request has no remaining coordinate for quotient stream equality, host real equality, selected limits, completion data, an embedding principle, or a $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Project the source packet using Definition 301.130. Each finite request first sees the same constant $\mathsf{StreamName}^{\uparrow}$ schedule and the same displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row d.

For every requested finite window, apply Definition 301.131. This supplies the requested radius rows, the equal-endpoint distance row, the regularity bound, the displayed hsame comparisons, the Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ provenance.

Next apply Definition 301.133. The classifier row read by the $\mathsf{Real}^{\uparrow}$ seal is therefore the finite dyadic-tolerance row already carried by the constant $\mathsf{RegSeqRat}^{\uparrow}$ packet.

Use Definition 301.134 for any requested tail reads. It replaces the tail requests by their common cofinal finite window while preserving the same schedule rows, endpoint row, regularity row, classifier row, transport rows, route rows, package row, and naming row.

Finally close with Definition 301.132. The handoff permits the constant packet to reach the $\mathsf{Real}^{\uparrow}$ seal only through the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. Consequently the finite request is exhausted by the listed BEDC rows and cannot export quotient stream equality, host real equality, selected limits, completion data, embedding principles, or $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 301.137 (RegSeqRat constant dyadic finite-request union seal)**.** *Let C be a $\mathsf{RegSeqRat}^{\uparrow}$ constant dyadic source packet over a displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint d. Suppose a finite family of $\mathsf{Real}^{\uparrow}$-facing finite requests to C has requested tail windows admitting a common cofinal finite window. Then the family factors through one displayed union packet whose rows are exactly the constant $\mathsf{StreamName}^{\uparrow}$ schedule, the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row d, the union of the requested dyadic-radius rows, the equal-endpoint distance rows, the $\mathsf{RegSeqRat}^{\uparrow}$ regularity ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier ledger, the terminal $\mathsf{Real}^{\uparrow}$ seal row, the componentwise hsame comparisons, the displayed Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ provenance.*

The union packet exports no quotient stream equality, host real equality, selected limit, completion datum, countable-choice selector, embedding principle, or $\mathsf{Real}^{\uparrow}$ completeness row.

Proof. Apply Definition 301.136 to each request in the finite family. Every component request is already exhausted by the constant schedule, the endpoint row d, its requested radius rows, the regularity and classifier ledgers, the transport rows, the route rows, Pkg provenance, and local $\mathsf{NameCert}$ provenance.

Use Definition 301.134 to move all requested tail reads to the chosen common cofinal finite window. This preserves the constant $\mathsf{StreamName}^{\uparrow}$ schedule, the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row, the equal-endpoint distance rows, the componentwise hsame comparisons, the displayed Cont routes, and the provenance rows while replacing the separate tail windows by the single finite window seen by the union packet.

Next apply Definition 301.133. The classifier rows for all component requests are identified with the same dyadic endpoint ledger, so their finite union only records the union of the requested radius rows and does not introduce a second classifier surface.

Finally close with Definition 301.132. The seal route passes through exactly the visible $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. Hence the displayed union packet has the listed BEDC rows and no coordinate for quotient stream equality, host real equality, selected limits, completion data, countable-choice selectors, embedding principles, or $\mathsf{Real}^{\uparrow}$ completeness. □

The $\mathsf{RegSeqRat}^{\uparrow}$ readback row is a consumed coordinate of the reciprocal-window route in chapter 703. That consumer may read the regular rational sequence only after the finite $\mathsf{StreamName}^{\uparrow}$ window and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger have been displayed, so the reciprocal budget receives the row as part of the finite route $W \longmapsto D \longmapsto R$ rather than as a host inverse or quotient-real equality surface.

Theorem 301.138 (RegSeqRat reciprocal-budget visible route exhaustion)**.** *Every reciprocal-facing consumer of a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row inside an accepted* $\mathsf{CauchyInverseBudget}^{\uparrow}$ *packet factors through the displayed finite route. The route first exposes the apartness budget* A *and modulus row* M*, then selects the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, then reads the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and reciprocal ledger* D*, then consumes the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*, and finally reaches the* $\mathsf{Real}^{\uparrow}$ *seal row* S *through the displayed* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

Consequently the reciprocal-facing consumer receives only the finite route

$$A, M, W, D, R, S, H, C, P, N.$$

It receives no host inverse, quotient stream equality, total reciprocal, trichotomy, selected limit, countable choice datum, or ambient completeness principle.

Proof. Start from the route paragraph above: it places the RegSeqRat readback behind the finite window and dyadic ledger as $W \longmapsto D \longmapsto R$.

Apply Definition 703.7. It expands that local RegSeqRat handoff to the CauchyInverseBudget carrier rows X, A, M, W, D, R, with the apartness budget and modulus exposed before the dyadic reciprocal ledger can be consumed.

Apply Definition 703.8. The downstream $\mathsf{Real}^{\uparrow}$ seal is then reached only after the same readback row R, so the seal consumer cannot bypass the displayed finite route.

Finally apply Definition 703.17. It adds the visible hsame, Cont, Pkg, and local NameCert rows to the same packet, exhausting the reciprocal-facing consumer surface and excluding host inverse, quotient stream equality, total reciprocal, trichotomy, selected limits, countable choice, and ambient completeness. □

Theorem 301.139 (RegSeqRat finite-request source section)**.** *Let* R *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let* S *be a public finite request to the accepted packet. Then* S *factors through one displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source section carried by a finite* BHist *packet. The visible rows of that section are exactly the following rows:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows selected by the request;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite dyadic-distance rows read at those schedule positions;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row and the regularity rows certifying the accepted packet;*
4. *the componentwise* hsame *rows tying the schedule, dyadic endpoint, radius, distance, classifier, and regularity rows to the same request packet;*
5. *the displayed* Cont *routes from the StreamName schedule through the dyadic rows and the RegSeqRat classifier surface;*
6. *the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* NameCert*;*
7. *the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows for the request.*

No other row is part of the RegSeqRat source section.

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatFiniteRequestSourceSection`

Proof. Begin with the StreamName finite-observation section of Definition 126.527. It gives the displayed schedule rows named by the finite request and places them in one finite source packet.

Apply the RegSeqRat tail-budget section lock, Definition 126.530. The lock prevents the request from replacing the displayed schedule by an off-packet tail selector, so every later RegSeqRat row is read over the same finite window.

Next use the exact RegSeqRat handoff, Definition 301.69. It supplies the dyadic endpoint, radius, finite distance, classifier, and regularity rows over the displayed schedule.

Now apply Definition 301.74. The common ledger identifies the componentwise hsame rows, Cont routes, package provenance, and local naming rows as part of the same finite RegSeqRat packet. This gives one BHist source section and no second source coordinate. □

Theorem 301.140 (RegSeqRat Real request section nonescape)**.** *Let R be an accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet, and let S be a public finite request to R that is consumed by a $\mathsf{Real}^{\uparrow}$ seal. Then the same displayed source section of Definition 301.139 is the entire source section seen by the seal. In particular the section cannot export quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, choice data, or a second $\mathsf{Real}^{\uparrow}$ seal coordinate.*

Proof. First factor the request through Definition 301.139. The factorization has only the StreamName schedule rows, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier and regularity rows, and the displayed transport, route, package, and local naming rows.

Apply the Real finite-request fusion theorem, Definition 38.698. It says that a Real seal which consumes the same request reads through one finite BHist packet with the same schedule, dyadic, classifier, regularity, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Finally compare the two packets through Definition 301.69 and Definition 301.74. These theorems keep the StreamName, DyadicRatCore, and RegSeqRat faces as the only source faces available to the seal-facing request. Since those faces carry no row for quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, choice data, or a second Real seal coordinate, the consumed section cannot export any such datum. □

Theorem 301.141 (RegSeqRat finite-request Real seal correspondence)**.** *Let R be an accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet, and let S be a public finite request to R that is consumed by a $\mathsf{Real}^{\uparrow}$ seal. The finite request source section of Definition 301.139 determines the seal-visible source section of Definition 301.140: its rows restrict exactly to the StreamName schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and dyadic-distance rows, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows, the componentwise hsame rows, the displayed Cont routes, the Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows. Conversely any seal-visible section for the same request restricts to exactly those rows of the finite request source section. The correspondence carries no quotient stream equality, host sequence equality, selected limits, ambient completeness, metric-completeness data, choice data, or second seal coordinate.*

Proof. First build the finite source packet with Definition 301.139. This gives the unique displayed request section whose visible rows are the StreamName schedule rows, the dyadic endpoint, radius, and finite distance rows, the RegSeqRat classifier and regularity rows, and the displayed hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Next route the same public request to the Real consumer by Definition 38.698. The fusion theorem forces the seal to read through the finite BHist packet already named by the request, so the consumer has no independent source packet from which additional rows could be drawn.

The common visible rows are then fixed by Definition 301.69 and Definition 301.74. These theorems identify the schedule, dyadic, classifier, regularity, hsame, Cont, package, and naming

rows on both sides of the handoff, giving the restriction from the finite source section to the seal-visible section.

For the converse, start with a seal-visible section for the same request and apply Definition 301.140. Nonescape says that the seal-visible section is already the displayed RegSeqRat finite source section, so restricting it back along the request recovers exactly the same StreamName schedule, dyadic endpoint, radius, distance, classifier, regularity, hsame, Cont, Pkg, and local NameCert rows. The excluded rows are absent on both sides, so the correspondence introduces no quotient stream equality, host sequence equality, selected limit, ambient or metric completeness, choice datum, or second seal coordinate. □

Theorem 301.142 (RegSeqRat finite-request terminal budget factorization)**.** *Let R be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S be a public finite request to R that is consumed by a* $\mathsf{Real}^{\uparrow}$ *seal. Every terminal budget consumer of the finite seal request factors through exactly the rows of the finite request source section:*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows selected by S;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite dyadic-distance rows read at those schedule positions;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row and regularity rows;*
4. *the componentwise* hsame *rows for the schedule, dyadic endpoint, radius, distance, classifier, regularity, and seal-facing request packet;*
5. *the displayed* Cont *routes from the schedule through the dyadic rows, classifier surface, regularity rows, and seal read;*
6. *the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
7. *the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows from the finite request source section.*

The factorization exports no quotient stream equality, host real equality, host sequence equality, selected limit, choice datum, ambient completeness principle, metric-completeness datum, or second seal coordinate.

Proof. Start with the finite request source section of Definition 301.139. It displays the StreamName schedule, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier and regularity rows, componentwise hsame, displayed Cont, package provenance, and local RegSeqRat naming rows as one finite BHist source section.

Next use the request nonescape theorem, Definition 301.140. It says that a $\mathsf{Real}^{\uparrow}$ seal consuming the same public finite request sees no source section beyond those displayed rows, so quotient streams, host equality rows, selected limits, completeness principles, choice data, and second seal coordinates remain outside the request surface.

The correspondence theorem Definition 301.141 identifies the seal-visible section with the finite request source section in both directions. Thus any consumer that reaches the seal-facing request must first restrict to the same StreamName, DyadicRatCore, RegSeqRat, transport, route, provenance, and local naming rows.

Finally apply the Real finite-request selector-budget lock, Definition 38.699, and the completion-consumer section exactness theorem, Definition 38.701. The lock prevents a terminal budget consumer from replacing the displayed finite section by a second selector or off-packet tail route, and

section exactness says that completion-facing acceptance is exactly factorization through that section. Repacking these two Real-side facts through the RegSeqRat correspondence gives the stated terminal factorization and no additional exported coordinate. □

Theorem 301.143 (RegSeqRat finite-request audit-threshold source lock)**.** *Let R be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S be a public finite request to R consumed by a* $\mathsf{Real}^{\uparrow}$ *seal. Suppose the finite request source section of Definition 301.139 is the same section through which the terminal budget factorization of Definition 301.142 consumes S.*

Then the current Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read on S is locked to exactly that finite source section. The read is the objectwise four-face threshold on*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

over the displayed support rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

It has no coordinate for quotient streams, selected limits, countable choice, metric-completeness data, aggregate formalstatus*, aggregate bridge rows, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply the terminal budget factorization, Definition 301.142. It says that every terminal budget consumer of S factors through the displayed finite request source section, with the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces carried by the local BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply the four-face audit-threshold factorization, Definition 301.219. Since the terminal budget factorization has already fixed the finite source section, the current Phase $\mathsf{Real}^{\uparrow}$ and Completion threshold read can only be read through the same four local faces and the same displayed support rows.

The threshold remains objectwise. Use Definition 126.509 to read the StreamName-side threshold from the four local face records, and use Definition 291.107 to keep the DyadicRatCore, StreamName, RegSeqRat, and Real rows on the shared BHist, hsame, Cont, Pkg, and NameCert interface.

Finally invoke Definition 38.471. The Phase Real and Completion audit is pulled back from the local face records rather than from a cached route-level status. Therefore quotient streams, selected limits, countable choice, metric-completeness data, aggregate formalstatus, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness cannot move the read away from the finite request source section fixed above. □

Theorem 301.144 (RegSeqRat finite-request source-section intersection lock)**.** *Let R be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be public finite requests to R consumed by local* $\mathsf{Real}^{\uparrow}$ *seals. Suppose the displayed source sections of S and T agree on the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the componentwise* hsame *rows, the displayed* Cont *rows, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows.*

Then the common restriction of the two seal-facing requests is exactly one finite $\mathsf{RegSeqRat}^{\uparrow}$ *source section over those rows. No quotient stream, host equality, selected limit, choice datum, ambient or metric completeness principle, or second seal coordinate can distinguish S from T on that restriction.*

Proof. First apply the finite request source section theorem, Definition 301.139, to S and to T. The agreement hypotheses identify the displayed schedule, dyadic, classifier, regularity, transport, continuation, provenance, and local naming rows of the two finite source packets.

Next pass to the seal-visible side with Definition 301.141. The local $\mathsf{Real}^{\uparrow}$ seals see only the restriction of those finite source packets, so the same displayed rows give one seal-facing restriction for both requests.

Use the support composition theorem, Definition 301.149, to compose the two agreed support faces through their common displayed rows. The composed support face still contains exactly the StreamName, DyadicRatCore, RegSeqRat, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows named in the statement.

Finally apply the terminal budget factorization theorem, Definition 301.142, to each seal-facing request. Every terminal consumer factors through the finite source section already identified above. Since that section carries no quotient stream, host equality, selected limit, choice datum, completeness principle, or second seal coordinate, no such external datum can separate the two requests on the common restriction. □

Theorem 301.145 (RegSeqRat finite-request intersection chain stability)**.** *Let R be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $S_0, \ldots, S_n$ be a finite nonempty chain of accepted public finite requests to R consumed by local* $\mathsf{Real}^{\uparrow}$ *seals. Suppose each adjacent pair (S_i, S_{i+1}) agrees on the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the componentwise* hsame *rows, the displayed* Cont *rows, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Suppose also that every adjacent pair agrees on its support subpacket and on the classifier-visible finite request section over those rows.*

Then every pairwise common restriction determined by the chain has the same Real-seal-facing finite $\mathsf{RegSeqRat}^{\uparrow}$ *source section. The direct restriction from S_0 to S_n and every iterated adjacent restriction determine that same section. The statement does not identify quotient stream equality, host real equality, selected limits, choice data, ambient or metric completeness, duplicate* $\mathsf{Real}^{\uparrow}$ *seal coordinates, aggregate formalstatus rows, or bridge rows.*

Proof. First lock each adjacent intersection. Apply Definition 301.144 to every adjacent pair (S_i, S_{i+1}). The hypotheses give exactly the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows required by that lock, so each adjacent common restriction has one Real-seal-facing finite source section.

Next compose the support faces along the chain. Use Definition 301.149 for each two-leg composite and then Definition 301.150 for the finite nonempty chain. These results identify all parenthesized adjacent support-face composites with the direct S_0 to S_n support face, while keeping only the displayed StreamName, DyadicRatCore, RegSeqRat, hsame, Cont, Pkg, and local naming rows.

Finally compare the source sections read from those support faces. The section-refinement composition theorem, Definition 301.244, says that the direct restriction and the iterated adjacent restriction have the same finite request section and the same local $\mathsf{Real}^{\uparrow}$ seal on the displayed rows. Substituting the adjacent intersection locks into this comparison gives one Real-seal-facing finite $\mathsf{RegSeqRat}^{\uparrow}$ source section for every pairwise common restriction determined by the chain.

The cited lock, support-composition, chain-induction, and section-refinement routes are all finite BEDC routes over displayed request rows. None supplies a quotient stream equality, host real equality, selected limit, choice datum, completeness principle, duplicate Real seal coordinate, aggregate formalstatus row, or bridge row. Hence the chain stability result does not claim any of those objects. □

Theorem 301.146 (RegSeqRat finite-request classifier alignment)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be public finite requests to P consumed by the public* $\mathsf{Real}^{\uparrow}$ *seal route. The following data determine one another:*

1. *agreement of the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows of* S *and* T*;*
2. *agreement of the classifier-visible finite request section of* S *and* T *inside the source section of Definition 301.139.*

Thus the rows consumed by the Real seal route are exactly the classifier rows visible in the finite request section. The alignment has no coordinate for quotient stream equality, host real equality, selected limits, choice data, ambient completeness, metric-completeness data, or second seal coordinates.

Proof. For the forward direction, start with the finite request source section of Definition 301.139. Agreement of the displayed rows in the first item names the same StreamName schedule, dyadic endpoint, radius, distance, RegSeqRat classifier, regularity, transport, continuation, package, and local naming rows in that finite BHist section.

Next apply Definition 301.69. It keeps the schedule rows, dyadic rows, RegSeqRat classifier surface, and terminal $\mathsf{Real}^{\uparrow}$ seal row on one ordered handoff rather than allowing a separate seal-facing source packet. Hence the agreed displayed rows are precisely the classifier-visible finite request section.

For the reverse direction, suppose the classifier-visible finite request sections agree. Use Definition 301.160 to identify that agreement with agreement of the shared selector surface on the same schedule, dyadic, classifier, regularity, terminal seal, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Finally apply Definition 301.159. The terminal pullback reads the same displayed selector surface as the same $\mathsf{Real}^{\uparrow}$ seal route, so the first list of rows agrees component by component. Since the source section and selector surface contain no rows for quotient stream equality, host real equality, selected limits, choice data, ambient or metric completeness, or a second seal coordinate, the equivalence cannot transport any of those objects. □

Theorem 301.147 (RegSeqRat finite-request support transport)**.** *Let* P *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let* S *and* T *be public finite requests to* P *consumed by the public* $\mathsf{Real}^{\uparrow}$ *seal route. Suppose the classifier-visible finite request sections of* S *and* T *agree. Then the support rows transported through that section are the same support packet: the componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows of* S *and* T *agree component by component. Conversely, equality of that transported support packet recovers agreement of the support part of the classifier-visible finite request section. This support transport has no coordinate for quotient stream equality, host sequence equality, selected limits, choice data, ambient completeness, metric-completeness rows, or duplicate* $\mathsf{Real}^{\uparrow}$ *seal coordinates.*

Proof. Begin with the source section theorem, Definition 301.139. It displays the support part of each finite request as the componentwise hsame rows, displayed Cont rows, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows in one finite BHist source packet.

For the forward direction, apply the classifier alignment theorem, Definition 301.146. Agreement of the classifier-visible sections forces agreement on every row of the displayed source section that the classifier can see. The four support families listed in the statement are part of that displayed section, so transporting them through the agreed section yields one support packet.

Next use the StreamName-Dyadic-Real handoff exactness theorem, Definition 301.69. It keeps the schedule, dyadic, classifier, regularity, and terminal seal rows on the same finite handoff, so the support packet cannot detach from the section or acquire a second seal-facing coordinate.

Now apply the Real finite-request fusion theorem, Definition 38.698. The $\mathsf{Real}^{\uparrow}$ consumer reads through the same finite BHist packet, with the same hsame, Cont, Pkg, and local naming rows. Thus the support packet transported through the RegSeqRat section is the support packet consumed by the Real seal route.

For the converse, assume the transported support packets are equal. Reading them back through the source section identifies exactly the support sublist of the classifier-visible finite request section. The classifier alignment theorem then recovers agreement of that support part and no larger object, because the cited source, handoff, and fusion routes contain no rows for quotient stream equality, host sequence equality, selected limits, choice data, ambient or metric completeness, or duplicate Real seal coordinates. □

Theorem 301.148 (RegSeqRat Real seal support face uniqueness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be public finite requests to P consumed by the public* $\mathsf{Real}^{\uparrow}$ *seal route. Suppose the classifier-visible finite request sections of S and T agree on the support subpacket. Then the Real-seal-facing support face is unique: the displayed* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows form the same support face for S and T. Every accepted* $\mathsf{Real}^{\uparrow}$ *seal consumer that exposes those rows factors through that face. Conversely, equality of the Real-seal support face recovers equality of the support part of the classifier-visible* $\mathsf{RegSeqRat}^{\uparrow}$ *finite request section. The uniqueness has no coordinate for quotient stream equality, host real equality, selected limits, choice data, ambient completeness, metric-completeness rows, or duplicate* $\mathsf{Real}^{\uparrow}$ *seal coordinates.*

Proof. Start with the support transport theorem, Definition 301.147. It transports agreement of the support subpacket through the componentwise hsame rows, displayed Cont rows, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows, so the two requests present one support packet on the RegSeqRat side.

Next apply the classifier alignment theorem, Definition 301.146. The classifier-visible section sees exactly the displayed support rows named above. Thus equality of the support subpacket is equality of the support part of the finite request section, not equality of any hidden host or quotient object.

Now use the Real finite-request fusion theorem, Definition 38.698. The public $\mathsf{Real}^{\uparrow}$ consumer reads the same finite BHist packet and the same displayed support rows. Hence any accepted seal consumer exposing hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ data must factor through that single Real-seal-facing support face.

For the converse, assume the Real-seal support faces agree. Reading the agreed face back through the fusion packet and the classifier-visible section returns the same support part of the RegSeqRat finite request section. The source, transport, alignment, and fusion routes expose no rows for quotient stream equality, host real equality, selected limits, choice data, ambient completeness, metric-completeness rows, or duplicate Real seal coordinates, so no external coordinate can distinguish two support faces with the same displayed rows. □

Theorem 301.149 (RegSeqRat finite-request support face composition)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S_0, S_1, and S_2 be accepted public finite requests to P consumed along the public* $\mathsf{Real}^{\uparrow}$ *seal route. Suppose the classifier-visible finite request sections of (S_0, S_1) and (S_1, S_2) agree on their support subpackets. Suppose also that the middle support face exposes the same* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows on both legs.*

Then the composed route from S_0 to S_2 has one Real-seal-facing support face, and that face contains exactly the displayed $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows exposed by the middle face. It exports no quotient stream equality, host real equality, selected limit, countable-choice data, metric-completeness rows, duplicate Real seal, aggregate formalstatus row, or bridge row.*

Proof. First identify the two classifier-visible sections. Apply Definition 301.146 to the pair (S_0, S_1) and again to the pair (S_1, S_2). The hypotheses say that the two legs display the same support subpacket at S_1, so the classifier sees one finite support surface through the middle request.

Next transport the displayed support rows along each leg. By Definition 301.147, the shared componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows determine the same transported support packet on the RegSeqRat side for (S_0, S_1) and for (S_1, S_2). The listed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ classifier rows keep that support packet attached to the same finite request face.

Now pass to the Real-seal-facing side. Use Definition 301.148 on the transported support packet to pin the unique Real-facing support face exposed by each leg. Since both legs expose the same middle face, uniqueness identifies their Real-facing support faces as one displayed face.

Finally compare the direct and two-step finite request routes. The section refinement composition theorem, Definition 301.244, says that the one-step route from S_0 to S_2 and the route through S_1 have the same finite request section and local Real seal on the displayed rows. Therefore the composed route has exactly the support face already pinned above.

All cited routes are finite classifier, support-transport, uniqueness, and section-refinement routes over the displayed BEDC rows. None carries quotient stream equality, host real equality, selected-limit data, countable-choice data, metric-completeness rows, duplicate Real seal data, aggregate formalstatus rows, or bridge rows, so the composed support face exports none of those objects. □

Theorem 301.150 (RegSeqRat finite-request support face chain induction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $S_0, \ldots, S_n$ be a finite nonempty chain of accepted public finite requests to P consumed along the public* $\mathsf{Real}^{\uparrow}$ *seal route. Suppose each adjacent pair (S_i, S_{i+1}) has agreeing classifier-visible finite request sections on the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Suppose also that every adjacent pair agrees on its support subpacket.*

Then every parenthesized adjacent support-face composite along the chain and the direct comparison from S_0 to S_n determine the same terminal $\mathsf{Real}^{\uparrow}$ *seal-facing support face. That face contains exactly the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows carried by the adjacent finite request sections, and it exports no quotient stream equality, host real equality, selected limit, choice data, ambient completeness, metric-completeness rows, duplicate* $\mathsf{Real}^{\uparrow}$ *seal, aggregate formalstatus row, or bridge row.*

Proof. The base case is the one-object chain. The direct comparison from S_0 to S_0 is reflexive on the displayed finite request section, so the terminal support face is the same Real-seal-facing face read from that section. No composition data are introduced.

For a one-step chain, apply Definition 301.147 to the adjacent pair and then apply Definition 301.148. The agreed classifier-visible section and the agreed support subpacket pin one Real-facing support face for the two requests.

For the induction step, assume the prefix from S_0 to S_k has a unique terminal support face independent of parenthesization. Compose that prefix face with the last adjacent face from S_k to S_{k+1} using Definition 301.149. The theorem keeps the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows on the same Real-seal-facing support face, so the result is independent of whether the last leg is attached before or after the prefix composite.

It remains to compare the iterated composite with the direct first-to-last section. The section-refinement composition route used in Definition 301.149 identifies the direct S_0 to S_{k+1} classifier-visible section with the composed finite section on the displayed rows. Applying support-face uniqueness once more gives the same terminal $\mathsf{Real}^{\uparrow}$ seal-facing support face.

Every step uses only classifier alignment, support transport, support-face uniqueness, and finite section composition over the listed BEDC rows. These routes contain no rows for quotient streams, host real equality, selected limits, choice data, ambient completeness, metric-completeness rows, duplicate Real seals, aggregate formalstatus rows, or bridge rows, so the chain induction cannot export any of those objects. □

Theorem 301.151 (RegSeqRat Real seal support face classifier readback)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be public finite requests to P consumed by the public* $\mathsf{Real}^{\uparrow}$ *seal route. Suppose the terminal Real-seal-facing support faces of S and T are equal, and suppose the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows agree component by component. Then the classifier-visible finite request sections of S and T are equal.*

The readback has no coordinate for quotient stream equality, host real equality, selected limits, choice data, ambient completeness, metric-completeness rows, duplicate $\mathsf{Real}^{\uparrow}$ *seal coordinates, aggregate formalstatus rows, or bridge rows.*

Proof. First read the terminal support face back through Definition 301.148. Equality of the Real-seal-facing support faces recovers equality of the support part of the classifier-visible $\mathsf{RegSeqRat}^{\uparrow}$ finite request section.

Next identify that recovered support part with the finite request support rows. Apply Definition 301.147: the componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows are exactly the transported support packet seen by the classifier-visible section.

Now combine the recovered support rows with the displayed non-support rows. The hypotheses already identify the $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and dyadic-distance rows, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows. Hence the four visible faces of the finite request section agree.

Finally apply Definition 301.146. Agreement of the displayed four-face data recovers equality of the full classifier-visible finite request sections. The nonescape argument is the same one used in Definition 301.150: the classifier, support-transport, and Real-seal uniqueness routes contain only the displayed BEDC rows. They contain no rows for quotient stream equality, host real equality, selected limits, choice data, ambient completeness, metric-completeness rows, duplicate Real seal coordinates, aggregate formalstatus rows, or bridge rows, so the readback cannot export any of those objects. □

Theorem 301.152 (RegSeqRat StreamName Real scope triad)**.** *For every accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier P, every public* $\mathsf{Real}^{\uparrow}$ *seal read of P is exposed through the three visible scope gates*

1. *the* $\mathsf{StreamName}^{\uparrow}$ *finite observation schedule selecting the requested windows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and tail-budget rows read from those windows;*

3. the $\mathsf{Real}^{\uparrow}$ *seal row that consumes the resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-Cauchy classifier surface.*

The triad preserves the displayed hsame *comparisons,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It contains no quotient stream equality, host real equality, selected limit, completion object, ambient completeness datum, or second seal coordinate.*

Proof. Start with the exact handoff of Definition 301.69. It routes public seal reads through StreamName schedules, DyadicRatCore ledgers, RegSeqRat classifier rows, and the public RealUp seal.

Next apply the source lock of Definition 301.110. The StreamName schedule and the dyadic endpoint, radius, and distance rows are one finite source surface attached to the accepted carrier P.

Finally use Definition 301.111. It identifies the downstream consumer as the same finite regular-Cauchy route with its displayed transports, continuations, package provenance, and local name row. Since those cited surfaces expose only the listed rows, the excluded quotient, host, completion, and second-seal data cannot enter the triad. □

Theorem 301.153 (RegSeqRat dyadic tail-budget totality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, and let a tail-budget consumer request any completion-facing comparison of P. The comparison is total over the displayed dyadic budget rows: it reads a* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the matching* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the requested dyadic radius rows, the dyadic distance rows, the regularity bound rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance. No comparison step has a separate source outside those rows.*

Consequently every tail comparison that can feed the $\mathsf{Real}^{\uparrow}$ *seal is a read of the same finite dyadic budget surface, not a quotient-stream comparison, host real comparison, selected-limit comparison, completion comparison, or ambient completeness comparison.*

Proof. Project the common dyadic tail ledger from Definition 301.74. It lists the schedule, endpoint, radius, distance, classifier, regularity, transport, continuation, package, and naming rows available to tail reads.

Use Definition 301.109 to order a completion-facing request through that ledger before any RealUp-facing surface is visible. The request therefore has no earlier coordinate from which a completion or host comparison could be read.

Now apply Definition 301.114. The terminal surface preserves exactly the same finite dyadic budget rows all the way to the RealUp seal. Thus the comparison is total over the displayed budget surface and nowhere else. □

Theorem 301.154 (RegSeqRat consumer seal unblock surface)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier P, the downstream* $\mathsf{Real}^{\uparrow}$ *handoff surface is unblocked precisely by the two rows supplied by Definition 301.152 and Definition 301.153: the StreamName–RegSeqRat–RealUp scope triad and the total dyadic tail-budget surface. Once these rows are present, every public RealUp consumer reads the finite regular-Cauchy packet through the visible* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces, preserving* hsame, Cont, Pkg, *and* NameCert *provenance.*

Moreover, two downstream $\mathsf{Real}^{\uparrow}$ *handoff surfaces exposing the same* $\mathsf{StreamName}^{\uparrow}$ *finite observation schedules,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and tail-budget rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* hsame, *displayed* Cont, Pkg *provenance, and local* NameCert *provenance determine the same public consumer seal surface.*

The unblock surface is only this downstream handoff. It does not provide a quotient stream, host real equality, selected limit, metric-completion object, ambient completeness theorem, aggregate

formalstatus, aggregate bridge status, route-level leantarget, route-level completeness coordinate, or bridge-checked RealUp consumer.

Proof. First assemble the scope row using Definition 301.152. This places every public seal read behind the StreamName schedule, the dyadic observation budget, and the RealUp seal.

Next assemble the budget row using Definition 301.153. It says that every tail-budget comparison available to a completion-facing consumer is already a read of the displayed dyadic ledger.

Finally combine the public consumer factorization of Definition 301.111 with the terminal seal surface of Definition 301.114. These facts package the scope row and the budget row as the downstream RealUp handoff.

The determinacy of that package is the finite-row determinacy of Definition 301.164: the dyadic ledger, the RegSeqRat selector presentation, and the terminal Real seal read are three presentations of the same displayed surface. Thus two handoff surfaces with the same schedule, dyadic, classifier, readback, seal, transport, continuation, package, and local naming rows determine the same public consumer seal surface.

Finally apply Definition 38.837. It keeps formalstatus, leantarget, bridgestatus, and completeness reports attached to their displayed faces rather than turning their conjunction into a route-level coordinate. Since the package exposes no quotient, host, selected-limit, completion, completeness, aggregate-status, route-target, or bridge-checked coordinate, the consumer is unblocked exactly at the stated finite surface. □

Theorem 301.155 (RegSeqRat consumer seal defect localization)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, and suppose a downstream* $\mathsf{Real}^{\uparrow}$ *handoff from P does not read through the consumer seal surface of Definition 301.154. Then the defect is visible on at least one displayed row of that surface: the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, or tail-budget rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier or readback rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, or the support rows* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

No quotient stream, host real equality, selected limit, metric-completeness object, aggregate formalstatus row, bridge row, or $\mathsf{Real}^{\uparrow}$ *completeness datum repairs such a failed read. Any repair must restore one of the displayed rows above.*

Proof. Apply Definition 301.152. It restricts every public RealUp read of an accepted RegSeqRat carrier to the StreamName schedule, the dyadic observation rows, and the terminal RealUp seal, with the displayed transport, continuation, package, and name rows preserved.

Apply Definition 301.153. It makes each completion-facing comparison that can feed the terminal seal a read of the finite dyadic budget surface, including endpoint, radius, distance, regularity, classifier, readback, transport, continuation, package, and local naming data.

Now use Definition 301.154. The theorem says that the positive consumer handoff is exactly the finite package formed from those rows. Therefore a failed downstream read of that handoff must remove, alter, or fail to present at least one row in the displayed package.

Finally apply Definition 38.837. It keeps formalstatus, bridge status, leantarget reports, and completeness reports on their own faces rather than letting them act as hidden RealUp repair coordinates. The excluded quotient, host-real, selected-limit, completion, aggregate-status, bridge, and completeness objects therefore cannot repair the failed read; the obstruction is localized on the stated finite rows. □

Theorem 301.156 (RegSeqRat scope unblock)**.** *The* $\mathsf{RegSeqRat}^{\uparrow}$ *face of the current L10 route is unblocked exactly by the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance,*

and tail-budget rows, the $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed support*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

When those rows are present, the RegSeqRat consumer-facing route is public; when any one is missing, no quotient stream, host real equality, selected limit, metric-completion object, aggregate formalstatus row, bridge row, or $\mathsf{Real}^{\uparrow}$ *completeness datum repairs the route.*

Proof. First apply Definition 301.152. It places every public RealUp-facing read behind the StreamName schedule, the dyadic endpoint, radius, distance, and tail-budget rows, the RegSeqRat classifier surface, and the terminal RealUp seal.

Next apply Definition 301.153. This makes the completion-facing comparison total over the displayed dyadic budget and support rows, so the RegSeqRat face has no earlier source outside that finite ledger.

For sufficiency, use Definition 301.154. The theorem packages the scope triad and the dyadic budget totality as the consumer-facing unblock surface, including classifier, readback, seal, transport, continuation, package, and local naming rows.

For necessity, apply Definition 301.155. If the route does not read through the unblock surface, the defect is visible on one of the displayed schedule, dyadic, classifier, readback, seal, or support rows. The same theorem and Definition 38.837 exclude quotient streams, host equality, selected limits, metric completion, aggregate status, bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness as repair coordinates. □

Definition 301.157 (RegSeqRat shared-window selector surface)**.** *For an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet* P*, the shared-window selector surface is the finite* BHist *surface consisting of the following displayed rows:*

1. $\mathsf{StreamName}^{\uparrow}$ *schedule rows selecting the public finite windows read by the request;*
2. $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows attached to those windows;*
3. $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and tail-budget rows for the same selected windows;*
4. *componentwise* hsame *rows, displayed* Cont *replay rows,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *row;*
5. *the terminal* $\mathsf{Real}^{\uparrow}$ *seal row consuming the displayed regular-rational source surface.*

The surface contains only the rows visible in the $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *handoff. It has no quotient stream equality, host real equality, selected limit, completion point, ambient completeness datum, hidden selector, or second seal coordinate.*

Theorem 301.158 (RegSeqRat shared-window selector determinacy)**.** *Let* P *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let* S *and* T *be accepted finite requests whose displayed selector surfaces are the shared-window surface of Definition 301.157. If* S *and* T *display the same* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and tail-budget rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, local* $\mathsf{NameCert}$ *row, and terminal* $\mathsf{Real}^{\uparrow}$ *seal row, then* S *and* T *determine the same RegSeqRat tail-window route up to the displayed* hsame *transport and* Cont *replay.*

The determinacy is internal to the shared-window surface. It does not identify quotient streams, host real values, selected limits, completion points, ambient completeness data, hidden selector choices, or any seal outside the displayed $\mathsf{Real}^{\uparrow}$ *row.*

Proof. First use the scope triad of Definition 301.152. It places every public $\mathsf{Real}^{\uparrow}$ seal read behind the visible StreamName schedule, the dyadic endpoint and radius rows, and the RegSeqRat classifier surface before the seal row is consumed.

Next apply the finite request source section of Definition 301.139. The two finite requests have the same displayed source rows, so their schedule, dyadic ledger, classifier, regularity, transport, continuation, package, and naming coordinates are one public source section.

Now use the tail-selector RealUp seal exhaustion theorem, Definition 301.123. It prevents either request from using a quotient stream, hidden selector, selected limit, completion point, or second seal to distinguish a separate tail-window route.

Finally cite the StreamName-Dyadic-Real handoff exactness of Definition 301.69. Transport through hsame and replay through Cont preserve the same handoff rows, so the two accepted requests reach the same RegSeqRat tail-window route and then the same displayed $\mathsf{Real}^{\uparrow}$ seal row. □

Theorem 301.159 (RegSeqRat shared-window terminal pullback equivalence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be accepted finite requests to P whose displayed selector surfaces are the shared-window surface of Definition 301.157. The following data determine one another:*

1. *equality of the shared-window selector surface displayed by S and T;*
2. *equality of the terminal* $\mathsf{Real}^{\uparrow}$ *seal reads obtained from S and T after both requests factor through the ordered four-face packet*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Equivalently, every terminal-budget consumer accepted by S is accepted by T with the same visible dyadic, stream, regular-rational, terminal seal, BHist*, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows, and conversely. The correspondence exposes no quotient stream equality, host real equality, selected limit, hidden selector, completion carrier, ambient completeness datum, or second terminal seal.*

Proof. For the forward direction, apply Definition 301.158. Agreement on the shared-window selector surface identifies the finite StreamName schedule rows, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier and tail-budget rows, componentwise transports, continuations, package provenance, local naming row, and displayed terminal seal coordinate.

Next use Definition 301.142 and Definition 38.713. The two accepted finite requests therefore factor through the same ordered four-face packet from $\mathsf{DyadicRatCore}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$, with the same support rows. The seal uniqueness theorem, Definition 38.714, then identifies their visible terminal $\mathsf{Real}^{\uparrow}$ seal reads.

For the reverse direction, suppose the terminal $\mathsf{Real}^{\uparrow}$ seal reads agree after both requests have been read through the four-face packet. The exhaustion theorem places every visible terminal-budget row of each request on that packet, and seal uniqueness prevents a second terminal read from separating requests with the same displayed faces and support rows.

It remains to recover the selector surface. The finite-request factorization returns exactly the StreamName, DyadicRatCore, RegSeqRat, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows listed in Definition 301.157. Hence equality of the terminal seal reads on the factored packet is equality of the shared-window selector surface.

For the consumer form, take any terminal-budget consumer accepted by S. By terminal-budget exhaustion it reads only the four displayed faces and support rows, so the already established

surface equality repacks the same visible rows as an accepted consumer for T; the converse is symmetric. Finally, Definition 301.167 excludes quotient streams, host real equality, selected limits, hidden selectors, completion carriers, ambient completeness data, and second seals from both sides of the correspondence. □

Theorem 301.160 (RegSeqRat tail-selector section pullback)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be accepted finite requests to P whose displayed selector surfaces are the shared-window surface of Definition 301.157. Agreement of the shared-window selector surface displayed by S and T is equivalent to agreement of the finite-request source section of Definition 301.139, restricted exactly to the* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and tail-budget rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows.*

The pullback has no coordinates for quotient stream equality, host real equality, selected limits, completion points, ambient completeness data, choice data, or second seal coordinates. Thus the selector surface and the finite-request source section name the same finite request data over the ordered handoff

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Proof. For the forward direction, begin with Definition 301.158. Agreement of the shared-window selector surface identifies the visible schedule, dyadic ledger, classifier, regularity, tail-budget, transport, continuation, package, naming, and terminal seal rows.

Apply the finite-request source section theorem, Definition 301.139. It records exactly those visible rows as the finite source section of each accepted request. The StreamName-Dyadic-Real handoff exactness theorem, Definition 301.69, keeps the schedule rows, dyadic endpoint and radius rows, regular-rational classifier rows, and terminal seal row on the same finite handoff, so the two source sections agree on precisely the displayed rows named in the statement.

For the reverse direction, suppose the finite-request source sections agree on those rows. Use Definition 301.142 to factor both accepted requests through the common terminal-budget section. Then Definition 38.713 places every visible Real-facing consumer on that same four-face packet, and Definition 38.714 identifies the terminal seal row.

It remains only to rule out hidden coordinates. The selector surface definition contains no row for quotient streams, host equality, selected limits, completion points, ambient completeness, choice data, or a second seal coordinate. Applying Definition 301.167 removes those candidates from the Real-facing boundary, so agreement of the finite-request source section repacks exactly as agreement of the shared-window selector surface. □

Theorem 301.161 (RegSeqRat shared-window reindex pullback coherence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be accepted finite requests to P whose displayed selector surfaces are the shared-window surface of Definition 301.157. Suppose R_S and R_T are certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes over the displayed selector surfaces of S and T. Assume that the reindex routes preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and tail-budget rows, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows.*

Then the RegSeqRat tail-selector section pullback of Definition 301.160 before applying R_S and R_T is equivalent to the tail-selector section pullback after applying them. Moreover, both terminal

$\mathsf{Real}^{\uparrow}$ *seal reads factor through the same ordered four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The coherence is internal to the displayed finite surface. It introduces no quotient stream equality, host real equality, selected limit, completion point, choice datum, ambient completeness row, or second seal coordinate.

Proof. First compare the StreamName windows before and after reindexing. Apply Definition 126.639 to the certified routes R_S and R_T. The hypotheses name the same schedule, endpoint, BHist, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ rows, so the public finite observation section is unchanged by the reindex routes.

Next place that preserved section on the terminal side. By Definition 126.642, the reindexed reads expose the same $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal. The four-face exit naturality theorem, Definition 126.647, keeps this terminal read natural in the certified reindex route rather than in any hidden host coordinate.

Now return to the RegSeqRat selector surface. Apply Definition 301.160 before reindexing and again after reindexing. Since the preserved rows are exactly the StreamName schedule rows, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier, regularity, and tail-budget rows, terminal seal row, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows, the two pullback readings are the same finite source-section comparison.

Finally use Definition 301.159 to identify the terminal seal read with that same selector surface, and use Definition 301.167 to exclude extra coordinates. Thus the pre-reindex and post-reindex pullbacks transport through the same four-face route and cannot be separated by quotient streams, host real equality, selected limits, completion points, choice data, ambient completeness rows, or second seals. □

Theorem 301.162 (RegSeqRat shared-window reindex composition law)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S and T be accepted finite requests to P whose displayed selector surfaces are the shared-window surface of Definition 301.157. Suppose R_1 and R_2 are composable certified public* $\mathsf{StreamName}^{\uparrow}$ *finite-window reindex routes on those displayed surfaces, and suppose their certified composite route is $R_2 \circ R_1$. Assume that R_1, R_2, and $R_2 \circ R_1$ preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and tail-budget rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows.*

Then applying R_1 and then R_2 gives the same RegSeqRat tail-selector section pullback, and the same terminal $\mathsf{Real}^{\uparrow}$ *seal read, as applying the certified composite route $R_2 \circ R_1$ once. The equality is only equality of the displayed finite selector surface over the ordered handoff*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

It does not identify quotient stream equality, host real equality, selected limits, completion points, choice data, ambient completeness rows, or second seal coordinates.

Proof. First work inside the public StreamName window. The reindex composition law of Definition 126.20 identifies the two-step certified route R_1 followed by R_2 with the single certified route $R_2 \circ R_1$ on the finite StreamName observation section.

Next transport the displayed rows through this identification. Apply Definition 126.639 to the two certified presentations, and use Definition 126.647 to keep the StreamName window, DyadicRatCore ledger, RegSeqRat readback, and terminal Real seal on the same four-face exit route.

Now return to the RegSeqRat selector section. The hypotheses say that each route preserves exactly the rows listed in Definition 301.157: schedule, dyadic endpoint, radius, distance, classifier, regularity, tail budget, terminal seal, hsame, Cont, Pkg, and local NameCert. Applying Definition 301.161 to the first route, then to the second route, and then to the composite route gives the same tail-selector section pullback on those rows.

Finally identify the terminal seal boundary. By Definition 301.159, equality of the displayed selector pullback is equality of the terminal $\mathsf{Real}^{\uparrow}$ seal read through the same ordered handoff. The nonescape theorem, Definition 301.167, removes quotient streams, host real equality, selected limits, completion points, choice data, ambient completeness rows, and second seal coordinates from the comparison, so no hidden coordinate can distinguish the two-step route from its certified composite. □

Theorem 301.163 (RegSeqRat shared-window triple-overlap cocycle)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S, T, and U be accepted finite requests to P. Suppose every pair among S, T, and U displays the shared-window selector surface of Definition 301.157. Pairwise agreement on the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and dyadic-distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, regularity, and tail-budget rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* NameCert *rows determines one triple-overlap selector surface over the ordered handoff*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Conversely, one such triple-overlap selector surface restricts to the three pairwise pullback equivalences between (S,T), (T,U), and (S,U).

The triple-overlap surface contains no quotient stream equality, host real equality, selected limit, completion point, ambient completeness datum, choice data, or second seal coordinate. It is exactly the common finite BHist *surface on the displayed StreamName, DyadicRatCore, RegSeqRat, terminal Real,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

Proof. Start with the three pairwise selector surfaces. On each pair, apply Definition 301.158 to identify the displayed schedule, dyadic ledger, classifier, regularity, tail-budget, transport, continuation, package, naming, and terminal seal rows.

Next pass from pairwise selector agreement to finite-request source sections using Definition 301.160. The three source-section comparisons have the same visible rows, and Definition 126.549 identifies their StreamName–RegSeqRat source restrictions as one source surface on the common triple overlap.

Now attach the terminal Real row. The terminal pullback equivalence of Definition 301.159 and the Real finite-window cocycle Definition 38.191 make the three terminal seal restrictions the restrictions of one $\mathsf{Real}^{\uparrow}$ boundary over the same four-face handoff.

This gives the forward direction: the common source surface and the common terminal boundary are precisely the shared-window selector rows listed in Definition 301.157, so they determine one triple-overlap selector surface.

For the reverse direction, restrict a single triple-overlap selector surface to the three displayed pairwise faces. Each restriction has the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, terminal $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and local NameCert rows, so Definition 301.160 returns the finite-request source-section equivalence and Definition 301.159 returns the terminal pullback equivalence for each pair.

Finally apply Definition 301.167. Since the shared-window surface has no row for quotient streams, host real equality, selected limits, completion points, ambient completeness data, choice

data, or second seals, none of those objects can distinguish the triple-overlap surface from its three pairwise restrictions. □

Theorem 301.164 (RegSeqRat dyadic triangle selector equivalence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S, T, and U be accepted finite requests to P whose pairwise faces display the shared-window selector surface of Definition 301.157. The following presentations determine one another on exactly the displayed finite rows:*

1. *pairwise agreement of the* $\mathsf{DyadicRatCore}^{\uparrow}$ *common scale-window triangle ledger on the signed mantissa row, refined positive-unary exponent row, denominator ledger, common-exponent comparison row, and dyadic distance/radius rows;*
2. *agreement of the* $\mathsf{RegSeqRat}^{\uparrow}$ *shared-window triple-overlap selector surface on the* $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier/readback/tail-budget rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows;*
3. *equality of the terminal* $\mathsf{Real}^{\uparrow}$ *seal read after the three requests are read through the ordered route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Thus the dyadic triangle ledger and the RegSeqRat selector surface are the same BEDC-visible finite data at the terminal $\mathsf{Real}^{\uparrow}$ *boundary. The equivalence adds no quotient rational, quotient stream, host real equality, selected limit, completion point, choice data, ambient completeness datum, or second seal.*

Proof. Begin with the dyadic presentation. Apply Definition 291.83 to pass from pairwise agreement of the common scale-window triangle ledger to the terminal four-face pullback over the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ route.

Next identify that four-face pullback with the RegSeqRat selector surface. The terminal pullback equivalence of Definition 301.159 says that equality of the shared-window selector surface and equality of the terminal $\mathsf{Real}^{\uparrow}$ seal read through the same four faces determine one another on the listed StreamName, dyadic, regular-rational, transport, continuation, package, naming, and seal rows.

For three requests, use Definition 301.163. The three pairwise selector faces restrict from one triple-overlap selector surface, and conversely that surface restricts back to the three pairwise pullbacks. Hence the dyadic triangle ledger, the RegSeqRat triple-overlap surface, and the terminal seal read are three presentations of the same finite boundary data.

Finally apply Definition 301.167. Since the selector surface has no row for quotient streams, host real equality, selected limits, completion points, choice data, ambient completeness rows, or second seals, the correspondence cannot be enlarged by any of those objects. □

Theorem 301.165 (RegSeqRat finite four-face current-phase exit coverage)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let C be a finite current-phase RegSeqRat consumer reading P through the Phase Real and Completion exit surface. The consumer is accepted by that exit surface if and only if it displays the same four visible faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

over one finite BHist *surface, with the same componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows as the shared-window selector surface of Definition 301.157.*

Equivalently, the current-phase exit test is exactly the finite four-face coverage test that reads the dyadic common-scale ledger, the public StreamName common refinement, the RegSeqRat selector/readback surface, and the terminal Real finite-cover face as one BEDC-visible boundary. It does not accept or compare quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate formalstatus rows, bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, start with an accepted current-phase consumer. Apply Definition 126.240 to read its StreamName schedule as a public finite common refinement, with the displayed BHist, hsame, Cont, Pkg, and local NameCert rows preserved.

Next apply Definition 301.164. This identifies the dyadic common-scale triangle ledger, the RegSeqRat shared-window selector surface, and the terminal Real seal read as three presentations of the same finite four-face boundary. Finally use Definition 38.771 to paste the terminal $\mathsf{Real}^{\uparrow}$ finite-cover face onto that boundary without adding any completion datum.

For the reverse direction, assume the consumer displays exactly those four faces over the same finite rows. The StreamName common-refinement theorem supplies the public refinement face, the RegSeqRat dyadic-triangle equivalence supplies the selector/readback face, and the Real finite-cover pasting theorem supplies the terminal finite-cover face. These three certificates repack the displayed rows as the Phase Real and Completion exit surface.

The exclusions are part of the same packaging. None of the three cited surfaces has a row for quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate formalstatus rows, bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Therefore acceptance by the current-phase exit surface is exactly acceptance of the four displayed finite faces and no stronger comparison. □

Theorem 301.166 (RegSeqRat selector-composition visible boundary)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S, T, and U be accepted finite requests to P whose pairwise faces display the shared-window selector surface of Definition 301.157. The route that first reads the $S \to T$ selector and then reads the $T \to U$ selector determines the same terminal* $\mathsf{Real}^{\uparrow}$ *seal boundary as the direct $S \to U$ selector if and only if the two-step and direct presentations agree on exactly the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-scale rows,* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and tail-budget rows, terminal* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *rows, displayed* Cont *rows,* Pkg *provenance, and local* NameCert *rows.*

The comparison is only a comparison of the BEDC-visible terminal boundary over the ordered handoff

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

It has no coordinate for quotient streams, host real equality, selected limits, completion points, choice data, ambient completeness, or any second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. For the forward direction, apply Definition 301.163. The two-step read through $S \to T$ and $T \to U$ and the direct read through $S \to U$ are restrictions of one triple-overlap selector surface, so their visible StreamName, DyadicRatCore, RegSeqRat, terminal Real, hsame, Cont, Pkg, and local NameCert rows are the same rows.

Next use Definition 301.164. It identifies the common-scale dyadic triangle ledger with the RegSeqRat selector surface and the terminal $\mathsf{Real}^{\uparrow}$ seal read on the same ordered four-face route. Thus agreement of the displayed rows is exactly agreement of the terminal visible boundary for the two-step and direct selector presentations.

For the reverse direction, suppose the terminal $\mathsf{Real}^{\uparrow}$ seal boundary exposed by the two-step route agrees with the boundary exposed by the direct $S \to U$ route. Apply Definition 301.159 to recover the shared-window selector surface from the terminal boundary on each compared route.

The recovered selector surfaces have the same displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, terminal $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows. Applying Definition 301.163 repacks those rows as one triple-overlap surface, and Definition 301.164 presents the same data as the dyadic triangle ledger.

Finally, Definition 301.167 excludes quotient streams, host real equality, selected limits, completion points, choice data, ambient completeness rows, and second seal coordinates from both routes. Hence no hidden coordinate can separate the two-step selector read from the direct selector read once the displayed terminal boundary agrees. □

Theorem 301.167 (RegSeqRat Real seal selector non-escape)**.** *A* $\mathsf{Real}^{\uparrow}$ *seal consumer of the RegSeqRat shared-window selector surface receives only the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and tail-budget rows, componentwise* hsame *rows, displayed* Cont *replay rows,* Pkg *provenance, local* $\mathsf{NameCert}$ *provenance, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. The consumer receives no quotient stream, host real equality, selected limit, hidden selector, detached completeness row, or second* $\mathsf{Real}^{\uparrow}$ *seal.*

Proof. Begin with Definition 301.123. It exhausts a selector-facing seal read by the finite StreamName, DyadicRatCore, RegSeqRat, and RealUp rows of the accepted packet.

Apply the finite request Real seal correspondence of Definition 301.141. A finite request reaches the seal only through its displayed source section, not through an external real equality or selected limit.

Use the terminal tail-budget seal theorem Definition 301.114. It keeps the tail budget and seal route on the same finite dyadic ledger and removes detached completion and completeness coordinates from the consumer inventory.

The handoff exactness theorem Definition 301.69 supplies the remaining source-lock: the StreamName schedule and dyadic rows travel together into the Real-facing seal. Since the shared-window selector surface has no row for the excluded objects, the consumer cannot export any of them. □

Definition 301.168 (RegSeqRat tail-budget packet)**.** *The RegSeqRat tail-budget packet is the finite packet displayed to a* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier. Its rows are the dyadic observation rows from* $\mathsf{DyadicRatCore}^{\uparrow}$*, the StreamName window rows naming the finite request, the regularity-budget rows of the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier, the tail-selector rows used by the request, the componentwise transport rows, displayed* Cont *continuations,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *naming row.*

The packet has no hidden completion carrier. Its visible data are exactly the tail-budget source rows that feed the public $\mathsf{Real}^{\uparrow}$ *seal.*

Theorem 301.169 (RegSeqRat tail-budget non-escape)**.** *A* $\mathsf{Real}^{\uparrow}$ *seal consumer of a RegSeqRat tail-budget packet can read only the displayed dyadic observation rows, StreamName window rows, regularity-budget rows, tail-selector rows, transport, continuation, provenance, and local naming rows of Definition 301.168. It cannot obtain quotient sequence equality, a selected limit, countable choice, or ambient completeness from that packet.*

Proof. Begin with Definition 301.114. It places every completion-facing tail-budget consumer on the finite route through the StreamName schedule, DyadicRatCore ledger, RegSeqRat classifier and regularity rows, displayed support rows, and the public RealUp seal.

Next apply Definition 301.158. The shared-window selector is determined by the displayed finite source rows and by the local transport, continuation, provenance, and naming data; hidden selectors and selected limits do not distinguish a second route.

Use Definition 301.167 to remove the excluded coordinates at the Real-facing boundary. It prevents quotient streams, selected limits, detached completion rows, and second seal data from being exported by the selector surface.

The rows remaining after these references are precisely the packet rows of Definition 301.168. Since no cited boundary supplies quotient sequence equality, a selected limit, countable choice, or ambient completeness, a RealUp seal consumer cannot obtain them from the tail-budget packet. □

Theorem 301.170 (RegSeqRat tail-budget sibling route)**.** *Every RegSeqRat tail-budget packet used by a* $\mathsf{Real}^{\uparrow}$ *seal consumer factors through the sibling chapter surfaces chapter 126, chapter 291, and chapter 38 before Definition 301.169 applies. The StreamName surface supplies the finite windows, the DyadicRatCore surface supplies the dyadic tolerances, and the RealUp surface supplies the terminal seal reads for the same displayed packet.*

Proof. Use Definition 301.169. Its route inventory already identifies the dyadic observation rows, StreamName window rows, regularity-budget rows, tail-selector rows, transports, continuations, provenance, and local naming rows that can be read by a RealUp seal consumer.

The three sibling surfaces provide the named external faces of that inventory. The StreamName chapter supplies the finite-window reads, the DyadicRatCore chapter supplies the dyadic tolerance rows, and the Real chapter supplies the terminal RealUp seal reads. Once those faces are displayed, the local non-escape theorem applies to the same tail-budget packet. □

Theorem 301.171 (RegSeqRat tail-budget four-face uniqueness)**.** *Let two* $\mathsf{Real}^{\uparrow}$ *seal consumers of RegSeqRat tail-budget packets expose the same four visible faces: the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity, classifier, and provenance rows, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal row. Then they determine the same BEDC-visible terminal seal route through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

This uniqueness statement uses only the visible tail-budget packet. It does not identify quotient streams, choose a limit, assert host real equality, use countable choice, assume ambient completeness, or add standard bridge rows.

Proof. Begin with Definition 301.169. It fixes the packet inventory available to a $\mathsf{Real}^{\uparrow}$ seal consumer: the finite StreamName rows, dyadic observation rows, regularity-budget rows, selector rows, transport, continuation, provenance, and local naming data. The same theorem excludes quotient stream equality, selected limits, countable choice, and ambient completeness from that inventory.

Next use Definition 301.170. The visible rows are read through the StreamName, DyadicRatCore, and Real sibling surfaces, so the two consumers have the same three external supports for the same tail-budget packet.

Now apply Definition 301.61. Agreement on the StreamName finite-window face, DyadicRatCore tolerance face, RegSeqRat regularity/classifier/provenance face, and terminal $\mathsf{Real}^{\uparrow}$ seal face is complete for the accepted terminal classifier surface.

Finally invoke Definition 301.59. That theorem identifies the terminal route once the four faces and the displayed support rows agree. The StreamName terminality theorem Definition 126.449, the DyadicRatCore refinement uniqueness theorem Definition 291.96, and the Real L10 terminal correspondence Definition 38.455 name the same external faces of the L10 route. Therefore the two consumers determine one BEDC-visible terminal seal route through the displayed BHist, hsame, Cont, Pkg, and local NameCert rows, with no quotient stream equality, selected limit, host real equality, countable-choice row, ambient-completeness row, or standard bridge row added. □

Theorem 301.172 (RegSeqRat tail-budget exhaustion)**.** *Every finite dyadic request admitted by the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail selector is exhausted by a displayed tail budget and cannot escape the* $\mathsf{Real}^{\uparrow}$ *seal route. The displayed budget contains the StreamName window row, DyadicRatCore tolerance row, RegSeqRat regularity row, selected tail row,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows.*

Thus no admitted finite dyadic request can be consumed as a Real-facing request without passing through the same tail-budget packet and the same public seal boundary.

Proof. Begin with the tail-budget handoff of Definition 301.109. It names the finite StreamName window, DyadicRatCore observation rows, RegSeqRat regularity rows, and local support rows that any Real-facing tail-budget request must display.

Apply the tail selector Real-seal exhaustion theorem, Definition 301.114. The selector cannot export a finite dyadic request to the Real seal unless the displayed budget rows already carry that request.

Now use the non-escape result Definition 301.169. It removes quotient sequence equality, selected limits, countable choice, and ambient completeness from the tail-budget consumer route.

The remaining data are exactly the displayed tail budget and the public RealUp seal route. Therefore every admitted finite dyadic request is exhausted by that budget and cannot escape the seal boundary. □

Theorem 301.173 (RegSeqRat tail-budget exit status product)**.** *Every accepted finite dyadic request admitted by the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail selector and consumed as a Phase Real and Completion endpoint is audit-readable only as the componentwise status product of four local face records: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. Each face contributes its own* closurestatus *and* formalstatus *record, while the shared transport is only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

The exit read contains no quotient stream, host equality, selected limit, countable-choice principle, ambient completeness datum, metric-completion datum, bridge row, aggregate formalstatus *token, or promotion from one status axis to the other.*

Proof. Start with Definition 301.172. It puts every admitted finite dyadic request on the displayed tail-budget packet and keeps the Real-facing consumer inside the same public $\mathsf{Real}^{\uparrow}$ seal boundary.

Next apply Definition 301.58 and Definition 301.62. These results identify the terminal read as the four-face ledger consisting of the DyadicRatCore tolerance face, StreamName finite-window face, RegSeqRat regularity and classifier face, and terminal Real seal face, transported only by the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Finally read the ledger through the two-axis discipline of chapter 9203. A face's closure record and verification record remain local to that face, so their product is only a componentwise audit surface. It cannot add a quotient stream, host equality, selected limit, countable-choice principle, completeness datum, bridge row, aggregate verification token, or implication from one axis to the other. □

Theorem 301.174 (RegSeqRat tail-budget status product reverse)**.** *Any finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget packet exposing exactly the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows presents the same public Phase Real and Completion exit status product.*

The packet has no aggregate formalstatus *coordinate, bridge coordinate, route-level completeness coordinate, quotient stream, host real equality, selected limit, or countable-choice selector. Its public read is therefore exactly the componentwise four-face status product of Definition 301.173.*

Proof. Apply Definition 301.172. Every admitted finite dyadic request has already been forced onto the displayed tail-budget packet before the public $\mathsf{Real}^{\uparrow}$ seal can consume it.

Next use Definition 301.58. The exposed DyadicRatCore tolerance ledger, StreamName finite-window row, RegSeqRat regularity and classifier row, and local Real seal row form the same terminal four-face pullback over the displayed BHist, hsame, Cont, Pkg, and NameCert support.

Now apply Definition 301.169. No quotient stream, host equality, selected limit, countable-choice principle, ambient completeness datum, or metric-completion datum can enter the consumer route from outside those rows.

Finally use Definition 301.177. Since the displayed face rows and support rows are exactly the support-minimal packet, adding a route-level formalstatus token, bridge row, or completeness coordinate would not be a component of the accepted public read.

Read the result through the two-axis discipline of chapter 9203. The same face-local rows reconstruct the same componentwise status product, and no route-level token is introduced. □

Theorem 301.175 (RegSeqRat four-face exit consumer normal form)**.** *Every Phase Real and Completion consumer that reads an accepted finite dyadic request from the* $\mathsf{RegSeqRat}^{\uparrow}$ *selector factors through exactly four displayed faces: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. The transport between these faces is only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

Conversely, any consumer exposing these four faces with the same displayed transport has the same public L10 exit read. The normal form exports no quotient stream, host real equality, selected limit, countable-choice selector, metric-completeness datum, aggregate formalstatus *row, or bridge row.*

Proof. Start with Definition 301.173. It places every accepted finite dyadic request consumed at a Phase Real and Completion endpoint on the four componentwise status faces and records the admissible transport rows.

Next apply Definition 301.58. The terminal pullback identifies the same four faces as a single finite BHist surface and shows that the route is carried only by the displayed hsame, Cont, Pkg, and local NameCert rows.

Use Definition 126.372 and Definition 291.110 to align the consumer-side finite-window read with the objectwise DyadicRatCore, StreamName, RegSeqRat, and Real exit records. These identifications make the forward factorization and the reverse same-read criterion the same public L10 read.

Finally apply the two-axis discipline of section 9467.2. It keeps closure rows, verification rows, and bridge rows local to their own faces, so the consumer normal form cannot introduce quotient streams, host real equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus rows, or bridge rows. □

Theorem 301.176 (RegSeqRat tail-budget finite-window refusal localization)**.** *Let a finite dyadic request be addressed to a* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget route. If the request is not accepted as a Phase Real and Completion four-face exit consumer, then the defect is localized to at least one displayed face row or one displayed support row.*

The possible face rows are exactly the $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. The possible support rows are exactly* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, aggregate* formalstatus *tokens, aggregate bridge rows, and* $\mathsf{Real}^{\uparrow}$ *completeness cannot serve as the defect carrier.*

Proof. Apply Definition 301.172. Any finite dyadic request that reaches the tail selector is exhausted by the displayed tail budget before the public $\mathsf{Real}^{\uparrow}$ seal can read it, so a non-accepted request cannot be explained by an off-budget object.

Next use Definition 301.173. The accepted endpoint is a componentwise status product over the four listed faces, transported only by BHist, hsame, Cont, Pkg, and NameCert. Hence a missing acceptance witness must remove one of those component rows or one of those transport rows.

Now apply Definition 301.175. That normal form is also the reverse public-read criterion: exposing the same four faces with the same displayed transport gives the same L10 exit read. Therefore any request that does not expose such a read has its defect on the named face or support rows.

Finally read the conclusion through the two-axis discipline of section 9467.2. Since closure rows, verification rows, and bridge rows do not promote into one another, no quotient equality, host equality, selected limit, choice principle, completeness datum, aggregate status token, aggregate bridge row, or $\mathsf{Real}^{\uparrow}$ completeness claim can replace the missing displayed row. □

Theorem 301.177 (RegSeqRat tail-budget support minimality)**.** *Every accepted finite dyadic request consumed by the Phase Real and Completion* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget route has a support-minimal four-face packet. Its face rows are exactly the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity and classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. Its shared support rows are exactly the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Deleting any one of these face or support rows destroys the accepted public read. Quotient stream equality, host real equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus *tokens, aggregate bridge rows, and* $\mathsf{Real}^{\uparrow}$ *completeness cannot replace the missing row.*

Proof. Apply Definition 301.175. The forward direction factors every accepted finite dyadic request through the four displayed faces and the listed transport support. The reverse direction says that the same four faces with the same support rows give the same public L10 exit read.

Now delete one displayed face row or one displayed support row. The resulting packet no longer satisfies the reverse same-read criterion, so it is not an accepted four-face exit consumer for the same request.

Apply Definition 301.176 to the failed read. Its defect must localize to one of the displayed face rows or support rows, and the localization list is exactly the list removed from the packet above.

Finally use Definition 301.173 together with the two-axis discipline of section 9467.2. Aggregate verification tokens and bridge rows are not component rows of the status product, and neither quotient equality, host equality, selected limits, choice principles, completeness data, nor $\mathsf{Real}^{\uparrow}$ completeness can promote into the missing face or support row. Thus no displayed row can be dropped. □

Theorem 301.178 (RegSeqRat tail-window stability)**.** *Let an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget packet expose a finite tail window as a Phase Real and Completion four-face exit consumer. If that finite tail window is replaced by a certified finer tail window with the same displayed request and support rows, then the public exit read preserves the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal row.*

The stability read exports no quotient stream equality, selected limit, countable-choice selector, $\mathsf{Real}^{\uparrow}$ *completeness datum, metric-completion datum, aggregate* formalstatus *token, or bridge row.*

Proof. Start with Definition 301.172. The original accepted request is already exhausted by the displayed tail budget before the public $\mathsf{Real}^{\uparrow}$ seal can consume it.

Apply Definition 301.173. The public read is componentwise: the DyadicRatCore tolerance ledger, StreamName finite-window row, RegSeqRat regularity and classifier row, and Real seal row remain separate faces over the same BHist, hsame, Cont, Pkg, and NameCert support.

Now use Definition 301.175. A certified finer tail window with the same displayed support rows exposes the same four-face consumer normal form, so it has the same L10 public exit read as the original window.

Finally apply Definition 301.177. Since the four face rows and shared support rows are exactly the support-minimal packet, the refinement can neither drop a displayed row nor replace one by quotient stream equality, a selected limit, countable choice, $\mathsf{Real}^{\uparrow}$ completeness, metric completeness, an aggregate status token, or a bridge row. □

Theorem 301.179 (RegSeqRat tail-budget common-threshold exhaustion)**.** *Let q_0 and q_1 be accepted finite dyadic requests for the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-budget route. Suppose they share the same displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, local* $\mathsf{Real}^{\uparrow}$ *seal row, and displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

Then the two requests admit one common displayed threshold packet. Every Real-facing consumer of either request factors through that packet and the same four-face exit surface. The common-threshold read exports no quotient stream, selected limit, host equality, countable choice, metric-completion datum, aggregate formalstatus *token, or bridge row capable of distinguishing the two requests.*

Proof. Start with Definition 301.178. Since the requests share the same schedule, tolerance, classifier, regularity, Real-seal, and support rows, refining either finite tail window along the common support preserves the same four displayed faces.

Next apply Definition 301.175. A Real-facing consumer can read an accepted request only through the DyadicRatCore tolerance face, StreamName finite-window face, RegSeqRat classifier face, Real seal face, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Use Definition 301.177. The shared face and support rows are exactly the support-minimal packet, so a common displayed threshold can be chosen inside that finite support and no omitted row can be recovered from outside it.

Finally the normal-form non-escape clauses remove quotient streams, selected limits, host equality, countable choice, metric-completion data, aggregate verification tokens, and bridge rows from the consumer route. Thus no Real-facing consumer distinguishes q_0 from q_1 except through the common displayed threshold packet, and both requests factor through it. □

Definition 301.180 (RegSeqRat common-tail window packet)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail window packet is a finite* BHist *packet over one accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source P with the following displayed rows:*

1. *two certified cofinal tail shifts T_0 and T_1 of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P;*
2. *one common* $\mathsf{StreamName}^{\uparrow}$ *refinement window W_* through which the selected tail windows of T_0 and T_1 both restrict;*
3. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows read on W_*, together with the displayed radius rows and regularity bounds*
$$2^{-n} + 2^{-m}$$
for the selected unary indices;
4. *the* RegSeqRatClassifier *rows for the two tail-window reads and for their transported read on W_*;*

5. *the* $\mathsf{Real}^{\uparrow}$ *seal-source rows consumed from the same common finite surface by Definition 301.22;*
6. *the componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance attached to the StreamName, DyadicRatCore, RegSeqRat, and RealUp-facing rows.*

The packet is only a finite common-tail source surface. It stores no quotient stream, host real value, selected limit, metric-completion point, $\mathsf{Real}^{\uparrow}$ *completeness datum, or standard-bridge coordinate beyond the displayed rows.*

Theorem 301.181 (RegSeqRat common-tail union classifier determinacy)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the two shifted tail-window reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. Then the union window determined by that common-tail packet determines one accepted* RegSeqRatClassifier *read for both shifted tail windows, over exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows,* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance.*

The determinacy statement is only a finite BEDC classifier read on the common union window. It exports no quotient stream equality, host real equality, selected limit, ambient completeness row, metric-completeness row, hidden completion carrier, or additional seal coordinate.

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatCommonTailUnionClassifierDeterminacy`

Proof. Project the common-tail window packet of Definition 301.180. Its rows provide the two certified cofinal tail shifts, the common $\mathsf{StreamName}^{\uparrow}$ refinement W_*, the transported dyadic endpoint and radius ledgers, the two tail classifier rows, the common transported classifier row, and the displayed hsame, Cont, Pkg, and NameCert provenance.

Apply Definition 301.9 to the two transported tail reads on W_*. The hypotheses identify the transported $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows, radius rows, regularity ledgers, classifier ledgers, componentwise comparisons, continuation routes, and package provenance, so the two shifted schedules expose one RegSeqRatClassifier read on the common union window.

Use Definition 301.25. The common $\mathsf{StreamName}^{\uparrow}$ refinement locks the dyadic endpoint, radius, distance, and regularity rows to the same finite ledger, so the accepted classifier read cannot branch through a separate schedule coordinate or a separate dyadic coordinate.

Finally route the common classifier through Definition 301.182 and Definition 301.22. The bridge identifies the shared classifier and seal-source surface already present on W_*, and the seal handoff consumes exactly those finite regular-rational rows. Hence quotient stream equality, host real equality, selected limits, ambient completeness, metric-completeness rows, hidden completion carriers, and extra seal data have no displayed row from which to distinguish the two shifted tail windows. □

Theorem 301.182 (RegSeqRat common-tail window classifier bridge)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source, and let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule of P. Suppose two tail-window classifier reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. Then the two reads determine the same* $\mathsf{Real}^{\uparrow}$ *seal-source surface and the same* RegSeqRatClassifier *read after restriction to W_*.*

The bridge conclusion is a statement about the displayed finite packet only. It exports no quotient stream, host real equality, selected limit, metric-completion point, $\mathsf{Real}^{\uparrow}$ *completeness datum, or additional seal coordinate.*

Proof. First use Definition 301.36. The two seal consumers carried by the cofinal tail shifts factor through one accepted common finite window, and the visible rows of that window are exactly the StreamName schedule rows, DyadicRatCore endpoint and radius ledgers, RegSeqRat classifier and regularity ledgers, and the displayed provenance.

Next read the common-tail packet rows componentwise. The definition lists the cofinal tail shifts, the common $\mathsf{StreamName}^{\uparrow}$ refinement W_*, the DyadicRatCore endpoint and radius ledgers, the classifier rows, the $\mathsf{Real}^{\uparrow}$ seal-source rows, and the hsame, Cont, Pkg, and NameCert provenance. Thus each tail-window read restricts to the same finite source surface on W_*.

Apply Definition 301.30. The refined-window gluing surface factors the RealUp-facing handoff through the displayed finite packet W_*, so the two tail-window origins cannot supply separate seal-source surfaces once their rows have been restricted to the common refinement.

Use Definition 301.25 to lock the $\mathsf{StreamName}^{\uparrow}$ schedule rows to the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers inside the common window. The classifier reads inspect only those locked rows together with the regularity ledgers and provenance, so their transported RegSeqRat classifier read on W_* is the same displayed read.

Finally invoke Definition 301.22. The $\mathsf{Real}^{\uparrow}$ seal consumes exactly the accepted regular-rational finite source surface already identified, and the carrier has no coordinate for quotient streams, host real equality, selected limits, metric completions, completeness data, or further seal coordinates. □

Theorem 301.183 (RegSeqRat common-tail window terminality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the two shifted tail reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. Every completion-facing* $\mathsf{Real}^{\uparrow}$ *consumer whose visible rows are exactly the two shifted reads, the common* $\mathsf{StreamName}^{\uparrow}$ *window W_*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and regularity rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, the displayed* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance factors through that common-tail packet.*

The terminal factorization exports no quotient stream, host real equality, selected limit, metric-completion point, $\mathsf{Real}^{\uparrow}$ *completeness datum, or additional seal coordinate.*

Proof. First apply Definition 301.36 to the two cofinal tail shifts. The tail-stable cover places both completion-facing seal consumers on one accepted common finite window with the StreamName schedule rows, DyadicRatCore endpoint and radius ledgers, RegSeqRat classifier and regularity ledgers, and displayed provenance.

Next use Definition 301.30. The common refinement W_* repacks the two shifted tail reads into one RealUp-facing seal source, so every consumer whose visible rows are limited to the displayed shifts and the common window is already routed through the common-tail packet.

Apply Definition 301.25. It locks the common $\mathsf{StreamName}^{\uparrow}$ refinement to the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and regularity rows, leaving the consumer no separate dyadic or schedule coordinate outside W_*.

Now invoke Definition 301.182. The transported classifier read and the transported seal-source rows are the same rows listed by the common-tail packet, including the displayed hsame, Cont, Pkg, and NameCert provenance.

Finally apply Definition 301.22. Since the $\mathsf{Real}^{\uparrow}$ seal consumes exactly this accepted regular-rational finite source surface, the consumer factors through the common-tail packet. Quotient streams, host real equality, selected limits, metric-completion points, $\mathsf{Real}^{\uparrow}$ completeness data, and extra seal coordinates have no displayed carrier row from which to be read. □

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatCommonTailWindowTerminality`

Theorem 301.184 (RegSeqRat common-tail finite-request Real seal pullback)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, and let the two shifted tail reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. For any finite-request* $\mathsf{Real}^{\uparrow}$ *seal consumer whose request is visible along that common-tail packet, the visible pullback of the consumer is exactly the finite source surface listed in Definition 301.180: the* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *provenance.*

Equivalently, the common-tail window source surface and the finite-request $\mathsf{Real}^{\uparrow}$ *seal pullback present the same BEDC-visible rows. The equivalence exports no quotient stream, selected limit, host real equality, ambient completeness row, hidden completion carrier, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First apply Definition 301.183. Any completion-facing consumer whose visible rows are the shifted tail reads, the common window W_*, the dyadic ledger, classifier, seal-source rows, transports, continuations, package provenance, and local naming must factor through the common-tail packet.

Next use Definition 301.113. A finite-request $\mathsf{Real}^{\uparrow}$ seal consumer has visible pullback exactly the StreamName schedule row, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier and regularity rows, displayed hsame, Cont, Pkg provenance, and local NameCert row.

Now apply Definition 301.159. It identifies equality of the shared selector surface with equality of the terminal $\mathsf{Real}^{\uparrow}$ seal reads after both requests have been read through the ordered finite packet from $\mathsf{DyadicRatCore}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$. Thus the common-tail presentation and the finite-request pullback presentation determine one another on the same displayed rows.

Finally invoke Definition 301.167. The selector boundary removes the excluded coordinates from both descriptions: quotient streams, selected limits, host real equality, ambient completeness data, hidden completion carriers, and second seal data have no row in either surface. The remaining rows are precisely the StreamName schedule and refinement rows, DyadicRatCore endpoint, radius, and distance rows, RegSeqRat classifier and regularity rows, RealUp seal-source rows, componentwise hsame, displayed Cont, Pkg provenance, and local NameCert provenance listed in Definition 301.180. □

Theorem 301.185 (RegSeqRat common-tail visible packet assembly)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose a finite-request* $\mathsf{Real}^{\uparrow}$ *seal consumer exposes exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows,* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *provenance for the two shifted tail reads. Then those rows assemble a common-tail window packet of Definition 301.180 with common refinement W_*.*

The assembled packet is unique at the displayed-row level. It exports no quotient stream, selected limit, host real equality, ambient completeness, metric-completeness row, hidden completion carrier, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. First use Definition 301.36. The two certified cofinal tail shifts and the finite-request seal consumer are forced onto one common finite window, so the candidate refinement W_* is the shared support on which the displayed rows may be read.

Next apply Definition 301.25. The exposed $\mathsf{StreamName}^{\uparrow}$ schedule and refinement rows lock the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and distance rows to the same finite ledger, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and regularity rows are therefore read on that locked window.

Use Definition 301.45 and Definition 301.48. These results say that the visible finite-request $\mathsf{Real}^{\uparrow}$ seal boundary has no further source rows beyond the listed schedule, dyadic, classifier, seal-source, hsame, Cont, Pkg, and NameCert data. Hence the displayed rows are exactly the rows required by Definition 301.180.

Finally invoke Definition 301.184. The pullback theorem identifies the assembled common-tail packet with the finite-request seal boundary on the same visible rows. Uniqueness follows because two assemblies with the same W_* and the same displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows have no remaining BEDC coordinate on which to differ, and the excluded quotient, limit, equality, completeness, carrier, and second-seal coordinates are not part of the packet. □

Theorem 301.186 (RegSeqRat common-tail Real boundary equivalence)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, and suppose the shifted tail reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. Then the common-tail packet and the finite-request* $\mathsf{Real}^{\uparrow}$ *seal boundary determine one another exactly on the* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *provenance.*

The public boundary is only this finite BEDC surface. It excludes quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, and any completion row not displayed by the common-tail packet.

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatCommonTailRealBoundaryEquivalence`

Proof. First apply Definition 301.182. The two cofinal tail reads restrict to one classifier and one seal-source surface on W_*, so the common-tail packet already determines the RegSeqRat and RealUp-facing rows of the boundary.

Next use Definition 301.183. Every completion-facing consumer whose visible rows are the two shifts, the common StreamName window, the dyadic endpoint-radius-distance ledger, the classifier and regularity ledger, and the displayed structural rows factors through the common-tail packet. Thus a finite-request $\mathsf{Real}^{\uparrow}$ seal boundary cannot add a second route outside that packet.

Now apply Definition 301.185. It assembles any finite-request boundary exposing exactly the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows back into the common-tail packet on the same refinement W_*.

Then use Definition 301.184. It identifies the visible pullback of any finite-request seal consumer with exactly the rows listed in Definition 301.180. Hence the finite-request boundary and the common-tail packet determine one another on the same displayed rows.

Finally compose the Real L10 four-face route results. The canonical route and exactness theorems, Definition 38.450 and Definition 38.457, place the accepted Real-and-Completion read on the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. The terminal correspondence and pullback uniqueness theorems, Definition 38.455 and Definition 38.458, then repack the same displayed rows as one terminal finite boundary. Since none of the cited packets carries quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, or hidden completion data, the two presentations determine one another exactly on the stated BEDC-visible surface. □

Theorem 301.187 (RegSeqRat common-tail support descent nonescape)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let T_0 and T_1 be two certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, and suppose the shifted tail reads land in a common-tail window packet of Definition 301.180 with common refinement W_*. A* $\mathsf{Real}^{\uparrow}$*-facing terminal consumer or finite-cover consumer descends through the common-tail packet if and only if its visible support rows are exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont, Pkg*, and local* $\mathsf{NameCert}$ *provenance.*

This descent surface excludes quotient stream equality, selected limits, host real equality, countable choice, metric-completeness data, ambient $\mathsf{Real}^{\uparrow}$ *completeness, aggregate route-level* $\mathsf{formalstatus}$ *rows, and bridge rows. No such coordinate can be used to escape the finite support displayed by the common-tail packet.*

Proof. For the forward direction, suppose the terminal or finite-cover consumer descends through the common-tail packet. Apply Definition 301.186. The descended consumer has the same finite boundary as the common-tail packet, hence its visible rows are confined to the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface.

Use Definition 301.184. It identifies the visible pullback of any finite $\mathsf{Real}^{\uparrow}$ seal request through the packet with exactly those source rows. Then Definition 126.558 keeps the $\mathsf{StreamName}^{\uparrow}$ section rows terminal under restriction to the cofinal tail window, so a finite-cover refinement cannot introduce a second schedule coordinate.

Finally apply Definition 38.846. The L10 terminal cover exhausts the Real-facing coordinate list on the four displayed faces, and the common-tail equivalence has already identified those faces with the packet rows. Thus the descended consumer exposes precisely the stated support and nothing else.

For the reverse direction, suppose the consumer exposes exactly the displayed support rows. The $\mathsf{StreamName}^{\uparrow}$ schedule and refinement rows, together with terminal section coherence, place the request on the same finite section window W_*. The DyadicRatCore endpoint-radius-distance ledger and the RegSeqRat classifier and regularity rows are therefore read on the same locked common-tail surface.

Apply Definition 301.184 to read the consumer as the finite $\mathsf{Real}^{\uparrow}$ seal pullback over that surface. Then use Definition 301.186 to identify this pullback with the common-tail packet boundary. The terminal-cover coordinate exhaustion theorem supplies the finite-cover case by showing that every retained cover coordinate is already one of the displayed rows.

The nonescape clause is the row inventory of these four applications. The common-tail equivalence, finite-request pullback, StreamName terminal coherence, and Real L10 coordinate exhaustion expose no quotient stream equality, selected limit, host real equality, countable-choice principle, metric-completeness datum, ambient $\mathsf{Real}^{\uparrow}$ completeness row, aggregate route-level status row, or bridge row. Hence the descent criterion cannot factor through any support outside the displayed packet. □

Theorem 301.188 (RegSeqRat common-tail retained-window induction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{W} = \{W_i\}_{i\in I}$ be a nonempty finite retained family of common-tail window packets over certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the retained family is closed under the displayed finite refinements used by Definition 301.185 and that every retained pair has the classifier bridge and finite-request* $\mathsf{Real}^{\uparrow}$ *seal pullback of Definition 301.182 and Definition 301.184. Then finite induction over $\mathcal{W}$ preserves exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger,*

the $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *provenance.*

The induction invariant is the finite common-tail packet surface itself. At the base window, at each retained refinement step, and after adjoining any further retained window, the resulting packet is equivalent to its finite-request $\mathsf{Real}^{\uparrow}$ *boundary in the sense of Definition 301.186. The induction exports no quotient stream, selected limit, host real equality, countable-choice principle, metric-completeness row, ambient* $\mathsf{Real}^{\uparrow}$ *completeness datum, hidden completion carrier, or additional seal coordinate.*

Proof. For the base window, read the chosen member of $\mathcal{W}$ through Definition 301.180. Its visible rows are precisely the StreamName schedule and refinement rows, DyadicRatCore endpoint-radius-distance ledger, RegSeqRat classifier and regularity rows, RealUp seal-source rows, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ provenance.

For a retained refinement step, apply Definition 301.182. The classifier and seal-source rows restrict to the common refinement without changing the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, or $\mathsf{NameCert}$ surface.

Next apply Definition 301.184. It identifies the visible pullback of every finite $\mathsf{Real}^{\uparrow}$ seal request with exactly the same packet rows, so the induction step cannot add a quotient stream, selected limit, host real equality, metric-completeness row, ambient completeness datum, or second seal coordinate.

When adjoining another retained window, use Definition 301.185. The displayed rows assemble again into a common-tail packet over the retained refinement, and the nonempty finite hypothesis lets this step iterate through the retained family in the usual finite induction order.

Finally invoke Definition 301.186. At every stage the current retained packet and the finite-request $\mathsf{Real}^{\uparrow}$ boundary determine one another on the same BEDC-visible rows. Thus the induction preserves exactly the stated packet surface and refuses quotient streams, selected limits, host real equality, countable choice, metric-completeness data, ambient $\mathsf{Real}^{\uparrow}$ completeness, hidden completion carriers, and additional seal coordinates. □

Theorem 301.189 (RegSeqRat common-tail four-face cocycle determinacy)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0, T_1, and T_2 be three certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose each pair (T_i, T_j) lands in a common-tail window packet of Definition 301.180, and suppose the three pairwise packets restrict to one triple* $\mathsf{StreamName}^{\uparrow}$ *refinement W_* with the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger and the same* $\mathsf{Real}^{\uparrow}$ *seal-source row.*

Then the three pairwise common-tail $\mathsf{Real}^{\uparrow}$ *boundaries satisfy one finite four-face cocycle exactly when the displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows agree on the triple refinement W_*. The cocycle surface has no coordinate for quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, standard-bridge data, or hidden completion carriers.*

Proof. Apply Definition 301.186 to the three pairs (T_0, T_1), (T_1, T_2), and (T_0, T_2). Each pairwise boundary is thereby identified with the same kind of finite common-tail source surface: StreamName schedule and refinement rows, DyadicRatCore endpoint-radius-distance rows, RegSeqRat classifier and regularity rows, RealUp seal-source rows, and the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance.

On the triple refinement W_*, the definition of the common-tail window packet identifies those rows componentwise. The hypotheses give one StreamName refinement, one dyadic ledger, and one

Real seal-source row, so the RegSeqRat classifier and regularity rows and the support provenance are the only remaining displayed coordinates to compare.

For the forward direction, a finite four-face cocycle already pastes the three pairwise Real boundaries along the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. The Real L10 canonical route and exactness results, Definition 38.450 and Definition 38.457, force that pasted surface to read through the displayed rows on W_*, so disagreement on any listed row would give two different finite boundaries for the same face.

For the reverse direction, assume the displayed rows agree on W_*. Use the Real L10 terminal correspondence and pullback uniqueness results, Definition 38.455 and Definition 38.458, to repack the shared rows as one terminal four-face surface. The three pairwise common-tail boundaries are the restrictions of that surface, hence they satisfy the finite cocycle.

No additional boundary coordinate remains to choose. The preceding common-tail Real boundary equivalence and finite-request seal pullback show that quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, standard bridges, and hidden completion data are not rows of the packet, so they cannot split the cocycle after the displayed surface agrees. □

Theorem 301.190 (RegSeqRat common-tail triple-overlap cocycle)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0, T_1, and T_2 be three certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose each shifted pair (T_i, T_j) lands in a common-tail window packet of Definition 301.180, and suppose the three packets restrict to one triple refinement W_* carrying the same* $\mathsf{StreamName}^{\uparrow}$ *schedule rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the same* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*, displayed* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance.*

Then the three pairwise $\mathsf{Real}^{\uparrow}$ *boundary equivalences agree on the triple refinement if and only if W_* exposes exactly that same finite common-tail surface. This triple-overlap cocycle exports no quotient stream, host real equality, selected limit, countable choice, ambient completeness, metric-completeness row, standard-bridge coordinate, or completion datum outside the displayed packet.*

Proof. First apply Definition 301.182 to the three pairs (T_0, T_1), (T_1, T_2), and (T_0, T_2). Each pairwise shifted read is transported to the same kind of common-tail classifier and seal-source surface on its refinement face.

Use Definition 301.183 next. Every completion-facing consumer whose visible rows are the shifted reads, the common StreamName refinement, the dyadic endpoint-radius-distance ledger, the classifier and regularity rows, the seal-source rows, componentwise hsame, displayed Cont, Pkg provenance, and local $\mathsf{NameCert}$ provenance factors through the corresponding common-tail packet.

For the forward direction, assume the three pairwise $\mathsf{Real}^{\uparrow}$ boundary equivalences agree on W_*. Apply Definition 301.186 on each face. The Real L10 canonical route and exactness results cited there, Definition 38.450 and Definition 38.457, identify a unique BEDC-visible boundary on the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces. Therefore any row visible to the triple refinement must be one of the displayed common-tail rows, and each such row has the same value on the three faces.

For the reverse direction, suppose W_* exposes exactly the common finite surface listed in the statement. The three pairwise boundaries are then restrictions of one displayed packet. Apply Definition 301.186 on each pair and use the Real L10 terminal correspondence and pullback uniqueness results, Definition 38.455 and Definition 38.458, to identify the same terminal finite boundary on all three restrictions.

The exclusions are forced by the carrier rows already used. Neither Definition 301.180 nor the Real L10 four-face route supplies quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, standard-bridge coordinates, or hidden completion data, so no such coordinate can distinguish the triple-overlap cocycle once the displayed common-tail surface agrees. □

Theorem 301.191 (RegSeqRat common-tail cocycle descent)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0, T_1, and T_2 be three certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose each shifted pair (T_i, T_j) lands in a common-tail window packet of Definition 301.180, and suppose the three pairwise common-tail windows restrict to one triple refinement W_* carrying the same* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows, componentwise* hsame, *displayed* Cont, *displayed* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance.*

If the three pairwise $\mathsf{Real}^{\uparrow}$ *boundary equivalences agree on W_*, then the three boundaries descend to a single finite four-face exit boundary over exactly the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces, with precisely the same componentwise* hsame, *displayed* Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows. Conversely, any single displayed four-face boundary with exactly those rows restricts to the three pairwise common-tail boundary equivalences. The descent boundary contains no quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, standard bridge data, or hidden completion carriers.*

Proof. Assume first that the three pairwise $\mathsf{Real}^{\uparrow}$ boundary equivalences agree on W_*. Apply Definition 301.190. The triple refinement exposes exactly the common finite tail surface on the StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Now use Definition 301.189. Since the displayed rows agree on the triple refinement, the three pairwise common-tail boundaries satisfy the finite four-face cocycle criterion. This turns pairwise agreement into one cocycle surface rather than three unrelated boundary presentations.

Package that surface by applying Definition 38.455 and Definition 38.458. The terminal Real L10 pullback identifies the shared StreamName, DyadicRatCore, RegSeqRat, and RealUp rows as one finite four-face exit boundary, and uniqueness prevents any second boundary with the same displayed rows.

For the converse direction, start with a single displayed four-face boundary over exactly those four faces and support rows. Restrict it along the three pairwise common-tail windows. Each restriction has precisely the rows required by Definition 301.186, so it recovers the corresponding pairwise $\mathsf{Real}^{\uparrow}$ boundary equivalence.

The exclusions follow from the same displayed-row accounting. The common-tail packet, the cocycle criterion, and the Real L10 terminal pullback provide no coordinates for quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, standard bridge data, or hidden completion carriers, so none can appear in the descended boundary or in its pairwise restrictions. □

Theorem 301.192 (RegSeqRat common-tail cofinal-bundle four-face descent)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let $\mathcal{P}$:* $\mathsf{ProbeBundle}$ *be a finite bundle of certified unary observations served by the shared tail-compatible* $\mathsf{StreamName}^{\uparrow}$ *selector, and let T_0, T_1, and T_2 be three certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the bundled observations have* $\mathsf{InBundle}$ *witnesses, a shared finite-window budget, and pointwise* $\mathsf{RatHistoryClassifier}$ *handoff rows through the selector; suppose each shifted pair (T_i, T_j) lands in a RegSeqRat common-tail window packet of Definition 301.180; and suppose the three pairwise packets restrict to one triple refinement carrying the same bundled StreamName rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius,*

and distance ledger, the same $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the same* $\mathsf{Real}^{\uparrow}$ *seal-source rows, and the same support rows* hsame, Cont, Pkg, *and* NameCert.

Then the bundled StreamName unary rows, their InBundle *witnesses, the shared tail selector, the finite-window budget, the pointwise* RatHistoryClassifier *handoff rows, the dyadic endpoint-radius-distance ledger, the RegSeqRat classifier and regularity rows, the RealUp seal-source rows, and the support rows descend to one finite four-face boundary over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *This boundary contains no quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, ambient* $\mathsf{Real}^{\uparrow}$ *completeness datum, standard bridge coordinate, or hidden completion carrier.*

Proof. First apply Definition 126.548 to the finite bundle $\mathcal{P}$. The bundled unary rows, their InBundle witnesses, the shared selector, the budget surface, the pointwise rational-history classifier handoffs, and the support rows are exhausted by one displayed StreamName packet.

Next restrict the three RegSeqRat common-tail packets to the stated triple refinement. By Definition 301.190, the three pairwise Real boundary equivalences agree exactly when that refinement exposes the common finite surface on the StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows.

Now use Definition 301.191. The pairwise common-tail surfaces therefore descend to a single displayed four-face exit boundary with the same StreamName rows, dyadic ledger, RegSeqRat classifier and regularity rows, RealUp seal-source rows, and support provenance.

Finally apply Definition 38.455 and Definition 38.458. Terminality repacks the displayed boundary over the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and prevents a second boundary with the same rows.

The nonescape clauses in Definition 126.548, Definition 301.190, and Definition 301.191 remove the remaining possible coordinates. Quotient streams, selected limits, host real equality, countable choice, metric completeness, ambient $\mathsf{Real}^{\uparrow}$ completeness, standard bridge data, and hidden completion carriers are not rows of the bundled packet or of the common-tail descent boundary. □

Theorem 301.193 (RegSeqRat common-tail support induction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{P}$:* ProbeBundle *be a finite bundle of certified unary observations over P. A common-tail four-face boundary over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *is accepted for $\mathcal{P}$ exactly when the displayed finite support of $\mathcal{P}$ admits an induction with the following constructors:*

1. *the empty support exposes only the accepted packet rows of P and no boundary beyond the visible common-tail packet;*
2. *a singleton observation exposes the same* BHist, *componentwise* hsame, Cont, Pkg, *and local* NameCert *rows on the StreamName, DyadicRatCore, RegSeqRat, and RealUp faces, and the observation restricts through the common-tail window packet of Definition 301.180;*
3. *a union support is accepted exactly when its two accepted sub-supports have matching displayed* BHist, hsame, Cont, Pkg, *and local* NameCert *rows on their overlap, each added observation restricts through the common-tail packet, and the triple-overlap cocycle descends to the same four-face boundary.*

The induced boundary is exhausted by the bundled StreamName unary rows, their InBundle *witnesses, the shared tail selector, the finite-window budget, the pointwise* RatHistoryClassifier *handoff rows, the dyadic endpoint-radius-distance ledger, the RegSeqRat classifier and regularity rows, the RealUp seal-source rows, and the support rows* BHist, hsame, Cont, Pkg, *and* NameCert.

No quotient stream, selected limit, host real equality, countable choice, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ *completeness datum, standard bridge coordinate, or hidden completion carrier has a support row in this induction principle.*

Proof. For the empty support, the accepted packet P supplies the only rows to inspect. Apply Definition 301.180 and Definition 301.185. They identify the vacuous support surface with the finite common-tail packet whose coordinates are the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows.

For a singleton support, restrict the certified unary observation along the shared tail-compatible selector. The cofinal exhaustion theorem Definition 126.548 places the observation, its InBundle witness, the finite-window budget, and the rational-history handoff row on one displayed StreamName packet. Then Definition 301.184 identifies the same observation with the common-tail Real seal pullback.

Now suppose two finite supports have already been accepted and are being joined. The induction hypotheses give the same displayed BHist, hsame, Cont, Pkg, and local NameCert rows on each accepted sub-support. On the overlap, apply Definition 301.181 to obtain one classifier read for the union window.

The boundary comparison for the joined support is then forced by Definition 301.186. It says that the common-tail packet and the finite-request Real boundary determine one another on exactly the displayed support rows, so no separate boundary can appear after the union classifier has been fixed.

It remains to check coherence for a further observation added to the joined support. Apply Definition 301.190 on the two old support pieces and the new observation. The triple refinement exposes the same common finite surface, and Definition 301.191 descends the pairwise restrictions to one finite four-face boundary.

Conversely, assume a finite four-face boundary for $\mathcal{P}$ is accepted. Restrict it to each constructor layer of the displayed finite support. The empty and singleton restrictions recover the packet and visible observation rows by the first two readings above, while every union restriction recovers matching overlap rows by union classifier determinacy and Real boundary equivalence. The triple-overlap cocycle theorem recovers the required descent datum for each added observation.

Induction on the displayed finite support therefore gives precisely the accepted common-tail four-face boundary stated in the theorem. The row inventory of the cited packet, exhaustion, pullback, determinacy, boundary-equivalence, and cocycle-descent results contains no quotient stream, selected limit, host real equality, countable choice, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ completeness datum, standard bridge coordinate, or hidden completion carrier, so none can become a support row of the induction. □

Theorem 301.194 (RegSeqRat common-tail face-status objectwise pullback)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let T_0, T_1, and T_2 be three certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the shifted pairs land in accepted RegSeqRat common-tail triple-overlap packets whose pairwise boundaries agree on the shared* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Then the only status data pulled back by the resulting common-tail four-face cocycle are the four local face records read objectwise from the $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *chapters' own* closurestatus *blocks. The cocycle creates no aggregate* formalstatus*, no aggregate bridge token, no ambient* $\mathsf{Real}^{\uparrow}$ *completeness row, and no metric-completeness or countable-choice coordinate.*

Proof. First apply Definition 301.190. The accepted triple-overlap surface is exactly the finite common-tail surface on the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows, with no hidden completion or bridge coordinate.

Next use Definition 301.186. The common-tail packet and the finite-request $\mathsf{Real}^{\uparrow}$ boundary determine one another on the same visible rows. Thus any status read available to the cocycle must pass through the same four visible faces rather than through a separate Real-completion carrier.

Now apply Definition 126.504. The terminal four-object boundary is built from the ordered $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces plus their displayed support rows. Terminality leaves no fifth status object in which an aggregate verification grade, bridge datum, completeness theorem, or choice principle could be stored.

Finally use Definition 126.507. That result reads closure grades, formalstatus tokens, Lean targets, and bridge rows only from the corresponding face chapters' own closurestatus records. Pulling those four records through the RegSeqRat common-tail cocycle therefore preserves them object by object, while metric completeness, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, and aggregate bridge or verification data remain absent from the packet. □

Theorem 301.195 (RegSeqRat common-tail terminal section cover)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\{T_i\}_{i\in I}$ be a finite family of certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose every pair (T_i, T_j) lands in a RegSeqRat common-tail window packet, every triple overlap restricts to one common refinement carrying the same displayed rows, and these pairwise and triple-overlap rows satisfy the common-tail cocycle conditions of Definition 301.189 and Definition 301.191. Then the family determines exactly one terminal finite section cover over the ordered faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$.

The visible rows of this section cover are precisely the $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source rows, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *provenance. The cover contains no quotient streams, host real equality, selected limits, countable choice, ambient completeness row, metric-completeness row, aggregate* formalstatus *token, standard-bridge data, or completion coordinate outside those displayed rows.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatCommonTailTerminalSectionCover`

Proof. First apply Definition 301.183 to each pairwise packet. Each completion-facing consumer whose visible rows are the shifted reads, the common StreamName refinement, the dyadic endpoint-radius-distance ledger, the classifier and regularity ledger, the RealUp seal-source rows, componentwise hsame, displayed Cont, Pkg, and local NameCert provenance factors through the corresponding common-tail packet.

Next use Definition 301.186. Pairwise common-tail packets and finite-request $\mathsf{Real}^{\uparrow}$ seal boundaries determine one another on exactly the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows, so the local sections have the same boundary vocabulary on every overlap.

The triple-overlap compatibility is supplied by Definition 301.189 and Definition 301.191. The determinacy theorem turns agreement of the displayed rows on a triple refinement into the finite four-face cocycle condition, and the descent theorem packages the pairwise boundaries as one displayed four-face boundary whenever those cocycle rows agree.

Now compose the Real L10 terminal correspondence with pullback uniqueness. The theorems Definition 38.455 and Definition 38.458 identify the pasted StreamName, DyadicRatCore, RegSeqRat, and RealUp rows as one terminal finite boundary. Applying Definition 301.194 then keeps

the four face-status records objectwise, so the section cover does not acquire an aggregate status object while it is being pasted.

Uniqueness follows from the same pullback calculation. Any second section cover with the same visible local sections restricts to the same pairwise common-tail packets, hence to the same Real L10 terminal boundary on every four-face overlap. Since the listed packets provide no coordinates for quotient streams, host real equality, selected limits, countable choice, ambient or metric completeness, aggregate formalstatus, standard-bridge data, or hidden completion rows, there is no remaining BEDC-visible row on which two terminal section covers could differ. □

Theorem 301.196 (RegSeqRat common-tail finite-support gluing exhaustion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let* $\mathcal{P} : \mathsf{ProbeBundle}$ *be a finite bundle of certified unary observations over P served by the shared tail-compatible* $\mathsf{StreamName}^{\uparrow}$ *selector. Suppose every pair of observations in the displayed support lands in a RegSeqRat common-tail window packet, every triple overlap exposes the common-tail cocycle rows, and the pairwise packets are compatible with the finite support constructors of Definition 301.193.*

Then the finite support induction data determine exactly one terminal four-face boundary over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Its visible rows are precisely the* $\mathsf{StreamName}^{\uparrow}$ *bundle rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the* $\mathsf{Real}^{\uparrow}$ *seal-source row, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support.*

This finite-support boundary has no quotient stream, selected limit, host real equality, countable-choice principle, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ *completeness datum, aggregate status row, standard bridge datum, or completion coordinate outside those rows.*

Proof. First apply Definition 301.193 to the displayed support of $\mathcal{P}$. The empty, singleton, and union constructors give finite support acceptance for exactly the bundled observations served by the shared tail-compatible selector, with the same BHist, hsame, Cont, Pkg, and local NameCert rows on every retained overlap.

Next use Definition 126.548. The shared selector exhausts the StreamName finite bundle rows, their InBundle witnesses, the finite-window budget, and the pointwise rational-history handoff rows on one displayed StreamName surface.

The dyadic face is supplied by Definition 291.83. It reads the same finite support through the endpoint, radius, and distance ledger and places that ledger on the common four-face packet without adding a separate completion coordinate.

Now apply Definition 301.195. The accepted support, the pairwise common-tail packets, and the triple-overlap cocycle rows assemble into one terminal finite section cover over the ordered $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces.

Finally use Definition 38.455 together with pullback uniqueness. The Real L10 terminal correspondence identifies the section cover with the terminal four-face boundary over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and uniqueness prevents a second boundary with the same visible finite support rows.

The exclusion list follows from the row inventories of the cited support induction, StreamName exhaustion, dyadic pullback, terminal section cover, and Real L10 terminality results. None of those packets contains a quotient stream, selected limit, host real equality, countable-choice principle, metric-completeness row, ambient $\mathsf{Real}^{\uparrow}$ completeness datum, aggregate status row, standard bridge datum, or hidden completion carrier, so none is a row of this boundary. □

Theorem 301.197 (RegSeqRat common-tail terminal section Real seal-source uniqueness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\{T_i\}_{i\in I}$ be a finite family of certified cofinal tail shifts*

of the $\mathsf{StreamName}^{\uparrow}$ *schedule carried by* P*. Suppose the pairwise common-tail window packets and triple-overlap refinements satisfy the hypotheses of Definition 301.195, so that they determine a terminal finite section cover over the ordered faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

Let $\mathcal{R}$ *and* $\mathcal{S}$ *be two* $\mathsf{Real}^{\uparrow}$ *seal-source reads exposed over this cover. Suppose their visible rows are the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and refinement rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance rows, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the same* $\mathsf{Real}^{\uparrow}$ *seal row, and the same displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then* $\mathcal{R}$ *and* $\mathcal{S}$ *expose the same finite* $\mathsf{Real}^{\uparrow}$ *seal-source surface.*

This uniqueness statement exports no quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness row, standard bridge data, or hidden completion carrier.

Proof. Apply Definition 301.195 to the accepted RegSeqRat packet and the finite common-tail family. The output is the terminal finite section cover whose visible vocabulary is exactly the four-face row inventory listed in the statement.

Next use Definition 301.198. Since $\mathcal{R}$ and $\mathcal{S}$ agree on the pairwise common-tail packets, triple-overlap refinements, and displayed support rows through the section cover, they determine the same BEDC-visible terminal four-face boundary.

Now apply the Real-side uniqueness results. By Definition 38.410, two finite $\mathsf{Real}^{\uparrow}$ seal-source reads with the same displayed StreamName, DyadicRatCore, RegSeqRat, Real seal, BHist, hsame, Cont, Pkg, and NameCert rows have the same finite seal-source surface. By Definition 38.692, this surface is the terminal Real name-seal source seen by any downstream finite readback through the same packet.

The final row inventory is the nonescape clause. The common-tail cover, the four-face cocycle uniqueness theorem, and the Real seal-source uniqueness theorems provide no coordinate for quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric completeness, standard bridge data, or hidden completion carriers. There is therefore no remaining displayed BEDC row on which the two Real seal-source surfaces can differ. □

Theorem 301.198 (RegSeqRat terminal four-face cocycle uniqueness)**.** *Let* P *be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let* $\mathcal{U}$ *and* $\mathcal{V}$ *be two finite common-tail terminal section covers over the same ordered faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Suppose the two covers have identical pairwise common-tail window packets, identical triple-overlap cocycle rows, and the same displayed support rows* hsame*,* Cont*,* Pkg*, and* NameCert *on every finite refinement. Then* $\mathcal{U}$ *and* $\mathcal{V}$ *are the same BEDC-visible terminal four-face boundary.*

Conversely, if $\mathcal{U}$ *and* $\mathcal{V}$ *are equal as terminal four-face boundaries, then their restrictions have the same pairwise common-tail packets, the same triple-overlap cocycle rows, and the same displayed* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. This uniqueness statement exports no quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, aggregate* formalstatus *token, standard bridge data, or completion coordinate outside the displayed four-face packet.*

Proof. Assume first that the pairwise packets, triple-overlap rows, and displayed support rows of $\mathcal{U}$ and $\mathcal{V}$ agree. Apply Definition 301.195 to each cover. Both covers are terminal finite section covers over the same ordered StreamName, DyadicRatCore, RegSeqRat, and RealUp faces and with the same visible local sections.

Use Definition 301.191 on the common pairwise and triple-overlap data. The shared cocycle rows descend to one displayed four-face exit boundary carrying exactly the common $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows.

Now apply Definition 38.455 and Definition 38.458. The Real L10 terminal pullback repacks the shared displayed packet as a single terminal boundary and forbids a second BEDC-visible boundary with the same four faces and support rows. By Definition 301.194, this identification keeps the four face-status records objectwise and adds no aggregate status coordinate.

For the converse direction, start from equality of the terminal four-face boundaries. Restrict the common boundary along each pairwise common-tail window and along each triple refinement. Terminal equality preserves exactly the displayed rows on those restrictions, so the pairwise packets, triple-overlap cocycle rows, and support rows hsame, Cont, Pkg, and NameCert agree componentwise.

The exclusions follow from the same row inventory. The terminal section cover, the cocycle descent, the objectwise face-status pullback, and the Real L10 terminal pullback provide no coordinates for quotient streams, host real equality, selected limits, countable choice, ambient completeness, metric-completeness rows, aggregate formalstatus, standard bridge data, or hidden completion carriers. Therefore such data cannot split two boundaries after the displayed four-face packet has been fixed, nor can it appear in the restrictions read back from an equal terminal boundary. □

Theorem 301.199 (RegSeqRat common-tail terminal section restriction exactness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\{T_i\}_{i\in I}$ be a finite family of certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose every pair (T_i, T_j) lands in a RegSeqRat common-tail window packet, every triple overlap carries the common-tail cocycle rows, and these rows determine the terminal finite section cover of Definition 301.195. For any finite subfamily $J \subseteq I$, restrict the pairwise packets and triple-overlap cocycle rows to the indices in J.*

Then the restriction of the terminal section cover on I to J is exactly the terminal finite section cover obtained by applying Definition 301.195 to the restricted pairwise and triple-overlap rows. The restricted cover has precisely the visible $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows inherited from the original family, and it introduces no quotient stream, selected limit, host real equality, countable choice, ambient completeness, metric-completeness row, aggregate* formalstatus *token, standard bridge datum, or completion coordinate outside those rows.*

Proof. Project the finite family cover along the inclusion $J \subseteq I$. The projection keeps exactly the pairwise common-tail packets indexed by pairs in J, the triple-overlap cocycle rows indexed by triples in J, and the displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows on their finite refinements.

Apply Definition 301.195 to the restricted data. The hypotheses are inherited by finite restriction: every retained pair still lands in the same common-tail window packet, every retained triple still exposes the same cocycle rows, and the row vocabulary is still the displayed four-face vocabulary of the original cover.

It remains to identify the projected cover with the independently assembled subcover. Use Definition 301.198. The projected cover and the subcover have identical restricted pairwise packets, identical restricted triple-overlap cocycle rows, and the same displayed support rows on every retained finite refinement, so they are the same BEDC-visible terminal four-face boundary.

Finally apply the row inventory from Definition 301.194 together with the Real L10 terminal correspondence and pullback uniqueness results already used in Definition 301.195. Terminal

restriction preserves the four objectwise face records and leaves no additional coordinate through which quotient streams, selected limits, host real equality, choice principles, ambient or metric completeness, aggregate status data, bridge rows, or hidden completion carriers could enter the finite subfamily cover. □

Theorem 301.200 (RegSeqRat four-face terminal section functoriality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\{T_i\}_{i\in I}$ be a finite family of certified cofinal tail shifts of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Let $J \subseteq I$ and $K \subseteq J$ be finite request subfamilies. Suppose every pair in I lands in a RegSeqRat common-tail window packet, every triple overlap carries the common-tail cocycle rows, and these rows determine the terminal finite section cover of Definition 301.195.*

Then the terminal section cover obtained by restricting the common-tail four-face cover directly from I to K is the same finite BEDC packet as the cover obtained by first restricting from I to J and then restricting from J to K. Both routes display exactly the inherited $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows, and neither route introduces quotient streams, selected limits, host real equality, countable choice, ambient completeness, aggregate* formalstatus *data, standard bridge data, or any non-displayed completion coordinate.*

Proof. Apply Definition 301.199 to the refinement $J \subseteq I$. The first restriction is exactly the terminal finite section cover assembled from the pairwise common-tail packets and triple-overlap cocycle rows whose indices lie in J.

Apply the same restriction exactness theorem to the refinement $K \subseteq J$. The second restriction keeps only the rows indexed by K and again produces the terminal section cover determined by those restricted pairwise and triple-overlap rows.

Now apply Definition 301.199 directly to $K \subseteq I$. The direct route has the same restricted pairwise packets, the same restricted triple-overlap cocycle rows, and the same displayed support rows as the two-step route.

It remains to identify the two displayed packets. Use Definition 301.198 together with the descent calculation in Definition 301.195. Since both routes expose the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows on every retained finite refinement, they are the same BEDC-visible terminal four-face boundary.

The exclusion list follows from the row inventory already used in the restriction exactness theorem. Neither direct restriction nor two-step restriction contains a coordinate for quotient streams, selected limits, host real equality, countable choice, ambient completeness, aggregate formalstatus data, standard bridge data, or a hidden completion carrier, so functoriality is witnessed entirely inside the displayed finite BEDC packet. □

Theorem 301.201 (RegSeqRat common-tail terminal section intersection exactness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Let $\{T_i\}_{i\in I}$ and $\{S_j\}_{j\in J}$ be two finite common-tail terminal section covers of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, both over the ordered faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Suppose every pairwise packet, every triple-overlap cocycle row, and every displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *support row of the first cover agrees with the corresponding row of the second cover on each retained index in the finite intersection $I \cap J$.*

Then the restriction of the first terminal section cover to $I \cap J$ and the restriction of the second terminal section cover to $I \cap J$ are the same BEDC-visible terminal four-face boundary. The common boundary is determined only by the retained common-tail packets and their displayed four-face support rows, and it contains no quotient stream, selected limit, host real equality, countable choice, ambient completeness, aggregate formalstatus *data, standard bridge row, or hidden completion carrier.*

Proof. Apply Definition 301.199 to the first cover along the inclusion $I \cap J \subseteq I$. Apply the same theorem to the second cover along $I \cap J \subseteq J$. The two restricted covers are terminal finite section covers built from exactly the pairwise common-tail packets, triple-overlap cocycle rows, and displayed support rows retained by the finite intersection.

The hypothesis identifies those retained rows component by component. Hence the two restricted covers have identical pairwise packets, identical triple-overlap cocycle rows, and the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows on every overlap that remains in $I \cap J$.

Use Definition 301.198. Since the restricted covers expose the same retained finite data, uniqueness identifies them as one BEDC-visible terminal four-face boundary.

The descent and Real terminality inputs make the identification intrinsic to the displayed packet. By Definition 301.191, the common retained pairwise packets descend to one four-face boundary. By Definition 38.455 and Definition 38.458, that descended boundary is the unique terminal pullback over the ordered StreamName, DyadicRatCore, RegSeqRat, and RealUp faces.

The exclusions follow from the same row inventory. The restriction theorem, cocycle uniqueness, cocycle descent, and Real L10 pullback uniqueness provide no coordinate for quotient streams, selected limits, host real equality, countable choice, ambient completeness, aggregate formalstatus data, standard bridge rows, or hidden completion carriers. Thus the meet boundary is exact on the retained finite intersection and nowhere else. □

Theorem 301.202 (RegSeqRat common-tail terminal four-face sheaf exactness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\{T_i\}_{i\in I}$ be a finite family of common-tail terminal section covers of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, all over the ordered faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Suppose the family carries compatible pairwise common-tail packets and triple-overlap cocycle rows on the finite intersections of the index set.*

Then those data determine a unique BEDC-visible terminal four-face boundary if and only if the covers agree on all finite intersections. The visible rows of the boundary are exactly the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *together with* BHist, hsame, Cont, Pkg, *and* NameCert. *No quotient stream, host real equality, selected limit, countable-choice principle, ambient completeness row, metric-completeness row, aggregate* formalstatus *token, standard bridge row, or hidden completion carrier is part of the glued boundary.*

Proof. Assume first that the covers agree on all finite intersections. Apply Definition 301.195 to each local common-tail family. Each local packet is a terminal finite section cover with the same displayed StreamName, DyadicRatCore, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows on its finite window.

Use Definition 301.199 to pass from a cover to any retained finite subfamily, and use Definition 301.201 on every overlap of two such subfamilies. These two exactness statements identify the retained pairwise packets and triple-overlap cocycle rows on the intersections, so the local terminal boundaries have one common displayed packet wherever they meet.

The compatible local packets now have one global boundary. Apply Definition 301.198: any two terminal four-face presentations with the same pairwise packets, triple-overlap rows, and support rows are the same BEDC-visible boundary. Thus the glued packet is unique on the displayed rows.

Finally keep the glued packet on the finite Real L10 route. The theorems Definition 38.455 and Definition 38.458 repack the StreamName, DyadicRatCore, RegSeqRat, and RealUp rows as the terminal four-face pullback and forbid a second boundary with the same visible support data.

Conversely, suppose a unique BEDC-visible terminal four-face boundary is already determined by the family. Restrict that boundary to any finite intersection of covers. By Definition 301.199,

each restricted cover is the terminal finite section cover obtained from the retained pairwise and triple-overlap data.

Apply Definition 301.201 to the two restricted presentations. Since both are restrictions of the same terminal boundary, their displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows agree on the retained finite intersection.

The exclusion clauses follow from the row inventory in the cited cover, restriction, intersection, uniqueness, and Real L10 pullback results. Those results expose only the four named faces and the listed support rows, so quotient streams, host real equality, selected limits, countable choice, ambient or metric completeness, aggregate status data, standard bridge rows, and hidden completion carriers cannot appear in the sheaf boundary or distinguish two glued presentations. □

Definition 301.203 (RegSeqRat common-tail descent atlas)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. A RegSeqRat common-tail descent atlas for P is a finite family $\mathcal{A} = \{U_i\}_{i\in I}$ of common-tail terminal section covers of the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P, together with the following BEDC-visible rows:*

1. *for every retained pair (i, j), a RegSeqRat common-tail window packet on $U_i \cap U_j$ with the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces;*
2. *for every retained triple (i, j, k), the triple-overlap cocycle rows asserting that the three pairwise packets restrict to the same common-tail boundary on $U_i \cap U_j \cap U_k$;*
3. *restriction maps from each U_i to every finite subfamily and intersection agreements for every finite meet of subfamilies;*
4. *support rows* BHist, hsame, Cont, Pkg, *and* NameCert *witnessing that all local faces, pairwise packets, triple rows, restrictions, and intersection agreements are carried by the same finite BEDC packet.*

The atlas is accepted when each local cover is terminal in the sense of Definition 301.195, each finite restriction satisfies Definition 301.199, and each finite meet satisfies Definition 301.201. The atlas contains no quotient stream, host real equality, selected limit, countable-choice principle, ambient completeness row, metric-completeness row, aggregate formalstatus *token, standard bridge row, or hidden completion carrier outside the displayed four-face and support rows.*

Theorem 301.204 (RegSeqRat common-tail descent atlas Real seal exactness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A} = \{U_i\}_{i\in I}$ be an accepted RegSeqRat common-tail descent atlas for P. Then $\mathcal{A}$ determines a unique Real seal-visible terminal four-face boundary over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *if and only if its finite section covers agree on all finite intersections.*

The boundary displays exactly the atlas rows BHist, hsame, Cont, Pkg, *and* NameCert *together with the four named faces. It exports no quotient stream, host real equality, selected limit, countable-choice principle, ambient completeness row, metric-completeness row, aggregate* formalstatus *token, standard bridge row, or hidden completion carrier.*

Proof. Assume first that the finite section covers in $\mathcal{A}$ agree on all finite intersections. By the atlas acceptance clauses and Definition 301.195, every U_i supplies a terminal common-tail section cover over the same ordered StreamName, DyadicRatCore, RegSeqRat, and RealUp faces. Its support rows are the displayed BHist, hsame, Cont, Pkg, and NameCert rows of the atlas.

Use Definition 301.199 for finite subfamilies and Definition 301.201 for finite meets. These two exactness results identify the pairwise packets, triple-overlap cocycle rows, restriction maps, and intersection agreements on every retained overlap.

Now apply Definition 301.202. The compatible finite atlas rows glue to one BEDC-visible terminal four-face boundary, and the same theorem gives uniqueness among terminal presentations with the displayed rows.

Finally pass from the RegSeqRat common-tail boundary to the Real seal-visible boundary. The Real L10 terminal four-face correspondence and pullback uniqueness theorems, Definition 38.455 and Definition 38.458, identify the glued StreamName, DyadicRatCore, RegSeqRat, and RealUp packet with the unique terminal Real seal boundary seen by downstream Phase Real and Completion reads.

Conversely, suppose $\mathcal{A}$ determines a unique Real seal-visible terminal four-face boundary. Restrict that boundary to any finite intersection of atlas covers. By Definition 301.199, the restriction is the terminal finite section cover assembled from the retained pairwise packets and triple-overlap cocycle rows.

Apply Definition 301.201 to any two such restricted presentations. Since both are restrictions of the same Real seal-visible terminal boundary, their displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows agree on the finite meet.

The nonescape statement follows from the same inventory. The atlas definition, the terminal cover theorem, the restriction and intersection exactness theorems, the sheaf exactness theorem, and the Real L10 terminal pullback provide no coordinate outside the named faces and support rows. Hence no quotient stream, host real equality, selected limit, choice principle, ambient or metric completeness row, aggregate status token, standard bridge row, or hidden completion carrier can distinguish two descended Real seal boundaries. □

Theorem 301.205 (RegSeqRat common-tail descent atlas finite-request coverage)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A} = \{U_i\}_{i\in I}$ be an accepted RegSeqRat common-tail descent atlas for P. Every finite-request* $\mathsf{Real}^{\uparrow}$ *seal consumer whose visible rows are carried by $\mathcal{A}$ factors through a unique atlas member or finite intersection. The pullback exposed to that consumer is exactly the four faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *together with* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

No quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, metric-completeness row, aggregate formalstatus *token, standard bridge row, or hidden completion carrier is exported by this finite-request factorization.*

Proof. Let C be a finite-request $\mathsf{Real}^{\uparrow}$ seal consumer whose visible rows are carried by $\mathcal{A}$. The request reads only finitely many displayed rows, so its support is contained in one retained atlas member or in a finite meet of retained members.

If the support is contained in one member U_i, apply Definition 301.199. The consumer factors through the terminal section cover on U_i, and terminality gives uniqueness of the factorization over the displayed StreamName, DyadicRatCore, RegSeqRat, and RealUp rows.

If the support uses several members, apply Definition 301.201. The finite meet carries the same retained pairwise packets, triple-overlap cocycle rows, and support rows, so the request factors through that finite intersection with a unique displayed pullback.

Now use Definition 301.184. It identifies the local member or intersection factorization with the finite $\mathsf{Real}^{\uparrow}$ seal pullback seen by C, and it exposes exactly the four named faces together with BHist, hsame, Cont, Pkg, and NameCert.

The local pullbacks glue to one atlas boundary by Definition 301.202. Finally, Definition 301.204 identifies this glued boundary with the unique Real seal-visible terminal boundary of the accepted atlas. Therefore every finite request carried by $\mathcal{A}$ is covered by a unique member or finite-intersection factorization.

The exclusion statement follows from the same row inventory. The cited pullback, restriction, intersection, sheaf, and atlas exactness theorems contain no coordinate for quotient streams, host real equality, selected limits, countable choice, ambient or metric completeness, aggregate status data, standard bridge data, or hidden completion carriers. □

Theorem 301.206 (RegSeqRat common-tail filtered colimit normal form)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A} = \{U_i\}_{i\in I}$ be a finite directed atlas of accepted common-tail windows for P. Suppose every refinement map in $\mathcal{A}$ preserves the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the shared* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. Then the filtered colimit read of $\mathcal{A}$ has a unique finite BEDC normal form over exactly the four faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with those support rows.*

The normal form is the retained finite atlas display: each finite consumer factors through one retained common-tail member or retained finite intersection, and two such displays are equal precisely when their four face rows and support rows agree there. It exports no quotient stream equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First reduce the directed atlas to its finite support. Apply Definition 301.193 to the retained common-tail observations. The empty, singleton, and union constructors keep every schedule row, dyadic endpoint-radius ledger, RegSeqRat classifier and readback row, local Real seal row, and support row inside the same finite BEDC packet.

Next glue the retained windows. The finite-support gluing exhaustion theorem Definition 301.196 says that pairwise packets, triple-overlap cocycle rows, and compatible support rows assemble to one finite four-face boundary. The descent-atlas coverage theorem Definition 301.205 then places every finite $\mathsf{Real}^{\uparrow}$ seal request on a retained member or retained finite intersection.

Now identify the four faces read by the L10 route. Use Definition 301.69 to keep the StreamName schedule, DyadicRatCore ledger, RegSeqRat readback, and Real seal rows on the same handoff surface. The Real L10 terminal correspondence and pullback uniqueness theorems, Definition 38.455 and Definition 38.458, repack that surface as the unique terminal finite boundary over the four named faces.

It remains to compare two proposed colimit reads. Restrict both reads to any retained member or retained finite intersection. By finite-request coverage they have the same visible local factorization, and by the terminal pullback uniqueness theorem a second normal form with the same displayed rows has no BEDC coordinate on which to differ. Hence the colimit read is the unique finite normal form carried by the atlas.

The excluded data have no route into the construction. The cited support induction, finite-support gluing, descent coverage, handoff exactness, and Real terminal boundary theorems expose only the four face rows and the shared BHist, hsame, Cont, Pkg, and NameCert support. Quotient stream equality, selected limits, countable choice, metric completeness, aggregate status records, aggregate bridge records, and ambient $\mathsf{Real}^{\uparrow}$ completeness therefore cannot be exported by the normal form. □

Theorem 301.207 (RegSeqRat common-tail descent atlas classifier completeness)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A} = \{U_i\}_{i\in I}$ be an accepted RegSeqRat common-tail descent atlas for P. For any two finite* $\mathsf{Real}^{\uparrow}$ *seal consumers visible through $\mathcal{A}$, the consumers determine the same Real seal-visible terminal boundary exactly when their displayed* RegSeqRatClassifier *rows agree on every retained finite section and every retained finite intersection of the atlas.*

The complete finite witness for that boundary is precisely the atlas display over the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *together with the* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. No quotient stream, host real equality, selected limit, choice principle, ambient completeness row, metric-completeness row, standard bridge row, or hidden completion carrier is exported by the classifier-complete Real seal boundary.*

Proof. Assume first that the two visible $\mathsf{Real}^{\uparrow}$ seal consumers determine the same Real seal-visible terminal boundary through $\mathcal{A}$. Apply Definition 301.204. The shared boundary restricts to the same accepted finite section cover on every retained section and every finite intersection of the atlas.

Use Definition 301.202. Since the restricted presentations are one terminal four-face boundary, their displayed StreamName, DyadicRatCore, RegSeqRat, and RealUp rows agree on each retained finite meet. Applying Definition 301.182 on those common-tail windows identifies the transported RegSeqRatClassifier rows seen by the two consumers.

Conversely, suppose the displayed RegSeqRatClassifier rows of the two consumers agree on every retained finite section and finite intersection of $\mathcal{A}$. The bridge theorem Definition 301.182 turns each common-tail agreement into one shared classifier and seal-source surface on the corresponding finite window.

Apply Definition 301.202. The matching classifier rows, together with the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert support rows, glue to one BEDC-visible terminal four-face boundary. Then Definition 301.204 identifies that glued boundary with the unique Real seal-visible terminal boundary determined by the accepted atlas.

Finally use the Real L10 terminal correspondence and pullback uniqueness theorems, Definition 38.455 and Definition 38.458. They say that a terminal presentation over the ordered StreamName, DyadicRatCore, RegSeqRat, and RealUp faces is uniquely read as the Real seal boundary. Thus the classifier rows are complete for the finite boundary witnessed by $\mathcal{A}$.

The nonescape clause is just the row inventory of the construction. The cited atlas exactness, classifier bridge, sheaf exactness, and Real L10 terminal pullback results expose only the four named faces and the listed support rows, so the excluded quotient, equality, limit, choice, completeness, bridge, and hidden-carrier data have no displayed coordinate in the classifier-complete boundary. □

Theorem 301.208 (RegSeqRat common-tail descent atlas boundary naturality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ and $\mathcal{B}$ be accepted RegSeqRat common-tail descent atlases for P. Suppose a finite boundary-preserving atlas morphism sends every retained member, retained pairwise packet, retained triple-overlap cocycle row, and displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *support row of $\mathcal{A}$ to the corresponding displayed row of $\mathcal{B}$. Then the Real seal-visible terminal boundary induced by $\mathcal{A}$ maps to the Real seal-visible terminal boundary induced by $\mathcal{B}$.*

Conversely, for any such finite atlas morphism, equality of the induced Real seal-visible terminal boundary forces agreement of the displayed RegSeqRatClassifier *rows on every retained member and every retained finite intersection of $\mathcal{A}$ and $\mathcal{B}$.*

No quotient stream equality, selected limit, host real equality, countable-choice principle, ambient completeness row, metric-completeness row, aggregate status row, standard bridge row, or hidden completion carrier is exported or used by this naturality statement.

Proof. First consider the forward transport. By Definition 301.204, the Real seal-visible terminal boundary of each accepted atlas is identified by its displayed common-tail section covers, finite

intersections, and four named faces. The morphism preserves exactly those retained rows, so it carries the boundary presentation of $\mathcal{A}$ to a boundary presentation over the displayed rows of $\mathcal{B}$.

Use Definition 301.205 to factor every finite Real seal request through a retained member or retained finite intersection. On those factors the morphism is already row-preserving by hypothesis. The restriction and intersection exactness theorems, Definition 301.199 and Definition 301.201, keep the transported packet inside the same finite L10 display.

The transported local packets glue in $\mathcal{B}$ by Definition 301.202. Since the glued packet has the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows of $\mathcal{B}$, another application of Definition 301.204 identifies it with the Real seal-visible terminal boundary induced by $\mathcal{B}$.

Now assume the induced Real seal-visible terminal boundaries are equal along the same morphism. Restrict the equality to any retained member or retained finite intersection. The finite-request coverage theorem places that restriction in the displayed finite section cover, and the restriction and intersection exactness theorems identify the common-tail window on which both atlas presentations are compared.

Apply Definition 301.207. Equality of the Real seal-visible terminal boundary on each retained finite window recovers equality of the displayed $\mathsf{RegSeqRatClassifier}$ rows there. Hence the morphism forces classifier agreement on every retained member and every retained finite intersection.

The nonescape clause follows from the same inventory. The atlas definition, the Real seal exactness theorem, finite-request coverage, classifier completeness, restriction and intersection exactness, and four-face sheaf exactness expose only the four named faces and the listed support rows. Therefore quotient stream equality, selected limits, host real equality, countable choice, ambient or metric completeness, aggregate status rows, standard bridge rows, and hidden completion carriers have no coordinate through which this naturality result can factor. □

Theorem 301.209 (RegSeqRat audit-threshold atlas naturality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ and $\mathcal{B}$ be accepted RegSeqRat common-tail descent atlases for P. Suppose a finite boundary-preserving atlas morphism sends every retained member, retained pairwise packet, retained triple-overlap cocycle row, and displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support row of $\mathcal{A}$ to the corresponding displayed row of $\mathcal{B}$. Then the morphism transports the Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold coordinate induced by $\mathcal{A}$ to the audit-threshold coordinate induced by $\mathcal{B}$.*

Conversely, for any such finite atlas morphism, equality of the induced Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold coordinates forces agreement of the displayed* $\mathsf{RegSeqRatClassifier}$ *rows on every retained member and every retained finite intersection of $\mathcal{A}$ and $\mathcal{B}$.*

No quotient stream, selected limit, host real equality, countable-choice principle, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness row, aggregate* $\mathsf{formalstatus}$ *row, aggregate bridge row, or hidden completion carrier is exported or used by this audit-threshold naturality statement.*

Proof. First transport the underlying atlas boundary. Apply Definition 301.208. The finite morphism preserves the retained members, finite intersections, four displayed faces, and support rows, so it carries the Real seal-visible terminal boundary induced by $\mathcal{A}$ to the one induced by $\mathcal{B}$.

Next read the audit-threshold coordinate on the transported boundary. Apply Definition 301.219. The Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read is the RegSeqRat four-face exit-threshold equivalence together with the local closurestatus and formalstatus records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

It remains to identify those local records after transport. Use Definition 126.509 for the StreamName-side threshold readback, Definition 38.471 for the Phase $\mathsf{Real}^{\uparrow}$ and Completion audit

pullback, and Definition 291.107 for the shared NameCert interface over BHist, hsame, Cont, Pkg, and NameCert. Since the morphism preserves each of these displayed rows, the audit-threshold coordinate read from $\mathcal{A}$ is the coordinate read from $\mathcal{B}$.

For the converse, assume the induced audit-threshold coordinates are equal along the same finite morphism. The factorization theorem reads both coordinates through the same RegSeqRat four-face exit-threshold surface and the same four local face records, while the StreamName readback, Real audit pullback, and DyadicRatCore interface theorem keep the support rows objectwise.

Apply Definition 301.208 to the boundary left by these equal threshold reads. Its converse clause recovers agreement of the displayed RegSeqRatClassifier rows on every retained member and every retained finite intersection.

The nonescape clause is the row inventory of the construction. The cited boundary naturality, audit-threshold factorization, StreamName readback, Real audit pullback, and DyadicRatCore interface theorems expose only the four named faces and the listed support rows. Therefore quotient streams, selected limits, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness data, aggregate status data, aggregate bridge data, and hidden completion carriers have no coordinate through which this naturality result can factor. □

Theorem 301.210 (RegSeqRat common-tail atlas finality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ be an accepted common-tail descent atlas for P in the sense of Definition 301.203. Let $\mathcal{T}$ be any finite L10 terminal presentation over the same four faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$. *Suppose every finite* $\mathsf{Real}^{\uparrow}$ *seal request of $\mathcal{T}$ factors through a retained member or retained finite intersection of $\mathcal{A}$, and suppose the displayed* RegSeqRatClassifier *rows of $\mathcal{T}$ agree with the rows of $\mathcal{A}$ on all such overlaps. Then there is a unique boundary-preserving morphism from $\mathcal{T}$ into $\mathcal{A}$.*

Equivalently, $\mathcal{A}$ is terminal among finite common-tail presentations inducing the same Real seal-visible boundary and the same Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold coordinate. This terminal surface exports no quotient streams, selected limits, host real equality, countable choice, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness rows, aggregate* formalstatus *rows, aggregate bridge rows, or hidden completion carriers.*

Proof. First build the local comparison map. By Definition 301.205, each finite $\mathsf{Real}^{\uparrow}$ seal request of $\mathcal{T}$ is read inside a retained member or retained finite intersection of $\mathcal{A}$. The hypotheses therefore place every displayed StreamName, DyadicRatCore, RegSeqRat, local RealUp, BHist, hsame, Cont, Pkg, and NameCert row of $\mathcal{T}$ on a retained atlas window.

On each retained window, apply Definition 301.207. Agreement of the displayed classifier rows on overlaps identifies the Real seal-visible boundary carried by $\mathcal{T}$ with the boundary of the corresponding retained part of $\mathcal{A}$. The Real seal exactness theorem Definition 301.204 then supplies the unique local factorization into the accepted atlas boundary.

The local factorizations glue because they agree on every retained finite intersection. This is exactly the boundary-preserving content of Definition 301.208: a finite atlas morphism preserving the retained rows transports the Real seal-visible terminal boundary and, conversely, boundary equality recovers classifier agreement on the overlaps. Hence the locally defined comparison maps assemble into one boundary-preserving morphism $\mathcal{T} \to \mathcal{A}$.

Uniqueness follows by applying the same two readings in reverse. Any boundary-preserving morphism from $\mathcal{T}$ into $\mathcal{A}$ has the same finite $\mathsf{Real}^{\uparrow}$ seal requests by Definition 301.204; it has the same overlap classifier rows by Definition 301.207; and it has the same Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate by Definition 301.209. Thus no second morphism can differ on any retained member, finite intersection, boundary row, or audit-threshold coordinate.

The nonescape clause is the displayed row inventory. The atlas definition and the cited exactness, coverage, classifier, boundary-naturality, and audit-threshold-naturality theorems expose only the four named faces and the support rows BHist, hsame, Cont, Pkg, and NameCert. There is no coordinate for quotient streams, selected limits, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric-completeness rows, aggregate formal-status rows, aggregate bridge rows, or hidden completion carriers. □

Theorem 301.211 (RegSeqRat common-tail atlas refinement invariance)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, let $\mathcal{A}$ be an accepted common-tail descent atlas for P, and let $\mathcal{B}$ be a finite certified refinement of $\mathcal{A}$. Suppose the refinement preserves every retained member of $\mathcal{A}$ by a finite cover in $\mathcal{B}$, preserves the retained pairwise packets and triple-overlap cocycle rows, and preserves the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *local* $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then the Real seal-visible terminal boundary induced by $\mathcal{B}$ factors through the boundary induced by $\mathcal{A}$, and the induced Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold coordinate of $\mathcal{B}$ agrees with the coordinate induced by $\mathcal{A}$ under this factorization.*

Conversely, any finite certified refinement with the same retained-row preservation and with the same induced Real seal-visible terminal boundary and audit-threshold coordinate is already equivalent to $\mathcal{A}$ on every retained common-tail member, pairwise packet, and triple-overlap cocycle row.

This refinement-invariance surface exports no quotient streams, selected limits, host equality, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness rows, aggregate* formalstatus *rows, aggregate bridge rows, or hidden completion carriers.*

Proof. First identify the support packet visible to the refinement. Apply Definition 126.662: the refined finite cover cannot introduce a second $\mathsf{StreamName}^{\uparrow}$ support surface, so every retained StreamName coordinate of $\mathcal{B}$ reads through the support packet already displayed by $\mathcal{A}$.

Next perform the finite-cover comparison on the RegSeqRat and Real faces. The refinement hypotheses give exactly the retained members, pairwise packets, triple-overlap cocycle rows, and support rows required by Definition 301.64. Applying Definition 301.92 then identifies the refined Real seal-visible terminal boundary with the boundary obtained from $\mathcal{A}$ through the certified finite cover.

Now pass from finite covers to atlas boundaries. Use Definition 301.208 to view the refinement as a boundary-preserving atlas morphism. By Definition 301.210, the resulting finite common-tail presentation has the unique factorization into $\mathcal{A}$, so the boundary induced by $\mathcal{B}$ factors through the boundary induced by $\mathcal{A}$.

It remains to compare the audit-threshold coordinate. Apply Definition 301.209 to the same boundary-preserving refinement morphism. Since the refinement preserves the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows, the Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate read from $\mathcal{B}$ is the one read from $\mathcal{A}$.

For the converse, assume the refined atlas has the same boundary and audit-threshold coordinate under the retained-row preservation hypotheses. The converse clauses of boundary naturality and audit-threshold atlas naturality recover agreement of the displayed RegSeqRatClassifier rows on each retained member and finite intersection. The retained pairwise packets and triple-overlap cocycle rows are therefore the same certified finite data as those of $\mathcal{A}$.

The nonescape statement is again a row inventory. The support-minimality, finite-cover refinement, Real-seal refinement, boundary-naturality, atlas-finality, and audit-threshold-naturality theorems use only finite retained covers and the displayed support rows, leaving no coordinate for

quotient streams, selected limits, host equality, choice, ambient or metric completeness, aggregate status data, aggregate bridge data, or hidden completion carriers. □

Theorem 301.212 (RegSeqRat descent atlas audit-threshold fusion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ be an accepted common-tail descent atlas for P in the sense of Definition 301.203. The atlas presents the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read if and only if the following three conditions hold:*

1. *its finite section covers satisfy common-tail terminal four-face sheaf exactness;*
2. *its displayed* $\mathsf{RegSeqRatClassifier}$ *rows satisfy descent-atlas classifier completeness on every retained member and finite intersection;*
3. *its Real seal-visible boundary is final among finite common-tail presentations inducing the same four local face records.*

When these conditions hold, the audit read is exhausted exactly by the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$, *together with* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$.

No quotient stream, selected limit, host equality, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness row, aggregate* $\mathsf{formalstatus}$ *row, aggregate bridge row, or hidden completion carrier is part of the presented audit-threshold read.*

Proof. For the forward direction, assume that $\mathcal{A}$ presents the current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. Apply Definition 301.219. The threshold read factors through the RegSeqRat four-face exit surface, so the only local face records available to the presentation are the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$ records.

The exactness and classifier clauses are then read back on the atlas itself. Use Definition 301.209 to transport the threshold coordinate through boundary-preserving atlas maps, and use Definition 301.210 to compare any finite common-tail presentation with $\mathcal{A}$. The StreamName readback, Real audit pullback, and DyadicRatCore interface theorems, Definition 126.509, Definition 38.471, and Definition 291.107, identify the support rows as BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

It remains, in the forward direction, to record that the three displayed conditions are precisely the atlas witnesses used by the presentation. The sheaf condition is Definition 301.202; the classifier condition is Definition 301.207; and the finality condition is Definition 301.210. Thus a presentation of the audit-threshold read exposes all three witnesses and no additional carrier.

Conversely, assume the three conditions. Common-tail terminal four-face sheaf exactness glues the finite section covers to one BEDC-visible terminal boundary over the four named faces. Classifier completeness identifies the same Real seal-visible boundary for every finite consumer whose displayed classifier rows agree on the retained members and finite intersections.

Now apply atlas finality. Any finite common-tail presentation inducing the same four local face records has a unique boundary-preserving morphism into $\mathcal{A}$. Audit-threshold atlas naturality then identifies the Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate along that unique morphism, so the atlas carries a single objectwise audit read.

Finally apply the StreamName, Real, and Dyadic L10 interface theorems cited above. They read the unique threshold coordinate through exactly the four local faces and the support rows BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$. Since none of the cited exactness, classifier, finality, naturality, or L10 pullback results exports quotient streams, selected limits, host equality, countable choice, ambient or metric completeness, aggregate status data, aggregate bridge data, or hidden completion carriers, the presented read is exhausted by the displayed rows. □

Theorem 301.213 (RegSeqRat common-tail descent atlas support minimality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ be an accepted common-tail descent atlas for P in the sense of Definition 301.203. Suppose $\mathcal{A}$ presents the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read. If one deletes any retained member, retained pairwise packet, retained triple-overlap cocycle row, or any displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *local* $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *or* $\mathsf{NameCert}$ *support row, the remaining finite surface no longer presents that audit-threshold read.*

Conversely, any accepted common-tail descent atlas carrying all retained members, retained pairwise packets, retained triple-overlap cocycle rows, all displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *local* $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support rows, and the three fusion conditions of Definition 301.212, presents the same current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read.*

This support-minimality statement exports no quotient streams, selected limits, host equality, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness rows, aggregate* $\mathsf{formalstatus}$ *rows, aggregate bridge rows, or hidden completion carriers.*

Proof. First read the accepted atlas through the fusion theorem. By Definition 301.212, presenting the audit-threshold read is equivalent to the common-tail terminal four-face sheaf condition, descent-atlas classifier completeness, and finality among finite common-tail presentations with the same four local face records. The same theorem identifies the displayed support as exactly $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Now delete one retained member, retained pairwise packet, or retained triple-overlap cocycle row. The finite-support gluing exhaustion theorem Definition 301.196 says that every finite Real seal request is exhausted by retained members and finite intersections of $\mathcal{A}$. Removing one of those rows leaves a request or overlap without its displayed factorization, so the sheaf and classifier clauses required by the fusion theorem can no longer be witnessed.

If instead one deletes one displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, or $\mathsf{NameCert}$ support row, apply Definition 301.209. Audit-threshold transport is defined only along boundary-preserving atlas morphisms that preserve precisely those rows. With any one of them absent, the transported Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate has no objectwise support coordinate, so the remaining surface cannot be the same presented read.

Finality gives the necessity conclusion. By Definition 301.210, every finite common-tail presentation of the same boundary and audit-threshold coordinate factors uniquely through $\mathcal{A}$. A surface obtained by deleting a retained row would either omit a finite request required by gluing exhaustion or fail to preserve a support coordinate required by naturality. Such a surface therefore cannot receive the unique final comparison as a presentation of the same read.

For the converse, assume an accepted atlas keeps all listed rows and satisfies the three fusion conditions. Apply Definition 301.212 to obtain a presented audit-threshold read. Then use Definition 301.211 to compare it with $\mathcal{A}$ along the retained-row refinement surface, and use Definition 301.209 to transport the coordinate. The result is the same current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read.

The exclusions are part of the same inventory. The proof uses only threshold fusion, atlas finality, refinement invariance, audit-threshold naturality, and finite-support gluing exhaustion; none of these results supplies a coordinate for quotient streams, selected limits, host equality, countable choice, ambient or metric completeness, aggregate status data, aggregate bridge data, or hidden completion carriers. □

Theorem 301.214 (RegSeqRat terminal support carrier inversion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $\mathcal{A}$ be an accepted common-tail descent atlas for P in the sense of Definition 301.203. Suppose $\mathcal{A}$ presents the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read. Then every downstream L10 read of the Real seal-visible terminal boundary presented by $\mathcal{A}$, when read as the same Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold coordinate, projects exactly the four carrier and classifier faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$, *together with the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows.*

Conversely, if two downstream L10 reads of that presented terminal boundary have the same projected $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and local* $\mathsf{Real}^{\uparrow}$ *face rows and the same displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows, then they determine the same Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read.*

The carrier-inversion surface exports no quotient streams, selected limits, host equality, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness rows, aggregate* formalstatus *rows, aggregate bridge rows, or hidden completion carriers.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatCommonTailTerminalSupportCarrierInversion`

Proof. First read the terminal boundary through the fusion theorem. By Definition 301.212, the hypothesis that $\mathcal{A}$ presents the audit-threshold read is equivalent to the common-tail terminal four-face sheaf condition, descent-atlas classifier completeness, and atlas finality over the same four local face records. The same theorem identifies the complete support inventory as $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Now apply support minimality. Theorem 301.213 says that deleting any retained atlas row or displayed support row destroys the presented audit-threshold read. Hence a downstream L10 read of the same presented boundary cannot project through a smaller carrier surface, and any visible carrier row it uses must already be one of the listed rows.

It remains to identify the readback as objectwise, not merely by absence. Use Definition 301.210: every finite common-tail presentation of the same Real seal-visible boundary and audit-threshold coordinate factors uniquely into $\mathcal{A}$. Then apply Definition 301.209 to the resulting boundary-preserving comparison. The StreamName readback, Real audit pullback, and DyadicRatCore interface theorems, Definition 126.509, Definition 38.471, and Definition 291.107, read that comparison through exactly the four face rows and the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For the converse, take two downstream reads with the same projected face rows and support rows. Atlas finality gives each read the same unique comparison into $\mathcal{A}$, because there is no retained member, finite intersection, boundary row, or support coordinate on which the comparisons can differ. Audit-threshold atlas naturality then transports both reads to the same Phase $\mathsf{Real}^{\uparrow}$ and Completion coordinate.

The exclusions follow from the same support inventory. The fusion, support-minimality, finality, naturality, StreamName readback, Real pullback, and Dyadic interface results cited above expose no coordinate for quotient streams, selected limits, host equality, countable choice, ambient or metric completeness, aggregate status rows, aggregate bridge rows, or hidden completion carriers, so no downstream readback can recover such a carrier from the terminal atlas boundary. □

Theorem 301.215 (RegSeqRat local-threshold exit descent)**.** *Let $\mathcal{E}$ be an accepted objectwise Phase* $\mathsf{Real}^{\uparrow}$ *and Completion exit-threshold read whose public classifier coordinate is read on the same visible terminal packet. Suppose the visible source of $\mathcal{E}$ is an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal four-face packet with rows over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and the local* $\mathsf{Real}^{\uparrow}$ *seal. Then the exit-threshold coordinate descends to that same finite source record.*

The descended record carries exactly the $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The descent uses only the displayed finite BHist *packet, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *support. It exports no quotient streams, selected limits, host real equality, countable-choice row, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data, aggregate* formalstatus *row, or aggregate bridge row.*

Proof. First read the threshold and classifier coordinates from one visible packet. Apply Definition 38.789. The objectwise exit-threshold read and the public classifier coordinate are two readings of the same finite four-face record over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, local $\mathsf{Real}^{\uparrow}$, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next identify the terminal pullback. Apply Definition 38.458 to the accepted Phase Real and Completion terminal read. The terminal boundary has only one pullback packet with those four visible faces and those support rows, so the exit-threshold coordinate cannot be read from a second completion-facing source.

Now descend through the RegSeqRat side. Use Definition 301.237. Since the visible source is an accepted $\mathsf{RegSeqRat}^{\uparrow}$ terminal four-face packet and the StreamName, DyadicRatCore, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, and local NameCert rows agree with the terminal pullback, the RegSeqRat source section is exactly the same finite record.

Finally compare the common-tail boundary rows. The common-tail bridge and terminal section results, Definition 301.186, Definition 301.195, and Definition 301.202, keep the RegSeqRat regularity and common-tail rows on the same four-face surface. The four-face exactness theorem Definition 301.239 then reads the local $\mathsf{Real}^{\uparrow}$ seal from that displayed packet.

Thus the threshold coordinate descends to the same finite record over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. None of the cited packets contains a coordinate for quotient streams, selected limits, host real equality, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, metric completeness, aggregate verification status, or bridge rows, so no such data can appear in the descended source. □

Theorem 301.216 (RegSeqRat local-threshold four-face sufficiency)**.** *Let* $\mathcal{R}$ *be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record. Suppose* $\mathcal{R}$ *carries the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the displayed support*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

If these rows satisfy the four-face exactness criterion of Definition 301.239, then the objectwise Phase $\mathsf{Real}^{\uparrow}$ *and Completion exit-threshold coordinate is accepted on the same record* $\mathcal{R}$*.*

The accepted coordinate exports no quotient stream, selected limit, host real equality, countable-choice row, metric-completeness data, aggregate formalstatus *row, aggregate bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the displayed four-face data on $\mathcal{R}$. Apply Definition 301.239. The StreamName finite window, DyadicRatCore endpoint and radius ledger, RegSeqRat classifier and common-tail face, and local Real rows therefore present a Real terminal seal on exactly the same finite source record.

Next read the classifier and threshold coordinates from that terminal seal. Apply Definition 38.789. The public classifier coordinate and the objectwise exit-threshold coordinate are two visible readings of the same four-face packet, with support only from the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Finally compare the accepted threshold read with the original RegSeqRat source. Use Definition 301.215. Since the visible source already is $\mathcal{R}$ and the terminal four-face exactness step supplies the local Real seal on $\mathcal{R}$, the descended source of the accepted exit-threshold coordinate is $\mathcal{R}$ itself.

The construction has used only the finite rows named in the statement. No cited component introduces quotient streams, selected limits, host real equality, countable choice, metric-completeness structure, aggregate verification status, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so the accepted coordinate contains none of those excluded fields. □

Theorem 301.217 (RegSeqRat local-threshold terminal-window fusion)**.** *Let T be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source presented to the Phase* $\mathsf{Real}^{\uparrow}$ *and Completion exit. An accepted local-threshold coordinate for the Phase* $\mathsf{Real}^{\uparrow}$ *and Completion read exists on T if and only if T carries one fused terminal-window packet whose visible faces are*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

and whose support is only

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Under this equivalence, the local-threshold coordinate and the fused terminal-window packet determine the same BEDC-visible terminal source.

The fused packet refuses quotient streams, host real equality, selected limits, countable choice, metric-completeness data, aggregate status rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, start with an accepted Phase $\mathsf{Real}^{\uparrow}$ and Completion local-threshold coordinate on the finite source T. Apply Definition 301.215. The coordinate descends to the same RegSeqRat terminal source and exposes only the StreamName, DyadicRatCore, RegSeqRat, local Real, and displayed support rows named in the statement.

Next apply Definition 301.239. The descended source is therefore the exact four-face terminal surface over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Then use Definition 126.626 to repack that surface as one fused terminal-window packet without changing the source T.

Finally apply Definition 291.107. It identifies the fused four-face packet with the local NameCert interface consumed by the L10 exit, so the packet carries precisely the displayed BHist, hsame, Cont, Pkg, and NameCert support rows.

For the reverse direction, assume T carries one fused terminal-window packet over the four displayed faces and the five displayed support rows. The source-exhaustion theorem Definition 126.626 reads this packet as the same public finite-request section, and Definition 291.107 reads it as the local NameCert interface for the Phase $\mathsf{Real}^{\uparrow}$ and Completion exit.

Now apply Definition 301.239 to obtain the local $\mathsf{Real}^{\uparrow}$ terminal seal on T. With that exact four-face surface in place, Definition 301.216 supplies the accepted local-threshold coordinate on the same source.

The non-escape clause is inherited in both directions. The descent theorem, the four-face sufficiency theorem, the RegSeqRat terminal exactness theorem, the StreamName source-exhaustion

theorem, and the DyadicRatCore local NameCert interface all expose only finite BHist, hsame, Cont, Pkg, and NameCert support. None supplies a coordinate for quotient streams, host real equality, selected limits, countable choice, metric-completeness data, aggregate status rows, standard bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so the equivalence cannot export any of those fields. □

Theorem 301.218 (RegSeqRat four-face exit-threshold equivalence)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record whose visible rows are exactly the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support, and no other completion-facing coordinates. Then $\mathcal{R}$ satisfies the real terminal four-face exactness criterion of Definition 301.239 if and only if the objectwise Phase* $\mathsf{Real}^{\uparrow}$ *and Completion exit-threshold coordinate is accepted on the same record $\mathcal{R}$.*

The equivalence is terminal over the displayed four faces: it exports no quotient stream, selected limit, host real equality, countable-choice row, metric-completeness row, aggregate formalstatus *row, aggregate bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, assume the displayed rows of $\mathcal{R}$ satisfy the four-face exactness criterion. Apply Definition 301.216. Since the source record already has exactly the StreamName finite-window rows, DyadicRatCore endpoint, radius, distance, and regularity rows, RegSeqRat classifier and common-tail rows, local Real seal rows, and the displayed support rows, the objectwise Phase $\mathsf{Real}^{\uparrow}$ and Completion exit-threshold coordinate is accepted on $\mathcal{R}$ itself.

For the reverse direction, assume the objectwise Phase $\mathsf{Real}^{\uparrow}$ and Completion exit-threshold coordinate is accepted on $\mathcal{R}$. Apply Definition 301.215 to descend that accepted coordinate to the same finite RegSeqRat terminal source. The descent identifies the accepted source with the four visible faces and the same BHist, hsame, Cont, Pkg, and NameCert support carried by $\mathcal{R}$.

It remains to read the descended source as the terminal four-face record. Use Definition 38.796 to identify the accepted exit coordinate with the objectwise product of the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and local $\mathsf{Real}^{\uparrow}$ threshold records. Then apply Definition 301.239 to read those four rows as the RegSeqRat real terminal four-face exactness certificate on $\mathcal{R}$.

All steps are performed on the finite source record named in the statement. The cited criteria mention only the displayed four faces and support rows, so quotient streams, selected limits, countable choice, metric-completeness rows, aggregate verification or bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are excluded from both directions. □

Theorem 301.219 (RegSeqRat four-face audit-threshold factorization)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record whose exposed rows are exactly the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then $\mathcal{R}$ satisfies the current Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read exactly when the RegSeqRat four-face exit-threshold equivalence of Definition 301.218 holds on $\mathcal{R}$ and each of the four face chapters* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *supplies its own local closurestatus and formalstatus record at the roadmap threshold.*

The factorization is objectwise. It preserves no quotient stream, no host real equality, no selected limit, no countable-choice coordinate, no metric-completeness row, no aggregate formalstatus *row, no aggregate bridge row, and no ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. For the forward direction, assume $\mathcal{R}$ satisfies the current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. Apply Definition 38.471. The audit boundary is the product of the four local face records, with each closurestatus, formalstatus, leantarget, and bridgestatus row read from its own face chapter.

Next apply Definition 301.218. Since the source is the displayed finite $\mathsf{RegSeqRat}^{\uparrow}$ terminal record, the accepted exit-threshold coordinate is equivalent to the RegSeqRat four-face exactness criterion on that same record.

It remains to read the roadmap threshold objectwise. Use Definition 126.509 for the StreamName-side threshold readback, and use Definition 291.107 to identify the shared $\mathsf{NameCert}$ surface consumed by the dyadic ledger, StreamName finite window, RegSeqRat readback, and local Real seal. Thus the audit read factors through the four local closurestatus and formalstatus records rather than through a route-level credential.

For the reverse direction, assume the RegSeqRat four-face exit-threshold equivalence holds on $\mathcal{R}$ and the four face chapters supply their own local closurestatus and formalstatus records at the roadmap threshold. The equivalence gives the accepted Phase $\mathsf{Real}^{\uparrow}$ and Completion exit-threshold coordinate on $\mathcal{R}$.

Apply Definition 126.509 and Definition 38.471. Together they read that accepted threshold as the objectwise product of the four local audit-clean face records, with no cached aggregate status. The DyadicRatCore interface theorem Definition 291.107 supplies the same displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support surface, so the product is exactly the current audit-threshold read on $\mathcal{R}$.

The excluded boundary is preserved in both directions. The cited exit equivalence, StreamName readback, Real audit pullback, and DyadicRatCore interface mention only the four local faces and the displayed finite BEDC support rows. None introduces quotient streams, host real equality, selected limits, countable choice, metric-completeness data, aggregate formalstatus, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 301.220 (RegSeqRat audit-threshold missing-face obstruction)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record accepted by the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read. Then the accepted read requires the four local face records*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

on that same finite source. If any one of these four local face records is absent, the read is inadmissible at the RegSeqRat audit threshold.

No aggregate $\mathsf{formalstatus}$ *row, aggregate bridge row, selected limit, quotient stream, countable-choice row, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row can compensate for the absent face. In particular, the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support rows certify the displayed local interface only after all four faces are present.*

Proof. Start with the audit-threshold factorization of Definition 301.219. It identifies any accepted current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read on $\mathcal{R}$ with the RegSeqRat four-face exit-threshold equivalence together with local closurestatus and formalstatus records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Now apply Definition 301.218. The accepted threshold coordinate is equivalent to the exact four-face terminal surface on the same finite $\mathsf{RegSeqRat}^{\uparrow}$ record, so removing one displayed face destroys the surface on which the equivalence is stated. The read therefore has no RegSeqRat-local source after any face is absent.

It remains to exclude replacements. The DyadicRatCore interface theorem Definition 291.107 supplies only the local NameCert interface over the displayed BHist, hsame, Cont, Pkg, and NameCert support rows, and Definition 126.509 reads the audit-clean threshold through the four local faces objectwise. Finally, Definition 38.471 reads the current Phase Real and Completion audit from those local records rather than from an aggregate row. Hence selected limits, quotient streams, countable choice, metric-completeness data, aggregate verification or bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness cannot supply the missing local face. □

Theorem 301.221 (RegSeqRat audit-threshold objectwise face necessity)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record. The record $\mathcal{R}$ satisfies the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read if and only if $\mathcal{R}$ carries the four objectwise local records*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

on the same terminal source, with support only from

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

The four local records are exactly the StreamName finite-window rows, the DyadicRatCore endpoint, radius, distance, and regularity rows, the RegSeqRat classifier and common-tail rows, and the local Real seal rows.

The equivalence excludes quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate formalstatus *rows, aggregate bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness. None of these excluded coordinates is part of the objectwise source required by the audit threshold.*

Proof. For the forward direction, assume $\mathcal{R}$ satisfies the current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. Apply Definition 301.219. The audit read factors through the RegSeqRat four-face exit-threshold equivalence and through the four local face records for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 301.218. The accepted exit-threshold coordinate is placed on the same finite RegSeqRat terminal source record, so the four local records are not external witnesses. They are the objectwise faces of $\mathcal{R}$.

It remains to identify the local records read by the factorization. Use Definition 126.509 to read the StreamName finite-window threshold objectwise. Use Definition 291.107 to read the DyadicRatCore endpoint, radius, distance, regularity, and shared NameCert interface over the displayed BHist, hsame, Cont, Pkg, and NameCert support. Use Definition 38.471 to read the Phase Real and Completion audit as the product of the four local face records rather than as an aggregate route row.

For the reverse direction, assume $\mathcal{R}$ carries the four displayed local records on the same terminal source and only the displayed support rows. Apply Definition 301.219 with those four records supplied locally. The factorization reduces the audit-threshold read to the RegSeqRat four-face exit-threshold equivalence on $\mathcal{R}$.

Finally apply Definition 301.218. Since the StreamName, DyadicRatCore, RegSeqRat, and local Real rows are already present on $\mathcal{R}$, the equivalence supplies the accepted Phase $\mathsf{Real}^{\uparrow}$ and Completion exit-threshold coordinate, and the factorization reads it as the accepted audit-threshold coordinate.

The boundary exclusions follow from the same objectwise path. The factorization theorem, the exit-threshold equivalence, the StreamName readback, the DyadicRatCore interface, and the

Real audit pullback mention only the four local records and the displayed finite BEDC support rows. Therefore quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not available to witness either direction. □

Theorem 301.222 (RegSeqRat audit-threshold face-status minimality)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record satisfying the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read. The BEDC-visible status interface of this read is exactly the four local records*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

where each record contributes only its own closurestatus*,* formalstatus*,* leantarget*, and* bridgestatus *rows.*

No proper subfamily of these four local status records witnesses the audit threshold on $\mathcal{R}$. No aggregate formalstatus *row, aggregate bridge row, selected limit, quotient stream, countable-choice row, metric-completeness datum, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row witnesses it either.*

Conversely, if the same finite source $\mathcal{R}$ carries the four displayed local status records and the RegSeqRat four-face exit-threshold equivalence of Definition 301.218, then $\mathcal{R}$ satisfies the current Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read.*

Proof. For necessity, apply Definition 301.219 to the accepted audit-threshold read on $\mathcal{R}$. The read factors through the RegSeqRat four-face exit-threshold equivalence together with the local status records of $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The records are read objectwise. By Definition 301.221, the four faces are the StreamName finite-window rows, the DyadicRatCore endpoint, radius, distance, and regularity rows, the RegSeqRat classifier and common-tail rows, and the local Real seal rows on the same terminal source. The facewise status pullback Definition 301.119 and the common-tail status pullback Definition 301.194 then keep each closurestatus, formalstatus, leantarget, and bridgestatus row attached to its own face chapter.

It remains to prove minimality. Apply Definition 301.220. If any one of the four local face records is absent, the audit-threshold read has no RegSeqRat-local source. Since every proper subfamily omits at least one displayed face, no proper subfamily can witness the read.

The same obstruction excludes replacements. The factorization theorem has no coordinate for an aggregate verification row or aggregate bridge row, and the objectwise face pullbacks expose no selected limit, quotient stream, countable-choice row, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ completeness row. Those data therefore cannot replace a missing local status record.

For sufficiency, assume the four local status records and the RegSeqRat four-face exit-threshold equivalence on the same finite source $\mathcal{R}$. Apply Definition 301.219 in the reverse direction. The supplied local status rows give exactly the status side of the factorization, and the supplied exit-threshold equivalence gives the threshold side. Hence $\mathcal{R}$ satisfies the current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. □

Theorem 301.223 (RegSeqRat audit-threshold status pullback square)**.** *Let $\mathcal{R}$ be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source record whose visible faces are*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and whose support rows are only

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Read from the four faces the local closurestatus*,* formalstatus*,* leantarget*, and* bridgestatus *rows. Then the square*

$$\begin{array}{ccc} \mathsf{FaceStatus}(\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}) & \longrightarrow & \mathsf{RealL10TerminalPullback} \\ \downarrow & & \downarrow \\ \mathsf{RegSeqRatFourFaceExitThreshold} & \longrightarrow & \mathsf{BEDCVisibleStatusInterface}(\mathcal{R}) \end{array}$$

commutes: reading the four local status records and then applying the $\mathsf{Real}^{\uparrow}$ *L10 terminal pullback gives the same BEDC-visible status interface as first applying the RegSeqRat four-face exit-threshold equivalence and then reading the face records objectwise.*

The commutative square is exactly objectwise over the four displayed faces. It excludes quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate formalstatus *rows, aggregate bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 301.219. The audit read on $\mathcal{R}$ is identified with the RegSeqRat four-face exit-threshold equivalence together with the local status records on $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next use Definition 301.222. The only status records available to the audit threshold are the four local closurestatus, formalstatus, leantarget, and bridgestatus rows, so the upper-left corner of the displayed square has no aggregate status or bridge coordinate.

The vertical attachment is objectwise. By Definition 301.194, each RegSeqRat common-tail status row remains attached to its own face chapter. By Definition 126.509, the StreamName audit-clean threshold is read back from the same four visible faces rather than from a route-level row.

Finally apply Definition 38.471 and Definition 38.458. Both paths in the square pass through the same four-face terminal packet, so the resulting BEDC-visible status interface on $\mathcal{R}$ is unique. Since none of the cited pullbacks supplies quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, those coordinates are outside the square. □

Theorem 301.224 (RegSeqRat audit-threshold determinacy)**.** *Let* $\mathcal{R}_0$ *and* $\mathcal{R}_1$ *be finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source records. Suppose both records expose the same four visible face rows*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the same support rows

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

If $\mathcal{R}_0$ *and* $\mathcal{R}_1$ *both satisfy the current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read, then the two accepted audit reads determine the same BEDC-visible terminal source record.*

The determined source is only the displayed four-face RegSeqRat terminal record. The determinacy claim excludes quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate formalstatus *rows, aggregate bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 301.219 separately to the accepted audit-threshold reads on $\mathcal{R}_0$ and $\mathcal{R}_1$. Each accepted read factors through the RegSeqRat four-face exit-threshold equivalence and through the local closurestatus and formalstatus records of $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 301.218 to both factorizations. Since the two records expose the same StreamName finite-window rows, DyadicRatCore endpoint, radius, distance, and regularity rows, RegSeqRat classifier and common-tail rows, local Real rows, and displayed support, the exit-threshold coordinate in each read is placed on the same finite four-face source surface.

It remains to rule out a hidden route-level distinction between the two accepted reads. The StreamName threshold readback Definition 126.509 reads the audit-clean threshold from the visible four faces, Definition 38.471 pulls the current Phase Real and Completion audit back to the local face records, and Definition 291.107 identifies the shared $\mathsf{NameCert}$ interface over the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Thus every coordinate used by either accepted audit read is already fixed by the common four visible faces and common support rows. None of the cited components supplies quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate verification status, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness. Those absent coordinates cannot distinguish $\mathcal{R}_0$ from $\mathcal{R}_1$, so the two reads determine the same BEDC-visible terminal source record. □

Theorem 301.225 (RegSeqRat audit-threshold finite-refinement invariance)**.** *Let $\{\mathcal{R}_i\}_{i\in I}$ be a finite family of $\mathsf{RegSeqRat}^{\uparrow}$ terminal source records whose displayed faces are*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Suppose a finite cover refinement replaces this family by $\{\mathcal{R}'_j\}_{j\in J}$ and preserves, on every refined member, the four displayed face rows together with the shared

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}$$

rows. If the original family carries the current Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate objectwise, then the refined family carries the same coordinate objectwise. Conversely, any refined family with these preserved rows determines the same coordinate on the original finite family.

The invariant coordinate is only the four-face audit-threshold read of the displayed RegSeqRat terminal source. The comparison excludes quotient streams, selected limits, countable choice, metric-completeness rows, aggregate $\mathsf{formalstatus}$ *rows, aggregate bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness.*

Proof. First compare the common-tail part of the two presentations. Apply Definition 301.211. It identifies the RegSeqRat classifier, common-tail atlas, and overlap rows read from the original finite family with the rows read from the refined family, because the refinement preserves the displayed $\mathsf{RegSeqRat}^{\uparrow}$ face and the shared BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Next compare the dyadic and Real exit data. The DyadicRatCore finite-cover theorem, Definition 291.120, keeps the endpoint, radius, distance, regularity, and ledger rows fixed under the same finite cover comparison. The Real functoriality theorem, Definition 38.805, transports the local $\mathsf{Real}^{\uparrow}$ exit certificate across the support-row-preserving finite refinement.

Now apply the status pullback square Definition 301.223. Since the StreamName, DyadicRatCore, RegSeqRat, and local Real rows agree after the preceding comparisons, both routes through the square read the same BEDC-visible status interface and the same Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate.

Finally use Definition 301.224. Any two objectwise audit reads obtained from the original family and from the refined family expose the same four face rows and the same displayed support

rows, so they determine one BEDC-visible terminal source record. The reverse direction is the same argument applied to the common finite refinement that maps back to the original finite cover.

Every cited comparison is facewise and support-row preserving. None supplies quotient streams, selected limits, countable choice, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so no excluded coordinate can alter the invariant audit-threshold read. □

Theorem 301.226 (RegSeqRat four-face audit source uniqueness)**.** *Let $\mathcal{R}_0$ and $\mathcal{R}_1$ be finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal source records equipped with accepted current Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold reads. Suppose the two reads expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, distance, and regularity rows, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the same local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the same displayed support*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then the two accepted reads determine the same RegSeqRat four-face source and the same accepted audit-threshold coordinate.

The uniqueness is local to the displayed four faces. It excludes quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate formalstatus *rows, aggregate bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 301.219 to the accepted audit-threshold reads on $\mathcal{R}_0$ and $\mathcal{R}_1$. Each read factors through the RegSeqRat four-face exit-threshold equivalence and through the local closurestatus and formalstatus records of $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Next apply Definition 301.218 to the two factorizations. Because the StreamName finite window, DyadicRatCore endpoint, radius, distance, and regularity rows, RegSeqRat classifier and common-tail rows, local Real seal rows, and displayed BHist, hsame, Cont, Pkg, and NameCert support are the same, the accepted exit-threshold coordinate is read on the same four-face source surface.

Now use Definition 301.224. The theorem identifies the BEDC-visible terminal source determined by the two accepted audit reads, so the source left by the two factorizations is a single RegSeqRat four-face source.

Finally read the objectwise face records. The $\mathsf{StreamName}^{\uparrow}$ finite-window rows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, distance, and regularity rows, $\mathsf{RegSeqRat}^{\uparrow}$ classifier and common-tail rows, and local $\mathsf{Real}^{\uparrow}$ seal rows are exactly the four records used by the factorization and exit-threshold equivalence. Since the displayed BHist, hsame, Cont, Pkg, and NameCert support is also shared, no second accepted audit-threshold coordinate remains.

The cited records are objectwise local. They do not provide quotient streams, selected limits, host real equality, countable choice, metric-completeness data, aggregate verification status, aggregate bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so none of those excluded coordinates can distinguish a second completion-facing source or a route-level status credential. □

Theorem 301.227 (RegSeqRat audit-threshold finite-cover gluing)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections for a Phase* $\mathsf{Real}^{\uparrow}$ *and Completion consumer. Assume that every nonempty overlap agrees on the* $\mathsf{StreamName}^{\uparrow}$ *finite windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the shared support*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Assume also that the overlap status-pullback squares of Definition 301.223 agree under these displayed identifications.

Then the glued terminal section satisfies the Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read if and only if every local section satisfies the objectwise audit-threshold read and the overlap status-pullback squares agree. The glued read is objectwise over the finite four-face packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with only the displayed BHist, hsame, Cont, Pkg, *and* NameCert *support.*

The gluing theorem exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatAuditThresholdFiniteCoverGluing`

Proof. For the forward direction, restrict the glued Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read to a local section S_i. The restriction preserves the displayed StreamName finite window, DyadicRatCore endpoint, radius, and distance ledger, RegSeqRat classifier and common-tail rows, local Real seal rows, and the shared BHist, hsame, Cont, Pkg, and NameCert support.

Apply Definition 301.218 on each restricted terminal packet. The local threshold coordinate is therefore the same objectwise four-face read as the RegSeqRat terminal exactness certificate. Then apply Definition 301.223 to read the local closurestatus, formalstatus, leantarget, and bridgestatus rows through the same four faces.

The overlap agreement is inherited from the glued packet. By Definition 301.224 and Definition 301.226, two local restrictions with the same displayed overlap rows determine one BEDC-visible terminal source and one accepted audit-threshold coordinate. Hence every local section satisfies the objectwise audit-threshold read, and the status-pullback squares agree on overlaps.

For the reverse direction, assume each local section satisfies the objectwise audit-threshold read and the overlap status-pullback squares agree. Apply Definition 301.240 to the underlying four-face local packets. The StreamName windows, DyadicRatCore ledgers, RegSeqRat classifier and common-tail rows, local Real seal rows, and support rows glue to one accepted $\mathsf{Real}^{\uparrow}$ terminal seal over the finite cover.

Next apply Definition 38.796. It reads the glued terminal seal as the objectwise Phase $\mathsf{Real}^{\uparrow}$ and Completion threshold certificate over the four local records. The overlap status-pullback hypothesis supplies the facewise status interface required by Definition 301.223, so the threshold certificate is read as the Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read on the glued terminal section.

It remains to identify the glued audit source. Use Definition 301.224 on any two local presentations carried into the glued packet, and then use Definition 301.226 to remove any second audit-threshold coordinate over the same displayed faces. The resulting source is the single finite four-face $\mathsf{RegSeqRat}^{\uparrow}$ terminal section obtained by gluing the cover.

All cited constructions use only the finite rows named in the statement. None introduces quotient streams, selected limits, countable choice, metric-completeness data, aggregate verification status, aggregate bridge data, standard bridge data, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so the glued audit-threshold read contains none of those excluded coordinates. □

Theorem 301.228 (RegSeqRat four-face status cofinal descent)**.** *Let* $\{S_i\}_{i\in I}$ *be a compatible finite cover satisfying the hypotheses of Definition 301.227, and let* $\{T_j\}_{j\in J}$ *be a cofinal finite cover refining it. Assume each refinement map sends every* T_j *into some* S_i *and preserves the*

$\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, the shared support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert},$$

and the overlap status-pullback squares of Definition 301.223. Assume moreover that the refinement is cofinal on displayed observations: every row of the original four-face packet is the pullback of a finite family of rows on the refined cover, and compatible refined overlap rows descend to the original overlap row.

Then the refined cover glues to the same Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read if and only if the original cover glues to that read. The common glued read is determined by the same finite four-face packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with exactly the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support.*

The descent exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate $\mathsf{formalstatus}$ *row, aggregate bridge row, standard bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Suppose first that the original cover glues to the displayed Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. Pull this glued packet along each refinement map. The preservation hypotheses keep the StreamName windows, DyadicRatCore ledgers, RegSeqRat classifier and common-tail rows, Real seal rows, and support rows unchanged on every refined member.

The overlap status-pullback square is stable under these pullbacks by hypothesis. Apply Definition 301.227 to the refined cover. The refined local reads therefore glue to an audit-threshold section over the same four faces and support.

It remains to identify this refined glued section with the original one. Use Definition 301.224 on the two glued presentations over the shared finite rows, and then apply Definition 301.226 to rule out a second audit source over the same StreamName, DyadicRatCore, RegSeqRat, and Real faces. Thus the refined cover glues to the same read.

Conversely assume that the refined cover glues to that read. Cofinality on displayed observations descends the refined StreamName windows, DyadicRatCore ledgers, RegSeqRat classifier and common-tail rows, local Real seals, support rows, and compatible overlap status-pullback squares to the original finite cover.

Apply Definition 301.227 to the descended original cover. Its glued read has the same four-face data as the refined glued read. The local status-pullback square transports the closurestatus, formalstatus, leantarget, and bridgestatus rows through the same finite faces, so determinacy again identifies the two presentations.

All objects used in both directions are rows of the displayed finite covers or their status-pullback squares. The argument never selects a limit, forms a quotient stream, invokes countable choice, uses metric completeness, aggregates status or bridge rows, adds a standard bridge row, or appeals to ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 301.229 (RegSeqRat audit-threshold refinement composition)**.** *Let* $\{S_i\}_{i\in I}$, $\{T_j\}_{j\in J}$, *and* $\{U_k\}_{k\in K}$ *be finite covers of compatible local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections. Suppose* $\{T_j\}_{j\in J}$ *cofinally refines* $\{S_i\}_{i\in I}$ *and* $\{U_k\}_{k\in K}$ *cofinally refines* $\{T_j\}_{j\in J}$. *Assume all refinement maps preserve the displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and*

distance ledgers, the $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, the support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert},$$

and the status-pullback squares of Definition 301.223. Assume also that the composite refinement maps from $\{U_k\}_{k\in K}$ *to* $\{S_i\}_{i\in I}$ *are cofinal on the same displayed observations.*

Then the Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read obtained by descending along*

$$\{U_k\}_{k\in K} \longrightarrow \{T_j\}_{j\in J} \longrightarrow \{S_i\}_{i\in I}$$

is identical to the read obtained by the direct cofinal refinement

$$\{U_k\}_{k\in K} \longrightarrow \{S_i\}_{i\in I}.$$

Both reads are the finite four-face packet

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with exactly the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

The composition exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 301.228 to the refinement from $\{T_j\}_{j\in J}$ to $\{S_i\}_{i\in I}$. The hypotheses identify the audit-threshold read on the T cover with the read on the S cover through the same StreamName, DyadicRatCore, RegSeqRat, Real, and support rows.

Apply Definition 301.228 again to the refinement from $\{U_k\}_{k\in K}$ to $\{T_j\}_{j\in J}$. The two-step descent therefore carries the U cover to the same T read and then to the same S read, without changing any displayed status-pullback square.

For the direct route, use the cofinality of the composite maps from $\{U_k\}_{k\in K}$ to $\{S_i\}_{i\in I}$. A third application of Definition 301.228 identifies the directly descended U read with the S read over the same four visible faces.

It remains to compare the witnesses supplied by the two routes. Apply Definition 301.227 on each of the three covers to identify the glued read determined by its compatible local packets. Then use Definition 301.224 and Definition 301.226 to rule out a second audit source over the same StreamName, DyadicRatCore, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows.

All data used by the comparison are rows already preserved by the refinement maps or status-pullback squares already present in the covers. No quotient stream, selected limit, countable choice, metric-completeness datum, aggregate status row, aggregate bridge row, standard bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness is introduced. □

Theorem 301.230 (RegSeqRat finite-cover overlap no-confusion)**.** *Let* $\{S_i\}_{i\in I}$ *and* $\{T_j\}_{j\in J}$ *be compatible finite covers of local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections for the same Phase* $\mathsf{Real}^{\uparrow}$ *and Completion consumer. Suppose both covers satisfy the hypotheses of Definition 301.227. Assume that, after passing to the common finite overlap refinement, the two presentations expose the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and distance ledger rows, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and common-tail rows, the same local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the same support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the glued Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold reads supplied by the two covers are identical.*

Conversely, if the glued Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold reads of the two covers are identical, the common read recovers exactly the displayed overlap rows: the four L10 faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the shared BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. It recovers no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate* formalstatus *row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim.*

Proof. Apply Definition 301.227 to $\{S_i\}_{i\in I}$ and to $\{T_j\}_{j\in J}$. Each cover produces a glued audit-threshold read whose source data are precisely the displayed StreamName, DyadicRatCore, RegSeqRat, Real, BHist, hsame, Cont, Pkg, and NameCert rows.

The common overlap refinement identifies these displayed rows on the two covers. Use Definition 301.224 to compare the two glued presentations over that shared finite packet, and use Definition 301.226 to rule out a second BEDC-visible audit source over the same four faces and support. This proves equality of the glued Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold reads.

For the converse, start from equality of the glued reads and restrict the common read back along the finite covers. The finite-cover gluing theorem says that every local and overlap row used by either glued read is one of the displayed four faces or one of the displayed support rows. Thus equality of the read identifies exactly those rows on the common overlap surface.

Cofinal changes of the finite cover do not add a new recovery coordinate. Apply Definition 301.228 to compare either cover with any common finite overlap refinement, and apply Definition 301.229 to identify the direct and two-step descent routes. The recovered rows are therefore independent of the chosen overlap refinement.

It remains to exclude hidden substitutes. Invoke Definition 301.231: deleting any displayed face row or support row prevents presentation of the same glued read, while quotient streams, selected limits, countable choice, metric-completeness data, aggregate status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness are not replacement coordinates for the deleted row. Hence equality of the glued audit-threshold read recovers exactly the four L10 faces and BEDC support rows, and nothing outside that surface. □

Theorem 301.231 (RegSeqRat audit-threshold support-removal descent)**.** *Let* $\{S_i\}_{i\in I}$ *be a finite cover satisfying the hypotheses of Definition 301.227, and let* G *be the glued terminal section supplied by that theorem. Delete from one displayed local section or overlap one row among the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, or distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier or common-tail row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, or one of the shared support rows*

$$\mathsf{BHist}, \quad \mathsf{hsame}, \quad \mathsf{Cont}, \quad \mathsf{Pkg}, \quad \mathsf{NameCert}.$$

Then the resulting cover cannot present the same glued Phase $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read on* G*.*

The obstruction is support-local and descends to the glued threshold. Quotient streams, selected limits, countable choice, metric-completeness data, aggregate formalstatus *rows, aggregate bridge rows, standard bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness are not replacement coordinates for the deleted row.*

Proof. First read the original cover through Definition 301.227. The glued audit-threshold section is determined by the finite four-face packet

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

and by the displayed BHist, hsame, Cont, Pkg, and NameCert support. Thus every row named in the statement is part of the terminal presentation used by the glued read.

If the deleted row is one of the four visible local faces, apply Definition 301.220 to the affected local terminal packet. The RegSeqRat audit-threshold read has no admissible local source after the face is absent, so the finite cover no longer satisfies the local hypotheses required by the gluing theorem.

If the deleted row is one of the shared support rows, apply Definition 126.665 on the StreamName–DyadicRatCore–RegSeqRat–Real route carried by the same finite cover. The cover-descent terminal support packet then cannot present the same $\mathsf{Real}^{\uparrow}$ seal-visible source. The status-pullback square of Definition 301.223 transports this defect to the RegSeqRat audit-threshold read, because the status rows are read through the same displayed faces and support.

It remains to rule out replacement data. The finite-cover gluing theorem already exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, standard bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness claim. The missing-face obstruction and the StreamName support-removal obstruction exclude the same objects as substitutes for a deleted local row. Therefore the altered cover cannot present the same glued Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. □

Theorem 301.232 (RegSeqRat four-face support induction)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections satisfying the hypotheses of Definition 301.227. Then the glued Phase* $\mathsf{Real}^{\uparrow}$ *and Completion audit-threshold read is generated by finite induction over the cover from exactly the four visible L10 faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the displayed support

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

The base packet is a singleton local terminal section. The induction step glues one compatible local terminal packet to an already glued finite subcover by the overlap status-pullback square, and the resulting audit-threshold read is independent of the order of adjoining local packets and of cofinal finite refinements.

The induction exports no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness claim. Removing any displayed face row or support row destroys the possibility of presenting the same glued read.*

Proof. For the base case, take a singleton local terminal packet S_i. The hypotheses of Definition 301.227 reduce to the local objectwise audit-threshold read and the displayed support rows, so the generated packet is precisely the four-face $\mathsf{RegSeqRat}^{\uparrow}$ terminal section with BHist, hsame, Cont, Pkg, and NameCert support.

For the induction step, assume a finite subcover has already been glued from the same displayed faces and support. Adjoin one further compatible local section. The overlap hypotheses identify the StreamName windows, DyadicRatCore ledgers, RegSeqRat classifier and common-tail rows,

Real seal rows, and support rows on the common overlap. Apply Definition 301.227 to glue the enlarged finite cover.

The induction step has no hidden branch. Use Definition 301.230 on the overlap between the previously glued subcover and the adjoined local section. Equality of glued reads recovers exactly the four visible faces and support rows, so no second audit source or extra coordinate can enter at the adjoining boundary.

Cofinal presentations of the same finite induction are identified by Definition 301.228. When two adjoining schedules are compared through a common refinement, Definition 301.229 identifies the direct descent with the two-step descent. Hence the finite induction does not depend on the order of adjoining local packets or on the chosen finite refinement.

Finally apply Definition 301.231. If any StreamName, DyadicRatCore, RegSeqRat, Real, BHist, hsame, Cont, Pkg, or $\mathsf{NameCert}$ row is removed from a local member or overlap, the altered cover cannot present the same glued Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read. Since the gluing, descent, composition, no-confusion, and support-removal steps all exclude quotient streams, selected limits, countable choice, metric-completeness data, aggregate status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness, the finite induction derives the L10 audit-threshold read exactly from the stated four-face support surface. □

Theorem 301.233 (RegSeqRat finite-cover status-gluing completeness)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections satisfying the hypotheses of Definition 301.227. Suppose moreover that every local member and every overlap displays the four Phase* $\mathsf{Real}^{\uparrow}$ *and Completion faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

with support

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert},$$

and that the overlap maps carry the corresponding status-pullback squares.

Then the Phase $\mathsf{Real}^{\uparrow}$ *and Completion status-gluing interface for this finite cover is complete exactly when the finite induction of Definition 301.232 supplies the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows together with the overlap status-pullback squares. Equivalently, no quotient stream, selected limit, countable-choice row, metric-completeness datum, aggregate* $\mathsf{formalstatus}$ *row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate can be part of the same status-gluing read.*

Proof. First apply Definition 301.227. The compatible local terminal sections glue to one Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold read over exactly the displayed four faces and support rows.

The resulting read is independent of presentation. Cofinal descent in Definition 301.228 identifies cofinal finite covers of the same local data, and refinement composition in Definition 301.229 identifies a direct descent with any two-step descent through a common finite refinement.

Uniqueness of the status-gluing read is forced on overlaps. By Definition 301.230, two glued reads agreeing as terminal status objects agree row-by-row on the four visible faces, on BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$, and on the overlap status-pullback squares. Thus no second source of status data can be hidden inside the glued object.

Necessity of every displayed row follows from Definition 301.231. Removing any named face row, support row, or overlap square prevents the altered cover from presenting the same glued Phase $\mathsf{Real}^{\uparrow}$ and Completion read.

Finally, Definition 301.232 says that the whole finite cover is generated by adjoining local terminal packets through those overlap squares. Combining the existence, refinement-independence,

no-confusion, support-removal, and finite-induction clauses proves the exact completeness assertion and excludes quotient streams, selected limits, countable choice, metric-completeness data, aggregate status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness from the same status-gluing interface. □

Theorem 301.234 (RegSeqRat zero-source finite-cover gluing)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections satisfying the hypotheses of Definition 301.227. Suppose each local section also displays the same* $\mathsf{RegularCauchyZero}^{\uparrow}$ *source boundary through the constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *zero endpoint and radius ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *zero readback row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared support*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then the glued terminal section carries the same $\mathsf{RegularCauchyZero}^{\uparrow}$ *zero-source boundary. Its terminal read is the finite four-face packet*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

specialized to the constant zero source, and it exports no quotient stream, host real equality, selected limit, countable-choice row, metric-completeness datum, aggregate formalstatus *row, bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First apply Definition 301.227 to the underlying compatible terminal sections. The result is one glued audit-threshold read over the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces with only the listed BHist, hsame, Cont, Pkg, and NameCert support.

Now identify the zero source on the glued packet. The local zero-source hypotheses say that every finite-window face is the constant $\mathsf{StreamName}^{\uparrow}$ zero row, every dyadic face is the same zero endpoint and radius ledger, every regular face is the same $\mathsf{RegSeqRat}^{\uparrow}$ zero readback row, and every seal face is the local $\mathsf{Real}^{\uparrow}$ seal row of the $\mathsf{RegularCauchyZero}^{\uparrow}$ packet. Apply Definition 126.551 to paste the StreamName and RegSeqRat source rows, and apply Definition 126.552 to paste the local seal rows over the same finite cover.

The pasted four-face packet is still the zero packet. Use Definition 624.3 to read the constant StreamName and dyadic ledger faces as the sibling route of the accepted $\mathsf{RegularCauchyZero}^{\uparrow}$ source, and use Definition 624.8 to identify the glued read with the same terminal zero-source boundary on every downstream consumer.

Finally apply Definition 624.6 and Definition 624.7. Their boundary excludes quotient streams, host real equality, selected limits, nonzero witnesses, and ambient completeness from the zero packet. The additional exclusions for countable choice, metric-completeness data, aggregate formalstatus rows, and bridge rows follow from Definition 301.177 and the audit-threshold gluing theorem, because those objects are not among the displayed four faces or support rows. □

Theorem 301.235 (RegSeqRat zero-source deleted-row obstruction)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover satisfying the hypotheses of Definition 301.234, and let G be the glued terminal section carrying the resulting* $\mathsf{RegularCauchyZero}^{\uparrow}$ *boundary. Delete from one local section or overlap one row among the constant* $\mathsf{StreamName}^{\uparrow}$ *zero-window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *zero endpoint or radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *zero readback row, the local* $\mathsf{Real}^{\uparrow}$ *seal row, or one of the shared support rows*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Then the altered finite cover cannot present the same glued $\mathsf{RegularCauchyZero}^{\uparrow}$ *zero-source boundary on G.*

The obstruction is terminal-consumer visible. Quotient streams, host real equality, selected limits, countable-choice rows, metric-completeness data, aggregate formalstatus *rows, bridge rows, and ambient* $\mathsf{Real}^{\uparrow}$ *completeness do not replace the deleted zero-source row.*

Proof. First apply Definition 301.234 to the original cover. The glued read is the zero specialization of the four-face packet

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with only the displayed BHist, hsame, Cont, Pkg, and NameCert support. Hence every row named in the statement is part of the source boundary used by the terminal consumer.

If the deleted row is one of the displayed zero faces, apply Definition 301.220 to the affected local terminal packet. The missing constant StreamName window, zero dyadic ledger, RegSeqRat zero readback, or local Real seal prevents the local packet from supplying the same audit-threshold source. The zero-source gluing theorem therefore has no compatible local zero packet from which to recover the same boundary on G.

If the deleted row is one of the shared support rows, first apply Definition 301.231 to transport the support loss to the glued RegSeqRat audit-threshold read. Then apply Definition 126.665 on the StreamName–DyadicRatCore–RegSeqRat–Real route. The altered cover no longer carries the global support needed to present the same zero-source seal-visible boundary.

It remains to exclude external substitutes. Apply Definition 624.8 to identify any alleged presentation of the same glued boundary with the terminal zero-source consumer. Then use Definition 624.6 and Definition 624.7 to rule out quotient streams, host real equality, selected limits, nonzero witnesses, and ambient completeness as alternate witnesses.

The countable-choice, metric-completeness, aggregate status, and bridge rows are also outside the finite source packet. By Definition 301.177 and the finite-cover gluing theorem, none of them is among the four displayed zero faces or the shared BHist, hsame, Cont, Pkg, and NameCert support. Thus the altered finite cover cannot present the same glued $\mathsf{RegularCauchyZero}^{\uparrow}$ zero-source boundary. □

Theorem 301.236 (RegSeqRat stream-dyadic real section coherence)**.** *Let R be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let S be an accepted finite request section whose displayed rows include the* $\mathsf{StreamName}^{\uparrow}$ *pointwise window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and the* $\mathsf{Real}^{\uparrow}$ *finite-section readback. If those rows are consumed by a Phase Real and Completion reader, then the StreamName window, dyadic ledger, regular-rational readback, and Real finite-section readback factor through one common source section carried by the same finite* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

The coherent section is only the finite L10 route

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

It exports no quotient stream equality, selected limit, host real equality, ambient completeness row, metric-completion point, countable-choice selector, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Begin with the finite request source section of Definition 301.139. It places the accepted request on one displayed BHist packet with the StreamName schedule rows, DyadicRatCore endpoint, radius, and finite-distance rows, RegSeqRat classifier and regularity rows, componentwise hsame, displayed Cont routes, Pkg provenance, and local naming.

Next attach the dyadic and Real faces. The exact handoff of Definition 301.69 keeps the StreamName window, DyadicRatCore ledger, and RegSeqRat classifier on the same finite route,

while Definition 301.132 records the constant dyadic case as a special Real-facing handoff through the same four visible faces.

Now use the common-tail bridge. The classifier bridge of Definition 301.182 and the finite-request pullback of Definition 301.184 identify common-tail and finite-request presentations with the same StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows.

Finally compare the sibling finite-section surfaces. The StreamName finite-section pullback and lock, Definition 126.586 and Definition 126.589, identify the pointwise window as a finite section over the same dyadic and RegSeqRat rows. The Real terminal finite-section pullback and four-face exactness, Definition 38.720 and Definition 38.457, read the terminal Real section from that same ordered packet.

Thus the StreamName pointwise window, DyadicRatCore ledger, RegSeqRat readback, and Real finite-section readback are four projections of one common finite source section. The sibling chapters chapter 126, chapter 291, and chapter 38 supply only those displayed finite rows, so the excluded quotient, limit, host-equality, completeness, choice, and second-seal coordinates have no row from which to be read. □

Theorem 301.237 (RegSeqRat terminal four-face source uniqueness)**.** *Let R_0 and R_1 be accepted Phase Real and Completion terminal consumers of finite* $\mathsf{RegSeqRat}^{\uparrow}$ *sections. Suppose that they display the same* $\mathsf{StreamName}^{\uparrow}$ *finite-section window, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the same local* $\mathsf{Real}^{\uparrow}$ *finite-section readback, and the same* BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows. Then R_0 and R_1 determine the same common finite* $\mathsf{RegSeqRat}^{\uparrow}$ *source section.*

The unique source is the four-face packet over

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

There is no independent $\mathsf{RegSeqRat}^{\uparrow}$ *readback branch, second* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream, selected limit, countable-choice row, host equality, ambient completeness row, or aggregate bridge or status row available to distinguish the two terminal consumers.*

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatTerminalFourFaceSourceUniqueness`

Proof. Apply Definition 301.236 to both terminal consumers. Each read is thereby placed on the same four visible projections: the StreamName finite window, the DyadicRatCore ledger, the RegSeqRat classifier and regularity surface, and the local Real finite-section readback.

Next identify the StreamName and dyadic coordinates. The StreamName finite-section pullback Definition 126.586 and the real, RegSeqRat, and dyadic lock Definition 126.589 force the two window coordinates to be the same finite section. The dyadic source uniqueness theorem Definition 291.84 then identifies the endpoint, radius, and distance rows as one dyadic source over that shared window.

Now keep the Real readback terminal. By Definition 38.720, each accepted terminal consumer reads its local Real section from the displayed finite packet. The four-face exactness theorem Definition 38.457 keeps that packet on the ordered $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces with only the listed BHist, hsame, Cont, Pkg, and NameCert rows.

Finally apply Definition 38.458. A second RegSeqRat source over the same displayed support rows would give a second four-face terminal packet for the same Phase Real and Completion boundary. Terminal pullback uniqueness identifies those packets, so the common finite $\mathsf{RegSeqRat}^{\uparrow}$ source section is determined uniquely. Since the cited four-face packet has no coordinate for

quotient streams, selected limits, choice rows, host equality, ambient completeness, a second Real seal, or an aggregate bridge or status surface, none of those rows can separate the two consumers. □

Theorem 301.238 (RegSeqRat four-face refinement functoriality)**.** *Let R be an accepted Phase Real and Completion terminal consumer over a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *section, and let R' be an accepted cofinal refinement of R. Suppose the refinement preserves the displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-section window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, the local* $\mathsf{Real}^{\uparrow}$ *finite-section readback, and the same* BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows. Then R and R' determine the same common finite* $\mathsf{RegSeqRat}^{\uparrow}$ *source section.*

Equivalently, accepted cofinal refinement acts functorially on the terminal four-face packet

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow},$$

with identity action on the common finite source. It creates no quotient stream, selected limit, choice row, host equality, ambient completeness row, or second $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Apply Definition 301.236 to the terminal consumer R and to its accepted refinement R'. Both reads are therefore represented by four visible faces over the same displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ support rows.

The preserved StreamName window is fixed by Definition 126.586. The preserved dyadic endpoint, radius, and finite-distance ledger are fixed by Definition 291.84. The local Real terminal readback is fixed by Definition 38.458.

It remains only to compare the RegSeqRat source face. Since the refinement preserves the RegSeqRat classifier and regularity rows and the other three faces have already been identified, both terminal reads satisfy the hypotheses of Definition 301.237. That theorem identifies the common finite $\mathsf{RegSeqRat}^{\uparrow}$ source section for R and R'.

The same packet supplies no coordinate for quotient streams, selected limits, choice rows, host equality, ambient completeness, a second Real seal, or any independent aggregate status surface. Hence the refinement has no additional row along which it could move the accepted terminal consumer away from the common finite source. □

Theorem 301.239 (RegSeqRat real terminal four-face exactness)**.** *Let S be a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal section presented to the Phase Real and Completion exit. Then S is accepted by the* $\mathsf{Real}^{\uparrow}$ *terminal seal if and only if its finite ledger contains one compatible four-face packet consisting of the* $\mathsf{StreamName}^{\uparrow}$ *finite-request section, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *common scale-window witness, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity witness, and the* $\mathsf{Real}^{\uparrow}$ *terminal seal row, all carried by the same* BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

The exact packet is the concrete terminal surface

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

It asserts no quotient stream equality, no selected limit existence, and no completeness property of $\mathsf{Real}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.RegSeqRatUp.RegSeqRatRealTerminalFourFaceExactness`

Proof. For the forward direction, start with the accepted $\mathsf{Real}^{\uparrow}$ terminal seal. By Definition 301.236, the terminal read factors through a single finite source section whose visible coordinates are

the StreamName finite-request window, the DyadicRatCore endpoint, radius, and finite-distance ledger, the RegSeqRat classifier and regularity rows, and the Real finite-section readback.

The compatibility of those faces is already part of the same finite ledger: the StreamName rows are tied to the displayed dyadic rows by Definition 126.589, the dyadic common scale-window rows are locked by Definition 291.84, and the terminal Real readback is pulled from the displayed packet by Definition 38.720. Thus the accepted seal supplies exactly the four required finite faces over one BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

For the reverse direction, suppose that those four compatible faces are present in the finite ledger. The StreamName face gives the finite-request section, the DyadicRatCore face gives the common scale-window witness, the RegSeqRat face gives the regularity witness, and the Real face gives the terminal seal row. Applying Definition 301.236 packages these rows as one common terminal section.

It remains only to identify the terminal consumer. The source uniqueness result Definition 301.237 shows that any accepted Phase Real and Completion consumer with these four faces must come from this same finite $\mathsf{RegSeqRat}^{\uparrow}$ source. The Real terminal pullback uniqueness theorem Definition 38.458 then identifies the displayed Real seal row as the terminal acceptance surface for S.

Every step used only rows visible in the finite BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ ledger. There is no coordinate for quotient stream equality, no selector for an external limit, and no ambient completeness field for $\mathsf{Real}^{\uparrow}$, so none of those stronger claims is produced by the exactness criterion. □

Theorem 301.240 (RegSeqRat four-face local gluing covers the Real seal)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local $\mathsf{RegSeqRat}^{\uparrow}$ terminal sections for a Phase Real and Completion consumer. Assume that on every nonempty overlap the two local presentations agree on the $\mathsf{StreamName}^{\uparrow}$ finite window, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and finite-distance ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback, the $\mathsf{Real}^{\uparrow}$ finite-section readback, and the shared BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ support rows. Then the local sections glue to one accepted $\mathsf{Real}^{\uparrow}$ terminal seal if and only if each local section satisfies the four-face exactness criterion of Definition 301.239.*

The glued seal is covered only by the finite terminal faces

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

It contains no quotient stream coordinate, selected limit, host equality, ambient completeness row, countable-choice selector, standard bridge row, or second terminal seal.

Proof. For the forward direction, suppose the finite cover glues to an accepted $\mathsf{Real}^{\uparrow}$ terminal seal. Restrict the glued terminal consumer to any local piece S_i. The restriction keeps exactly the same displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows.

Apply Definition 301.239 to this local restriction. The accepted terminal seal therefore supplies the local StreamName finite-request section, DyadicRatCore common scale-window witness, RegSeqRat regularity witness, and Real terminal row as one compatible four-face packet. Since the argument is local in i, every member of the finite cover satisfies the exactness criterion.

For the reverse direction, assume each S_i satisfies the four-face criterion. Each local packet has a common source section by Definition 301.236. On overlaps, Definition 126.587 identifies the StreamName classifier read from the shared finite window, and Definition 301.237 identifies the RegSeqRat terminal source because all DyadicRatCore, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows agree.

Thus the overlap data satisfy the finite-section descent hypothesis. Apply Definition 126.594 to glue the finite StreamName windows, carrying along the already identified dyadic ledger, RegSeqRat readback, Real finite-section readback, and support rows. The result is a single compatible four-face terminal packet over the finite cover.

Finally apply Definition 301.239 to the glued packet. The four compatible faces give exactly one accepted $\mathsf{Real}^{\uparrow}$ terminal seal for the covered $\mathsf{RegSeqRat}^{\uparrow}$ terminal section. The construction used only finite overlap agreement and the displayed ledger rows, so it cannot produce quotient streams, selected limits, host equality, ambient completeness, countable choice, standard bridge rows, or an additional terminal seal. □

Theorem 301.241 (RegSeqRat four-face gluing uniqueness)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local $\mathsf{RegSeqRat}^{\uparrow}$ terminal sections, and let T and T' be accepted $\mathsf{Real}^{\uparrow}$ terminal seals obtained from this same cover. Assume that both gluing presentations use the same $\mathsf{StreamName}^{\uparrow}$ finite windows, the same $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, and finite-distance ledgers, the same $\mathsf{RegSeqRat}^{\uparrow}$ classifier and readback rows, the same $\mathsf{Real}^{\uparrow}$ finite-section readbacks, and the same* BHist*,* hsame*,* Cont*,* Pkg*, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ support rows on every cover member and every nonempty overlap. Then T and T' are the same BEDC-visible four-face terminal packet.*

The comparison is internal to the four displayed faces

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

It introduces no quotient stream, selected limit, host equality, ambient completeness row, countable-choice selector, standard bridge row, or second terminal seal.

Proof. Apply Definition 301.240 separately to the presentations of T and T'. For each cover member S_i, both seals therefore restrict to local packets satisfying the four-face exactness criterion of Definition 301.239 with the same StreamName, DyadicRatCore, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows.

On each local member and each nonempty overlap, use Definition 301.237. Since the two presentations have identical finite windows, endpoint, radius, distance, classifier, readback, and support ledgers, the local $\mathsf{RegSeqRat}^{\uparrow}$ terminal source sections coincide as BEDC-visible records.

The overlap ledger is now the same for the two presentations. Apply Definition 126.594 to the common StreamName finite windows. The glued StreamName section obtained from T and the glued StreamName section obtained from T' are the same finite descent object, carrying the already identified dyadic, RegSeqRat, RealUp, and support rows.

It remains to compare the terminal Real row. The common local four-face packet is read by Definition 301.239, and terminal pullback uniqueness Definition 38.458 identifies the accepted $\mathsf{Real}^{\uparrow}$ terminal row over that packet. Hence T and T' present the same BEDC-visible four-face terminal packet.

All identifiers used in the comparison come from the finite cover and its overlap ledger. There is no field in the argument for a quotient stream, selected limit, host equality, ambient completeness principle, countable choice, standard bridge row, or independent second terminal seal, so none is introduced by the uniqueness comparison. □

Theorem 301.242 (RegSeqRat four-face finite-section restriction functoriality)**.** *Let $\{S_i\}_{i\in I}$ be a finite cover of compatible local $\mathsf{RegSeqRat}^{\uparrow}$ terminal sections whose accepted $\mathsf{Real}^{\uparrow}$ terminal seal is presented by the four faces*

$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}.$$

Restrict the cover to a finite subcover, or replace the local sections by a finite family obtained through support-row-preserving $\mathsf{StreamName}^{\uparrow}$ *reindex routes. Assume that the reindex routes preserve the finite request windows, tail-window rows, dyadic endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the* $\mathsf{Real}^{\uparrow}$ *finite-section readback, and the shared* BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

Then the terminal packet over the restricted or reindexed family is exactly the restriction of the original four-face boundary. Conversely, any four-face terminal packet over such a restricted family is read from precisely the restricted local sections and the corresponding support rows.

This object-level comparison is confined to the finite terminal faces displayed above. It does not identify quotient streams, select limits, compare host reals, assume countable choice, add ambient or metric completeness, aggregate formal-status rows, or introduce standard bridge rows.

Proof. First restrict the accepted terminal seal to the chosen finite subcover or to the support-row-preserving reindexed family. Apply Definition 301.240 to the original cover. Each retained or reindexed local section is therefore covered by a four-face local packet satisfying the exactness criterion, with only the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows present.

For the $\mathsf{StreamName}^{\uparrow}$ face, use Definition 126.648 to transport the terminal four-face boundary along the reindex route. Use Definition 126.649 to identify the tail-window terminal rows after restriction. Thus the retained StreamName request windows and terminal rows are exactly the old ones read on the smaller finite support.

For the dyadic and real faces, apply Definition 291.84 to the endpoint, radius, and finite-distance ledger, and apply Definition 38.458 to the terminal $\mathsf{Real}^{\uparrow}$ seal over the same four-face packet. These two uniqueness results leave no freedom to create a different dyadic source or a different terminal Real row after finite restriction.

It remains to compare the whole packet. The restricted presentation and the packet read directly from the retained local sections have identical StreamName, DyadicRatCore, RegSeqRat, RealUp, and support rows on every retained member and overlap. Apply Definition 301.241. The two presentations are the same BEDC-visible four-face terminal packet.

Conversely, suppose a four-face terminal packet is given over the restricted or support-row-preserving reindexed family. Local acceptance follows from Definition 301.240, and the same StreamName, dyadic, and Real uniqueness references identify each face with the corresponding restricted row of the original cover. Hence the packet is read from exactly the retained local sections and support rows.

Every step only restricts finite indices, transports finite request windows, or invokes terminal uniqueness over the displayed four faces. The argument has no constructor or field for quotient stream equality, selected limits, host real equality, countable choice, ambient or metric completeness, aggregate formal-status data, or standard bridge rows, so none is introduced. □

Theorem 301.243 (RegSeqRat finite-request section cocycle Real seal)**.** *Let* S_0, S_1, *and* S_2 *be three compatible finite-request terminal sections over the same accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Suppose every pairwise overlap agrees on the* $\mathsf{StreamName}^{\uparrow}$ *finite request window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

Then the three pairwise Real-seal-visible packets satisfy the finite section cocycle condition: their restrictions to each triple overlap are the same terminal four-face packet. Consequently the three sections determine one BEDC-visible terminal packet over

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The conclusion is only about the finite request section and its displayed terminal Real seal. It does not introduce quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate status rows, standard bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First place each pairwise overlap on the local Real-seal surface. Apply Definition 301.240 to the three pairwise families. Each overlap is therefore represented by the same four visible faces and by the listed BHist, hsame, Cont, Pkg, and NameCert support rows.

Next identify the common finite request spine. The pairwise hypotheses give the same $\mathsf{StreamName}^{\uparrow}$ finite windows on all double overlaps, so Definition 126.594 glues the three windows to one finite descent object. The dyadic endpoint, radius, and finite-distance ledger are then forced by Definition 291.84; no second dyadic source can sit over the same finite request data.

Now compare the Real-seal-visible rows on a triple overlap. By Definition 301.242, restricting a pairwise packet to the triple overlap reads exactly the restricted StreamName, DyadicRatCore, RegSeqRat, RealUp, and support rows. Those rows are common by hypothesis and by the preceding descent step, so Definition 38.458 identifies the three restricted Real terminal rows as one terminal pullback.

The cocycle condition follows from this triple-overlap identification. To obtain the single terminal packet, apply Definition 301.241 to the three pairwise Real-seal-visible presentations. Since their restrictions agree on every overlap, the glued four-face packet is independent of the chosen pairwise route and is the unique BEDC-visible terminal packet determined by S_0, S_1, and S_2.

All data used in the construction are finite request windows, dyadic ledger rows, classifier and readback rows, the local Real seal, and the named support coordinates. The cited gluing, restriction, and terminal-uniqueness theorems have no coordinate for quotient streams, selected limits, host real equality, countable choice, metric-completeness rows, aggregate status rows, standard bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so the cocycle packet does not claim any of them. □

Theorem 301.244 (RegSeqRat finite-request section refinement composition)**.** *Let S_0, S_1, and S_2 be accepted finite-request terminal sections over the four-face route*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Suppose $\rho_{01} : S_0 \to S_1$ and $\rho_{12} : S_1 \to S_2$ are compatible certified refinements preserving the finite $\mathsf{StreamName}^{\uparrow}$ *request windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-scale endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows. Suppose also that the direct certificate $\rho_{02} : S_0 \to S_2$ is accepted on the same visible support and has the same facewise restriction as the composite $\rho_{12} \circ \rho_{01}$.*

Then refining S_0 to S_2 in one certified step by ρ_{02} or in two certified steps by ρ_{01} followed by ρ_{12} determines the same terminal four-face packet and the same local $\mathsf{Real}^{\uparrow}$ *seal. The comparison is confined to finite request sections and their displayed support rows; it does not identify quotient streams, select limits, compare host reals, use countable choice, add metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, or assert* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First read both refinement routes on their visible finite supports. By Definition 301.242, each restriction of the one-step route and each restriction of the two-step route is exactly the packet obtained by restricting the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and support rows.

Next compare the request spines. Apply Definition 126.597 to identify the finite $\mathsf{StreamName}^{\uparrow}$ windows carried by the direct certificate with the windows obtained after the two successive re-

strictions. Apply Definition 291.90 to the dyadic endpoint, radius, and finite-distance ledger. The common-scale window seen by ρ_{02} is therefore the same dyadic window seen by $\rho_{12} \circ \rho_{01}$.

The local Real seal is then forced on every overlap. Use Definition 301.243 on the three sections S_0, S_1, and S_2 to identify the pairwise Real-seal-visible packets on triple overlaps. Finally apply Definition 38.796 to read that common overlap packet as the local $\mathsf{Real}^{\uparrow}$ threshold seal for the same four visible faces and support rows.

It remains only to repack the terminal object. The direct refinement route and the two-step refinement route now have identical StreamName request windows, dyadic common-scale rows, RegSeqRat classifier and readback rows, local Real seal rows, and support coordinates on every finite member and overlap. Applying Definition 301.242 once more, both routes determine the same terminal four-face packet.

All cited inputs are finite restriction, finite cocycle, common-scale composition, and local Real threshold statements over the displayed BEDC rows. None of these constructions carries quotient stream equality, selected-limit data, host real equality, countable-choice data, metric-completeness rows, aggregate formalstatus rows, aggregate bridge rows, or a $\mathsf{Real}^{\uparrow}$ completeness field, so the composition law does not claim any such structure. □

Theorem 301.245 (RegSeqRat four-face finite-cover induction)**.** *Let $\mathcal{S}$ be a finite family of compatible accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections over the visible four-face route*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Assume that the empty and singleton subfamilies are the displayed local packets of Definition 301.240. Assume also that the successor clause glues any previously accepted subcover to one additional accepted section along overlap rows preserving the finite $\mathsf{StreamName}^{\uparrow}$ *request windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

Then the whole finite cover $\mathcal{S}$ determines exactly one accepted $\mathsf{Real}^{\uparrow}$ *terminal seal over the same four visible faces. Moreover, every accepted* $\mathsf{Real}^{\uparrow}$ *terminal seal whose visible support is the cover $\mathcal{S}$ is obtained by this finite-cover induction from the local empty, singleton, and successor clauses.*

The claim is only the finite descent principle for the displayed $\mathsf{RegSeqRat}^{\uparrow}$ *section cover. It does not identify quotient streams, select limits, compare host real equality, use countable choice, assume ambient or metric completeness, aggregate formalstatus rows, or introduce standard bridge rows.*

Proof. Put the finite cover into a section-by-section descent order. Apply Definition 126.600 to replace the cover by its finite request normal form. The empty and singleton entries are then exactly the local four-face packets supplied by Definition 301.240.

For the successor step, suppose a subcover has already produced an accepted terminal $\mathsf{Real}^{\uparrow}$ seal. Glue this seal to the next section along the stated overlap rows. The preservation hypotheses give the same BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ rows on the common support, so Definition 301.242 reads both sides on the same restricted four-face packet.

The overlap condition is coherent because the pairwise restrictions satisfy Definition 301.243. Hence the new section and the previously accepted subcover have a common terminal overlap packet. Applying Definition 301.241 gives one accepted $\mathsf{Real}^{\uparrow}$ terminal seal for the enlarged subcover, and uniqueness prevents any second seal from being carried by the same visible rows.

Iterating this finite successor construction reaches the full cover $\mathcal{S}$. Refining the descent order does not change the resulting seal: adjacent regroupings are identified by Definition 301.244, while

all restrictions back to smaller subcovers are controlled by Definition 301.242. Thus the terminal seal is independent of the chosen finite normal form.

Finally let T be any accepted $\mathsf{Real}^{\uparrow}$ terminal seal over the same cover. Restrict T to every empty, singleton, and successor subcover in the normal form. The local gluing theorem supplies the base packets, the restriction theorem identifies the visible rows, the cocycle theorem supplies the overlap compatibility, and gluing uniqueness identifies each successor seal with the induction seal. Therefore T is obtained by the same finite-cover induction.

Every step uses only finite request normal forms, local four-face gluing, restriction functoriality, cocycle compatibility, uniqueness, and certified refinement composition. None of these cited inputs contains a coordinate for quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, metric completeness, aggregate formalstatus rows, or standard bridge rows, so the induction theorem does not claim any of that structure. □

Theorem 301.246 (RegSeqRat four-face finite-cover normal form)**.** *A finite family $\mathcal{S}$ of compatible accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections presents an accepted* $\mathsf{Real}^{\uparrow}$ *terminal seal precisely when its visible support is the following finite row data:*

1. *the finite* $\mathsf{StreamName}^{\uparrow}$ *request windows;*
2. *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledgers;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows;*
4. *the local* $\mathsf{Real}^{\uparrow}$ *seal rows; and*
5. *the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support rows.*

These rows must satisfy the local-gluing hypotheses of Definition 301.240, the restriction hypotheses of Definition 301.242, the cocycle hypotheses of Definition 301.243, the refinement-composition hypotheses of Definition 301.244, and the finite-cover induction hypotheses of Definition 301.245. No additional row for quotient streams, selected limits, host real equality, countable choice, ambient completeness, metric completeness, aggregate formalstatus data, aggregate bridge data, or standard bridge data is present or necessary.

Equivalently, those finite rows are necessary and sufficient for the $\mathsf{Real}^{\uparrow}$ *terminal seal determined by the RegSeqRat-to-Real four-face cover, and any other accepted terminal seal with exactly those visible rows is the same seal.*

Proof. For necessity, start with an accepted $\mathsf{Real}^{\uparrow}$ terminal seal presented by the finite compatible family $\mathcal{S}$. Apply Definition 301.245 to express the seal by empty, singleton, and successor cover clauses. Project the empty and singleton clauses through Definition 301.240; project the successor restrictions through Definition 301.242; and project the overlap rows through Definition 301.243. The visible support is therefore exactly the finite StreamName, DyadicRatCore, RegSeqRat, Real, and shared BEDC support rows listed in the statement.

For sufficiency, suppose the displayed finite rows and the named compatibility hypotheses are given. Package the empty, singleton, successor, cocycle, and refinement-composition data as the input cover for Definition 301.245. That theorem constructs an accepted $\mathsf{Real}^{\uparrow}$ terminal seal over the four visible faces.

It remains to identify possible alternatives. If T is any other accepted terminal seal with exactly the same visible rows, then its restrictions to the finite request windows have the same local gluing rows, the same finite restriction rows, and the same cocycle rows. Apply Definition 301.241 on each successor gluing step and then along the whole finite-cover induction order. The resulting seal is the one constructed from the displayed rows.

The excluded structures cannot enter the construction because every cited input theorem is stated over finite visible support rows. Thus quotient stream identification, selected-limit data, host real equality, countable-choice data, ambient or metric completeness, aggregate formalstatus rows, aggregate bridge rows, and standard bridge rows are neither consumed nor produced. □

Theorem 301.247 (RegSeqRat finite-cover normal form StreamName support refinement)**.** *Let $\mathcal{S}$ be a finite compatible family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections whose visible rows satisfy the normal-form clauses of Definition 301.246. Let $\mathcal{S}'$ be obtained from $\mathcal{S}$ by refining only the terminal* $\mathsf{StreamName}^{\uparrow}$ *request windows and by preserving, on every refined support row, the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledgers, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, the local* $\mathsf{Real}^{\uparrow}$ *seal rows, and the shared* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support.*

Assume the refined terminal windows satisfy Definition 126.657 and that transport from $\mathcal{S}$ to $\mathcal{S}'$ satisfies Definition 126.658. Then $\mathcal{S}$ and $\mathcal{S}'$ determine the same accepted $\mathsf{Real}^{\uparrow}$ *terminal seal exactly when the preserved* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledger rows agree with the local* $\mathsf{Real}^{\uparrow}$ *seal rows on the shared support.*

Equivalently, the finite-cover normal form factors through the StreamName terminal support surface: refining finite terminal windows changes no accepted $\mathsf{Real}^{\uparrow}$ *terminal seal unless it changes the shared DyadicRatCore ledger or the local Real seal row read on that support. The refinement surface has no coordinate for quotient stream equality, selected limits, host real equality, countable choice, ambient or metric completeness, aggregate formalstatus rows, aggregate bridge rows, or standard bridge rows.*

Proof. First normalize the original cover. Apply Definition 301.246. The accepted $\mathsf{Real}^{\uparrow}$ terminal seal is carried by exactly the finite StreamName request windows, the DyadicRatCore endpoint, radius, and finite-distance ledgers, the RegSeqRat classifier-readback rows, the local Real seal rows, and the shared BEDC support rows.

Next read the refined windows through the StreamName terminal support surface. By Definition 126.657, every accepted support coordinate of $\mathcal{S}'$ is one of the same four visible faces or one of the same displayed support rows. By Definition 126.658, the componentwise transport from $\mathcal{S}$ to $\mathcal{S}'$ preserves that support packet whenever those rows agree after replay.

Now compare the consumer ledger. Apply Definition 291.118 to the consumer read of each refined terminal packet. The consumer can read exactly the DyadicRatCore ledger rows, the StreamName finite-window rows, the RegSeqRat classifier-readback rows, the local Real seal rows, and the shared support. Therefore agreement of the DyadicRatCore endpoint and radius ledger with the local Real seal rows on the shared support is sufficient to make the refined consumer packet expose the same finite inventory as the original packet.

With the same inventory in hand, use Definition 301.240 on each refined local section and Definition 301.242 on the overlaps. The transported support rows give the same pairwise restrictions as before, so Definition 301.243 supplies the same finite cocycle. Applying Definition 301.241 along the finite-cover induction order identifies the accepted terminal seal produced by $\mathcal{S}'$ with the seal produced by $\mathcal{S}$.

Conversely, suppose the two covers determine the same accepted $\mathsf{Real}^{\uparrow}$ terminal seal. Project that common seal back through Definition 301.246 and then through Definition 291.118. Since the StreamName support exhaustion leaves no additional consumer coordinate, any accepted difference between the two finite presentations must be visible in the DyadicRatCore ledger rows or in the local Real seal rows. Equality of the terminal seal therefore forces the endpoint and radius ledger and the local Real seal rows to agree on the shared support.

All implications use only finite StreamName support exhaustion, support transport stability, the DyadicRatCore consumer normal form, local RegSeqRat gluing, finite restriction functoriality, cocycle compatibility, and gluing uniqueness. None of these cited surfaces supplies quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, metric completeness, aggregate formalstatus rows, aggregate bridge rows, or standard bridge rows, so the refinement theorem does not claim any of that structure. □

Theorem 301.248 (RegSeqRat finite-window map preservation)**.** *Let S be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row carried by a finite* BHist *packet with its displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, its* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, and finite-distance ledger, its* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity rows, and its* hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support. Let M be a uniformly controlled finite-window map row on the same support. Assume M sends every displayed StreamName window to a displayed StreamName window, transports the DyadicRatCore tolerance ledger by the stated finite modulus row, and preserves the RegSeqRat classifier and regularity rows on each finite observation window.*

Then the readback row obtained by applying M to S is again an accepted $\mathsf{RegSeqRat}^{\uparrow}$ *readback row over a finite four-face packet*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

with the transported BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support. The construction is finite-window inductive and introduces no quotient stream equality, selected limit, countable-choice row, host function equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or second* $\mathsf{Real}^{\uparrow}$ *seal coordinate.*

Proof. Start from the finite request source section of Definition 301.139. It places the source readback on one finite packet carrying the StreamName windows, DyadicRatCore tolerance ledger, RegSeqRat classifier and regularity rows, and the displayed support.

Apply the map row on the StreamName and dyadic faces. The StreamName pullback and lock results, Definition 126.586 and Definition 126.589, keep the transported windows as finite observed rows. The dyadic source uniqueness theorem Definition 291.84 keeps the transported endpoint, radius, and distance ledger on the same finite tolerance surface.

Now perform induction over the finite observation window family. The base window is the transported singleton read supplied by the map row. In the induction step, the preservation hypotheses identify the new overlap rows with the already transported StreamName and DyadicRatCore rows, while the RegSeqRat classifier and regularity rows are preserved by assumption.

The induction is glued by Definition 301.240 and Definition 301.227. Those theorems turn compatible local four-face packets into one accepted terminal readback without adding a quotient stream, selected limit, choice row, host equality, ambient completeness datum, or second Real seal.

Finally use Definition 301.236 and Definition 301.238. They identify the transported readback as a single RegSeqRat source section over the same StreamName, DyadicRatCore, RegSeqRat, and Real faces, so the output of M is accepted as a $\mathsf{RegSeqRat}^{\uparrow}$ readback row. □

Theorem 301.249 (RegSeqRat uniformly controlled Real seal handoff)**.** *Let S be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row whose terminal consumer is a Phase* $\mathsf{Real}^{\uparrow}$ *and Completion seal, and let M be a uniformly controlled finite-window map row satisfying the hypotheses of Definition 301.248. Then the* $\mathsf{Real}^{\uparrow}$*-facing seal read of the transported row factors through exactly the four finite faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the map-control row M and the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *support.*

This handoff is the RegSeqRat-side input needed by the $\mathsf{CauchyContinuousExtension}^{\uparrow}$ *route: it reads the mapped regular Cauchy data through StreamName windows, DyadicRatCore tolerances, the RegSeqRat accepted readback, and the terminal Real seal. It exports no quotient stream, host function equality, selected limit, countable-choice row, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or independent Real completion coordinate.*

Proof. Apply Definition 301.248 to the source readback and the map-control row. The result is an accepted transported $\mathsf{RegSeqRat}^{\uparrow}$ readback over the same finite support and the same four visible faces.

Read the transported row at the Real boundary. The terminal exactness theorem Definition 301.239 identifies its accepted Real seal precisely with the displayed StreamName, DyadicRatCore, RegSeqRat, and Real rows. The source uniqueness theorem Definition 301.237 rules out a second RegSeqRat source over those rows.

Next compare this handoff with the local cover surface. The finite-cover gluing theorem Definition 301.227 and the local four-face coverage theorem Definition 301.240 keep the seal read invariant under finite cover refinement of the transported windows. Thus every Real-facing read of the mapped row is recovered from the same finite four-face packet and the same map-control row.

Finally point the packet toward the completion-extension consumer. The $\mathsf{CauchyContinuousExtension}^{\uparrow}$ regular source handoff of Definition 1632.3 in chapter 1632 consumes regular source data only through StreamName finite windows, a DyadicRatCore tolerance ledger, a Cauchy-continuous map row, and the resulting completion surface. The handoff above supplies exactly the RegSeqRat source side of that route before any completed extension is read.

Since each cited step is a finite BEDC row calculation, no quotient stream, host function equality, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ completeness, or independent completion coordinate is available to enter the seal read. □

Theorem 301.250 (RegSeqRat uniform-continuity window modulus composition)**.** *Let S be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row with its displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Let M_0 and M_1 be uniformly controlled finite-window map rows, each satisfying the hypotheses of Definition 301.248. Assume that the output four-face packet of M_0 is the input four-face packet of M_1, with the same StreamName, DyadicRatCore, RegSeqRat, Real, history, continuity, package, and local NameCert rows exposed on the shared boundary.*

Then the composed finite-window row $M_1 \circ M_0$ preserves the accepted $\mathsf{RegSeqRat}^{\uparrow}$ *readback of S and exports a single Phase* $\mathsf{Real}^{\uparrow}$ *and Completion handoff through exactly the same four faces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. The composed route introduces no quotient stream, selected limit, countable-choice row, host function equality, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or second Real seal.*

Proof. Apply Definition 301.248 to S and M_0. This gives an accepted intermediate RegSeqRat readback over the output packet of M_0, with the transported StreamName windows, DyadicRatCore tolerance ledger, RegSeqRat classifier, Real face, BHist, hsame, Cont, Pkg, and local NameCert rows still displayed as finite BEDC data.

Use the boundary hypothesis to read that intermediate output packet as the input packet of M_1. A second application of Definition 301.248 therefore produces the accepted readback for $M_1 \circ M_0$. The four-face refinement functoriality theorem Definition 301.238 identifies the two finite transports with one composed route rather than two unrelated readback choices.

The cover bookkeeping is finite. Apply Definition 301.227 to glue the modulus windows used by M_0 and M_1 into the single observed finite cover seen by the composed row. This keeps the overlap checks inside the displayed StreamName, DyadicRatCore, RegSeqRat, and Real faces and does not add a new ambient equality principle.

Finally apply Definition 301.249 to the composed accepted readback. The handoff theorem reads the terminal seal only through the displayed four-face packet and its BHist, hsame, Cont, Pkg, and NameCert support. Since both preservation steps and the finite-cover gluing are internal row calculations, there is no quotient stream, selected limit, countable-choice row, host function equality, ambient $\mathsf{Real}^{\uparrow}$ completeness, or second Real seal available for the composed route. □

Theorem 301.251 (RegSeqRat uniform-continuity modulus fusion)**.** *In the setting of Definition 301.250, the dyadic modulus schedules of the two uniformly controlled finite-window rows fuse into one displayed finite support row consumed by the terminal* $\mathsf{Real}^{\uparrow}$ *seal. The fused row is read over the shared*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

boundary together with the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. It exports no selected limit, quotient stream, host function equality, ambient completeness coordinate, or second Real seal.*

Proof. Begin with Definition 301.250. It identifies the composite route $M_1 \circ M_0$ as one accepted finite-window transport over the shared StreamName, DyadicRatCore, RegSeqRat, and Real faces.

The modulus bookkeeping is the finite cover bookkeeping. Apply Definition 301.227 to the two observed modulus-window families. The gluing row records the common finite support on which the output windows of M_0 are the input windows of M_1, so the two dyadic schedules are consumed as one displayed finite support row.

Finally use Definition 301.249. The terminal Real seal reads the composed accepted row only through the four visible faces and the structural support rows. Since the fused support row is already the support used by that seal, there is no source for a selected limit, quotient stream, host function equality, ambient completeness coordinate, or second Real seal. □

Theorem 301.252 (RegSeqRat tail-modulus positive cofinality)**.** *Let S be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row carried by displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *positive-tolerance ledger, a* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, a terminal* $\mathsf{Real}^{\uparrow}$ *seal, and the supporting* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows. Suppose the displayed modulus schedule for S dominates a later positive dyadic tolerance request ε. Then there is a finite later window whose* $\mathsf{RegSeqRat}^{\uparrow}$ *readback refines the earlier ε request before the terminal* $\mathsf{Real}^{\uparrow}$ *seal is consumed.*

The refinement is read through the same four faces

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and through the same structural support rows. It introduces no quotient stream, selected limit, countable-choice row, ambient $\mathsf{Real}^{\uparrow}$ *completeness, or independent Real seal.*

Proof. Start with the displayed positive dyadic request ε. Since it is dominated by the modulus schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger contains a finite later tolerance row whose request is at most ε on the same StreamName support.

Use the common-window transport route for $\mathsf{RegSeqRat}^{\uparrow}$ readbacks. The later window is transported along the displayed hsame row and replayed through Cont, so the classifier remains on the same StreamName, DyadicRatCore, and RegSeqRat faces.

Apply the finite-cover gluing used in Definition 301.251. The gluing row places the later window and the earlier request on one finite support, and the dominance relation makes the later readback a refinement of the earlier positive request.

Finally use the Real-seal handoff Definition 301.249. The terminal seal consumes only the displayed four-face route, so the cofinal later window is available before any Real seal read and no quotient stream, selected limit, choice schedule, ambient completeness, or second seal can enter the route. □

Theorem 301.253 (RegSeqRat uniform-continuity composition terminal seal)**.** *Two displayed uniform-continuity packets over* $\mathsf{RegSeqRat}^{\uparrow}$ *compose to a single terminal* $\mathsf{Real}^{\uparrow}$*-seal handoff exactly through the shared* $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budgets,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal. The composed consumer receives one finite route, not two independently selected limit reads.*

The terminal seal contains no selected limit, quotient stream equality, countable choice, ambient Real completeness, or standard bridge coordinate.

Proof. Start with preservation, Definition 301.248, for the two displayed uniform-continuity packets. The first packet produces the finite output windows that the second packet consumes, all inside the visible RegSeqRat readback surface.

Apply the Real-seal handoff theorem Definition 301.249. It forces every terminal consumer to pass through the displayed StreamName, DyadicRatCore, RegSeqRat, and Real faces together with their support rows.

The window-modulus composition theorem Definition 301.250 identifies the two packet routes as one composed finite-window route. Then Definition 301.251 fuses the two dyadic modulus schedules into the single support row consumed by the terminal seal.

Therefore the composed Real-seal handoff is terminal and finite. Since the route has already exhausted its visible windows, tolerance budgets, classifier and readback rows, and Real seal, none of the excluded quotient, choice, completeness, selected-limit, or bridge coordinates can supply another composition read. □

Theorem 301.254 (RegSeqRat finite-cover induction diagonal)**.** *Let* $\{S_i\}_{i\in I}$ *be a finite family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections for one Phase* $\mathsf{Real}^{\uparrow}$ *and Completion consumer. Assume every* S_i *is read through a common* $\mathsf{StreamName}^{\uparrow}$ *window family, a displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, a* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity ledger, a local* $\mathsf{Real}^{\uparrow}$ *seal row, and the shared support*

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}.$$

Assume also that the accepted pairwise overlap rows glue by the finite-cover gluing theorem, that adjoining one more section preserves the induction-step rows, that the gluing operation is associative on displayed overlaps, and that every two local presentations admit the common-refinement rows of the RegSeqRat cover surface. Then finite induction over I *produces a single diagonal terminal window through which all local* $\mathsf{Real}^{\uparrow}$ *seal reads factor.*

The diagonal terminal window exposes exactly the common $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity ledgers, local* $\mathsf{Real}^{\uparrow}$ *seal rows, and displayed support rows named above. It exports no quotient stream equality, host real equality, selected limit,*

countable-choice schedule, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Induct on the finite cover. In the empty boundary there is no terminal seal read to compare, and in the singleton case the accepted section itself supplies the diagonal terminal window with its displayed StreamName, DyadicRatCore, RegSeqRat, Real, and support rows.

For the induction step, suppose a finite subcover has already been packed into one diagonal terminal window. Adjoin the next accepted section S_j. The common-refinement rows place the old diagonal window and S_j over one common $\mathsf{StreamName}^{\uparrow}$ window family and the same displayed dyadic tolerance ledger.

Apply the RegSeqRat finite-cover gluing row to the old diagonal window and the new local section. The induction-step hypotheses preserve the classifier rows, regularity ledgers, local Real seal rows, and the shared BHist, hsame, Cont, Pkg, and NameCert support while the two packets are glued.

Associativity identifies the result with any parenthesized order of adjoining the same finite sections. Thus the terminal window obtained after the last induction step is independent of the chosen bracketing and is the single diagonal window for the whole family.

Finally use the existing common-refinement determinacy and Real seal handoff rows. They force every local seal consumer to factor through the diagonal window just constructed, and they leave no coordinate for quotient streams, host real equality, selected limits, countable choice, metric completeness, completion points, or ambient Real completeness. □

Theorem 301.255 (RegSeqRat finite-cover diagonal Real-seal exhaustion)**.** *Let* $\{S_i\}_{i\in I}$ *be a finite family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections satisfying the common* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and regularity, local* $\mathsf{Real}^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support hypotheses of Definition 301.254. Then every* $\mathsf{Real}^{\uparrow}$*-facing read from any local section* S_i *factors through the diagonal terminal window produced by Definition 301.254.*

The factorization is exhaustive for the displayed family: no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness principle is exported by a local seal read outside the diagonal packet.*

Proof. Invoke Definition 301.254 for the displayed finite family. It supplies one diagonal terminal window carrying the same StreamName, DyadicRatCore, RegSeqRat, Real, and support rows as the local sections.

Now read an arbitrary $\mathsf{Real}^{\uparrow}$-facing consumer from a chosen local section S_i. The existing common-refinement determinacy rows in the RegSeqRat cover surface place that local read and the diagonal window over the same finite StreamName window family and the same dyadic tolerance ledger.

Use the Real seal handoff rows of the RegSeqRat chapter. They route the local Real seal through the displayed RegSeqRat classifier and regularity ledger before any terminal read is exposed, so the consumer cannot bypass the diagonal packet once the common-refinement row has been fixed.

Since i was arbitrary, every local Real-facing seal read factors through the same diagonal terminal window. The carrier has no coordinate for quotient stream equality, selected limits, countable-choice schedules, metric-completeness data, completion points, or ambient Real completeness, so none of those objects is exported by the exhaustion route. □

Theorem 301.256 (RegSeqRat finite-cover diagonal tail-budget preservation)**.** *Let* $\{S_i\}_{i\in I}$ *be a finite family of accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *terminal sections satisfying the hypotheses of Definition 301.254. The diagonal terminal window produced by finite-cover induction preserves every local tail-budget*

row when read through the common $\mathsf{StreamName}^{\uparrow}$ *window family and the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger.*

Consequently no local section may contribute a separate selected limit, quotient stream, countable-choice schedule, host sequence equality, metric-completeness row, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate to the terminal Real seal route.*

Proof. Invoke Definition 301.254. The induction constructs a single diagonal terminal window over the common StreamName window family, the same DyadicRatCore tolerance ledger, the RegSeqRat classifier and regularity rows, the local Real seal rows, and the shared support rows.

Now apply Definition 301.255. Every Real-facing read from a local section factors through that diagonal window, so the local tail-budget row is read through the same StreamName and DyadicRatCore data rather than through a private terminal coordinate.

The StreamName finite-request pullback and exactness rows identify the public request section used by the diagonal window, while the DyadicRatCore tolerance-halving handoff rows keep tolerance refinements inside the displayed ledger. Thus finite-cover induction preserves the tail-budget rows already visible in the common window family.

Since the diagonal packet has no coordinate for selected limits, quotient streams, countable choice, host sequence equality, metric completeness, completion points, or ambient Real completeness, no local section can export one of those objects along the tail-budget route. □

Theorem 301.257 (RegSeqRat tail-shift stability for scheduled finite windows)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let t be a displayed unary tail index for the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the shifted finite window exposes exactly the endpoint rows, dyadic-radius rows, regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance obtained by transporting the original window through the shifted* $\mathsf{StreamName}^{\uparrow}$ *schedule. Then the shifted window preserves the* $\mathsf{RegSeqRatClassifier}$ *read of P.*

Equivalently, every accepted classifier read on the original scheduled finite window factors through the shifted StreamName window and returns the same RegSeqRat finite source surface before any $\mathsf{Real}^{\uparrow}$ *seal row can be consumed. The stability statement exports no quotient stream equality, host real equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Project the original scheduled-window rows of the accepted packet. The visible source data are the $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius rows, the regularity ledgers, the classifier row, and the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Use the finite-window transport obligation for the displayed unary tail index t. It transports endpoint rows, dyadic-radius comparisons, and regularity ledgers componentwise along the shifted StreamName window, preserving exactly the rows that the classifier is allowed to inspect.

Apply classifier transport to the shifted window. Since the transported hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows are part of the same finite packet, the classifier read cannot add a second schedule, quotient stream, selected limit, or host real coordinate.

Finally close by common-refinement determinacy. The original scheduled window and the shifted window restrict to the same displayed finite RegSeqRat source surface on their common refinement, so their classifier reads agree before any terminal $\mathsf{Real}^{\uparrow}$ seal is opened. □

Theorem 301.258 (RegSeqRat two-shift common-refinement compatibility)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let t_0 and t_1 be two displayed unary tail indices for the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the two shifted finite windows admit one displayed common finite refinement on which they expose the same transported StreamName schedule, the same* $\mathsf{DyadicRatCore}^{\uparrow}$

endpoint and radius rows, the same regularity ledgers, the same componentwise hsame *rows, the same displayed* Cont *routes, the same* Pkg *provenance, and the same local* NameCert *rows. Then the two shifted reads determine the same* RegSeqRatClassifier *value before any* $\mathsf{Real}^{\uparrow}$ *seal row is consumed.*

Equivalently, whenever two displayed tail shifts of an accepted RegSeqRat packet are compared through a common finite refinement carrying the full StreamName, DyadicRatCore, regularity, transport, continuation, package, and naming support, the classifier has only one finite source row to read. The theorem exports no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Apply Definition 301.257 to the t_0-shifted window. Its classifier read is the original RegSeqRat finite source surface transported along the first displayed StreamName tail index.

Apply the same theorem to the t_1-shifted window. Its classifier read is likewise the original finite source surface transported along the second displayed tail index.

Use the common finite refinement to compare the two transported supports. By hypothesis the StreamName schedule, DyadicRatCore endpoint and radius rows, regularity ledgers, hsame, Cont, Pkg, and local NameCert rows coincide on that refinement, so common-refinement determinacy gives one visible finite source row for both shifted windows.

The classifier can inspect only that visible finite RegSeqRat source surface. Since neither shifted read opens a quotient stream, selected limit, choice schedule, metric-completeness datum, or ambient Real-completeness coordinate, no further row remains that could distinguish the two classifier values before the $\mathsf{Real}^{\uparrow}$ seal is consumed. □

Theorem 301.259 (RegSeqRat tail-shift finite-window stability)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let t_0 and t_1 be two displayed unary tail indices over the same* $\mathsf{StreamName}^{\uparrow}$ *source and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Suppose both shifted finite windows expose accepted endpoint rows, dyadic-radius rows, regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows for P. Then the two shifts admit a common finite window whose readback preserves the* RegSeqRatClassifier *value and the same downstream* $\mathsf{Real}^{\uparrow}$ *seal route.*

The common window exports only the finite StreamName source surface, dyadic tolerance ledger, regular-rational readback, transport, replay, provenance, and local naming rows. It does not expose quotient stream equality, selected limits, countable choice, metric-completeness data, completion points, or ambient Real-completeness coordinates.

Proof. Apply Definition 301.257 to the t_0-shifted window. The classifier read is the original finite RegSeqRat source surface transported along the first displayed StreamName tail index.

Apply the same theorem to the t_1-shifted window. The second read is transported from the same original source and the same dyadic tolerance budget, so it has the same kind of visible support.

Now use Definition 301.258. The two accepted shifted windows have a common finite refinement on which the StreamName schedule, DyadicRatCore rows, regularity ledgers, hsame, Cont, Pkg, and local NameCert rows determine one visible classifier read.

Finally project the finite carrier rows. Since the classifier is already fixed on the common window, the downstream $\mathsf{Real}^{\uparrow}$ seal route is read through the same finite support and no quotient stream, selected limit, choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate remains available. □

Theorem 301.260 (RegSeqRat tail-shift diagonal budget)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let t be a displayed unary tail index for the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. If the scheduled tail shift is read through a common finite window, then the shifted read preserves the diagonal dyadic tolerance budget consumed by the downstream* $\mathsf{Real}^{\uparrow}$ *seal route. The preserved budget is the same componentwise ledger used by the finite-cover diagonal induction of Definition 301.254; it is transported through the StreamName schedule, the DyadicRatCore endpoint and radius rows, the RegSeqRat regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The statement exports no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate.

Proof. Induct over the displayed finite window. In the initial window, the diagonal dyadic tolerance row is one of the visible DyadicRatCore budget rows consumed by the accepted RegSeqRat packet.

For the tail step, apply Definition 301.257. It transports the StreamName schedule, endpoint rows, dyadic-radius rows, regularity ledgers, and support rows along the displayed unary tail index.

Compare two shifted reads by Definition 301.258 and then restrict to the common finite window using Definition 301.259. The common refinement keeps the classifier read and downstream RealUp seal route on the same finite support.

Finally invoke Definition 301.254. The displayed diagonal budget rows are transported componentwise along the same finite window, so the Real seal consumes the preserved dyadic tolerance budget rather than an ambient limit or completeness coordinate. □

Theorem 301.261 (RegSeqRat tail-window cofinality)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let W_0 and W_1 be accepted scheduled tail windows over the same* $\mathsf{StreamName}^{\uparrow}$ *source and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Then W_0 and W_1 admit a common finite cofinal window whose* RegSeqRatClassifier *read agrees and whose downstream* $\mathsf{Real}^{\uparrow}$ *seal route is the same displayed route.*

The common cofinal window exposes only the shifted StreamName windows, DyadicRatCore tolerance ledger, RegSeqRat regularity ledgers, componentwise hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream equality, selected limits, countable choice, metric-completeness data, completion points, or ambient Real completeness.*

Proof. Apply tail-shift stability, Definition 301.257, to both scheduled tail windows. Each accepted window reads the same original finite RegSeqRat source surface through its displayed StreamName tail.

Use two-shift common-refinement compatibility, Definition 301.258. Since the two windows share the StreamName source and DyadicRatCore tolerance budget, their displayed supports admit a common finite refinement with one classifier read.

Next apply finite-window stability, Definition 301.259. It identifies the common refinement as a window on which the classifier read and downstream Real seal route are preserved together.

Finally invoke the diagonal budget theorem, Definition 301.260. The dyadic tolerance budget consumed by the downstream Real seal is the same componentwise ledger on the common cofinal window, leaving no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate. □

Theorem 301.262 (RegSeqRat tail-shift synchronized readback)**.** *Let P and Q be accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packets whose displayed tail-shift schedules share the same finite* $\mathsf{StreamName}^{\uparrow}$ *window and the same*

dyadic tail budget. If both schedules expose accepted endpoint rows, regularity ledgers, componentwise hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows on that shared window, then both schedules read back through one RegSeqRat row before any* $\mathsf{Real}^{\uparrow}$ *seal is exposed.*

The synchronized readback exports only the shared finite StreamName window, the dyadic tail budget, the regular rational classifier row, and the displayed transport, replay, provenance, and naming rows. It does not expose quotient stream equality, selected limits, countable choice, metric-completeness data, completion points, or ambient Real-completeness coordinates.

Proof. Apply Definition 301.257 to each displayed schedule. Each accepted tail shift transports the original finite source surface through the shared StreamName window and preserves the classifier rows allowed by the RegSeqRat packet.

Use Definition 301.258. The two schedules already share the finite StreamName window and dyadic tail budget, so their common refinement has the same endpoint rows, regularity ledgers, transport rows, replay rows, provenance, and local naming.

Apply Definition 301.259 on that common window and then Definition 301.260. The classifier read and the diagonal dyadic budget are synchronized on one finite RegSeqRat row before the downstream Real seal route is opened.

Since the proof has used only displayed finite rows, no quotient stream, selected limit, choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate remains available to distinguish the two readbacks. □

Theorem 301.263 (RegSeqRat tail-shift finite-section induction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let $t_0, \ldots, t_k$ be a finite displayed family of unary tail indices for the* $\mathsf{StreamName}^{\uparrow}$ *schedule carried by P. Suppose the shifted StreamName windows share accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *budgets,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows on their displayed common windows. Then induction over the finite family gives one synchronized finite readback route for all displayed shifts before the downstream* $\mathsf{Real}^{\uparrow}$ *seal is opened.*

The synchronized route exposes only the finite StreamName windows, dyadic budgets, regular-rational classifier rows, transport, replay, provenance, and local naming rows. It does not expose quotient stream equality, selected limits, countable choice, metric completeness, completion points, or ambient Real completeness.

Proof. Induct over the displayed finite family of tail indices. In the empty or singleton case, apply Definition 301.257 to read the shifted window through the original finite RegSeqRat source surface.

For the induction step, assume a synchronized readback route has already been built for the initial family. Compare the next shifted window with that route by Definition 301.258; the hypotheses provide the shared StreamName windows, DyadicRatCore budgets, regularity ledgers, hsame, Cont, Pkg, and local NameCert rows needed for the common refinement.

Apply Definition 301.259 to keep the extended family on one finite window, and then use Definition 301.262 to repack the accumulated family and the next shifted window as one synchronized readback. No proof step introduces quotient stream equality, selected limits, choice, metric completeness, completion points, or ambient Real completeness. □

Theorem 301.264 (RegSeqRat tail-shift Real-seal classifier lock)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let $t_0, \ldots, t_k$ be a finite displayed family of tail shifts admitted by Definition 301.263. Before any Real consumer may read the shifted sequence, the synchronized route must preserve the same* $\mathsf{StreamName}^{\uparrow}$ *finite section, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the same terminal* $\mathsf{Real}^{\uparrow}$ *seal classifier.*

Equivalently, every admitted tail-shift family is locked to the four displayed objects already visible in the finite-section route. The lock exports no quotient stream equality, selected limit, countable choice, metric completeness, completion point, or ambient Real completeness.

Proof. Apply Definition 301.263 to the displayed family. It gives one synchronized finite readback route whose available rows are the finite StreamName windows, dyadic budgets, regular-rational classifier rows, transport, replay, provenance, and local naming.

Next route that synchronized tail through the dyadic tolerance ledger. The same $\mathsf{DyadicRatCore}^{\uparrow}$ row supplies the budget consumed by each shifted finite section, so no shifted read can replace the ledger by a selected limit or by a host Cauchy object.

The readback and seal are downstream of that ledger. The $\mathsf{RegSeqRat}^{\uparrow}$ row is the only regular-rational classifier available to the synchronized route, and the terminal $\mathsf{Real}^{\uparrow}$ seal is opened only after the same finite section, tolerance row, and readback row have been displayed.

Thus a Real consumer receives the shifted family only through the locked four-object surface $\mathsf{StreamName}^{\uparrow}, \mathsf{DyadicRatCore}^{\uparrow}, \mathsf{RegSeqRat}^{\uparrow}, \mathsf{Real}^{\uparrow}$. Since the proof never adds quotient stream equality, selected limits, countable choice, metric completeness, completion points, or ambient Real completeness, no additional classifier coordinate remains. □

Theorem 301.265 (RegSeqRat tail-shift cofinal fusion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Let $t_0, \ldots, t_k$ and $u_0, \ldots, u_m$ be two finite displayed families of unary tail shifts over the same* $\mathsf{StreamName}^{\uparrow}$ *source and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Suppose both families expose the transported endpoint rows, dyadic-radius rows, regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of P. Then the two synchronized RegSeqRat readback routes admit one finite cofinal fusion route preserving the* RegSeqRatClassifier *value and the terminal* $\mathsf{Real}^{\uparrow}$ *seal.*

The fusion route exports only the shared finite StreamName windows, DyadicRatCore tolerance ledger, RegSeqRat regularity readback, transport, replay, provenance, and local naming rows. It exports no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate.

Proof. Apply Definition 301.263 to the first displayed family and again to the second. This gives two synchronized finite readback routes over the same StreamName source and DyadicRatCore tolerance budget.

Next use Definition 301.262 to compare the two synchronized routes on their shared finite support. The visible rows are exactly the transported endpoint rows, regularity ledgers, componentwise hsame rows, displayed Cont routes, Pkg provenance, and local NameCert rows, so a common cofinal window can read both routes as one RegSeqRat row.

Finally apply Definition 301.264. The fused route remains locked to the same $\mathsf{StreamName}^{\uparrow}$ finite section, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and terminal $\mathsf{Real}^{\uparrow}$ seal classifier before any Real-facing consumer opens the seal.

All rows used by the fusion are finite BEDC rows already displayed by the packet. Hence the fusion introduces no quotient stream equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient Real-completeness coordinate. □

Theorem 301.266 (RegSeqRat tail-shift regularity refinement)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let $t_0, \ldots, t_k$ be a finite displayed family of unary tail shifts over the same* $\mathsf{StreamName}^{\uparrow}$ *source and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Suppose every shifted window exposes the*

transported endpoint rows, dyadic-radius rows, regularity ledgers, componentwise hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of P. Then the finite-section synchronized route preserves the regularity ledger on a common refinement before any* $\mathsf{Real}^{\uparrow}$ *seal is consumed.*

The refinement is internal to the displayed RegSeqRat source surface. It does not identify quotient streams, select limits, use choice, appeal to metric completeness, or import ambient Real completeness.

Proof. Apply Definition 301.263 to the finite family of displayed tail shifts. This gives one synchronized finite readback route whose visible rows are the StreamName windows, dyadic budgets, regular-rational classifier rows, transport, replay, provenance, and local naming rows.

Next apply Definition 301.260 along each shifted window as it enters the synchronized route. The dyadic tolerance row used by the downstream seal is the same componentwise budget row carried by the RegSeqRat regularity ledger, so synchronization does not replace the ledger with a selected limiting object.

Finally compare the resulting common refinement with Definition 301.254. The finite-cover diagonal induction reads the same displayed endpoint, radius, and regularity rows on every finite section, and therefore preserves the regularity ledger before the Real seal is opened.

All rows used in the argument are finite BEDC rows of the packet. Thus no quotient stream equality, selected limit, choice principle, metric-completeness datum, completion point, or ambient Real-completeness coordinate is introduced. □

Theorem 301.267 (RegSeqRat tail-shift choice-free finite window)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let $t_0, \ldots, t_k$ be a finite displayed family of tail shifts over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Suppose the shifted windows expose the transported endpoint rows, dyadic-radius rows, regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of P. Then the family has a synchronized regularity readback whose downstream* $\mathsf{Real}^{\uparrow}$ *seal consumes only the displayed finite window.*

The readback exports no selected limit, quotient stream equality, countable-choice schedule, completion point, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 301.263 to the displayed finite family. This supplies one synchronized finite readback route for all tail shifts before the downstream Real seal is opened.

Use Definition 301.266 to preserve the regularity ledger on the common refinement. Then apply Definition 301.261 to keep the synchronized readback inside the same finite StreamName schedule and DyadicRatCore tolerance budget.

When the terminal radius is read by a Real-facing consumer, apply Definition 291.104. The half-radius row is already determined by the finite DyadicRatCore common-scale refinement, so the RegSeqRat route has no need for a selected limit, quotient stream equality, countable-choice schedule, completion point, metric-completeness datum, or ambient Real completeness. □

Theorem 301.268 (RegSeqRat tail-shift regularity)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let $t_0, \ldots, t_k$ be a finite displayed family of tail shifts over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget. Suppose every shifted finite window preserves the scheduled endpoint rows, dyadic-radius rows, regularity ledgers, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of P. Then every inspected tail window preserves the regular Cauchy inequality witnessed by the RegSeqRat regularity ledger before any downstream* $\mathsf{Real}^{\uparrow}$ *seal is consumed.*

The regularity preservation is choice-free: it uses only the displayed finite windows and does not introduce a new selector, quotient stream equality, terminal Real seal, metric-completeness datum, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Apply Definition 301.263 to the finite family of scheduled tail shifts. This builds one synchronized finite readback route whose rows are the shifted StreamName windows, DyadicRatCore tolerance budgets, regular-rational classifier rows, transport, replay, provenance, and local naming.

Next use Definition 301.262. The synchronized route keeps every inspected tail window on the same RegSeqRat readback row, so the regularity ledger is read from one finite source surface rather than from a selected limit.

Finally apply Definition 301.267. The choice-free finite-window theorem keeps the downstream Real-facing read inside the displayed StreamName schedule and DyadicRatCore tolerance budget. Therefore the regular Cauchy inequality carried by the RegSeqRat ledger is preserved on all inspected tail windows, with no new selector or terminal Real seal. □

Theorem 301.269 (RegSeqRat tail-shift budget stability)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet and let $t_0, \ldots, t_k$ be a finite displayed family of admitted tail shifts over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule. Suppose the shifted windows preserve the synchronized StreamName finite section, the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget, the regularity ledger, componentwise* hsame *rows, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegSeqRat}^{\uparrow}}$ *rows of P. Then every admitted finite tail shift preserves the same DyadicRatCore tolerance ledger and the same RegSeqRat regularity ledger before any downstream* $\mathsf{Real}^{\uparrow}$ *seal is opened.*

The preservation exports no quotient stream equality, selected limit, countable-choice schedule, terminal seal, metric-completeness datum, or ambient Real completeness.

Proof. Apply Definition 301.263 to the finite family of admitted shifts. This produces one synchronized finite section whose visible rows are the StreamName windows, dyadic tolerance budget, regularity ledger, transport, replay, provenance, and local naming rows.

Use Definition 301.267 to keep the readback inside that finite section. The theorem rules out replacing the displayed window by a selector or by a terminal Real-facing object.

Finally apply Definition 291.104. The terminal-radius read is forced by the displayed DyadicRatCore denominator and half-step rows, so each admitted tail shift consumes the same tolerance ledger that the RegSeqRat regularity ledger already names. □

Theorem 301.270 (RegSeqRat tail-halving closure)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let n be a displayed unary scale whose dyadic tolerance window is valid for the tail budget carried by P. Then there is a displayed successor route at the halved scale through the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows: the next finite StreamName window is read first, the DyadicRatCore tolerance ledger refines the visible radius from scale n to its halved successor, the RegSeqRat classifier reads back the same regular-rational source surface, and the downstream* $\mathsf{Real}^{\uparrow}$ *seal consumes only that displayed finite route.*

The route exports no quotient stream equality, selected limit, host real equality, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Project the accepted tail-budget rows of P. The visible data are the $\mathsf{StreamName}^{\uparrow}$ finite schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and tolerance rows, the RegSeqRat regularity ledger, the classifier row, the displayed hsame and Cont supports, Pkg provenance, local NameCert naming, and the downstream $\mathsf{Real}^{\uparrow}$ seal-source row.

Use the StreamName finite schedule to choose the next visible window after the displayed scale n. This is a window read inside the packet, not a choice of an infinite subsequence or a selected limit.

Apply the DyadicRatCore tolerance rows on that next window. Their monotonicity and halving budget refine the radius ledger from the scale n window to the halved successor window while preserving the same endpoint and regularity rows available to the classifier.

Now repackage the successor window through Definition 301.257. The shifted finite window has the transported StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat regularity rows, classifier support, hsame, Cont, Pkg, and local NameCert rows required for the same public classifier read.

Finally read the $\mathsf{Real}^{\uparrow}$ seal through the existing regular-rational handoff. Since the successor route has only displayed StreamName, DyadicRatCore, RegSeqRat, and RealUp-facing rows, quotient stream equality, selected limits, host real equality, completion data, and ambient completeness have no carrier coordinate from which to enter. □

Theorem 301.271 (RegSeqRat tail-halving induction)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let*

$$n_0 \to n_1 \to \cdots \to n_k$$

be a finite displayed unary ledger whose adjacent arrows are accepted tail-halving steps for the tail budget carried by P. Then the whole ledger composes into one route through the same $\mathsf{StreamName}^{\uparrow}$ *finite schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, and downstream* $\mathsf{Real}^{\uparrow}$ *seal. Every intermediate window is read by shifting the finite schedule already carried by P, and the terminal route exports no quotient stream equality, selected limit, countable choice, metric-completeness row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Induct on the displayed finite halving ledger.

In the base case the ledger has no successor step. The route is the original accepted $\mathsf{RegSeqRat}^{\uparrow}$ packet, whose StreamName schedule, DyadicRatCore tolerance ledger, classifier and readback rows, and RealUp seal are already displayed.

For the successor step, apply Definition 301.270 to the current accepted route. It supplies the next halved-scale window through the same StreamName, DyadicRatCore, RegSeqRat, and RealUp rows.

Use Definition 301.257 to shift the finite window before applying the induction hypothesis to the remaining ledger. The shifted route preserves the displayed schedule, tolerance, classifier, readback, hsame, Cont, Pkg, and local NameCert rows needed by the next step.

Composing the successor route with the induction hypothesis gives one finite route through the same packet rows. Since each adjacent step excludes quotient stream equality, selected limits, countable choice, metric completeness, and ambient RealUp completeness, the finite composite has no row from which any of those objects can enter. □

Theorem 301.272 (RegSeqRat terminal finite-window Real-seal)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let*

$$n_0 \to n_1 \to \cdots \to n_k$$

be a finite displayed unary halving ledger whose adjacent arrows are accepted tail-halving steps for the tail budget carried by P. Then the terminal halved window supplied by Definition 301.271 is the only finite input consumed by the downstream $\mathsf{Real}^{\uparrow}$ *seal: the route factors through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows, and the selection-free Real-seal input is exactly that terminal displayed window.*

The route exports no quotient stream equality, selected limit, host real equality, countable choice, metric-completeness row, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Apply Definition 301.271 to the displayed ledger. That theorem already packages the whole finite route through the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and downstream $\mathsf{Real}^{\uparrow}$ seal rows, with the terminal window determined by the last halving step.

Now read the nonescape wording of Definition 301.270. The seal boundary is only a row inventory: it keeps the displayed finite window and the listed support rows, and it removes any coordinate for quotient streams, selected limits, host real equality, countable choice, metric-completeness data, completion points, or ambient completeness.

Therefore the terminal halved window is exactly the selection-free Real-seal input. No other finite window can enter the seal, because the displayed route contains no additional row from which a different finite input could be selected. □

Theorem 301.273 (RegSeqRat tail-halving stability)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let P' be a finite tail-halving ledger over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier and readback rows, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *support. If P' is obtained from P by a displayed finite halving ledger, then replacing P by P' preserves the downstream* $\mathsf{Real}^{\uparrow}$ *seal handoff.*

The preserved handoff is still the finite terminal-window route and exports no quotient stream equality, selected limit, host real equality, countable choice, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Apply Definition 301.271 to the displayed finite halving ledger from P to P'. It composes the halving steps through the same StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat classifier and readback rows, and downstream RealUp seal.

Now apply Definition 301.272 to the terminal ledger. The theorem identifies the terminal halved window as the only finite input consumed by the downstream $\mathsf{Real}^{\uparrow}$ seal.

The support rows named in the statement are precisely the rows retained by those two theorems: hsame, Cont, Pkg, and local $\mathsf{NameCert}$ remain componentwise over the same public packet. Hence the replacement by P' preserves the seal handoff and cannot add quotient stream equality, selected limits, host real equality, choice, completion data, or ambient completeness. □

Theorem 301.274 (RegSeqRat tail-halving shift fusion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet. Suppose a displayed tail-shift row over the* $\mathsf{StreamName}^{\uparrow}$ *schedule and a displayed tail-halving row over the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger are both available for P. Then the two rows compose to a common finite tail window whose StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat readback, and downstream* $\mathsf{Real}^{\uparrow}$ *seal are the same public read.*

The fused window is a finite L10 four-object route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *It exports no quotient stream equality, selected limit, host real equality, metric-completeness datum, completion point, countable-choice schedule, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Project the existing tail-shift route of Definition 301.257. The shifted window exposes only the transported StreamName schedule, DyadicRatCore endpoint and radius rows, regularity ledgers, classifier support, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Apply the tail-halving closure route of Definition 301.270 to that shifted window. The halved successor refines the displayed dyadic tolerance ledger while keeping the same finite StreamName source and the same regular-rational classifier surface.

Now take the common finite tail window given by the shifted window and its halved successor. On that window the StreamName schedule is already fixed by the tail-shift row, and the DyadicRatCore tolerance ledger is fixed by the halving row. The RegSeqRat classifier can therefore read only one finite source surface.

Finally read the downstream $\mathsf{Real}^{\uparrow}$ seal through the same four-object route. Since the carrier rows have been exhausted by $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and local naming, no quotient stream equality, selected limit, host real equality, metric-completeness datum, completion point, countable-choice schedule, or ambient completeness coordinate remains available. □

Theorem 301.275 (RegSeqRat tail-shift halving fusion is choice-free)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let a finite displayed family of tail-shift rows and tail-halving rows be indexed over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger. Iterating Definition 301.274 over the family yields one finite common window with the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and the same downstream* $\mathsf{Real}^{\uparrow}$ *seal.*

The finite-family route preserves the four-object path through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. It does not select a limiting tail, invoke quotient stream equality, use host real equality, ask for countable choice, expose a completion point, or assume ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Induct over the displayed finite family. In the empty case, the original accepted packet supplies the common window, readback, and Real seal through its StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat rows, transport, replay, provenance, and local naming data.

For the successor step, apply Definition 301.274 to the current common window and the next displayed pair of tail-shift and tail-halving rows. The theorem fuses that pair into a finite tail window whose StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat readback, and Real seal are the same public read.

Repack the successor window as the induction invariant. The same four-object route is preserved because each step reads only $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, componentwise hsame, displayed Cont, Pkg, and local NameCert rows.

Thus the finite family has one common window without selecting a limiting tail. Since every step is finite and row-local, no quotient stream equality, host real equality, countable-choice schedule, completion point, or ambient Real completeness coordinate is introduced. □

Theorem 301.276 (RegSeqRat tail-halving classifier fusion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let a finite family of tail-shift and tail-halving rows share the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger. Then the resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier read is the same shared-window selector surface, and the family reaches one terminal* $\mathsf{Real}^{\uparrow}$ *seal.*

The classifier route is the finite L10 route through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. It does not introduce quotient stream equality, a selected limit, metric completeness, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 301.275 to the displayed finite family. It gives one common finite window with the shared StreamName schedule, DyadicRatCore tolerance ledger, RegSeqRat readback, and downstream Real seal.

Use the shared-window selector determinacy route for the same accepted packet. Since all rows are indexed over the same schedule and tolerance ledger, the classifier can read only the shared-window selector surface already exposed by the fused family.

Finally apply tail-shift regularity to keep the RegSeqRat row on the same regular-rational carrier. The terminal $\mathsf{Real}^{\uparrow}$ seal is reached through that finite route, and no quotient stream equality, selected limit, metric-completeness datum, or ambient Real completeness coordinate is introduced. □

Theorem 301.277 (RegSeqRat tail-halving common refinement)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *packet, and let two finite families of tail-shift and tail-halving rows be indexed over the same* $\mathsf{StreamName}^{\uparrow}$ *schedule and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger. Then the two families admit a common finite refinement whose* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier read and terminal* $\mathsf{Real}^{\uparrow}$ *seal agree.*

The refinement is the displayed BEDC route through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It does not introduce quotient streams, selected limits, metric completeness, countable choice, or ambient Real completeness.*

Proof. Apply Definition 301.275 separately to the two displayed finite families. Each family is reduced to one common finite window over the same StreamName schedule, dyadic tolerance ledger, RegSeqRat readback, and terminal Real seal route.

Compare the two resulting windows by the shared-window selector surface. Since both fused families are indexed over the same schedule and tolerance ledger, Definition 301.276 presents both classifier reads as the same shared-window selector surface.

Repack the comparison through the displayed hsame, Cont, Pkg, and local NameCert rows of the accepted packet. The terminal $\mathsf{Real}^{\uparrow}$ seal is read only after the StreamName, DyadicRatCore, and RegSeqRat rows agree on the common refinement, and the carrier has no quotient-stream, selected-limit, metric-completeness, countable-choice, or ambient-completeness coordinate that could supply a second route. □

Theorem 301.278 (RegSeqRat finite tail-window exhaustion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier row, let B be a finite displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tail-budget row for P, and let S be a* $\mathsf{StreamName}^{\uparrow}$ *pointwise certificate for the same scheduled source. For every finite family of requested dyadic radii carried by B, there is a unary threshold t and a finite tail-window ledger such that every request beyond t is witnessed by a pair of* $\mathsf{StreamName}^{\uparrow}$ *observations and by* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-scale comparison rows before the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback or downstream* $\mathsf{Real}^{\uparrow}$ *seal is consumed.*

The ledger is a finite BEDC route through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It exports no quotient stream equality, host real equality, selected limit, countable-choice schedule, metric-completeness datum, completion point, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Induct over the displayed finite family of requested dyadic radii. In the empty case, the accepted packet already supplies the $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{DyadicRatCore}^{\uparrow}$ tail-budget row, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier surface, and the structural BHist, hsame, Cont, Pkg, and NameCert support.

For the successor step, assume the previous requests have been placed behind a unary threshold and a finite tail-window ledger. Use the pointwise $\mathsf{StreamName}^{\uparrow}$ certificate to expose the next pair of scheduled observations beyond that threshold.

Next refine the dyadic comparison. The terminal-scale rows of $\mathsf{DyadicRatCore}^{\uparrow}$ place the new radius and the accumulated budget on one common finite scale, so the next request is represented by displayed endpoint, radius, and comparison rows rather than by a hidden modulus or a selected subsequence.

Apply the tail-halving shift fusion route of Definition 301.274. It fuses the transported tail window and the dyadic refinement into a common finite window with the same $\mathsf{RegSeqRat}^{\uparrow}$ readback surface.

Repack the successor ledger by increasing the threshold to cover the new observation pair. The induction invariant is preserved because every step uses only finite StreamName observations, DyadicRatCore common-scale comparisons, the existing RegSeqRat classifier route, and displayed structural rows.

Thus the finite request family is exhausted by a tail-window ledger after a unary threshold. Since no step introduces quotient stream equality, host real equality, selected limits, countable choice, metric completeness, completion points, or ambient Real completeness, the downstream $\mathsf{Real}^{\uparrow}$ seal can read only the displayed finite route. □

Theorem 301.279 (RegSeqRat finite tail-window shift exhaustion)**.** *Let P be an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *carrier row, let B be a finite displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tail-budget row for P, and let S be a* $\mathsf{StreamName}^{\uparrow}$ *pointwise certificate for the same scheduled source. If P is shifted by a displayed finite unary tail, then every retained request is still exhausted by a finite tail-window ledger whose* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal handoff,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows are the retained rows of the original ledger.*

The shift exports no quotient stream equality, host real equality, selected subsequence, countable-choice schedule, metric-completeness datum, completion point, or ambient $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Begin with the finite tail-window exhaustion theorem, Definition 301.278. It supplies a unary threshold and a finite ledger for every displayed family of dyadic radii, with StreamName observations and DyadicRatCore common-scale comparison rows visible before any RegSeqRat or Real handoff.

Shift the regular Cauchy name by the displayed finite unary tail. Retained requests are still beyond a displayed threshold, so the same finite StreamName windows remain the observation rows after dropping the shifted prefix.

Use the StreamName finite-section surface to keep the retained windows inside the same certified source, and use the DyadicRatCore tolerance handoff surface to keep the common-scale tolerance ledger attached to those windows. The RegSeqRat readback and Real seal handoff are therefore replayed through the same H, C, P, N support rows on every retained request.

Repack the shifted route as a finite tail-window ledger. Since the operation discards only the displayed finite prefix and preserves the retained request rows, it cannot add quotient stream equality, a selected subsequence, host equality, choice, metric completeness, completion points, or ambient Real completeness. □

Definition 301.280 (RegSeqRat tail-refinement carrier)**.** *A finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-refinement packet is a* BHist *row*

$$Q = (S, D, T, H, C, P, N)$$

whose displayed components are: a $\mathsf{StreamName}^{\uparrow}$ *finite request row S, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row D, a* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-window row T, componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and a local* NameCert *row N. The classifier reads only these seven rows and exports no quotient stream equality, selected limit, host real equality, metric-completeness datum, completion point, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Theorem 301.281 (RegSeqRat tail-refinement stability)**.** *Let $Q = (S, D, T, H, C, P, N)$ be an accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-refinement packet. Any retained tail request transported by componentwise* hsame *and replayed by the displayed* Cont *row is represented by the same* $\mathsf{StreamName}^{\uparrow}$

request row, $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, and* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-window row. Thus tail refinement is stable under the displayed transport and replay surface of* Q*.*

Proof. Project the carrier of Definition 301.280. The mathematical data rows are exactly S, D, T, while H records componentwise transport for those rows.

Replay the retained request through C. Since C is displayed as part of the same packet, it can only replay the finite request, tolerance, and tail-window rows already named by S, D, T.

The provenance and naming rows P, N do not add new tail data. Hence every transported retained request remains represented by the same finite tail-refinement surface. □

Theorem 301.282 (RegSeqRat tail-refinement Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-refinement packet*

$$Q = (S, D, T, H, C, P, N)$$

may read only the finite $\mathsf{RegSeqRat}^{\uparrow}$ *tail window* T *together with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D *and the supporting* $\mathsf{StreamName}^{\uparrow}$ *request row* S*. The handoff deliberately exposes finite tail-window and dyadic tolerance data, not quotient stream equality, a selected limit, host real equality, or a completion point.*

Proof. Start with a Real-facing read. The request row S displays the finite StreamName window being inspected, and the tolerance row D gives the dyadic scale at which the retained tail request is compared.

Read the tail-window row T. It is the only RegSeqRat row exported by the packet, so the Real-facing consumer receives a finite tail-window route rather than a quotient stream object or selected limit.

Finally transport and replay through H and C, with P, N recording provenance and local naming. These rows preserve the finite handoff and do not add host real equality, completion points, or ambient Real completeness. □

Theorem 301.283 (RegSeqRat tail-refinement composition)**.** *Let*

$$Q_0 = (S_0, D_0, T_0, H_0, C_0, P_0, N_0)$$

and

$$Q_1 = (S_1, D_1, T_1, H_1, C_1, P_1, N_1)$$

be adjacent accepted finite $\mathsf{RegSeqRat}^{\uparrow}$ *tail-refinement packets. If the retained* $\mathsf{StreamName}^{\uparrow}$ *request row of* Q_0 *is the source request row of* Q_1 *by componentwise* hsame *transport, and the terminal* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row of* Q_0 *is the tolerance row read by* Q_1*, then the two packets compose into one accepted finite tail-refinement packet preserving the* T, H, C, P, N *rows and the Real handoff surface.*

The composite packet exposes only finite $\mathsf{StreamName}^{\uparrow}$ *request data, displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, finite* $\mathsf{RegSeqRat}^{\uparrow}$ *tail windows, transport, replay, provenance, and local naming; it adds no selected subsequence, quotient stream equality, selected limit, host real equality, completion point, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Project the two carriers using Definition 301.280. Their public rows are exactly the finite request rows S_i, tolerance rows D_i, tail-window rows T_i, transport rows H_i, replay rows C_i, provenance rows P_i, and local naming rows N_i.

Identify the shared retained request. The hypothesis says that the retained $\mathsf{StreamName}^{\uparrow}$ request from Q_0 is transported by hsame to the source request of Q_1, so the two packets meet on a displayed finite request row rather than on a quotient stream.

Compose the displayed Cont replay. First replay the retained request through C_0, then replay the second tail refinement through C_1; the shared request row and shared tolerance row keep the composite inside the same finite DyadicRatCore and RegSeqRat support.

Package the result as the tail window obtained by following T_0 into T_1, with the inherited transport, replay, provenance, and local naming rows. Stability, Definition 301.281, shows that every retained request remains represented by those displayed rows.

Finally apply the Real handoff theorem, Definition 301.282, to the composite packet. A Real-facing consumer therefore reads only the composed finite tail window, the shared dyadic tolerance route, and the supporting StreamName request row, with no selected subsequence, quotient stream equality, selected limit, host equality, completion point, or ambient Real completeness. □

Chapter 302

A Concrete Naming Certificate for $\mathsf{IntervalArithmetic}^{\uparrow}$

The $\mathsf{IntervalArithmetic}^{\uparrow}$ interface names certified interval arithmetic over the real-name layer already present in $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Interval}^{\uparrow}$. In the constructive numerical-analysis sense represented by Moore, Kearfott, and Cloud's interval-analysis presentation, an interval computation is acceptable when the endpoint and enclosure ledgers are finite and inspectable. The BEDC surface therefore treats every operation as a row over dyadic endpoint histories and regular-sequence observations, not as a host interval object or a quotient-real interval.

The endpoint and enclosure rows consume chapter 291, chapter 126, chapter 301, and chapter 38; those chapters supply, respectively, dyadic endpoint histories, finite observation windows, regular-sequence readback, and the real-name seal used by the interval packet.

302.1 Endpoint carrier

Definition 302.1 (IntervalArithmetic BHist carrier)**.** *An* $\mathsf{IntervalArithmetic}^{\uparrow}$ *endpoint packet is a finite* BHist *row*

$$(\ell, u, \lambda, \upsilon, \epsilon, P)$$

with the following displayed coordinates:

1. ℓ *is a lower dyadic endpoint history certified by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. u *is an upper dyadic endpoint history certified by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
3. λ *and* υ *are the lower and upper observation rows read through* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$*;*
4. ϵ *is the enclosure predicate saying that the represented* $\mathsf{Real}^{\uparrow}$ *observation lies between the two endpoint histories at every displayed finite observation window;*
5. P *is the* Pkg *row naming the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{Interval}^{\uparrow}$ *dependency certificates.*

The carrier predicate is $\mathsf{IntervalArithmeticPacket}(\ell, u, \lambda, \upsilon, \epsilon, P)$*. Its classifier compares two accepted packets by endpoint* hsame *for* ℓ *and* u*, plus the finite-window* Cont *rows that transport* λ*,* υ*, and* ϵ *across the named dependency certificates.*

302.2 Operation ledgers

Theorem 302.2 (Outward-rounded addition ledger)**.** *Let $A = (\ell_A, u_A, \lambda_A, \upsilon_A, \epsilon_A, P_A)$ and $B = (\ell_B, u_B, \lambda_B, \upsilon_B, \epsilon_B, P_B)$ be accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packets. An outward-rounded addition ledger consists of the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *addition rows*

$$\ell_C \leq_{\mathsf{dyad}} \ell_A + \ell_B, \qquad u_A + u_B \leq_{\mathsf{dyad}} u_C,$$

the transported $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *observation rows for the two endpoints, and a* Pkg *row tying these data to P_A and P_B. The result packet $C = (\ell_C, u_C, \lambda_C, \upsilon_C, \epsilon_C, P_C)$ is an accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packet whose enclosure predicate contains every finite* $\mathsf{Real}^{\uparrow}$ *observation obtained by adding an observation enclosed by A to an observation enclosed by B.*

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticPacket outward rounded addition`
↪ variant `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket outward rounded addition`

Proof. Project the two endpoint packets. Their carrier rows expose only dyadic endpoint histories, observation histories, enclosure predicates, and package provenance.

Use the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ addition rows to form the candidate lower and upper endpoints. The outward inequalities are stored as rows of the ledger, so the result endpoint pair is not read from host rounding behavior.

Transport the lower and upper observation rows through the finite-window Cont data supplied by the two packages. At each finite window, the lower outward row lies below the sum of lower observations and the upper outward row lies above the sum of upper observations.

Repack the transported observation rows and the endpoint inequalities as ϵ_C. The resulting packet is exhausted by the displayed dyadic, stream, regular-sequence, real-name, and package rows, so the addition ledger exports no host real interval. □

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket outward addition closure`

Theorem 302.3 (IntervalArithmetic classifier transport)**.** *Suppose A and A' are accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packets whose lower and upper endpoint histories are related by endpoint* hsame*, and whose observation and enclosure rows are related by the displayed finite-window* Cont *transports. Then every outward-rounded operation ledger accepted for A transports to an accepted ledger for A', and the result packets are classified by the* $\mathsf{IntervalArithmetic}^{\uparrow}$ *classifier.*

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket transport`

Proof. Unpack the classifier. It gives endpoint hsame rows for the lower and upper dyadic histories and continuation rows for the observation and enclosure data.

Apply these rows to each coordinate of the operation ledger. The lower and upper dyadic bounds transport by endpoint hsame, and the observation windows transport by the corresponding Cont rows.

Finally repack the transported coordinates as the result ledger. Since the classifier for the result packet is built from the same endpoint and finite-window transports, the transported result is classified with the original result packet. □

Theorem 302.4 (RealUp enclosure soundness)**.** *For every accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packet $A = (\ell, u, \lambda, \upsilon, \epsilon, P)$, any* $\mathsf{Real}^{\uparrow}$ *observation row admitted by ϵ is enclosed by the displayed lower and upper endpoint histories at each finite observation window named by P. In particular, the soundness*

claim is a finite ledger claim over $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *observations, not a completeness or compactness claim about external real intervals.*

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket realup enclosure soundness`

Proof. Read the enclosure coordinate ϵ from the carrier. It is already indexed by the finite observation windows named in the package row.

For a chosen window, project the lower endpoint observation, the upper endpoint observation, and the admitted $\mathsf{Real}^{\uparrow}$ observation. The definition of ϵ supplies the two displayed order comparisons between them.

Because the projection uses only rows present in P, the conclusion is stable under the same finite-window transport used by the classifier. No open-cover compactness or quotient-real interval is invoked. □

302.3 Public surface

Theorem 302.5 (IntervalArithmetic public certificate surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{IntervalArithmetic}^{\uparrow}}$ *obligation surface consists of five rows:*

1. *the endpoint carrier of Definition 302.1;*
2. *the endpoint and finite-window classifier over* hsame *and* Cont*;*
3. *the stability transport row of Definition 302.3;*
4. *the outward-rounded operation ledger of Definition 302.2;*
5. *the public enclosure surface of Definition 302.4.*

These rows are the complete public surface presently claimed for certified interval arithmetic over the existing BEDC real-name infrastructure.

Proof. The carrier row supplies the lower endpoint, upper endpoint, observation, enclosure, and package coordinates. The classifier row is the restricted endpoint hsame plus finite-window Cont transport on those coordinates.

The stability row says that accepted ledgers survive classifier transport. The operation row supplies outward-rounded addition as a finite endpoint and enclosure ledger.

The public enclosure row is exactly the real-name readback permitted to downstream consumers. Since the five rows list every exported coordinate, the certificate surface has no coordinate for completeness, Heine–Borel, external real intervals, or bridge data. □

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket public certificate surface`

Theorem 302.6 (IntervalArithmetic monotone enclosure transport)**.** *Let* $A = (\ell, u, \lambda, \upsilon, \epsilon, P)$ *and* $A' = (\ell', u', \lambda', \upsilon', \epsilon', P')$ *be accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packets. Suppose the lower endpoint of* A' *tightens the lower endpoint of* A*, the upper endpoint of* A' *tightens the upper endpoint of* A*, and the endpoint rows are related by the displayed* hsame *and* Cont *transports of the classifier. Then every finite* $\mathsf{Real}^{\uparrow}$ *observation row enclosed by* A' *transports to an observation row enclosed by* A*, and the transported enclosure predicate is read from the same endpoint carrier and package rows.*

Proof. Project the two packets through Definition 302.1. The only rows available for the enclosure comparison are the lower endpoint, upper endpoint, observation, enclosure, and Pkg coordinates.

Use Definition 302.3 to move the endpoint and observation rows along the displayed hsame and Cont data. Tightening the lower row and tightening the upper row preserve the order comparisons used by the enclosure predicate at each named finite window.

Finally apply Definition 302.4. The admitted $\mathsf{Real}^{\uparrow}$ observation is read only through the transported finite-window endpoint rows, so the enclosure predicate for A' maps into the enclosure predicate for A without adding an external interval object. □

Theorem 302.7 (IntervalArithmetic width-bound stability)**.** *Let an accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packet carry a displayed dyadic width bound between its lower and upper endpoint histories. If its endpoint packet is transported by the classifier and then used in an outward-rounded addition ledger, the resulting packet carries the transported width bound obtained from the same endpoint rows and outward inequalities.*

The width row is therefore stable under endpoint classifier transport and outward rounding: it remains a finite dyadic endpoint ledger row, not a host metric estimate over external intervals.

Lean4 ✓ `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket width bound stability`

Proof. Read the width row from the endpoint carrier of Definition 302.1. It is a finite dyadic comparison between the displayed lower and upper endpoint histories.

Apply Definition 302.3. The lower and upper endpoints, the finite observation rows, and the enclosure predicate move componentwise along the displayed hsame and Cont rows, so the same dyadic width comparison is read after transport.

Apply Definition 302.2. The outward inequalities used by the addition ledger are stored as endpoint rows, and therefore compose with the transported width comparison inside the dyadic endpoint ledger.

The repacked result has only the endpoint, observation, enclosure, and package rows named by the carrier. Hence the width bound is stable as a finite certificate row and does not depend on an external interval metric. □

Theorem 302.8 (IntervalArithmetic refined-endpoint addition soundness)**.** *Let A, B, and C be accepted* $\mathsf{IntervalArithmetic}^{\uparrow}$ *packets such that C is produced from A and B by the outward-rounded addition ledger of Definition 302.2. If either input is replaced by a refined endpoint packet classified with it by the displayed endpoint* hsame *and finite-window* Cont *rows, then outward-rounded addition remains sound for the transported result packet.*

In particular, every finite $\mathsf{Real}^{\uparrow}$ *observation obtained by adding observations enclosed by the refined inputs is enclosed by the transported outward-rounded result packet.*

Proof. Start with the original outward-rounded ledger. By Definition 302.2, its lower and upper result endpoints are justified by displayed dyadic endpoint inequalities, and its enclosure predicate is built from the finite $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ observation rows.

Transport the replaced input through Definition 302.3. The endpoint hsame rows and finite-window Cont rows move the lower endpoint, upper endpoint, observation, and enclosure coordinates to the refined packet while preserving the accepted ledger shape.

Now reuse the outward-rounded addition ledger with the transported endpoint rows. The lower and upper inequalities remain valid in the displayed dyadic ledger, and the observation rows remain finite rows over the same named dependency certificates.

Finally apply Definition 302.4. The transported result packet encloses the finite $\mathsf{Real}^{\uparrow}$ observations obtained from the refined inputs, because the proof reads only the displayed endpoint, classifier, operation, and enclosure rows. □

Theorem 302.9 (IntervalArithmetic obligation enclosure package)**.** *The obligation package for* $\mathsf{IntervalArithmetic}^{\uparrow}$ *is the finite endpoint carrier, endpoint classifier, outward-rounded addition ledger, classifier transport,* $\mathsf{Real}^{\uparrow}$ *enclosure soundness row, monotone enclosure transport, width-bound stability row, and refined-endpoint addition soundness row.*

All coordinates are displayed over $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Interval}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*; no host interval carrier, external real equality, compactness principle, or completion object is part of the package.*

Proof. Start from Definition 302.1. It supplies the finite endpoint carrier, the endpoint classifier coordinates, and the displayed observation rows over the dyadic, stream, regular-sequence, real, and interval certificates.

Apply Definition 302.3 to account for the classifier transport rows, and apply Definition 302.2 to add the operation ledger. The latter contributes only outward-rounded dyadic endpoint evidence and finite observation provenance.

The enclosure obligations are then supplied by Definition 302.4 and Definition 302.6. These rows keep the $\mathsf{Real}^{\uparrow}$ observations and monotone transport inside the displayed endpoint and finite-window surface.

Finally use Definition 302.7 and Definition 302.8. They give the width-bound stability and refined-endpoint addition soundness rows, so the listed data form the full finite obligation package and introduce no additional host-level interval or real object. □

Theorem 302.10 (IntervalArithmetic standard bridge)**.** *The public endpoint packet of* $\mathsf{IntervalArithmetic}^{\uparrow}$ *bridges to the standard outward-rounded interval-arithmetic reading exactly through the rational endpoint rows,* $\mathsf{Real}^{\uparrow}$ *enclosure soundness row, monotone transport row, width-bound row, refined endpoint addition row, visible* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

The bridge withholds multiplication, division, dependency-aware narrowing, compactness, Heine–Borel, and completed-real equality. It is only the finite outward-rounded endpoint and enclosure surface displayed by the public packet.

Proof. Start with the endpoint packet and public certificate surface. The carrier in Definition 302.1 supplies the lower and upper dyadic endpoint histories, finite observation rows, enclosure predicate, and package provenance, while Definition 302.5 repacks these rows as the local $\mathsf{NameCert}_{\mathsf{IntervalArithmetic}^{\uparrow}}$ surface.

Add the outward-rounded operation row. Apply Definition 302.2 for the displayed endpoint addition ledger, and apply Definition 302.3 to keep that ledger stable under visible endpoint hsame and finite-window Cont transport.

The enclosure side is supplied by Definition 302.4 and Definition 302.6. These two rows keep every $\mathsf{Real}^{\uparrow}$ observation inside the displayed endpoint and monotone transport surface.

Finally use Definition 302.7, Definition 302.8, and Definition 302.9. Together they identify the bridge as the finite outward-rounded endpoint package with its width and refined-addition rows. None of the cited rows contains multiplication, division, dependency-aware narrowing, compactness, Heine–Borel, completed-real equality, or host interval semantics. □

Closure status for $\mathsf{NameCert}_{\mathsf{IntervalArithmetic}^{\uparrow}}$**.**

Constructive story: Certified interval arithmetic is represented by finite lower and upper dyadic endpoint histories, finite stream and regular-sequence observation rows, an enclosure predicate over $\mathsf{Real}^{\uparrow}$ observations, outward-rounded operation ledgers, and endpoint-plus-window classifier transport.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{IntervalArithmetic}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 302.10 binds the endpoint carrier, endpoint classifier, outward-rounded addition ledger, classifier transport, $\mathsf{Real}^{\uparrow}$ enclosure soundness, monotone enclosure transport, width-bound stability, refined-endpoint addition soundness, and obligation enclosure package over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Interval}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{IntervalArithmetic}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.IntervalArithmeticUp.IntervalArithmeticEndpointPacket\_public\_certificate\_surface`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close multiplication, division, dependency-aware narrowing, completeness, compactness, Heine–Borel, or completed-real equality.

Upgrade path: No further paper-side theory grade remains for the displayed outward-rounded endpoint and $\mathsf{Real}^{\uparrow}$ enclosure consumer package; formal bridge verification remains separate.

Chapter 303

A Concrete Naming Certificate for $\mathsf{ModularArithmetic}^{\uparrow}$

The $\mathsf{ModularArithmetic}^{\uparrow}$ interface names residue arithmetic over certified integer histories. In the standard sense of modular arithmetic developed in Ireland–Rosen and Hardy–Wright, a modulus determines residue classes and addition and multiplication are read by reducing integer operations modulo that modulus. The BEDC surface keeps the modulus and every residue representative as finite rows over $\mathsf{Int}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, $\mathsf{Mul}^{\uparrow}$, $\mathsf{Order}^{\uparrow}$, and $\mathsf{Rat}^{\uparrow}$; it does not introduce a quotient primitive.

The residue carrier consumes the signed-unary representative and modulus rows supplied by chapter 31. It then routes the $\mathsf{Add}^{\uparrow}$, $\mathsf{Mul}^{\uparrow}$, and $\mathsf{Order}^{\uparrow}$ reads over those displayed $\mathsf{Int}^{\uparrow}$ rows before handing the reduced residue boundary to $\mathsf{Rat}^{\uparrow}$ consumers.

303.1 Residue source

Definition 303.1 (ModularArithmetic residue source)**.** *A* $\mathsf{ModularArithmetic}^{\uparrow}$ *residue source is a finite* BHist *packet*

$$(m, u, r, \rho, P)$$

whose rows have the following shape:

1. *m is an accepted* $\mathsf{Int}^{\uparrow}$ *modulus row;*
2. *u is a positive* UnaryHistory *witness naming the nonzero modulus boundary;*
3. *r is an accepted* $\mathsf{Int}^{\uparrow}$ *representative row;*
4. *ρ is a finite residue ledger recording that r is classified by the remainder window selected by m and u;*
5. *P is the* Pkg *provenance row naming the* $\mathsf{Int}^{\uparrow}$*,* $\mathsf{Add}^{\uparrow}$*,* $\mathsf{Mul}^{\uparrow}$*,* $\mathsf{Order}^{\uparrow}$*, and* $\mathsf{Rat}^{\uparrow}$ *dependency certificates used by the packet.*

The carrier is the predicate $\mathsf{ModResidue}(m, u, r, \rho, P)$*. Its classifier compares two accepted residue packets exactly when their modulus rows and unary modulus witnesses transport by* hsame *and their representatives reduce to the same displayed remainder window through the carried ρ ledgers.*

Theorem 303.2 (ModularArithmetic residue carrier stability)**.** *Let $D = (m, u, r, \rho, P)$ be an accepted* $\mathsf{ModularArithmetic}^{\uparrow}$ *residue source and let $D' = (m', u', r', \rho', P')$ be obtained from D by displayed* hsame *transport of the modulus, unary witness, representative, residue ledger, and*

provenance rows. Then D' is again an accepted residue source, and its classifier reads the same remainder window through the transported $\mathsf{Int}^{\uparrow}$, $\mathsf{Order}^{\uparrow}$, *and* Pkg *rows.*

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource carrier stability`
Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueCarrier stability`

Proof. Project the residue source of Definition 303.1. Each coordinate is a displayed row rather than a quotient class, so an hsame transport of the coordinate gives the corresponding coordinate in D'.

The positivity and nonzero-modulus information is carried by the unary witness u. Transporting this witness gives u', and the remainder window selected by the transported modulus is read by the same finite order ledger.

Finally transport the residue ledger ρ and the package row P. Repacking the transported modulus, unary witness, representative, ledger, and provenance gives $\mathsf{ModResidue}(m', u', r', \rho', P')$, and the classifier has exactly the transported remainder-window rows available. □

Theorem 303.3 (ModularArithmetic addition and multiplication ledger)**.** *For accepted residue sources over the same transported modulus witness, the* $\mathsf{ModularArithmetic}^{\uparrow}$ *addition and multiplication reads consist of the following finite rows: the two* $\mathsf{Int}^{\uparrow}$ *representative rows, the shared modulus and unary witness, the* $\mathsf{Add}^{\uparrow}$ *sum row or* $\mathsf{Mul}^{\uparrow}$ *product row on representatives, the* $\mathsf{Order}^{\uparrow}$ *reduction window selecting the remainder, the resulting* $\mathsf{Int}^{\uparrow}$ *residue representative, and the* Pkg *provenance tying these rows to the same dependency certificates.*

The ledger exports no host quotient ring, no set of residue classes, and no equality outside the displayed hsame *and classifier rows.*

Proof. Start with two accepted sources and project their common modulus data. The carrier gives the two representative rows and the same transported nonzero-modulus witness.

For addition, read the displayed $\mathsf{Add}^{\uparrow}$ row on the two representatives. The order and modulus rows then select the finite remainder window, which is repacked as a new residue source by Definition 303.1.

For multiplication, use the same construction with the displayed $\mathsf{Mul}^{\uparrow}$ product row. In both cases the resulting packet is exhausted by the representative operation row, the reduction ledger, and the shared provenance, so no quotient-ring object is introduced. □

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource add mul ledger`

Theorem 303.4 (ModularArithmetic residue operation congruence)**.** *Let A, A', B, B' be accepted* $\mathsf{ModularArithmetic}^{\uparrow}$ *residue sources in the sense of Definition 303.1, all over the same transported modulus witness. Suppose that A classifies with A' and B classifies with B' by the residue classifier, using only the displayed* $\mathsf{Int}^{\uparrow}$ *representative rows,* $\mathsf{Order}^{\uparrow}$ *remainder windows,* BHist *packets,* hsame *transports,* Cont *routes,* Pkg *provenance, and* NameCert *dependency rows. Then the* $\mathsf{Add}^{\uparrow}$ *ledgers for $A + B$ and $A' + B'$ classify the two reduced sum packets, and the* $\mathsf{Mul}^{\uparrow}$ *ledgers for $A \cdot B$ and $A' \cdot B'$ classify the two reduced product packets. The resulting packets expose the same* $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ *handoff boundary and no quotient-ring equality beyond the displayed residue classifier.*

Proof. Project the four residue sources through Definition 303.1. The hypotheses identify the two A representatives through one transported remainder window and the two B representatives through another, while the modulus and unary modulus witness are shared by the same hsame and Cont routes.

For addition, read the displayed $\mathsf{Add}^{\uparrow}$ rows on the two representative pairs. Because the input representatives classify through the transported remainder windows, the resulting sum representatives are reduced through the same $\mathsf{Order}^{\uparrow}$ modulus window and give classified reduced sum packets.

For multiplication, repeat the same construction with the displayed $\mathsf{Mul}^{\uparrow}$ rows. The product representatives pass through the same modulus witness and the same finite reduction window, so the two reduced product packets are classifier-related as residue sources.

Finally repack both operation outputs using the carrier of Definition 303.1. The BHist rows, Pkg provenance, NameCert dependencies, and $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ handoff rows are exactly the rows already carried by the projected packets and operation ledgers, so the congruence is a statement about the displayed classifier only. □

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource operation congruence`

Theorem 303.5 (ModularArithmetic Int/Rat handoff)**.** *Every accepted* $\mathsf{ModularArithmetic}^{\uparrow}$ *residue packet exposes its representative and modulus through* $\mathsf{Int}^{\uparrow}$ *rows, and every rational normalization or denominator-side consumer may read the packet only through the corresponding* $\mathsf{Rat}^{\uparrow}$ *handoff rows, the modulus unary witness, the residue ledger,* hsame *transport,* Cont *routes, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource int rat handoff`

Proof. The source definition stores the representative and modulus as $\mathsf{Int}^{\uparrow}$ rows. Projecting the packet therefore gives the integer data needed by the residue classifier without invoking any external arithmetic carrier.

A $\mathsf{Rat}^{\uparrow}$ consumer can only receive the integer-to-rational handoff rows named by the same provenance package. The modulus witness and residue ledger remain visible, so the consumer sees which finite reduction window produced the representative.

Because the packet has no coordinate for a rational quotient of residue classes, the handoff is exactly the displayed $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ boundary with its hsame, Cont, and Pkg rows. □

Theorem 303.6 (ModularArithmetic NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}$ *obligation surface consists of five rows: the residue source carrier of Definition 303.1; the remainder-window classifier over transported modulus witnesses; the addition ledger of Definition 303.3; the multiplication ledger of the same theorem; and the* $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ *handoff boundary of Definition 303.5. These rows are the full public surface for residue arithmetic over certified integer histories.*

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource namecert obligation surface`

Proof. The carrier and classifier are the two projections of Definition 303.1. They provide the accepted residue packets and the visible equality test by common remainder windows.

The operation rows are supplied by Definition 303.3. Addition and multiplication both use the same modulus witness, representative rows, finite reduction window, and package provenance.

The handoff row is supplied by Definition 303.5. Together these projections list every coordinate readable from the packet, so the $\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}$ surface is exhausted by the five displayed rows and no quotient primitive is exported. □

Theorem 303.7 (ModularArithmetic scoped dependency boundary)**.** *The five local* $\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}$ *rows are scoped exactly by the displayed* $\mathsf{Int}^{\uparrow}$ *modulus and representative rows, the* $\mathsf{Add}^{\uparrow}$ *and* $\mathsf{Mul}^{\uparrow}$

operation rows, the $\mathsf{Order}^{\uparrow}$ *reduction-window row, the* $\mathsf{Rat}^{\uparrow}$ *handoff row, the positive* UnaryHistory *modulus witness, the* BHist *residue packet,* hsame *transports,* Cont *routes,* Pkg *provenance, and the dependency certificates named by* NameCert. *No quotient ring, host congruence class, finite-field structure, or external equality is exported from this scoped boundary.*

Proof. Project Definition 303.1. Its carrier and classifier coordinates give the representative row, modulus row, positive unary witness, residue packet, transported remainder window, continuation routes, package provenance, and dependency certificates.

Use Definition 303.3 for the operation surface. The addition and multiplication rows consume only the displayed $\mathsf{Add}^{\uparrow}$ and $\mathsf{Mul}^{\uparrow}$ dependencies before repacking the reduced residue through the same modulus witness and $\mathsf{Order}^{\uparrow}$ reduction window.

Use Definition 303.5 for the consumer boundary. The handoff exposes exactly the integer representative and modulus rows to $\mathsf{Rat}^{\uparrow}$ consumers, together with the same hsame, Cont, and Pkg ledgers.

These three projections exhaust the concrete BEDC rows visible in the packet. Since none of the named rows contains a coordinate for quotient-ring equality, host congruence classes, finite-field structure, or external equality, the scoped surface exports no such object. □

Lean4 ✓ `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource scoped dependency boundary`

Closure status for $\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}$.

Constructive story: Residue arithmetic is generated by choosing a certified integer modulus, a positive unary modulus witness, an integer representative, and a finite reduction ledger; addition and multiplication read the existing $\mathsf{Add}^{\uparrow}$ and $\mathsf{Mul}^{\uparrow}$ rows before reducing through the displayed $\mathsf{Order}^{\uparrow}$ window.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature finite residue package binds the residue carrier and classifier, addition and multiplication ledgers, $\mathsf{Int}^{\uparrow}/\mathsf{Rat}^{\uparrow}$ handoff rows, scoped dependency boundary, and downstream $\mathsf{Divisibility}^{\uparrow}$ consumer surface over certified integer histories.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModularArithmetic}^{\uparrow}}, \mathsf{axiomClean})$
