Lean target: `BEDC.Derived.ModularArithmeticUp.ModularArithmeticResidueSource\_scoped\_dependency\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient rings, Chinese-remainder structure, primality-specific arithmetic, finite-field laws, or a standard bridge.

Upgrade path: No further paper-side theory grade remains for the finite residue arithmetic package; bridgeChecked verification remains on the formal axis.

Chapter 304

A Concrete Naming Certificate for $\mathsf{ApartnessReal}^{\uparrow}$

The $\mathsf{ApartnessReal}^{\uparrow}$ interface names constructive apartness evidence between displayed real-name presentations. Following the Bishop–Bridges 1985 constructive-analysis treatment, it records positive finite separation witnesses in place of a trichotomy principle. It is a companion to $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$, not a quotient construction and not a completeness theorem.

Its certificate consumes the sealed real-name surface of chapter 38, the regular Cauchy source route of chapter 301, the dyadic positive-radius rows of chapter 291, and the finite observation windows of chapter 126. These four sibling chapters supply, respectively, the endpoint names, source classifier, positive radius, and finite window rows used by the apartness packet, so the positive-separation certificate is routed through the real-completion lattice rather than through an isolated kernel packet.

304.1 Carrier and classifier

Definition 304.1 (ApartnessReal carrier)**.** *An* $\mathsf{ApartnessReal}^{\uparrow}$ *carrier is a finite* BHist *packet containing two displayed* $\mathsf{Real}^{\uparrow}$ *names, or equivalently two displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source packets at the real-seal boundary, together with the finite rows needed to witness positive separation. The packet carries:*

1. *the left and right real-name rows, with their visible* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *provenance;*
2. *a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row* ρ*;*
3. *a finite* $\mathsf{StreamName}^{\uparrow}$ *observation window shared by the two presentations;*
4. *two endpoint readbacks* a *and* b *from that window;*
5. *a separation ledger displaying that the readbacks are separated by the radius* ρ*.*

The carrier accepts only the displayed positive-separation packet. It does not decide whether arbitrary real names are equal or apart, does not assert trichotomy, and does not add quotient classes of real-name presentations.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealTasteGate single carrier alignment`

Definition 304.2 (ApartnessReal classifier)**.** *For accepted* $\mathsf{ApartnessReal}^{\uparrow}$ *packets* P *and* Q*, the classifier* $\mathsf{ApartnessRealClassifier}(P, Q)$ *holds when every visible component of the separation packet*

transports componentwise through the available classifiers. The two real names transport by the existing $\mathsf{Real}^{\uparrow}$ *classifier, or by the* $\mathsf{RegSeqRat}^{\uparrow}$ *source classifier before the real-seal handoff; the radius row transports by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *classifier; the finite observation window transports by the* $\mathsf{StreamName}^{\uparrow}$ *schedule classifier; the two endpoint readbacks transport through the same* hsame *and* Cont *routes; and the separation ledger is repacked after those componentwise transports.*

Thus the classifier identifies two presentations only as presentations of the same finite apartness evidence. It supplies no host real inequality, no quotient equality of Cauchy streams, and no law deciding equality versus apartness for arbitrary real names.

304.2 Certificate obligations

Theorem 304.3 (ApartnessReal obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ApartnessReal}^{\uparrow}}$ *obligation surface has five finite rows:*

1. *carrier acceptance for the packet of Definition 304.1;*
2. *classifier stability for the componentwise transport relation of Definition 304.2;*
3. *symmetry, obtained by swapping the two endpoint readbacks and reversing the displayed separation ledger;*
4. *exactness, read as the finite-window separation witness exposed by the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows;*
5. *ledger visibility, asserting that the positive radius, window, endpoint readbacks, and separation ledger remain visible through the displayed* Cont *and* Pkg *rows.*

The surface supplies apartness evidence only. It does not supply trichotomy of constructive reals, completeness of real names, a metric-completion object, or a quotient carrier.

```
Lean4 ✓  BEDC.Derived.ApartnessRealUp.ApartnessRealNameCertObligationSurface rows
Lean4 ✓  BEDC.Derived.ApartnessRealUp.ApartnessRealCarrier namecert obligation surface
```

Proof. Project the carrier packet. Its rows are exactly the two real-name presentations, the positive dyadic radius, the finite stream window, the two endpoint readbacks, and the displayed separation ledger.

Project the classifier next. Componentwise transport of the two real-name rows, radius row, stream window, endpoint rows, and ledger is precisely the stability face of the certificate.

For symmetry, swap the left and right endpoint readbacks while keeping the same positive radius and observation window. The separation ledger is read in the reverse direction, and the componentwise hsame and Cont routes repack the swapped packet.

Exactness and visibility are finite-readback claims: every apartness witness consumed downstream is one of the displayed finite rows, and every such row remains inspectable through its Cont and Pkg provenance. Since the packet has no coordinate for trichotomy, completeness, or quotient classes, those principles cannot be exported. □

```
Lean4 ✓  BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket namecert obligation surface
```

Theorem 304.4 (ApartnessReal symmetry stability)**.** *If an accepted* $\mathsf{ApartnessReal}^{\uparrow}$ *packet witnesses positive separation from a displayed real name* x *to a displayed real name* y*, then swapping the two real-name rows and the two endpoint readbacks produces an accepted* $\mathsf{ApartnessReal}^{\uparrow}$ *packet witnessing positive separation from* y *to* x*. The swapped packet preserves the same positive*

DyadicRatCore$^{\uparrow}$ *radius row, the same finite* StreamName$^{\uparrow}$ *observation window, and the same* hsame, Cont, Pkg, *and* NameCert *provenance.*

This symmetry is stability of the displayed apartness evidence. It is not a decision procedure for whether x and y are equal or apart.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealCarrier symmetry stability`

Proof. Start from the accepted carrier of Definition 304.1. It contains the two real-name rows, the shared finite observation window, the positive radius, the two endpoint readbacks, and the separation ledger.

Exchange the left and right real-name rows and exchange the two endpoint readbacks. The finite observation window and the positive radius row are unchanged.

The ledger is repacked by reading the separation row in the opposite endpoint order and carrying along the same hsame, Cont, Pkg, and NameCert provenance. The classifier of Definition 304.2 accepts this componentwise transport, so the swapped packet is again an accepted apartness witness. No equality-or-apartness case split is introduced. □

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket symmetry stability`

Theorem 304.5 (ApartnessReal metric handoff)**.** *An accepted* ApartnessReal$^{\uparrow}$ *packet supplies exactly the finite positive-separation row needed by a later* Met$^{\uparrow}$ *or real-order consumer: two displayed real-name endpoints, a positive* DyadicRatCore$^{\uparrow}$ *radius, a finite* StreamName$^{\uparrow}$ *observation window, endpoint readbacks, and a separation ledger visible through* Cont *and* Pkg*.*

The handoff permits a downstream metric or order construction to consume apartness evidence as data. It does not provide real trichotomy, total order, completeness, quotient classes, or a standard bridge for constructive reals.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket metric handoff`
Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealMetricHandoffPacket transport`

Proof. Read the packet through Definition 304.3. The carrier and exactness rows expose the two endpoints, positive radius, finite observation window, endpoint readbacks, and separation ledger.

A metric or order consumer may use only those exposed rows. The classifier row transports the same evidence across accepted presentations, and Definition 304.4 supplies the reversible endpoint orientation expected of apartness.

Because the exported surface is a finite separation witness, it gives no way to select a separation witness for arbitrary distinct names and no way to decide equality against apartness. The handoff is therefore constructive apartness data only. □

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealPositiveSeparationCarrier metric handoff`

Definition 304.6 (ApartnessReal finite-window separation row)**.** *An* ApartnessReal$^{\uparrow}$ *finite-window separation row is the displayed* BHist *tuple consisting of:*

1. *a left endpoint row and a right endpoint row, each read either as a displayed* Real$^{\uparrow}$ *name or as its* RegSeqRat$^{\uparrow}$ *source row at the real-seal boundary;*
2. *one positive* DyadicRatCore$^{\uparrow}$ *radius row ρ;*
3. *one finite* StreamName$^{\uparrow}$ *observation window shared by the two endpoint presentations;*
4. *two endpoint readbacks from that window, one for each endpoint row;*

5. one separation ledger witnessing that the two readbacks are separated by the radius ρ.

The tuple is accepted only when these six rows are visible through the same hsame, Cont, Pkg, *and* NameCert *provenance used by Definition 304.1 and Definition 304.2. It is a finite certificate row, not a host-level inequality between real numbers and not a quotient class of real-name presentations.*

Theorem 304.7 (ApartnessReal finite-window separation transport)**.** *Let R and S be accepted* $\mathsf{ApartnessReal}^{\uparrow}$ *finite-window separation rows in the sense of Definition 304.6. If the two endpoint rows, the positive radius row, the finite observation window, the two endpoint readbacks, and the separation ledger of R transport componentwise to the corresponding rows of S through the displayed* hsame, Cont, Pkg, *and* NameCert *routes, then S repacks as an accepted finite-window separation row.*

This transport adds no trichotomy principle, quotient carrier, total order, or completeness datum for constructive reals.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket finite window transport`

Proof. Project the accepted carrier data from Definition 304.1. The only coordinates present are the two endpoint presentations, the positive dyadic radius, the finite stream window, the two endpoint readbacks, and the separation ledger.

Use Definition 304.2 to transport those coordinates one by one. The real-name endpoints transport either through their displayed $\mathsf{Real}^{\uparrow}$ classifiers or through their $\mathsf{RegSeqRat}^{\uparrow}$ source classifiers before the real-seal boundary; the radius and window rows transport through their own classifiers; the endpoint readbacks follow the same hsame and Cont routes.

It remains to repack the ledger. Since the ledger is assumed to transport componentwise through the same visible Pkg and NameCert provenance, the target tuple has exactly the six rows required by Definition 304.6. No additional coordinate can be read from this repacking, so no excluded-order, quotient, or completion principle is exported. □

Theorem 304.8 (ApartnessReal metric consumer separation boundary)**.** *A later* $\mathsf{Met}^{\uparrow}$ *or real-order consumer may consume exactly the* $\mathsf{ApartnessReal}^{\uparrow}$ *finite-window separation row of Definition 304.6, together with the existing handoff rows of Definition 304.5: the two displayed endpoint rows, the positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the finite* $\mathsf{StreamName}^{\uparrow}$ *observation window, the two endpoint readbacks, and the visible separation ledger.*

Such a consumer cannot read a host real inequality, total order, trichotomy decision, quotient carrier, or completion datum from the $\mathsf{ApartnessReal}^{\uparrow}$ *certificate surface.*

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealMetricHandoffPacket metric consumer separation boundary`
Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket metric consumer separation boundary`
Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealCarrier metric consumer separation boundary`

Proof. Apply Definition 304.3. Its carrier, classifier, exactness, and ledger-visibility rows expose precisely the finite endpoint, radius, window, readback, and separation-ledger data named in Definition 304.6.

Apply Definition 304.4 to account for the reversible orientation required by apartness consumers. The symmetry operation swaps only the two endpoint rows and the two endpoint readbacks while preserving the same positive radius, finite window, and provenance rows.

Finally apply Definition 304.5. That handoff is already limited to finite positive-separation evidence for downstream metric or order constructions. Composing these three surfaces leaves the

consumer with the finite-window row and no additional coordinate from which host inequality, total order, quotient, or completion data could be extracted. □

Theorem 304.9 (ApartnessReal located-window positive gap handoff)**.** *Let L and R be displayed* $\mathsf{LocatedReal}^{\uparrow}$ *packets. Suppose they share a finite* $\mathsf{StreamName}^{\uparrow}$ *observation window and their* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint ledgers display two disjoint enclosures with positive dyadic gap row ρ. If the two endpoint real-name rows, the common finite window, the two endpoint readbacks, and the visible gap ledger are all carried by the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *provenance of the two packets, then the tuple consisting of those two endpoint real-name rows, ρ, the common finite window, the two endpoint readbacks, and the visible separation ledger repacks as an accepted* $\mathsf{ApartnessReal}^{\uparrow}$ *finite-window separation row in the sense of Definition 304.6.*

The handoff exports finite positive-gap evidence only. It does not decide equality of real names, does not supply trichotomy or a total order, and does not identify located real packets by a quotient or host real equality.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket located window positive gap handoff`

Proof. Project both located packets through Definition 309.2. The carrier surface exposes the $\mathsf{RegSeqRat}^{\uparrow}$ source rows, the $\mathsf{StreamName}^{\uparrow}$ schedule row, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint ledger, and the locatedness classifier rows, all tied to the visible provenance.

Apply Definition 309.12 to read the shared observation window as a finite scheduled window. Apply Definition 309.10 to identify the two endpoint readbacks with rows of the displayed dyadic endpoint ledgers.

The disjoint-enclosure hypothesis supplies the positive dyadic gap row ρ. Repack that row as the separation ledger, using the same common window, endpoint readbacks, and provenance rows already projected from the two located packets.

Finally apply Definition 304.7 and then Definition 304.8. The first theorem identifies the repacked tuple as a stable finite-window separation row, and the second theorem restricts every later metric or order consumer to exactly that finite apartness evidence. □

Theorem 304.10 (Localized Cauchy apartness bridge)**.** *Let L and R be displayed* $\mathsf{LocatedReal}^{\uparrow}$ *packets whose finite* $\mathsf{StreamName}^{\uparrow}$ *observation window,* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *gap row, endpoint readbacks, and* hsame, Cont, Pkg, *and* NameCert *provenance agree componentwise. Suppose the displayed endpoint ledgers exhibit a positive located-window gap in the sense of Definition 304.9. Then the resulting* $\mathsf{ApartnessReal}^{\uparrow}$ *finite-window separation row is stable under the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier routes and may be consumed by* $\mathsf{Real}^{\uparrow}$ *metric or order interfaces only as positive apartness evidence.*

The bridge exports no host inequality, quotient equality, trichotomy decision, total order, or completeness datum over the real or completion substrate.

Proof. Apply Definition 304.9 to the two displayed located-real packets. The shared finite window, regular Cauchy source rows, positive dyadic gap row, endpoint readbacks, and visible provenance repack as the finite separation row of Definition 304.6.

Next read the packet through Definition 304.2. The componentwise agreement hypotheses are exactly the classifier coordinates needed to transport the two endpoint rows, the common window, the gap row, the two readbacks, and the separation ledger along the displayed $\mathsf{RegSeqRat}^{\uparrow}$ routes.

Apply Definition 304.7 to make that transport stable. The transported packet is still the same finite positive-gap row, now presented over the regular Cauchy classifiers feeding the real-name substrate.

Finally apply Definition 304.8. It restricts every $\mathsf{Real}^{\uparrow}$ metric or order consumer to the finite positive-apartness row and excludes any readback of host inequality, quotient equality, trichotomy, total order, or completion data. □

Theorem 304.11 (ApartnessReal real separation scope)**.** *The scoped separation surface consists exactly of the two displayed* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *endpoint rows, one positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, one finite* $\mathsf{StreamName}^{\uparrow}$ *observation window, two endpoint readbacks, the separation ledger, and their* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Any $\mathsf{Met}^{\uparrow}$ *or real-order consumer may read those rows as finite positive-separation data. The surface provides no host inequality, trichotomy decision, quotient carrier, total order, or completeness datum.*

Proof. Combine the obligation surface of Definition 304.3 with the finite-window row of Definition 304.6. Together they expose exactly the two endpoint rows, positive radius, finite window, endpoint readbacks, separation ledger, and visible provenance.

Apply Definition 304.7 to keep that tuple stable under the displayed hsame, Cont, Pkg, and NameCert routes. Then apply Definition 304.8 to identify the same tuple as the downstream metric or order consumer surface.

The carrier and classifier coordinate lists contain only those finite rows. Therefore a consumer has no coordinate from which to read host inequality, trichotomy, quotient-carrier, total-order, or completeness data. □

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket real separation scope`

Theorem 304.12 (ApartnessReal mature consumer coverage)**.** *Every metric, order, or* $\mathsf{RealAlgOrder}^{\uparrow}$ *consumer of the* $\mathsf{ApartnessReal}^{\uparrow}$ *positive-separation packet may read only the finite carrier, classifier, metric-consumer separation boundary, bridge boundary,* hsame*,* Cont*,* Pkg*, and* NameCert *rows already exposed by this chapter.*

The mature consumer surface does not export trichotomy, total order, completeness, quotient construction, metric completion, or standard constructive-real bridge data.

Lean4 ✓ `BEDC.Derived.ApartnessRealUp.ApartnessRealSeparationPacket mature consumer coverage`

Proof. Project the packet through Definition 304.6 and Definition 304.2. These rows expose the two endpoint names, positive radius, finite observation window, endpoint readbacks, separation ledger, and componentwise classifier transports.

Next apply Definition 304.7 and Definition 304.8. They restrict metric and order consumers to the same finite positive-separation carrier, classifier, hsame, Cont, Pkg, and NameCert rows.

Use Definition 304.9 and Definition 304.11 for the bridge boundary from located or sealed real-name packets to the displayed separation surface. These theorems repack the same finite rows and add no quotient, completion, or total-order coordinate.

The cited boundary theorems exhaust the rows available to metric, order, and $\mathsf{RealAlgOrder}^{\uparrow}$ consumers. Since the carrier, classifier, and bridge boundary contain no trichotomy, total order, completeness, quotient construction, metric completion, or standard constructive-real bridge datum, none is exported by the consumer coverage theorem. □

Closure status for $\mathsf{NameCert}_{\mathsf{ApartnessReal}^{\uparrow}}$**.**

Constructive story: An apartness-real packet is generated from two displayed $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ names, a positive $\mathsf{DyadicRatCore}^{\uparrow}$ radius, a finite $\mathsf{StreamName}^{\uparrow}$ observation window, two endpoint readbacks, and a visible separation ledger transported componentwise by hsame and Cont.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ApartnessReal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public boundary binds exactly the finite positive-separation carrier, located-window positive gap handoff, metric consumer separation boundary, real-separation scope, and their $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert provenance for $\mathsf{ApartnessReal}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ApartnessReal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ApartnessRealUp.ApartnessRealCarrier\_metric\_consumer\_separation\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not close trichotomy, total order, completeness, quotient construction, or metric-completion data.

Upgrade path: No further paper theory-axis grade is recorded; formal bridge work remains on the verification axis.

Chapter 305

A Concrete Naming Certificate for $\mathsf{BraidGroup}^{\uparrow}$

The braid-group interface $\mathsf{BraidGroup}^{\uparrow}$ packages the finite Artin-word presentation of the braid group as a BEDC naming surface. Its textbook source is the Artin generator presentation and braid-closure calculus appearing in Birman's braid monograph and in the Kassel–Turaev treatment of braid groups. The BEDC packet keeps the presentation finite: every generator letter, inverse letter, braid relation, inverse cancellation, far-commutation move, Weyl-action read, and knot-closure read is a displayed BHist, hsame, Cont, or Pkg row.

The finite Artin-word packet consumes the concatenation and inverse certificate surfaces of chapter 40 and chapter 41. It exports the symmetric shadow to chapter 117, the root-action ledger to chapter 145, and the closure ledger to chapter 254; these are dependency-lattice reads of the same displayed word, move, provenance, and naming rows rather than ambient presentation quotients.

305.1 Carrier And Ledger

Definition 305.1 (BraidGroup finite Artin-word carrier)**.** *A* $\mathsf{BraidGroup}^{\uparrow}$ *packet is a finite* BHist *tuple*

$$\mathcal{B} = (n, w, L, C, \rho, \lambda)$$

whose source row n is a positive unary strand-count ledger, whose word row w is a finite list of signed adjacent-strand letters σ_i^{ϵ} with $1 \leq i < n$ and $\epsilon \in \{-1, +1\}$, and whose classifier ledger L is generated by visible Artin moves:

1. *inverse cancellation rows $\sigma_i\sigma_i^{-1} \rightsquigarrow \mathsf{e}$ and $\sigma_i^{-1}\sigma_i \rightsquigarrow \mathsf{e}$;*
2. *braid rows $\sigma_i\sigma_{i+1}\sigma_i \rightsquigarrow \sigma_{i+1}\sigma_i\sigma_{i+1}$ and their signed inverse transports;*
3. *far-commutation rows $\sigma_i\sigma_j \rightsquigarrow \sigma_j\sigma_i$ when the displayed unary gap records $|i - j| > 1$.*

The row C is the classifier witness obtained by composing such ledger entries. The row ρ records the consumed $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Monoid}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{WeylGroup}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$ *package sources used by downstream consumers. The finite ledger λ lists exactly the word letters, move rows, classifier transports, action readbacks, closure readbacks, and provenance rows accepted by the packet.*

305.2 Certificate Surface

Theorem 305.2 (BraidGroup Artin ledger stability)**.** *Let $\mathcal{B}$ and $\mathcal{B}'$ be* $\mathsf{BraidGroup}^{\uparrow}$ *packets over the same displayed strand-count row. If their Artin words are related by a finite classifier ledger generated by braid relations, inverse cancellation, and far-commutation moves, then every transported word row remains a* $\mathsf{BraidGroup}^{\uparrow}$ *word row, and the composed ledger remains visible as* BHist *carrier data with the same* hsame*,* Cont*, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket artin ledger stability`

Proof. Read the classifier ledger L entry by entry. Each generator of L rewrites a finite subword whose indices are already checked against the unary strand-count row, so the target subword is again a finite list of signed adjacent-strand letters over the same row.

For inverse cancellation, delete only the displayed adjacent inverse pair and keep the surrounding word prefix and suffix unchanged. For the braid and far-commutation rows, replace the named subword by the displayed target subword and attach the corresponding Cont route to the same prefix and suffix.

Composing the entries gives the transported word row and classifier witness C. Since all entries come from the finite ledger and every transport is recorded by hsame, Cont, and Pkg rows, the result is still a $\mathsf{BraidGroup}^{\uparrow}$ packet rather than a quotient of Artin words. □

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupPacket artin ledger stability`
Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket ledger stability`

Theorem 305.3 (BraidGroup NameCert obligation surface)**.** *The seed* $\mathsf{NameCert}_{\mathsf{BraidGroup}^{\uparrow}}$ *obligation surface consists of the finite Artin-word carrier of Definition 305.1, the classifier ledger generated by braid relations, inverse cancellation, and far-commutation moves, the inherited monoid concatenation and group inverse rows from* $\mathsf{NameCert}_{\mathsf{Monoid}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{Group}^{\uparrow}}$*, the permutation boundary consumed by* $\mathsf{NameCert}_{\mathsf{SymGroup}^{\uparrow}}$*, the braid-row action boundary consumed by* $\mathsf{NameCert}_{\mathsf{WeylGroup}^{\uparrow}}$*, the closure-ledger boundary consumed by* $\mathsf{NameCert}_{\mathsf{Knot}^{\uparrow}}$*, and the exact* BHist*,* hsame*,* Cont*, and* Pkg *rows listed by the packet ledger.*

Proof. Project the packet of Definition 305.1. The carrier supplies the strand count, signed adjacent-strand word, classifier ledger, classifier witness, dependency provenance, and finite ledger rows.

The monoid and group faces are the visible concatenation, empty-word, and inverse-word operations on the same finite word lists. Their stability is the Artin ledger stability of Definition 305.2, because concatenating a displayed move with fixed prefixes and suffixes keeps the same finite move visible.

The consumer faces are projections of the same packet: $\mathsf{SymGroup}^{\uparrow}$ reads the adjacent transposition shadow, $\mathsf{WeylGroup}^{\uparrow}$ reads the root-action braid rows, and $\mathsf{Knot}^{\uparrow}$ reads braid closure as a finite closure ledger. No face adds host word equality, a presentation quotient, or an unrecorded isotopy class. □

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupPacket namecert obligation surface`
Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket namecert obligation surface`

Theorem 305.4 (BraidGroup Weyl root-action handoff)**.** *Every* $\mathsf{WeylGroup}^{\uparrow}$ *braid-row consumer of a* $\mathsf{BraidGroup}^{\uparrow}$ *packet reads exactly the signed Artin letters, the adjacent-strand index rows, the braid and far-commutation ledger entries, the symmetric-group shadow row, and the* BHist*,*

hsame, Cont, *and* Pkg *provenance exposed by Definition 305.1. The handoff supplies a finite root-action ledger and supplies no Coxeter completion, host reflection equality, or Artin-representation faithfulness claim.*

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket weyl root action handoff`
Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupPacket weyl root action handoff`

Proof. Project the Artin word to its adjacent-strand letters. Each letter has a displayed index row, so the $\mathsf{WeylGroup}^{\uparrow}$ consumer can read it as the corresponding adjacent simple-reflection action row only through the packet ledger.

Use Definition 305.2 for transport along braid and far-commutation moves. These are precisely the moves that a finite Weyl braid row consumes when comparing two displayed reduced-action ledgers.

The symmetric-group shadow is read from the same adjacent transposition sequence, while provenance remains the Pkg row of the packet. Because the packet contains no host reflection equality or faithfulness field, the handoff is only the finite root-action ledger just described. □

Theorem 305.5 (BraidGroup knot-closure ledger boundary)**.** *Every* $\mathsf{Knot}^{\uparrow}$ *closure consumer of a* $\mathsf{BraidGroup}^{\uparrow}$ *packet reads the strand-count row, the finite signed Artin-word row, the crossing ledger induced by those letters, the Artin move ledger, the closure endpoint rows, and the* BHist, hsame, Cont, *and* Pkg *provenance exposed by the braid packet. The boundary records finite braid closures as knot-diagram ledgers and does not claim Markov theorem, knot isotopy completeness, braid group faithfulness, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket knot closure empty boundary`

Proof. Read the signed Artin word from the carrier. Each positive or negative adjacent-strand letter determines one finite crossing entry with its incident strand indices and over-under orientation recorded in the closure ledger.

Transport of closure diagrams follows the Artin move ledger. Braid relations and far-commutations rewrite local crossing subledgers, while inverse cancellation removes a displayed opposite crossing pair; the closure endpoint rows remain attached to the same strand-count ledger.

The resulting object is the $\mathsf{Knot}^{\uparrow}$ crossing ledger read through the braid packet's Cont and Pkg rows. Since the packet does not contain a Markov-move classifier, an isotopy-completeness theorem, a faithfulness theorem, or a standard bridge row, none of those claims is exported by the closure boundary. □

Theorem 305.6 (BraidGroup scoped Artin source package)**.** *Every consumer-facing* $\mathsf{BraidGroup}^{\uparrow}$ *read is exhausted by the finite strand-count row, signed Artin word row, Artin move ledger, symmetric-group shadow, Weyl root-action handoff, knot-closure ledger, and the* BHist, hsame, Cont, *and* Pkg *provenance from the carrier. The package exports no Markov theorem, braid-group faithfulness, knot isotopy completeness, or standard bridge data.*

Proof. Project the carrier of Definition 305.1. It supplies the positive unary strand count, signed adjacent-strand word, classifier ledger, dependency provenance, and finite packet ledger.

Apply Definition 305.2 to identify every transported word read with the visible Artin move ledger. Then apply Definition 305.3 to account for the monoid, group, symmetric-group, Weyl-group, and knot dependency rows in the NameCert surface.

The two downstream faces are the finite projections already isolated by Definition 305.4 and Definition 305.5. Their exclusion clauses remove Markov moves, Artin-representation faithfulness,

knot isotopy completeness, and standard bridge data, leaving exactly the scoped Artin source package stated above. □

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket scoped artin source package`

Theorem 305.7 (BraidGroup public Artin interface)**.** *The finite signed Artin-word carrier, Artin ledger stability, NameCert obligation surface, Weyl root-action handoff, knot-closure ledger boundary, and scoped Artin source package assemble the public* $\mathsf{NameCert}_{\mathsf{BraidGroup}^{\uparrow}}$ *interface. It is readable by* $\mathsf{Group}^{\uparrow}$, $\mathsf{SymGroup}^{\uparrow}$, $\mathsf{WeylGroup}^{\uparrow}$, *and* $\mathsf{Knot}^{\uparrow}$ *consumers as strand-count rows, signed adjacent-strand word rows, braid/inverse/far-commutation ledgers, symmetric-group shadow rows, Weyl action rows, knot-closure ledger rows,* BHist, hsame, Cont, *and* Pkg *provenance.*

The interface exports no Markov theorem, braid-group faithfulness, knot isotopy completeness, presentation quotient, or standard bridge data.

Proof. Start with the finite carrier of Definition 305.1. It provides the strand count, signed Artin word, classifier ledger, dependency provenance, and packet rows that all four consumer directions read.

Apply Definition 305.2 to keep braid, inverse-cancellation, and far-commutation transport inside the displayed Artin ledger. Then use Definition 305.3 to expose the NameCert rows shared by the group, symmetric-group, Weyl-group, and knot readers.

The two non-group faces are exactly the finite handoffs isolated by Definition 305.4 and Definition 305.5. Finally Definition 305.6 gathers these rows into a single scoped Artin source package.

Since the cited package has no coordinate for Markov moves, representation faithfulness, isotopy completeness, presentation quotients, or standard bridge rows, repacking it as a public $\mathsf{NameCert}_{\mathsf{BraidGroup}^{\uparrow}}$ interface cannot export any of that data. □

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket public artin interface`

Theorem 305.8 (BraidGroup public NameCert export)**.** *The finite Artin-word carrier, Artin ledger stability, NameCert obligation surface, Weyl root-action handoff, knot-closure ledger boundary, and scoped Artin source package assemble the public* $\mathsf{NameCert}_{\mathsf{BraidGroup}^{\uparrow}}$ *export. Every consumer reads only signed Artin words, strand-count rows, braid/inverse/far-commutation ledgers, symmetric-group shadow, Weyl action handoff, knot closure ledger,* BHist, hsame, Cont, *and* Pkg *provenance, with no Markov theorem, braid faithfulness, knot-isotopy completeness, presentation quotient, or standard bridge.*

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket public namecert export`

Proof. Begin with the finite carrier of Definition 305.1. It displays the strand count, signed Artin word, classifier ledger, dependency provenance, and packet ledger that every public consumer can read.

Use Definition 305.2 and Definition 305.3. These theorems keep the braid, inverse, and far-commutation moves inside visible ledgers and identify the NameCert rows inherited by the group, monoid, symmetric-group, Weyl-group, and knot consumers.

Next apply Definition 305.4, Definition 305.5, and Definition 305.6. Their exclusion clauses remove Markov moves, braid faithfulness, knot-isotopy completeness, presentation quotients, and standard bridge data.

The cited carrier and theorem blocks exhaust the consumer-facing rows. Repacking them gives the public $\mathsf{NameCert}_{\mathsf{BraidGroup}^{\uparrow}}$ export with exactly the finite surface stated above. □

Theorem 305.9 (BraidGroup public certificate export)**.** *The finite Artin-word carrier, Artin ledger stability,* NameCert *obligation surface, Weyl root-action handoff, knot-closure ledger boundary, and scoped Artin source package assemble the public* $\mathsf{NameCert}_{\mathsf{BraidGroup}\uparrow}$ *export. The exported rows are exactly signed Artin words, strand counts, braid-relation ledgers, inverse-cancellation ledgers, far-commutation ledgers, symmetric-group shadow rows, Weyl root-action rows, knot-closure ledger rows,* BHist*,* hsame*,* Cont*, and* Pkg *provenance.*

This public certificate still withholds Markov theorem, braid group faithfulness, knot isotopy completeness, and standard bridge data.

Lean4 ✓ `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket public certificate export`

Proof. Project the carrier through Definition 305.1. The carrier provides only the finite strand-count row, signed Artin-word row, classifier ledger, dependency provenance, and packet ledger.

Next use Definition 305.2 and Definition 305.3. These results keep braid relations, inverse cancellation, far commutation, and the shared NameCert obligation rows inside the displayed finite ledger.

Apply Definition 305.4 and Definition 305.5 to account for the Weyl and knot-closure faces. Then apply Definition 305.6 to gather the group, symmetric-group, Weyl, and knot readers into one scoped Artin package.

Those cited theorem blocks exhaust the public certificate rows. None contains a Markov theorem, braid-group faithfulness theorem, knot-isotopy completeness theorem, or standard bridge datum, so the public export withholds exactly those objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{BraidGroup}\uparrow}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BraidGroup}\uparrow}$, maturePackageClosed)

Scope closed: The scoped boundary binds finite signed Artin words, visible braid-relation, inverse-cancellation, and far-commutation ledgers, the NameCert obligation surface, the Weyl root-action handoff, the knot-closure ledger boundary, and the BHist, hsame, Cont, and Pkg rows consumed by symmetric-group, Weyl-group, and knot-closure readers.

Constructive story: Construct the packet by listing a unary strand count, a finite signed adjacent-strand word, and a finite move ledger generated by the Artin relations; downstream group, symmetric-group, Weyl-action, and knot-closure rows are projections of that same ledger.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BraidGroup}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.BraidGroupUp.BraidGroupArtinPacket\_public\_certificate\_export`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not claim Markov theorem, braid group faithfulness, knot isotopy completeness, or a standard bridge.

Upgrade path: Formal bridge checking remains separate from the mature paper treatment of the finite Artin packet bridge surface.

Chapter 306

A Concrete Naming Certificate for $\mathsf{DyadicInterval}^{\uparrow}$

The $\mathsf{DyadicInterval}^{\uparrow}$ interface names finite dyadic interval packets in the sense of Moore–Kearfott–Cloud interval analysis. It sits between $\mathsf{DyadicRatCore}^{\uparrow}$, which supplies visible dyadic endpoint and radius ledgers, and $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$, which consume finite approximation packets without importing quotient reals or completeness principles.

306.1 Carrier and refinement ledger

The endpoint-order, midpoint, radius, and width rows consume the dyadic arithmetic carrier of chapter 291, while the finite tolerance and readback rows align with chapter 322. Thus $\mathsf{DyadicInterval}^{\uparrow}$ is the interval packet assembled from those sibling dyadic ledgers before $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumes the finite approximation surface.

Definition 306.1 (DyadicInterval BHist carrier)**.** *A* $\mathsf{DyadicInterval}^{\uparrow}$ *carrier row is a finite* BHist *packet*

$$I = (L, R, W, O, M, \rho, H, C, P, N)$$

with the following visible rows:

1. *left and right endpoint rows L and R accepted by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. *a unary nonnegative width row W naming the displayed dyadic width bound;*
3. *an endpoint-order ledger O proving $L \leq R$ by a* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-exponent comparison;*
4. *midpoint and radius rows M and ρ computed from the same endpoint window;*
5. *componentwise* hsame *rows H and displayed* Cont *routes C for endpoint, order, midpoint, radius, and width transport;*
6. *a* Pkg *provenance row P naming the consumed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{Int}^{\uparrow}$*, and* $\mathsf{StreamName}^{\uparrow}$ *source rows;*
7. *a* $\mathsf{NameCert}$ *row N recording that the public interval packet is classified only by endpointwise finite dyadic tolerance.*

The carrier has no coordinate for Dedekind cuts, open-cover compactness, quotient intervals, host real endpoints, or real-completeness data.

Theorem 306.2 (DyadicInterval nested refinement ledger)**.** *Let $I = (L, R, W, O, M, \rho, H, C, P, N)$ and $I' = (L', R', W', O', M', \rho', H', C', P', N')$ be accepted* DyadicInterval$^{\uparrow}$ *carriers. Suppose I' is obtained from I by a nested refinement: the transported endpoint rows satisfy $L \leq L' \leq R' \leq R$ in the displayed* DyadicRatCore$^{\uparrow}$ *common-exponent ledger, the width row W' is bounded by the transported width row W, and the midpoint and radius rows are recomputed from the refined endpoint window. Then I' repacks the same kind of endpoint, radius, width, order,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance rows as I.*

The finite source consumed by RegSeqRat$^{\uparrow}$ *is preserved: a scheduled regular-stream window may read the refined endpoint rows, radius row, width row, and provenance through the same visible finite dyadic interval surface, and it receives no quotient sequence, real-completion object, or hidden host-real endpoint.*

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket nested refinement ledger`

Proof. Project the carrier of Definition 306.1. The endpoint rows, width row, order ledger, midpoint row, radius row, componentwise hsame data, continuation routes, package provenance, and naming row are all visible finite rows.

Apply the nested-refinement hypotheses to the endpoint-order ledger. The refined endpoints are still accepted DyadicRatCore$^{\uparrow}$ rows, and the order comparisons are transported through the same common-exponent dyadic ledger.

Recompute the midpoint and radius rows from the refined endpoint window and transport the width row along the displayed nonnegative dyadic bound. These operations only repack the finite endpoint and arithmetic ledgers already named by the carrier.

Finally restrict the consumer view to the rows a RegSeqRat$^{\uparrow}$ scheduled window can read. That view consists exactly of endpoint, radius, width, regular dyadic comparison, hsame, Cont, Pkg, and NameCert provenance rows, so refinement preserves the finite source surface. □

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalEndpointPacket nested refinement ledger`

Theorem 306.3 (DyadicInterval nested window composition)**.** *Let $I_0 = (L_0, R_0, W_0, O_0, M_0, \rho_0, H_0, C_0, P_0, N_0)$, $I_1 = (L_1, R_1, W_1, O_1, M_1, \rho_1, H_1, C_1, P_1, N_1)$, and $I_2 = (L_2, R_2, W_2, O_2, M_2, \rho_2, H_2, C_2, P_2, N_2)$ be accepted* DyadicInterval$^{\uparrow}$ *carriers. Suppose I_1 is a nested refinement of I_0 and I_2 is a nested refinement of I_1 in the endpoint-order, width, midpoint, and radius ledgers of Definition 306.2. Then I_2 is a nested refinement of I_0.*

Moreover, the seal-source packet obtained by refining first from I_0 to I_1 and then from I_1 to I_2 exposes exactly the same endpoint, width, radius, order, hsame*,* Cont*,* Pkg*, and* NameCert *rows as the direct refinement from I_0 to I_2. It exposes no Dedekind cut, quotient interval, host-real endpoint, open-cover compactness witness, completeness datum, or standard bridge.*

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket nested window composition`

Proof. Project the three accepted packets through Definition 306.1. The only coordinates available for comparison are the endpoint rows, width row, order ledger, midpoint row, radius row, componentwise hsame rows, displayed Cont routes, Pkg provenance, and NameCert row.

Compose the endpoint-order ledgers. The hypotheses give $L_0 \leq L_1 \leq R_1 \leq R_0$ and $L_1 \leq L_2 \leq R_2 \leq R_1$ in the displayed DyadicRatCore$^{\uparrow}$ common-exponent comparisons, so transitivity of the finite comparison ledger gives $L_0 \leq L_2 \leq R_2 \leq R_0$. The width and radius transports compose in the same visible dyadic arithmetic rows, and the midpoint row is recomputed from the final endpoint window.

Apply Definition 306.2 to the first refinement and then to the second refinement. The two applications repack the same endpoint, width, radius, order, hsame, Cont, Pkg, and NameCert row kinds that the direct I_0 to I_2 refinement uses.

Finally apply Definition 306.7. That boundary exhausts the rows visible to a $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ finite-window consumer, so the two-step seal source and the direct seal source have the same consumer-visible rows. Since the carrier has no coordinate for Dedekind cuts, quotient intervals, host-real endpoints, open-cover compactness, completeness data, or standard bridges, neither refinement path can expose one. □

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket nested window seal source composition`
Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket nested window name certificate`

Theorem 306.4 (DyadicInterval NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicInterval}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *interval packet of Definition 306.1;*
2. *classifier: endpointwise dyadic tolerance, comparing left endpoints and right endpoints by* $\mathsf{DyadicRatCore}^{\uparrow}$ *common-exponent windows while preserving the displayed width and radius rows;*
3. *endpoint-order stability: componentwise* hsame *and* Cont *transport preserve the visible* $L \leq R$ *ledger;*
4. *nested refinement transport: the refinement ledger of Definition 306.2 repacks the same finite endpoint, midpoint, radius, width, provenance, and naming rows;*
5. $\mathsf{Real}^{\uparrow}$ *seal handoff boundary: a real-name seal may consume only the finite interval endpoint, radius, width, order, and provenance rows and gains no real-completeness, quotient-interval, or standard-bridge datum.*

Proof. The carrier row is Definition 306.1. It lists the only public coordinates exposed by an accepted $\mathsf{DyadicInterval}^{\uparrow}$ packet.

The classifier row is endpointwise because the carrier has separate left and right $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows. A dyadic-tolerance witness therefore uses two common-exponent comparisons, one for each endpoint, together with the displayed width and radius rows.

Endpoint-order stability follows by transporting the order ledger through the componentwise hsame and Cont rows named in the carrier. Nested refinement transport is exactly the repacking statement of Definition 306.2.

At the $\mathsf{Real}^{\uparrow}$ seal boundary, the available source rows are exhausted by the carrier, classifier, order, and refinement rows above. Since none of those rows contains a Dedekind cut, an open-cover compactness object, a quotient interval, or completeness data, the handoff remains a finite BEDC source surface. □

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket namecert obligation surface`

Theorem 306.5 (DyadicInterval endpoint classifier transport)**.** *Let* $I = (L, R, W, O, M, \rho, H, C, P, N)$ *and* $I' = (L', R', W', O', M', \rho', H', C', P', N')$ *be accepted* $\mathsf{DyadicInterval}^{\uparrow}$ *carriers. Suppose the displayed* H *rows provide componentwise* hsame *witnesses and the displayed* C *rows provide* Cont *routes from the coordinates of* I *to the corresponding coordinates of* I'*. Then every endpointwise dyadic-tolerance witness for the left and right endpoint rows of* I *transports componentwise to* I'*, and the same transport repacks the order, midpoint, radius, width,* Pkg*, and* NameCert *rows.*

Proof. Project the two carriers through Definition 306.1. The left endpoint, right endpoint, width, order, midpoint, radius, package, and naming coordinates are separate finite rows, and the carrier exposes the matching hsame and Cont rows for each coordinate.

Transport the classifier in the endpoint coordinates first. The dyadic-tolerance witness is endpointwise, so the left-endpoint comparison follows the left endpoint route and the right-endpoint comparison follows the right endpoint route.

It remains to repack the non-endpoint rows. The order, midpoint, radius, and width data are read from the same displayed carrier coordinates, while the Pkg and NameCert rows are transported by their own visible routes. This gives the componentwise target classifier without adding any extra source datum. □

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalEndpointPacket endpoint classifier transport`
↪ variant `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket endpoint classifier transport`

Theorem 306.6 (DyadicInterval width-radius ledger exactness)**.** *Every width, midpoint, and radius readback used by the* DyadicInterval$^{\uparrow}$ *endpoint classifier is projected from the carrier rows of Definition 306.1 and, under nested refinement, from the transported rows supplied by Definition 306.2. No classifier readback may use an external host-real radius, quotient-interval width, or completion-side midpoint.*

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket width radius ledger exactness`

Proof. The carrier projection exposes exactly the width row W, midpoint row M, and radius row ρ. These are the only rows named in Definition 306.1 for width, midpoint, and radius readback.

Under nested refinement, apply Definition 306.2. The refined endpoint window repacks the transported width row and recomputes the midpoint and radius rows from that finite window.

Thus every classifier readback is a projection from either the original carrier or its nested-refinement transport. Since neither source contains a host-real, quotient-interval, or completion coordinate, no such coordinate can participate in the readback. □

Theorem 306.7 (DyadicInterval RealUp seal source boundary)**.** *A* Real$^{\uparrow}$ *or* RegSeqRat$^{\uparrow}$ *consumer of a* DyadicInterval$^{\uparrow}$ *packet may read only the finite endpoint, radius, width, order, refinement,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed in Definition 306.1, Definition 306.2, and Definition 306.4. The consumer receives no Dedekind cut, quotient interval, open-cover compactness witness, host real equality, or completeness datum.*

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket real seal source boundary`

Proof. Start with the carrier projection. Its finite rows provide the endpoint, radius, width, order, hsame, Cont, Pkg, and NameCert coordinates, and the carrier statement explicitly excludes Dedekind, quotient, host-real, and completeness coordinates.

Add the refinement view from Definition 306.2. Refinement repacks the same finite rows after endpoint narrowing; it does not create a new completion-side object.

Finally use the obligation surface of Definition 306.4. The seal handoff row is therefore bounded by the carrier, refinement, and naming projections, so a Real$^{\uparrow}$ or RegSeqRat$^{\uparrow}$ consumer can read only the listed finite DyadicInterval rows. □

Theorem 306.8 (DyadicInterval regular-window seal handoff)**.** *Let* $I = (L, R, W, O, M, \rho, H, C, P, N)$ *be an accepted* DyadicInterval$^{\uparrow}$ *packet. For any finite regular-stream observation window requested by a* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer, nested refinement transports the endpoint, width, radius, order,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of* I *into a finite seal-source packet. The consumer*

receives no Dedekind cut, quotient interval, host-real equality, open-cover compactness witness, or completeness datum.

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket regular window seal handoff`

Proof. Project the accepted packet through Definition 306.1. The available rows are exactly the finite endpoint, width, order, midpoint, radius, hsame, Cont, Pkg, and NameCert coordinates, with no completion-side coordinate in the carrier.

Apply Definition 306.2 to the requested regular-stream observation window. Its endpoint narrowing and width-radius readback repack the same finite rows after refinement, so the window source is again a dyadic interval packet rather than a quotient or host-real object.

Finally use Definition 306.7. The $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer boundary can read only the carrier and refinement rows just identified. Hence every regular-window read is exhausted by the finite seal-source rows transported from I. □

Theorem 306.9 (DyadicInterval scoped dependency package)**.** *The carrier of Definition 306.1, endpoint classifier transport, nested-refinement ledger, width-radius ledger exactness,* $\mathsf{Real}^{\uparrow}$ *seal source boundary, and regular-window seal handoff jointly form the scoped dependency package for* $\mathsf{DyadicInterval}^{\uparrow}$*. Its readable rows are exactly the* BHist *endpoint, width, midpoint, radius, order, refinement,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{Int}^{\uparrow}$*, and* $\mathsf{StreamName}^{\uparrow}$*.*

The package exports no Dedekind cut, host real endpoint, quotient interval, open-cover compactness, real-completeness, or standard bridge datum.

Proof. Project the accepted carrier through Definition 306.1. This gives the finite endpoint, width, midpoint, radius, order, refinement, BHist, hsame, Cont, Pkg, and NameCert coordinates, with the arithmetic sources read through the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and $\mathsf{Int}^{\uparrow}$ rows.

Next use Definition 306.5 for endpoint classifier movement, Definition 306.6 for the width-radius row, and Definition 306.2 for finite nested refinement. These results repack the same dyadic endpoint, observation-window, and history rows under displayed hsame and Cont transport.

Finally apply Definition 306.7 and Definition 306.8. The $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumer boundaries read the same finite package through the visible Pkg, NameCert, and $\mathsf{StreamName}^{\uparrow}$ schedule rows.

Since the carrier and the cited handoff rows exhaust every accepted coordinate, there is no source from which a Dedekind cut, host real endpoint, quotient interval, open-cover compactness, real-completeness, or standard bridge datum can enter the scoped dependency package. □

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket scoped dependency package`

Theorem 306.10 (DyadicInterval refined-width enclosure package)**.** *The carrier of Definition 306.1, endpoint classifier transport, nested refinement ledger, width-radius exactness,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and regular-window seal handoff assemble the public* $\mathsf{NameCert}_{\mathsf{DyadicInterval}^{\uparrow}}$ *refined-width enclosure package. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of this package may read only finite endpoint, radius, width, order, refinement,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The package exports no Dedekind cut, host real endpoint, quotient interval, open-cover compactness witness, completeness datum, or standard bridge datum.

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket refined width enclosure package`
↪ variant `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket refined width radius transport`

Proof. Project an accepted public certificate through Definition 306.1. The carrier exposes the finite dyadic endpoint rows, midpoint, width, radius, order, BHist, hsame, Cont, Pkg, and NameCert coordinates, and it has no coordinate for a host real endpoint or a quotient interval.

Next read the certificate rows through Definition 306.4. Its endpointwise classifier and order clauses are the public naming tests for the carrier, so they add no object beyond the displayed finite endpoint and order ledgers.

Apply Definition 306.2, Definition 306.5, and Definition 306.6. These results transport and refine the same endpoint, width, radius, order, hsame, and Cont rows, with exact width-radius readback inside the dyadic packet.

Finally apply Definition 306.7 and Definition 306.8. The $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ boundaries read only the finite package just identified: endpoint, radius, width, order, refinement, hsame, Cont, Pkg, and NameCert rows.

The cited projections exhaust the public refined-width package. Since none of those projections supplies Dedekind cuts, host real endpoints, open-cover compactness, quotient intervals, completeness data, or standard bridge data, no consumer-facing interval certificate can export such a row. □

Theorem 306.11 (DyadicInterval public RegSeq Real bridge)**.** *The public refined-width enclosure package of Definition 306.10 bridges to every finite* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *observation-window consumer by exposing exactly dyadic endpoint rows, radius rows, width rows, order rows, nested refinement transport, endpoint classifier transport, width-radius exactness,* $\mathsf{StreamName}^{\uparrow}$ *schedule provenance,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The bridge surface exports no Dedekind cuts, host real endpoints, quotient intervals, open-cover compactness, real completeness, or standard bridge data.

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket public regseq real bridge`

Proof. Project the package through Definition 306.1. The carrier contains the finite dyadic endpoint, radius, width, order, BHist, hsame, Cont, Pkg, and NameCert coordinates, and no Dedekind-cut, host-real, quotient-interval, compactness, completeness, or standard-bridge coordinate.

Apply Definition 306.2 to transport the finite endpoint and width rows along the observation-window refinement ledger. Use Definition 306.5 for endpoint classifier movement and Definition 306.6 for the exact width-radius row.

Next read the consumer boundary through Definition 306.7 and Definition 306.8. These theorems attach the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ finite-window reads to the same $\mathsf{StreamName}^{\uparrow}$ schedule provenance and the same dyadic packet rows.

Finally repack the rows using Definition 306.10. The consumer bridge is therefore only the finite readback package just listed, so none of the excluded standard interval or real-completeness data is available. □

Theorem 306.12 (DyadicInterval standard interval bridge boundary)**.** *The standard interval-analysis reading of a public* $\mathsf{DyadicInterval}^{\uparrow}$ *refined-width enclosure may consume exactly the finite endpoint, radius, width, order, nested-refinement, endpoint-transport, width-radius exactness,* $\mathsf{Real}^{\uparrow}/\mathsf{RegSeqRat}^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and* NameCert *rows isolated by Definition 306.10. It may not read Dedekind cuts, quotient intervals, host real endpoints, open-cover compactness, real completeness, or external interval libraries.*

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket standard interval bridge boundary`

Proof. Project the enclosure through Definition 306.1. This gives the finite endpoint, radius, width, order, hsame, Cont, Pkg, and NameCert coordinates, with no coordinate for a host real endpoint, Dedekind cut, or quotient interval.

Use Definition 306.2 for the finite refinement rows, Definition 306.5 for endpoint transport, and Definition 306.6 for the exact width-radius readback. These rows keep the interval-analysis data inside the same dyadic packet.

Finally apply Definition 306.7, Definition 306.8, and Definition 306.10. The public refined-width theorem already exhausts the rows readable by $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumers, so a standard interval-analysis bridge has only the finite rows listed above. □

Theorem 306.13 (DyadicInterval regular-window bridge boundary)**.** *The refined-width package of Definition 306.10, together with the nested-refinement ledger, width-radius exactness row,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and regular-window seal handoff, forms the paper bridge from finite* $\mathsf{DyadicInterval}^{\uparrow}$ *packets to* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *finite observation windows. The consumer-visible rows are exactly endpoint, radius, width, order, refinement,* hsame*,* Cont*,* Pkg*,* NameCert*, and* $\mathsf{StreamName}^{\uparrow}$ *schedule rows.*

The bridge boundary still excludes Dedekind cuts, quotient intervals, host real endpoints, open-cover compactness, real completeness, and standard bridge data.

Lean4 ✓ `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket regular window bridge boundary`

Proof. Project the public package through Definition 306.10. This exposes the finite endpoint, radius, width, order, refinement, hsame, Cont, Pkg, and NameCert rows, while withholding host endpoints, quotient intervals, Dedekind cuts, compactness witnesses, completeness data, and standard bridge rows.

Next apply Definition 306.2 and Definition 306.6. These projections identify the refinement row and the exact width-radius readback as rows already present in the dyadic packet rather than as external real-analysis structure.

Finally use Definition 306.7 and Definition 306.8. They attach the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ finite-window reads to the same $\mathsf{StreamName}^{\uparrow}$ schedule rows and exhaust every row available at the seal boundary.

The cited projections account for every consumer-visible coordinate. Since no named component contains any of the excluded data, the paper bridge has exactly the finite regular-window surface stated above. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicInterval}^{\uparrow}}$**.**

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicInterval}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public refined-width enclosure package is exactly the finite BHist interval carrier, endpoint-wise classifier, endpoint-order ledger, nested-refinement transport, endpoint transport, width-radius exactness row, and $\mathsf{Real}^{\uparrow}/\mathsf{RegSeqRat}^{\uparrow}$ seal boundary over $\mathsf{DyadicRatCore}^{\uparrow}$.

Constructive story: Construct the interval packet by finite dyadic endpoint reads: $\mathsf{DyadicRatCore}^{\uparrow}$ supplies endpoints and arithmetic ledgers, the order and width rows record finite bounds, and refinement repacks the same visible rows for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicInterval}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.DyadicIntervalUp.DyadicIntervalPacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Dedekind cuts, open-cover compactness, real completeness, quotient intervals, or standard bridge data.

Upgrade path: No further paper theory-axis step is claimed for this chapter; formal bridge verification remains a separate status.

Chapter 307

A Concrete Naming Certificate for $\mathsf{Riccati}^{\uparrow}$

The $\mathsf{Riccati}^{\uparrow}$ interface records the finite control-theory ledger used by finite-horizon regulator and filtering certificates. Its textbook object is the Riccati recursion for linear-quadratic control and covariance propagation, as in Lancaster and Rodman, *The Algebraic Riccati Equation* (1995), or Anderson and Moore, *Optimal Control: Linear Quadratic Methods* (1990). The BEDC certificate is only the named finite packet consumed by $\mathsf{LQR}^{\uparrow}$ and $\mathsf{KalmanFilter}^{\uparrow}$.

The Riccati packet reads its matrix rows through chapter 49, its vector-space rows through chapter 47, its real-scalar rows through chapter 38, and its dynamic-system rows through chapter 195. Its downstream readers are chapter 296 and chapter 5102.

Definition 307.1 (RiccatiUp control packet carrier)**.** *A* $\mathsf{Riccati}^{\uparrow}$ *carrier is a finite* BHist *packet whose displayed rows are matrix state rows, matrix control rows, symmetric quadratic-cost rows, a finite horizon unary index, Riccati value-row ledger entries, backward* Cont *routes from each successor value row to the preceding value row,* hsame *transports for the state, control, cost, horizon, and value rows, and* Pkg *provenance naming* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{LQR}^{\uparrow}$*, and* $\mathsf{KalmanFilter}^{\uparrow}$*.*

The classifier accepts exactly the packets whose finite value-row ledger is read through these displayed matrix, vector-space, real-scalar, dynamic-system, continuation, transport, and provenance rows. It exports no host analytic operator equation, infinite-horizon limit, stabilizing solution, or external solver state.

Theorem 307.2 (RiccatiUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ *obligation surface has five rows:*

1. *the carrier row of Definition 307.1;*
2. *the classifier row accepting exactly the finite Riccati value-ledger packets with displayed* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DynSystem}^{\uparrow}$ *sources;*
3. *the stability row saying componentwise* hsame *transport of state, control, symmetric-cost, horizon, value,* Cont*, and* Pkg *rows remains inside the same carrier surface;*
4. *the finite ledger-closure row saying each backward value step consumes only the displayed successor value, transition, control, symmetric-cost, horizon, continuation, and provenance rows;*
5. *the consumer-boundary row saying* $\mathsf{LQR}^{\uparrow}$ *and* $\mathsf{KalmanFilter}^{\uparrow}$ *may read only the displayed finite Riccati rows and cannot demand an algebraic infinite-horizon equation or external solver from the certificate.*

Lean4 ✓ `BEDC.Derived.RiccatiUp.RiccatiControlPacketCarrier component transport`

Proof. Construct the surface by enumerating the finite carrier coordinates. The carrier row supplies the visible state, control, symmetric-cost, horizon, value, continuation, transport, and provenance fields.

The classifier is the same finite membership test restricted to those rows. Transport stability follows by replacing each visible row by its hsame match and reassembling the packet with the same horizon index and provenance names.

For ledger closure, inspect one backward horizon position. Its predecessor value row is generated from the displayed successor value, transition, control, symmetric-cost, continuation, and package rows, so no host Riccati equation or solver coordinate is available.

The consumer boundary is then a projection statement. $\mathsf{LQR}^{\uparrow}$ reads the finite value recursion as its dynamic-programming ledger, while $\mathsf{KalmanFilter}^{\uparrow}$ reads the covariance-style matrix ledger; both reads are confined to the displayed BHist coordinates. □

Theorem 307.3 (RiccatiUp finite ledger step closure)**.** *In an accepted* $\mathsf{Riccati}^{\uparrow}$ *packet, every finite backward ledger step is a* Cont *row from the displayed successor value row, state-transition row, control row, symmetric-cost row, finite horizon row, and* Pkg *provenance to the displayed predecessor value row. No accepted step reads an unlogged analytic value function, limiting algebraic Riccati solution, or external solver state.*

Lean4 ✓ `BEDC.Derived.RiccatiUp.RiccatiControlPacket finite ledger step closure`

Proof. Fix a backward position in the finite horizon unary index. By Definition 307.1, the only rows available at that position are the successor value row, transition and control rows, symmetric-cost row, continuation row, transport rows, and provenance rows.

The classifier in Definition 307.2 accepts the predecessor row only when it is assembled from those displayed coordinates. Since the carrier has no coordinate for a limiting solution or solver state, such data cannot contribute to the accepted step. □

Theorem 307.4 (RiccatiUp LQR and Kalman consumer boundary)**.** *Every* $\mathsf{LQR}^{\uparrow}$ *or* $\mathsf{KalmanFilter}^{\uparrow}$ *consumer of* $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ *may read only the finite value-row ledger, covariance-style matrix rows, horizon rows,* hsame *transports,* Cont *routes, and* Pkg *provenance of Definition 307.1. It cannot infer an infinite-horizon algebraic Riccati limit, a stabilizing solution theorem, or an external numerical solver from the* $\mathsf{Riccati}^{\uparrow}$ *certificate alone.*

Lean4 ✓ `BEDC.Derived.RiccatiUp.RiccatiControlPacket lqr kalman consumer boundary`

Proof. Read the consumer as a projection from the accepted carrier. The $\mathsf{LQR}^{\uparrow}$ side projects the state, control, symmetric-cost, horizon, and value-ledger rows needed for finite dynamic programming.

The $\mathsf{KalmanFilter}^{\uparrow}$ side projects the covariance-style matrix value ledger, transport rows, continuation rows, and provenance rows. These are the same finite BHist coordinates, interpreted by the filtering packet as prediction-update covariance data.

All remaining objects named in the theorem are absent from the carrier. Hence they are not readable through the $\mathsf{Riccati}^{\uparrow}$ certificate. □

Theorem 307.5 (RiccatiUp state-space control dependency)**.** *Every accepted* $\mathsf{Riccati}^{\uparrow}$ *finite value ledger must first read the state-transition and control rows through chapter 329. Only after those*

rows are displayed may $\mathsf{LQR}^{\uparrow}$ *and* $\mathsf{KalmanFilter}^{\uparrow}$ *consumers read the finite value and covariance-style rows through chapter 296 and chapter 5102. The dependency introduces no solver row and no infinite-horizon row.*

Proof. Project the carrier of Definition 307.1. Its visible fields include matrix state rows, matrix control rows, symmetric-cost rows, a finite horizon row, value ledger entries, continuation rows, transports, and provenance.

The state and control fields are the state-space read. They are therefore consumed through chapter 329 before any downstream regulator or filter view can read the value ledger.

The $\mathsf{LQR}^{\uparrow}$ consumer then reads the finite cost, horizon, control, and value rows through chapter 296. The $\mathsf{KalmanFilter}^{\uparrow}$ consumer reads the covariance-style matrix value rows through chapter 5102.

All three reads are projections from the same finite packet. Since the carrier has no solver coordinate and no infinite-horizon coordinate, the dependency row records only the displayed state-space, control, value, and covariance ledger. □

Theorem 307.6 (RiccatiUp seed NameCert surface)**.** *The carrier of Definition 307.1, together with the obligation surface of Definition 307.2, the finite ledger step closure of Definition 307.3, and the consumer boundary of Definition 307.4, forms the seed* $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ *surface over* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{LQR}^{\uparrow}$*,* $\mathsf{KalmanFilter}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* Pkg*.*

Proof. Assemble the carrier and obligation rows first. The carrier names every row that can be exported, and the obligation surface supplies the classifier, transport, ledger, and consumer-boundary fields.

Apply the finite ledger step closure to each horizon position in the unary index. Each backward row is therefore a displayed continuation between finite value rows with visible matrix, cost, horizon, and provenance inputs.

Finally, apply the LQR and Kalman consumer boundary. The resulting $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ surface is exactly the displayed packet and has no field for an infinite-horizon algebraic Riccati limit or an external solver. □

Theorem 307.7 (RiccatiUp finite horizon tail restriction)**.** *Let P be an accepted* $\mathsf{Riccati}^{\uparrow}$ *packet and let T be a displayed tail of its finite unary horizon. Restricting P to T repacks the same matrix state rows, matrix control rows, symmetric-cost rows, value ledger, backward* Cont *routes,* hsame *transports, and* Pkg *provenance over the tail horizon. Every* $\mathsf{LQR}^{\uparrow}$ *or* $\mathsf{KalmanFilter}^{\uparrow}$ *consumer of the restricted packet factors through these displayed rows. The restricted packet exports no infinite-horizon algebraic Riccati limit, stabilizing solution theorem, or external solver.*

Lean4 ✓ `BEDC.Derived.RiccatiUp.RiccatiControlPacketCarrier finite horizon tail restriction`

Proof. Apply Definition 307.2 to the accepted packet. The carrier, classifier, stability, ledger, and consumer-boundary rows are already listed as finite BHist coordinates with a unary horizon index.

Restrict to the displayed tail by projecting the horizon positions and keeping the same state, control, symmetric-cost, value, continuation, transport, and provenance coordinates on those positions. The classifier row from the obligation surface accepts the restricted packet because it is assembled from the same displayed finite coordinates.

Use Definition 307.3 for each retained backward position. Each predecessor value row is still generated only from the displayed successor value, transition, control, symmetric-cost, continuation, horizon, and package rows, so tail restriction does not introduce a new ledger source.

Finally apply Definition 307.4. The $\mathsf{LQR}^{\uparrow}$ and $\mathsf{KalmanFilter}^{\uparrow}$ consumers of the restricted packet can read only the displayed tail rows just described. Since the carrier has no coordinate for an infinite-horizon algebraic Riccati limit, a stabilizing solution theorem, or an external solver, none of those objects is exposed by the restricted packet. □

Theorem 307.8 (RiccatiUp public finite-ledger certificate)**.** *The carrier of Definition 307.1, the obligation surface of Definition 307.2, the finite ledger step closure of Definition 307.3, the LQR and Kalman consumer boundary of Definition 307.4, the seed NameCert surface of Definition 307.6, and the finite horizon tail restriction of Definition 307.7 assemble the public* $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ *certificate over* $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, BHist, hsame, Cont, *and* Pkg.

The certificate exposes only the finite control ledger. It exports no infinite-horizon algebraic Riccati limit, stabilizing solution theorem, convergence rate, or external solver.

Proof. Start with the seed surface of Definition 307.6. It packages the carrier, classifier, finite value ledger, component transport, and consumer boundary as the visible finite $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$ packet.

Apply the tail restriction of Definition 307.7. The same displayed matrix, vector-space, real-scalar, dynamic-system, continuation, transport, and provenance rows remain stable under the finite horizon views that downstream consumers may request.

Finally use the LQR and Kalman consumer boundary of Definition 307.4. It identifies the public consumers and excludes infinite-horizon limits, stabilizing solution theorems, convergence data, and external solvers. Repacking these displayed rows gives the stated public certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$**.**

Constructive story: A Riccati row is seeded by a finite BHist packet of matrix state and control rows, symmetric-cost rows, a finite horizon unary index, value-row ledger entries, backward Cont routes, hsame transports, and Pkg provenance naming $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, and $\mathsf{KalmanFilter}^{\uparrow}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public Riccati finite-ledger export is scoped by the component-transport, finite-ledger-step, $\mathsf{LQR}^{\uparrow}$/$\mathsf{KalmanFilter}^{\uparrow}$ consumer-boundary, finite-horizon tail-restriction, and public certificate rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Riccati}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RiccatiUp.RiccatiControlPacketCarrier\_component\_transport`

Bridge status: none

Origin: human

Not claimed: This chapter does not close infinite-horizon algebraic Riccati limits, stabilizing solution theorems, convergence rates, or external solvers.

Upgrade path: Only a separate standard bridge verification target can raise the independent formal bridge status.

Chapter 308

A Concrete Naming Certificate for $\mathsf{CofibrantReplacement}^{\uparrow}$

The $\mathsf{CofibrantReplacement}^{\uparrow}$ interface names the finite model-category row that displays one cofibrant replacement witness for one object. Hovey's *Model Categories* treats cofibrant replacement as a standard model-category construction; the BEDC surface below records only a finite displayed factorization packet, not a selection of replacements for every object.

The dependency boundary is $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{SimplicialSet}^{\uparrow}$, $\mathsf{Homotopy}^{\uparrow}$, and $\mathsf{Cat}^{\uparrow}$. The model-category row supplies cofibration, weak-equivalence, and factorization surfaces; the simplicial-set row supplies a concrete displayed source family when the model surface is read in that setting; the homotopy row records the weak-equivalence ledger; and the category row supplies the object and arrow typing rows.

The factorization row is consumed concretely through chapter 158: $\mathsf{ModelCat}^{\uparrow}$ supplies the cofibration, weak-equivalence, and factorization faces that the $\mathsf{CofibrantReplacement}^{\uparrow}$ packet repackages as one displayed witness, without a global replacement choice or homotopy-category quotient.

308.1 Finite factorization source

Definition 308.1 (CofibrantReplacement BHist source)**.** *A* $\mathsf{CofibrantReplacement}^{\uparrow}$ *source is a finite* BHist *packet*

$$(X, Q, i, p, F, \rho, \lambda)$$

whose visible rows have the following shape:

1. *X is the displayed object row read from* $\mathsf{ModelCat}^{\uparrow}$ *and typed through* $\mathsf{Cat}^{\uparrow}$*;*
2. *Q is the displayed cofibrant object row over the same model-category surface;*
3. *$i : Q \to X$ is the displayed arrow row whose model-category ledger marks it as a cofibration and as a weak equivalence;*
4. *p is the factorization provenance row recording the finite factorization step that produced Q and i;*
5. *F is a finite list of lifting-test rows attached to the displayed cofibration face;*
6. *ρ is the package row naming the* $\mathsf{ModelCat}^{\uparrow}$*,* $\mathsf{SimplicialSet}^{\uparrow}$*,* $\mathsf{Homotopy}^{\uparrow}$*, and* $\mathsf{Cat}^{\uparrow}$ *dependency certificates used by the packet;*

7. *λ is the continuation ledger that records the* Cont *routes and componentwise* hsame *comparisons used to read the packet downstream.*

The carrier predicate accepts exactly such packets. Its classifier compares accepted packets componentwise by the object, cofibrant-object, arrow, factorization, lifting-test, package, and continuation-ledger hsame *rows, and it does not identify replacements by a homotopy-category quotient.*

308.2 Certificate obligations

Theorem 308.2 (CofibrantReplacement factorization obligation)**.** *Every accepted* $\mathsf{CofibrantReplacement}^{\uparrow}$ *source exposes a finite factorization row over* $\mathsf{ModelCat}^{\uparrow}$*: the displayed object X, the displayed cofibrant object Q, the arrow $i : Q \to X$, the cofibration ledger for i, the weak-equivalence ledger for i, and the provenance row p that records this factorization as part of the displayed model-category surface.*

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementBHistSource factorization obligation`

Proof. Project the source packet of Definition 308.1. The first four coordinates are exactly X, Q, i, and p, and the arrow coordinate is stored with both model-category marks.

The category typing of the arrow is read through the $\mathsf{Cat}^{\uparrow}$ rows named in ρ. The model-category marks are read through the $\mathsf{ModelCat}^{\uparrow}$ row, while the provenance coordinate records that these rows come from a finite factorization step.

Since the carrier has no coordinate for a family of replacements, the obligation is exhausted by the displayed packet for this one object. □

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementBHistSource factorization readback`

Theorem 308.3 (CofibrantReplacement weak-equivalence ledger)**.** *In an accepted* $\mathsf{CofibrantReplacement}^{\uparrow}$ *source, every weak-equivalence read of $i : Q \to X$ factors through the finite homotopy and model-category ledger carried by the tuple $(X, Q, i, p, F, \rho, \lambda)$. Transporting the packet along its displayed* hsame *rows preserves the weak-equivalence ledger and introduces no localization, derived mapping space, or homotopy-category quotient.*

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementPacket weak equivalence ledger transport`

Proof. Read the arrow coordinate i in Definition 308.1. Its weak-equivalence mark is one of the displayed rows of the accepted packet, and ρ names the $\mathsf{Homotopy}^{\uparrow}$ and $\mathsf{ModelCat}^{\uparrow}$ certificates through which that mark is interpreted.

Transport uses the componentwise hsame comparisons stored in λ. These comparisons carry the source object, cofibrant object, arrow row, and weak-equivalence mark together, so the target packet reads the same weak-equivalence ledger.

No localization or quotient row is available in the source tuple. Therefore all weak-equivalence information remains inside the displayed finite ledger. □

Theorem 308.4 (CofibrantReplacement NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{CofibrantReplacement}^{\uparrow}}$ *obligation surface consists of five finite rows: the source carrier of Definition 308.1; the componentwise classifier over X, Q, i, p, F, ρ, and λ; the finite factorization obligation of Definition 308.2;*

the weak-equivalence ledger of Definition 308.3; and the dependency-boundary row over $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{SimplicialSet}^{\uparrow}$, $\mathsf{Homotopy}^{\uparrow}$, *and* $\mathsf{Cat}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementNameCertObligationSurface dependency transport`

Proof. The carrier and classifier are the two direct projections of the source definition. They list the accepted finite packets and the componentwise comparison relation used between them.

The factorization row is supplied by Definition 308.2. It records the object, cofibrant object, arrow, cofibration mark, weak-equivalence mark, and factorization provenance.

The weak-equivalence row is supplied by Definition 308.3. The remaining dependency-boundary row is the package coordinate ρ, which names exactly the four certificates used by the construction. □

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementBHistSource namecert obligation surface`

Theorem 308.5 (CofibrantReplacement dependency boundary)**.** *Any consumer of* $\mathsf{NameCert}_{\mathsf{CofibrantReplacement}^{\uparrow}}$ *may read only the displayed* $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{SimplicialSet}^{\uparrow}$, $\mathsf{Homotopy}^{\uparrow}$, *and* $\mathsf{Cat}^{\uparrow}$ *dependency rows, the factorization packet* $(X, Q, i, p, F, \rho, \lambda)$*, and the associated* hsame, Cont, Pkg, *and* NameCert *provenance. The packet does not export functorial cofibrant replacement, a global replacement assignment, localization data, derived-category objects, or homotopy-category quotients.*

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementPacket dependency boundary`
Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementBHistSource dependency boundary`

Proof. Project the package coordinate ρ. It names precisely the model-category, simplicial-set, homotopy, and category certificates used by the source.

Project the continuation ledger λ. It contains the visible Cont routes and componentwise hsame rows by which downstream consumers may transport the factorization packet.

All excluded objects require coordinates absent from the source tuple. A consumer can therefore read the single displayed factorization witness but cannot promote it to a functor, a global assignment, a localization, or a quotient category. □

Theorem 308.6 (CofibrantReplacement scoped kernel dependency package)**.** *Every accepted finite* $\mathsf{CofibrantReplacement}^{\uparrow}$ *factorization packet* $(X, Q, i, p, F, \rho, \lambda)$ *exposes its consumer-readable scope exactly through the displayed* BHist *packet rows, componentwise* hsame *comparisons, visible* Cont *routes, the dependency package* ρ*, and the local* NameCert *surface over* $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{SimplicialSet}^{\uparrow}$, $\mathsf{Homotopy}^{\uparrow}$, *and* $\mathsf{Cat}^{\uparrow}$.

The scoped package exports no global choice of replacements, functorial replacement operation, localization, derived mapping space, or homotopy-category quotient.

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementBHistSource scoped kernel dependency package`

Proof. Project the dependency package ρ and the continuation ledger λ. These coordinates name the four dependency certificates and the visible routes by which the finite packet may be transported componentwise.

Apply Definition 308.2 to read the object row X, the cofibrant object row Q, the arrow i, the factorization provenance p, and the finite lifting-test row F as displayed packet data. Apply

Definition 308.3 to keep the weak-equivalence read of i inside the same homotopy and model-category ledger.

Finally use Definition 308.5. It identifies the consumer boundary with the factorization packet, ρ, λ, and their visible provenance over the four named dependencies.

Since the source tuple contains no coordinate for a global replacement function, a functorial assignment, a localization, a derived mapping object, or a homotopy-category quotient, none of those objects can be exported by the scoped package. □

Theorem 308.7 (CofibrantReplacement five-row NameCert sketch)**.** *The* $\mathsf{CofibrantReplacement}^{\uparrow}$ *source supplies the five expected* NameCert *checks at the displayed finite boundary:*

1. *carrier inhabitance is witnessed by a displayed finite factorization row* $(X, Q, i, p, F, \rho, \lambda)$*;*
2. *classifier reflexivity, symmetry, and transitivity are componentwise* hsame *checks on* X*,* Q*,* i*,* p*,* F*,* ρ*, and* λ*;*
3. *carrier transport along the factorization ledger repacks the same object, cofibrant-object, arrow, factorization, and lifting-test rows;*
4. *weak-equivalence ledger stability follows from the transported* $\mathsf{Homotopy}^{\uparrow}$ *and* $\mathsf{ModelCat}^{\uparrow}$ *rows for* i*;*
5. *dependency-boundary non-leakage follows because* ρ *names only* $\mathsf{ModelCat}^{\uparrow}$*,* $\mathsf{SimplicialSet}^{\uparrow}$*,* $\mathsf{Homotopy}^{\uparrow}$*, and* $\mathsf{Cat}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.CofibrantReplacementUp.CofibrantReplacementPacket five row namecert surface`

Proof. For carrier inhabitance, use the displayed finite factorization row itself. It supplies the object, cofibrant object, arrow, factorization provenance, lifting tests, package row, and continuation ledger.

For the classifier, compare accepted packets componentwise. Reflexivity, symmetry, and transitivity are exactly the corresponding hsame moves on each coordinate, repacked into the tuple classifier.

For transport, follow the continuation ledger λ. It carries each coordinate of the factorization row through the displayed routes and repacks the target tuple with the same shape.

The weak-equivalence and dependency claims are the two boundary projections of the transported packet. The weak-equivalence mark remains attached to i through the $\mathsf{Homotopy}^{\uparrow}$ and $\mathsf{ModelCat}^{\uparrow}$ rows, and ρ contains no dependency certificate beyond the four named rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{CofibrantReplacement}^{\uparrow}}$**.**

Constructive story: A cofibrant-replacement packet is generated by displaying one object row X, one cofibrant object row Q, one arrow $i : Q \to X$ marked as a cofibration and weak equivalence, one factorization provenance row, finite lifting tests, dependency certificates, and continuation routes.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CofibrantReplacement}^{\uparrow}}$, publicClosed)

Scope closed: The scoped boundary binds the finite factorization packet, weak-equivalence ledger, dependency package, and scoped kernel dependency theorem over BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CofibrantReplacement}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close functorial cofibrant replacement, global choice of replacements, localization, derived mapping spaces, or homotopy category quotients.

Upgrade path: Bridge closure requires a standard bridge boundary for the displayed cofibrant-replacement packet.

Chapter 309

A Locatedness Route Surface for $\mathsf{LocatedReal}^{\uparrow}$

The $\mathsf{LocatedReal}^{\uparrow}$ surface names constructive located real-name packets between $\mathsf{RegSeqRat}^{\uparrow}$ and later metric or topological real constructions. Following the Bishop–Bridges constructive-analysis treatment of located real data, the chapter keeps interval endpoints, radii, and observation schedules as visible finite rows; it does not identify real names by a quotient or by host real equality.

Theorem 309.1 (LocatedReal L10 sibling dependency route)**.** *The concrete* $\mathsf{LocatedReal}^{\uparrow}$ *carrier route passes through the finite* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-sequence source of chapter 301, the finite* $\mathsf{StreamName}^{\uparrow}$ *observation schedule of chapter 126, the* DyadicRatCore *endpoint and radius ledger of chapter 291, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary of chapter 38.*

Thus every public $\mathsf{LocatedReal}^{\uparrow}$ *consumer receives only this finite L10 route: scheduled regular rational windows, dyadic endpoint and radius rows, enclosure evidence, and visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The route contains no quotient real, host equality, trichotomy, open-cover compactness, or completion datum.*

Proof. Project the carrier surface of Definition 309.2. Its first and third components identify the $\mathsf{RegSeqRat}^{\uparrow}$ source and the $\mathsf{StreamName}^{\uparrow}$ schedule as the only route by which a located real packet reads regular rational observations.

The second component and the locatedness classifier identify the DyadicRatCore ledger as the only source of dyadic endpoints, dyadic radii, and enclosure rows. Therefore every locatedness read factors through the displayed finite endpoint/radius ledger rather than through a completed real object.

Finally apply the $\mathsf{Real}^{\uparrow}$ seal compatibility row of Definition 309.5. It keeps the public handoff at the finite source-and-ledger surface, so downstream consumers receive exactly the L10 route stated above and none of the excluded quotient, equality, order-decision, compactness, or completion structure. □

309.1 Carrier and classifier

Definition 309.2 (LocatedReal carrier surface)**.** *A* $\mathsf{LocatedReal}^{\uparrow}$ *packet consists of four displayed components:*

1. *a* $\mathsf{RegSeqRat}^{\uparrow}$ *real-name source carrying the scheduled regular rational stream, dyadic-radius rows, regularity ledgers, and finite-window transport provenance;*

2. *a* DyadicRatCore *interval ledger naming dyadic endpoint pairs* (a_r, b_r) *for each displayed radius row* r*;*
3. *a* StreamName$^{\uparrow}$ *finite-observation schedule naming the finite rows at which the regular-sequence window is read;*
4. *a locatedness classifier which, for every displayed dyadic radius row, records a certified endpoint pair enclosing the current regular-sequence window.*

The enclosure row says that each endpoint read selected by the schedule lies inside the displayed dyadic interval for that radius, with the two endpoints read through the same DyadicRatCore *ledger and the same* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The packet stores only these finite rows. It contains no Dedekind cut, quotient real, trichotomy decision, open-cover compactness datum, or host real equality.

Theorem 309.3 (LocatedReal dyadic interval obligation)**.** *The local interval obligation for a* LocatedReal$^{\uparrow}$ *packet is the finite row that, for every displayed dyadic radius, exposes the* StreamName$^{\uparrow}$ *schedule row, the current* RegSeqRat$^{\uparrow}$ *regular-sequence window, the two* DyadicRatCore *endpoint rows, and the enclosure ledger proving that all displayed window endpoints lie between them.*

The obligation is exhausted by these dyadic endpoint, radius, schedule, regularity, hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Project the carrier surface of Definition 309.2. The schedule determines the finite regular-sequence window, and the interval ledger determines the displayed dyadic endpoint pair for the requested radius.

The locatedness classifier is a finite enclosure row over those same projections. Reading it at the selected radius gives exactly the endpoint pair and the proof that every displayed regular-sequence endpoint lies in the interval.

Since the carrier has no coordinate for a cut, quotient, trichotomy decision, compactness cover, or host real equality, no further row can be read by the interval obligation. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface dyadic interval obligation`

Theorem 309.4 (LocatedReal RegSeqRat classifier stability)**.** *Let* L *and* L' *be accepted* LocatedReal$^{\uparrow}$ *packets whose* RegSeqRat$^{\uparrow}$ *sources are related by the dyadic-tolerance classifier and whose finite-observation schedules, interval endpoint ledgers, and enclosure rows are transported componentwise by* hsame *and the displayed* Cont *routes. Then the locatedness classifier of* L *transports to the locatedness classifier of* L' *on every displayed dyadic radius row.*

The transported classifier reads only the scheduled RegSeqRat$^{\uparrow}$ *windows, the* DyadicRatCore *endpoint ledgers, and the visible provenance rows.*

Proof. Start with a displayed radius row of L. The carrier projection gives a finite StreamName$^{\uparrow}$ window and a certified dyadic endpoint pair enclosing the selected RegSeqRat$^{\uparrow}$ observations.

Transport the regular-sequence window along the stated RegSeqRat$^{\uparrow}$ classifier row. Transport the endpoint pair and radius ledger along the componentwise hsame rows, using the displayed Cont routes to keep the finite schedule aligned.

Repack the transported endpoint pair with the transported regular-sequence observations. The same finite enclosure row now witnesses the locatedness classifier for L' at that radius, and the construction has used only rows already named in the two packets. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface regseqrat classifier stability`

Theorem 309.5 (LocatedReal RealUp seal compatibility)**.** *Every accepted* $\mathsf{LocatedReal}^{\uparrow}$ *packet presents a* $\mathsf{Real}^{\uparrow}$ *seal-compatible source surface by forgetting only the locatedness interval rows and retaining the underlying* $\mathsf{RegSeqRat}^{\uparrow}$ *real-name source,* $\mathsf{StreamName}^{\uparrow}$ *schedule, dyadic-radius observations, regularity ledgers, finite-window transport rows, and provenance.*

Conversely, the locatedness rows may be attached to such a $\mathsf{Real}^{\uparrow}$ *seal source only as finite dyadic endpoint enclosures over the already displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *windows; they do not add a completed real object or an equality principle for real names.*

Proof. Use the $\mathsf{RegSeqRat}^{\uparrow}$ component of the carrier surface. It already contains the scheduled stream carrier, dyadic-radius rows, regularity ledger, classifier source rows, and finite-window transport provenance consumed at the $\mathsf{Real}^{\uparrow}$ seal boundary.

Forgetting the interval ledger and locatedness classifier leaves exactly that source surface. No seal consumer can read the forgotten rows, because the retained source has no coordinate for interval endpoints beyond the dyadic observations carried by $\mathsf{RegSeqRat}^{\uparrow}$.

For the converse attachment, choose a displayed seal source window and add only the DyadicRatCore endpoint pair and enclosure ledger required by Definition 309.2. This enriches the finite packet with locatedness data while leaving the $\mathsf{Real}^{\uparrow}$ seal source unchanged. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface realup seal compatibility`

Theorem 309.6 (LocatedReal NameCert boundary)**.** *The seed* $\mathsf{NameCert}_{\mathsf{LocatedReal}^{\uparrow}}$ *obligation sketch consists of five rows:*

1. *carrier inhabitance is witnessed by a constant dyadic* $\mathsf{StreamName}^{\uparrow}$ *stream whose* $\mathsf{RegSeqRat}^{\uparrow}$ *source is the constant regular sequence and whose interval ledger uses the same endpoint on both sides;*
2. *classifier reflexivity, symmetry, and transitivity are witnessed by interval refinement of displayed dyadic endpoint pairs;*
3. *carrier transport along* hsame *repacks the* $\mathsf{RegSeqRat}^{\uparrow}$ *source, schedule, endpoint ledger, and enclosure classifier componentwise;*
4. *ledger exactness says that every interval endpoint used by the locatedness classifier is one of the displayed* DyadicRatCore *endpoint rows;*
5. $\mathsf{Real}^{\uparrow}$ *seal compatibility is the handoff of Definition 309.5.*

The boundary claims neither Dedekind cuts, quotient reals, trichotomy, open-cover compactness, nor host real equality.

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealNameCertBoundary rows`

Proof. For inhabitance, take the constant dyadic stream. Its $\mathsf{StreamName}^{\uparrow}$ schedule reads the same dyadic endpoint at every displayed window, the $\mathsf{RegSeqRat}^{\uparrow}$ regularity ledger is the constant-window ledger, and each located interval can use that endpoint as both sides.

For classifier laws, refine finite interval ledgers. Reflexivity keeps the same endpoint pair, symmetry swaps the two classified packets while keeping the common refinement row, and transitivity composes two finite refinements by taking the displayed common endpoint ledger supplied by DyadicRatCore.

For transport, apply componentwise hsame to the regular-sequence source, observation schedule, endpoint rows, and enclosure classifier. The transported rows satisfy the same finite carrier definition.

Ledger exactness follows by projection from Definition 309.2: every classifier endpoint is drawn from the stored DyadicRatCore interval ledger. The $\mathsf{Real}^{\uparrow}$ seal row is then exactly Definition 309.5, so the five rows form the seed boundary without adding any excluded real-number principle. □

Theorem 309.7 (LocatedReal scoped source boundary)**.** *The scoped* $\mathsf{LocatedReal}^{\uparrow}$ *boundary is exactly the four carrier components of Definition 309.2 together with the dyadic interval obligation, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier-stability row, the* $\mathsf{Real}^{\uparrow}$ *seal-compatibility row, and the* NameCert *boundary rows. All rows are read through* $\mathsf{RegSeqRat}^{\uparrow}$*,* DyadicRatCore*,* $\mathsf{StreamName}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

This scoped boundary contains no Dedekind cut, quotient real, trichotomy decision, open-cover compactness datum, host real equality, or standard bridge.

Proof. Project the carrier definition of Definition 309.2. It exposes exactly the $\mathsf{RegSeqRat}^{\uparrow}$ source, the dyadic interval ledger, the finite observation schedule, and the locatedness classifier.

Apply Definition 309.3 to obtain the endpoint and radius rows. Apply Definition 309.4 to transport the scheduled regular-sequence reads, and apply Definition 309.5 to identify the seal-facing source surface.

Finally apply Definition 309.6 to bind inhabitance, classifier laws, transport, ledger exactness, and seal compatibility to the same displayed provenance. Since the carrier and the cited rows have no coordinate for cuts, quotient reals, trichotomy, compactness, host equality, or a standard bridge, the scoped source boundary exports none of those principles. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface scoped source boundary`

Theorem 309.8 (LocatedReal common refinement gluing)**.** *Let two* $\mathsf{LocatedReal}^{\uparrow}$ *packets be displayed through the carrier surface of Definition 309.2. If their* $\mathsf{StreamName}^{\uparrow}$ *schedules admit a common finite observation window and their* DyadicRatCore *endpoint ledgers transport along the visible* hsame *and* Cont *rows to that window, then the two packets determine one repacked locatedness classifier row over the common window.*

The repacked row uses only the displayed $\mathsf{RegSeqRat}^{\uparrow}$ *source data, the common schedule, the transported dyadic endpoint pairs, the enclosure classifier, and the visible* BHist*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface common refinement tail empty`
Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrier common refinement gluing`

Proof. Project both packets to the surface of Definition 309.2. The hypotheses identify a finite $\mathsf{StreamName}^{\uparrow}$ window receiving the two schedules and give the endpoint transports needed to view both dyadic interval ledgers over that window.

Use Definition 309.3 to keep the transported endpoint pairs inside the displayed DyadicRatCore interval ledger. Use Definition 309.4 to transport the regular-sequence source rows without changing the consumer-visible source surface.

Finally repack the common window, transported endpoint pairs, enclosure classifier, and provenance rows into the locatedness classifier coordinate of Definition 309.2. The repacking does not introduce any host real equality or completion datum, so it yields exactly one classifier row over the displayed common refinement. □

Theorem 309.9 (LocatedReal common-refinement consumer exactness)**.** *Let two accepted* $\mathsf{LocatedReal}^{\uparrow}$ *packets have a common finite* $\mathsf{StreamName}^{\uparrow}$ *observation window and transported* DyadicRatCore

endpoint ledgers as in Definition 309.8. Every later Met$^{\uparrow}$ *or real-order consumer read of their locatedness data factors through the repacked common-window row.*

The consumer can read only the RegSeqRat$^{\uparrow}$ *source, the schedule row, the dyadic endpoint pair, the enclosure classifier, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. It cannot read quotient reals, host real equality, trichotomy, open-cover compactness, metric completion, or standard bridge data.*

Proof. Use Definition 309.8 to repack the two accepted packets over the common finite window. The resulting row has exactly the common schedule, transported endpoint pairs, classifier coordinate, and visible provenance named in the carrier surface.

Apply Definition 309.10 to the endpoint side of the repacked row. This exhausts every dyadic endpoint consumed by the locatedness classifier by projection from the displayed DyadicRatCore interval ledger.

Finally apply Definition 309.11. Its downstream projection bound says that a metric or order consumer reads only the displayed source, schedule, ledger, classifier, and provenance coordinates. Since none of those coordinates contains quotient reals, host real equality, trichotomy, compactness, completion, or standard bridge data, the consumer read is exhausted by the common-window row. □

Theorem 309.10 (LocatedReal interval ledger exactness)**.** *Every dyadic endpoint consumed by the* LocatedReal$^{\uparrow}$ *locatedness classifier is the projection of an endpoint row from the* DyadicRatCore *interval ledger displayed in Definition 309.2.*

Consequently the classifier has no hidden endpoint source beyond the stored dyadic interval ledger, the finite StreamName$^{\uparrow}$ *observation schedule, and the transported* RegSeqRat$^{\uparrow}$ *source rows.*

Proof. Unfold the carrier surface of Definition 309.2. Its locatedness classifier coordinate is attached to the displayed endpoint ledger, so each endpoint read used in a classifier row is obtained by projection from that ledger.

Apply Definition 309.3 to the projected endpoints. The theorem records that the interval rows remain dyadic and are transported through the visible hsame and Cont provenance rather than through an ambient real object.

The stability row of Definition 309.4 accounts for the regular-sequence source data used beside the endpoints. Thus every consumed endpoint is ledger-visible, and no unrecorded endpoint coordinate is available to the classifier. □

Theorem 309.11 (LocatedReal metric consumer handoff)**.** *Any later* Met$^{\uparrow}$ *or real-order consumer of a* LocatedReal$^{\uparrow}$ *packet may read only the* RegSeqRat$^{\uparrow}$ *source, the* StreamName$^{\uparrow}$ *schedule, the dyadic endpoint and radius rows, the enclosure classifier, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Such a consumer cannot read a quotient-real carrier, host real equality, trichotomy decision, open-cover compactness datum, or metric-completion object from the LocatedReal$^{\uparrow}$ *certificate surface.*

```
Lean4 ✓  BEDC.Derived.LocatedRealUp.LocatedRealCarrier metric consumer empty boundary
Lean4 ✓  BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface metric consumer handoff
Lean4 ✓  BEDC.Derived.LocatedRealUp.LocatedRealCarrier metric consumer handoff
```

Proof. Begin with the source projection supplied by Definition 309.5. It identifies the Real$^{\uparrow}$ seal-facing part of the packet with the displayed RegSeqRat$^{\uparrow}$ source, finite schedule, dyadic radius data, and classifier source rows.

Next use Definition 309.10 for endpoint reads and Definition 309.8 for finite-window repacking. These two rows show that all interval and classifier data consumed downstream are already present in the carrier surface and remain stable under common refinements.

The handoff is therefore the projection of the named finite coordinates from Definition 309.2. Since that surface has no coordinate for quotient reals, host equality, trichotomy, compactness, or completion, no later metric or order consumer can extract such data from the certificate. □

Theorem 309.12 (LocatedReal scoped RegSeqRat dyadic window)**.** *Every scoped locatedness read from a* $\mathsf{LocatedReal}^{\uparrow}$ *packet factors through a displayed finite window: a* $\mathsf{RegSeqRat}^{\uparrow}$ *regular rational source window, a* $\mathsf{StreamName}^{\uparrow}$ *schedule row selecting the observations, and a* DyadicRatCore *endpoint ledger naming the dyadic enclosure endpoints. The factorization carries the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance used by the packet.*

Thus the scoped read exposes only finite regular-sequence observations, schedule entries, dyadic endpoint rows, enclosure ledgers, and their named provenance.

Proof. Project the carrier surface of Definition 309.2. It gives the $\mathsf{RegSeqRat}^{\uparrow}$ source, $\mathsf{StreamName}^{\uparrow}$ schedule, DyadicRatCore interval ledger, and locatedness classifier as displayed coordinates.

Apply Definition 309.4 to keep the scheduled regular-sequence reads stable under the visible hsame and Cont transports. Apply Definition 309.10 to identify every consumed endpoint with a stored dyadic ledger row.

Finally use Definition 309.8 to repack the finite window when the consumer asks for a common refinement, and use Definition 309.5 to keep the seal-facing source equal to the same regular rational surface. No coordinate outside the named carrier surface is introduced. □

Theorem 309.13 (LocatedReal scoped carrier transport)**.** *Let L be an accepted* $\mathsf{LocatedReal}^{\uparrow}$ *packet. If its* $\mathsf{RegSeqRat}^{\uparrow}$ *source,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* DyadicRatCore *endpoint ledger, and located enclosure row are transported componentwise by the displayed* hsame *and* Cont *routes, then the transported rows repack as an accepted* $\mathsf{LocatedReal}^{\uparrow}$ *carrier.*

The repacking uses only the transported finite rows and their BHist*,* Pkg*, and* NameCert *provenance; it does not use quotient-real data, host real equality, or an ambient completion object.*

Proof. Unpack L through Definition 309.2. The four carrier coordinates are the regular-sequence source, schedule, endpoint ledger, and locatedness classifier.

Transport the source and classifier by Definition 309.4. Transport the endpoint reads by Definition 309.10, and use Definition 309.8 when the transported schedule is read over a common finite window.

The transported rows satisfy the same carrier definition, so they repack as a $\mathsf{LocatedReal}^{\uparrow}$ packet. The $\mathsf{Real}^{\uparrow}$ seal compatibility of Definition 309.5 shows that the repacked source surface is still finite regular rational data rather than a quotient real or host equality principle. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface scope carrier transport`

Theorem 309.14 (LocatedReal scoped RealUp seal consumer)**.** *A* $\mathsf{Real}^{\uparrow}$ *seal consumer of a scoped* $\mathsf{LocatedReal}^{\uparrow}$ *packet may read exactly the* $\mathsf{RegSeqRat}^{\uparrow}$ *source surface together with the displayed located interval rows. Concretely, it may read the scheduled regular rational windows, dyadic radius and endpoint ledgers, enclosure classifier rows, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

It may not read a Dedekind cut, trichotomy decision, open-cover compactness witness, completion object, quotient-real carrier, or host real equality from the $\mathsf{LocatedReal}^{\uparrow}$ *seal boundary.*

Proof. Apply Definition 309.5. It identifies the seal-facing surface with the displayed $\mathsf{RegSeqRat}^{\uparrow}$ source, finite schedule, dyadic-radius observations, regularity ledgers, and transport provenance.

The additional located rows are bounded by Definition 309.10: every endpoint consumed by the classifier is drawn from the displayed DyadicRatCore ledger. The common-refinement row of Definition 309.8 keeps later reads inside the same finite window surface.

Together with Definition 309.4 and Definition 309.2, these rows exhaust the seal consumer boundary. Since none of the cited surfaces contains cuts, trichotomy, compactness, completion, quotient carriers, or host real equality, the consumer cannot read such data. □

Lean4 ✓ `BEDC.Derived.LocatedRealUp.LocatedRealCarrierSurface scope real seal consumer`

Theorem 309.15 (LocatedReal public RegSeqRat interval handoff)**.** *Every public consumer of* $\mathsf{NameCert}_{\mathsf{LocatedReal}^{\uparrow}}$ *receives a single finite package consisting of the* $\mathsf{RegSeqRat}^{\uparrow}$ *source window, the* $\mathsf{StreamName}^{\uparrow}$ *observation schedule, the* DyadicRatCore *endpoint ledger, the locatedness enclosure row, the* $\mathsf{Real}^{\uparrow}$ *seal handoff, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

No Dedekind cut, quotient real, trichotomy decision, open-cover compactness witness, host real equality, or completion object is exported by this public handoff.

Proof. Use Definition 309.12 to obtain the finite regular-sequence source window, finite schedule row, and dyadic endpoint ledger. The endpoint visibility needed by a public consumer is exactly the ledger projection of Definition 309.10.

Next apply Definition 309.13. It shows that any componentwise transport of the source, schedule, endpoint ledger, and located enclosure rows remains inside the accepted $\mathsf{LocatedReal}^{\uparrow}$ carrier surface, with only displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Finally apply Definition 309.14. The $\mathsf{Real}^{\uparrow}$ seal-facing consumer reads the same finite source and located interval rows, so the public package is the stated single handoff package. The excluded objects have no coordinate in the cited carrier, ledger, transport, or seal-consumer surfaces, hence they are not exported. □

Theorem 309.16 (LocatedReal standard bridge boundary)**.** *A* $\mathsf{LocatedReal}^{\uparrow}$ *packet whose* $\mathsf{RegSeqRat}^{\uparrow}$ *source row,* DyadicRatCore *interval endpoint rows,* $\mathsf{StreamName}^{\uparrow}$ *observation schedule,* $\mathsf{Real}^{\uparrow}$ *seal row, metric handoff row,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance, and classifier-transport rows are exactly the public rows displayed in Definition 309.15 admits the standard bridge surface used by downstream* $\mathsf{LocatedReal}^{\uparrow}$ *consumers.*

Conversely, any such standard bridge packet repacks to the public $\mathsf{LocatedReal}^{\uparrow}$ *boundary without adding quotient reals, trichotomy, open-cover compactness, host real equality, or completion data.*

Proof. First apply Definition 309.6. It binds the carrier, classifier transport, interval obligation, seal compatibility, and certificate provenance to the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 309.11. The metric and order consumer surface can read only the regular rational source, schedule, dyadic endpoint and radius rows, enclosure classifier, and visible provenance. Then apply Definition 309.15 to package those rows with the $\mathsf{Real}^{\uparrow}$ seal handoff as the public boundary.

The reverse direction forgets the bridge wrapper and keeps the same finite rows. The exclusions recorded in the closure status show that quotient reals, trichotomy, open-cover compactness, host real equality, and completion data have no coordinate in the bridge surface, so no off-table object enters during either packing. □

Closure status for $\mathsf{NameCert}_{\mathsf{LocatedReal}^{\uparrow}}$.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LocatedReal}^{\uparrow}}$, maturePackageClosed)

Constructive story: A $\mathsf{LocatedReal}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$ regular rational source window, a $\mathsf{StreamName}^{\uparrow}$ observation schedule, DyadicRatCore endpoint and radius rows, a locatedness enclosure row, $\mathsf{Real}^{\uparrow}$ seal provenance, visible BHist, hsame, Cont, and Pkg routes, and local NameCert rows.

Scope closed: The closed scope is the finite $\mathsf{RegSeqRat}^{\uparrow}$/$\mathsf{StreamName}^{\uparrow}$/DyadicRatCore/$\mathsf{Real}^{\uparrow}$ route through BHist, hsame, Cont, Pkg, and NameCert, covering the carrier surface, dyadic interval obligation, $\mathsf{RegSeqRat}^{\uparrow}$ classifier stability, $\mathsf{Real}^{\uparrow}$ seal compatibility, NameCert boundary, common-refinement gluing, metric consumer handoff, scoped carrier transport, public $\mathsf{RegSeqRat}^{\uparrow}$ interval handoff, and standard bridge boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LocatedReal}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.LocatedRealUp.LocatedRealCarrier\_realup\_regseqrat\_boundary`

Bridge status: paperBridge

Origin: human

Not claimed: The chapter does not close Dedekind cuts, quotient reals, trichotomy, open-cover compactness, host real equality, metric completion, or a checked standard bridge.

Upgrade path: The remaining formal work is bridgeChecked verification for the same finite locatedness route, with no further theory-closure upgrade.

Chapter 310

A Concrete Naming Certificate for $\mathsf{SemidefiniteCone}^{\uparrow}$

The $\mathsf{SemidefiniteCone}^{\uparrow}$ interface names the finite certificate surface used by semidefinite programming over symmetric matrix data. In the external optimization presentation of Boyd–Vandenberghe 2004, the semidefinite cone is read through symmetric matrices whose quadratic form is nonnegative on every vector. The BEDC packet below keeps only the displayed finite rows required to name that surface: matrix rows, vector-space rows, convex-combination ledgers, bilinear-form pairings, order witnesses, and package provenance.

The symmetric-matrix row is read through chapter 49, the vector row through chapter 47, and the convex ledger through chapter 208. Thus $\mathsf{SemidefiniteCone}^{\uparrow}$ is a consumer of those sibling carriers rather than an isolated kernel packet: it binds their displayed matrix, vector, and convex-combination surfaces into the cone certificate while the bilinear-form and order rows remain explicit finite BEDC evidence.

310.1 Carrier packet

Definition 310.1 (SemidefiniteCone carrier packet)**.** *A* $\mathsf{SemidefiniteCone}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$(M, V, C, B, N, P)$$

with the following rows:

1. *M is a symmetric-matrix row read through* $\mathsf{Mat}^{\uparrow}$*;*
2. *V is a vector-space row read through* $\mathsf{VecSpace}^{\uparrow}$ *over the same scalar boundary as M;*
3. *C is a convex-combination ledger from* $\mathsf{ConvexSet}^{\uparrow}$ *for displayed matrix rows;*
4. *B is a bilinear-form pairing row from* $\mathsf{BilinForm}^{\uparrow}$ *that reads $v^T M v$ as a scalar row for displayed vectors v;*
5. *N is an order and nonnegativity witness row saying that every vector row explicitly carried by the packet has nonnegative paired scalar value through* $\mathsf{Order}^{\uparrow}$*;*
6. *P is the* Pkg *provenance tying these rows to the cited* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{ConvexSet}^{\uparrow}$*,* $\mathsf{BilinForm}^{\uparrow}$*, and* $\mathsf{Order}^{\uparrow}$ *certificate boundaries.*

The carrier predicate is SDConePacket(M, V, C, B, N, P). *Two accepted packets classify together only when their matrix, vector-space, convex-ledger, bilinear-pairing, nonnegativity, and provenance rows transport by displayed* hsame *and by the same* Cont *routes named in* P.

Theorem 310.2 (SemidefiniteCone carrier stability)**.** *Let* $D = (M, V, C, B, N, P)$ *be an accepted* SemidefiniteCone$^{\uparrow}$ *carrier and let* $D' = (M', V', C', B', N', P')$ *be obtained by displayed* hsame *transport of all six rows, with the same* Cont *routes through the cited certificate boundaries. Then* D' *is again an accepted carrier, and its classifier reads exactly the transported matrix, vector, convex, bilinear, nonnegativity, and provenance rows.*

Lean4 ✓ `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket carrier stability`

Proof. Project the six coordinates of Definition 310.1. The matrix and vector-space coordinates are ordinary displayed rows, so hsame transport gives the rows M' and V' with the same scalar boundary.

Next transport the convex-combination ledger and the bilinear-form row. The stated Cont routes identify the same matrix and vector slots on the transported packet, so the pairing row remains readable as the displayed scalar value attached to M' and V'.

Finally transport the order/nonnegativity witness and the package row. Repacking these transported rows gives SDConePacket(M', V', C', B', N', P'), and the classifier has no coordinate other than the transported finite rows. □

Theorem 310.3 (SemidefiniteCone cone-operation ledger)**.** *For accepted* SemidefiniteCone$^{\uparrow}$ *carriers* D_0 *and* D_1 *over a common transported vector-space and scalar boundary, the cone-operation surface consists of finite rows for displayed matrix addition, displayed nonnegative scalar multiplication, the convex-combination ledger inherited from* ConvexSet$^{\uparrow}$, *the bilinear pairing rows inherited from* BilinForm$^{\uparrow}$, *the order witness rows inherited from* Order$^{\uparrow}$, *and* Pkg *provenance tying the operation packet to* D_0 *and* D_1.

The operation ledger exports no spectral decomposition, no eigenvalue existence claim, no analytic closure of the cone, and no positivity predicate from a host matrix library.

Lean4 ✓ `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket cone operation ledger`

Proof. Read the two input carriers through Definition 310.1. Their matrix rows and common vector-space row supply the finite endpoints of the operation packet.

For addition, use the displayed Mat$^{\uparrow}$ addition row and the ConvexSet$^{\uparrow}$ ledger that records the resulting matrix row as a convex or conic combination with visible coefficients. For nonnegative scalar multiplication, use the scalar row together with the Order$^{\uparrow}$ witness that the coefficient is nonnegative.

The bilinear-form row then reads each displayed vector test against the resulting matrix row. Because each nonnegativity assertion is an explicit order row and all dependencies are named in Pkg, the ledger is exhausted by finite BEDC rows and does not appeal to spectral or analytic facts. □

Theorem 310.4 (SemidefiniteCone dual-pairing boundary)**.** *Every accepted* SemidefiniteCone$^{\uparrow}$ *packet exposes its dual-facing read only through the displayed* BilinForm$^{\uparrow}$ *pairing row and the transported* Order$^{\uparrow}$ *nonnegativity witness. A consumer may compare a matrix row with a displayed vector or test row through the finite scalar value named by the packet,* hsame *transport,* Cont *routes, and* Pkg *provenance.*

The packet does not assert self-duality of the cone, closedness under analytic limits, or equality with any host-space positive-semidefinite predicate.

Lean4 ✓ `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket dual pairing empty boundary`

Proof. Project the bilinear-form row B and the nonnegativity row N from the carrier. These are the only coordinates that connect a matrix row to scalar comparison data.

A dual-facing consumer therefore receives a scalar pairing value only after following the displayed $\mathsf{BilinForm}^{\uparrow}$ row and the package routes named by P. The comparison of that scalar value with zero is an $\mathsf{Order}^{\uparrow}$ row, transported by hsame when the underlying matrix or vector row is replaced.

No coordinate in the carrier contains a host dual cone, a topological closure assertion, or a spectral certificate. Thus the boundary is exactly the finite pairing-and-order surface stated in the theorem. □

Theorem 310.5 (SemidefiniteCone NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet of Definition 310.1;*
2. *classifier and stability: the displayed transport statement of Definition 310.2;*
3. *cone-operation ledger: the addition and nonnegative scalar-multiplication rows of Definition 310.3;*
4. *dual-pairing boundary: the bilinear pairing and order rows of Definition 310.4;*
5. *provenance: the* Pkg *row tying the packet to* $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{BilinForm}^{\uparrow}$, *and* $\mathsf{Order}^{\uparrow}$.

These rows are the full public seed surface for the semidefinite-cone name.

Proof. The carrier row supplies the displayed matrix, vector-space, convex-ledger, bilinear-pairing, order, and provenance coordinates. This fixes the source domain of the name.

The stability row supplies the classifier behavior under hsame and Cont transport. The cone-operation row records the only operation reads available to downstream optimization packets, and the dual-pairing boundary records the only scalar comparison reads.

The provenance row names every dependency certificate used by the packet. Since the construction withholds spectral decomposition, eigenvalue existence, analytic closure, and host matrix positivity, the listed rows exhaust the $\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}$ obligation surface. □

Lean4 ✓ `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket namecert obligation surface`

Theorem 310.6 (SemidefiniteCone scoped provenance package)**.** *Every accepted* $\mathsf{SemidefiniteCone}^{\uparrow}$ *packet exposes its public scope only through* $\mathsf{Mat}^{\uparrow}$ *symmetric-matrix rows,* $\mathsf{VecSpace}^{\uparrow}$ *vector rows,* $\mathsf{ConvexSet}^{\uparrow}$ *cone-combination rows,* $\mathsf{BilinForm}^{\uparrow}$ *pairing rows,* $\mathsf{Order}^{\uparrow}$ *nonnegativity rows, and* Pkg *provenance, transported by displayed* hsame *and* Cont *routes. The scoped package exports no spectral decomposition, eigenvalue existence theorem, analytic closure of the cone, self-duality assertion, host matrix positivity predicate, or standard bridge data.*

Lean4 ✓ `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket scoped provenance package`

Proof. Project the carrier of Definition 310.1. Its six coordinates are the symmetric-matrix row, vector-space row, convex-combination ledger, bilinear-pairing row, order/nonnegativity witness, and package provenance, so the carrier has no dependency outside the displayed BEDC rows.

Use Definition 310.2 for classifier transport. The only permitted motion of an accepted packet is componentwise hsame transport along the same Cont routes named by the package row.

Use Definition 310.3 for the operation surface and Definition 310.4 for the scalar-facing boundary. These two rows consume precisely the displayed cone-operation, pairing, and order dependencies, then return to the same finite packet surface.

Finally apply Definition 310.5. The NameCert surface has no remaining coordinate from which a consumer could read spectral decomposition, eigenvalue existence, analytic closure, self-duality, host matrix positivity, or standard bridge data, so the scoped package is exactly the listed BEDC provenance boundary. □

Theorem 310.7 (SemidefiniteCone public packet certificate)**.** *Whenever the carrier stability, cone-operation ledger, dual-pairing boundary,* $\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}$ *obligation surface, and scoped provenance package rows of Definition 310.2, Definition 310.3, Definition 310.4, Definition 310.5, and Definition 310.6 hold, the displayed* BHist *matrix row, vector-space row, convex-ledger row, bilinear-pairing row, order row, provenance row, and package row form the exported public* $\mathsf{SemidefiniteCone}^{\uparrow}$ *packet. This public packet is the consumer-facing certificate surface for the semidefinite-cone name, and it exports no row beyond the ten-field roadmap entries already supplied by those finite BEDC dependencies.*

Proof. Use Definition 310.2 to fix the transported matrix, vector-space, convex-ledger, bilinear-pairing, order, and provenance coordinates of the accepted packet.

Use Definition 310.3 and Definition 310.4 to expose the only operation and scalar-comparison rows available to a consumer. These two rows are the cone-operation and dual-facing entries of the public packet.

Finally apply Definition 310.5 and Definition 310.6. Together they identify the carrier, classifier, stability, ledger, exactness, provenance, scope, absence, package, and bridge-boundary slots of the ten-field roadmap template, so the public packet is exactly their conjunction over the displayed BEDC rows. □

Theorem 310.8 (SemidefiniteCone standard bridge boundary)**.** *Any standard bridge for the public* $\mathsf{SemidefiniteCone}^{\uparrow}$ *packet must read and write exactly the displayed symmetric* $\mathsf{Mat}^{\uparrow}$ *row,* $\mathsf{VecSpace}^{\uparrow}$ *row,* $\mathsf{ConvexSet}^{\uparrow}$ *cone-operation ledger,* $\mathsf{BilinForm}^{\uparrow}$ *pairing row,* $\mathsf{Order}^{\uparrow}$ *nonnegativity witnesses,* hsame *and* Cont *transport rows, and* Pkg *provenance of Definition 310.7. The bridge boundary exports no spectral decomposition, eigenvalue existence, analytic closure, self-duality theorem, or host matrix positivity predicate.*

Proof. Project the public packet theorem. Its carrier coordinates are the symmetric matrix row, compatible vector-space row, convex cone-operation ledger, bilinear-pairing row, order nonnegativity witnesses, transport rows, and provenance rows.

The standard-facing bridge may therefore read those coordinates and may write back only the same rows after hsame and Cont transport. This is the full boundary because the public packet certificate has no additional output slot.

Spectral decomposition, eigenvalue existence, analytic closure, self-duality, and host matrix positivity are not among the projected rows. They cannot be exported by a bridge whose domain and codomain are restricted to the displayed public packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}$**.**

Constructive story: A semidefinite-cone packet is generated by a symmetric $\mathsf{Mat}^{\uparrow}$ row, a compatible $\mathsf{VecSpace}^{\uparrow}$ row, a $\mathsf{ConvexSet}^{\uparrow}$ cone-operation ledger, a $\mathsf{BilinForm}^{\uparrow}$ pairing row, displayed $\mathsf{Order}^{\uparrow}$ nonnegativity witnesses, and Pkg provenance for those finite rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 310.7, Definition 310.8, Definition 310.3, and Definition 310.4 bind the public packet certificate, standard bridge boundary, cone-operation ledger, and dual-pairing boundary as the mature packet surface over the displayed $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{BilinForm}^{\uparrow}$, $\mathsf{Order}^{\uparrow}$, hsame, Cont, and Pkg rows visible to $\mathsf{SemidefiniteCone}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SemidefiniteConeUp.SemidefiniteConePacket\_dual\_pairing\_empty\_boundary`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close spectral decomposition, eigenvalue existence, analytic closure, self-duality, host matrix positivity, or a machine-checked standard bridge.

Upgrade path: No further paper-side theory grade remains; formal bridge verification remains on the verification axis.

Chapter 311

A Concrete Naming Certificate for $\mathsf{DyadicBall}^{\uparrow}$

Following the Bishop–Bridges constructive-analysis treatment of rational balls, the $\mathsf{DyadicBall}^{\uparrow}$ interface names a finite center-radius enclosure packet for L10 real-name observations. It sits between the dyadic arithmetic surface of chapter 291, the regular rational stream surface of chapter 301, and the real-name seal surface of chapter 38.

311.1 Finite center-radius carrier

Definition 311.1 (DyadicBall finite enclosure carrier)**.** *A* $\mathsf{DyadicBall}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (c, r, k, o, \eta, H, C, P, N)$$

with the following visible rows:

1. *c is a center row accepted by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. *r is a positive dyadic radius row, displayed by the same dyadic arithmetic surface and readable as a one-sided* $\mathsf{DyadicInterval}^{\uparrow}$ *tolerance window;*
3. *k is a precision and schedule row supplied by* $\mathsf{StreamName}^{\uparrow}$*, with the requested tolerance coordinated by* $\mathsf{CauchyModulus}^{\uparrow}$ *when a regular source provides an explicit rate;*
4. *o is the scheduled observation row, either a finite* $\mathsf{RegSeqRat}^{\uparrow}$ *window endpoint or the finite source read of a* $\mathsf{Real}^{\uparrow}$ *seal;*
5. *η is the containment ledger proving that the displayed observation lies within the radius row around the center row;*
6. *H and C are the componentwise* hsame *witnesses and displayed* Cont *routes for the center, radius, schedule, observation, and containment rows;*
7. *P is the* Pkg *provenance naming the consumed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{DyadicInterval}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source surfaces;*
8. *N is the local* NameCert *row recording that classification is by componentwise finite transport of the displayed rows.*

The carrier has no quotient ball space, no host real equality, no completed metric object, and no hidden real-radius coordinate. Its classifier compares two accepted packets only by transporting the listed center, radius, schedule, observation, containment, hsame, Cont, Pkg, *and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallTasteGate single carrier alignment`

Theorem 311.2 (DyadicBall classifier laws)**.** *For accepted* $\mathsf{DyadicBall}^{\uparrow}$ *carriers* $B = (c, r, k, o, \eta, H, C, P, N)$ *and* $B' = (c', r', k', o', \eta', H', C', P', N')$*, the componentwise classifier on the center, radius, schedule, observation, containment,* hsame, Cont, Pkg, *and* NameCert *rows is reflexive, symmetric, and transitive. Whenever it relates* B *to* B'*, the displayed finite routes transport carrier acceptance from* B *to* B'*.*

These laws act only on the rows exposed by Definition 311.1. They introduce no quotient ball, host real equality, hidden metric point, or completed real.

↪variant `BEDC.Derived.DyadicBallUp.DyadicBallPacket classifier transport`
Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallPacket classifier laws`

Proof. Project the accepted packets through Definition 311.1. The only rows available to the classifier are the center, radius, schedule, observation, containment, routing, provenance, and naming rows.

Reflexivity uses the componentwise reflexive hsame witness on each visible row and the displayed identity Cont routes. Symmetry reverses the same componentwise witnesses and routes. Transitivity composes the center, radius, schedule, observation, containment, hsame, Cont, Pkg, and NameCert comparisons row by row.

For carrier transport, move the accepted rows of B along the classifier routes and keep the stated containment ledger in the target packet. Repacking the transported rows gives the accepted carrier B'. Since the repacking uses only the finite rows of the carrier, it cannot create a quotient ball, host real equality, hidden metric point, or completed real. □

Theorem 311.3 (DyadicBall radius refinement closure)**.** *Let* $B = (c, r, k, o, \eta, H, C, P, N)$ *be an accepted* $\mathsf{DyadicBall}^{\uparrow}$ *carrier, and let* r' *be a positive dyadic radius row whose displayed comparison ledger proves* $r' \leq r$*. If the same center row* c*, schedule row* k*, observation row* o*, and containment ledger are transported through finite* Cont *rows so that the observation remains inside the smaller displayed radius, then the repacked tuple*

$$B' = (c, r', k, o, \eta', H', C', P', N')$$

is again an accepted $\mathsf{DyadicBall}^{\uparrow}$ *carrier.*

The refinement changes only the visible radius and containment rows. It does not form a quotient of balls and does not compare centers by host real equality.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteCarrier radius refinement closure`

Proof. Project the carrier of Definition 311.1. The center, radius, schedule, observation, containment, routing, provenance, and naming coordinates are all explicit finite BHist rows.

Use the displayed comparison $r' \leq r$ to replace the radius coordinate. The extra hypothesis supplies the finite containment ledger η' for the same center and observation at the smaller radius.

Transport the remaining coordinates by the componentwise hsame witnesses and Cont routes. Repacking these rows gives the accepted packet B', and the construction has no coordinate from which a quotient ball space or host real equality could be read. □

Theorem 311.4 (DyadicBall RegSeqRat window handoff)**.** *Every accepted* DyadicBall$^{\uparrow}$ *packet supplies exactly the finite dyadic rows that a scheduled* RegSeqRat$^{\uparrow}$ *window may consume: the* StreamName$^{\uparrow}$ *precision row, the* DyadicRatCore$^{\uparrow}$ *center row, the positive dyadic radius row, the scheduled endpoint row, the containment ledger, and the associated* hsame, Cont, Pkg, *and* NameCert *provenance.*

The handoff may be read as a dyadic endpoint-radius window for the regular stream, but it exports no quotient stream, no completion object, and no external real value.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallPacket regseqrat window handoff`
↪ variant `BEDC.Derived.DyadicBallUp.DyadicBallFiniteEnclosure regseqrat window handoff`

Proof. Read the packet through Definition 311.1. The schedule row is already a StreamName$^{\uparrow}$ finite request, and the center and radius rows are accepted dyadic rows.

For a RegSeqRat$^{\uparrow}$ consumer, keep exactly the scheduled observation row and the containment ledger that compares it to the displayed center and radius. These are the endpoint and tolerance rows consumed by a finite regular-stream window.

The componentwise hsame, Cont, Pkg, and NameCert rows are the same rows listed in the carrier. Since the carrier contains no stream quotient or completed limit, the handoff cannot export one. □

Theorem 311.5 (DyadicBall finite-window packet RegSeqRat handoff)**.** *A finite-window* DyadicBall$^{\uparrow}$ *packet with* BHist *rows* $(center, radius, schedule, observation, containment, route, provenance, certRow, handoff, sealBoundary)$ *exposes exactly the* RegSeqRat$^{\uparrow}$ *handoff rows: unary center, radius, schedule, observation, containment, route, and handoff rows; the append-readback rows* hsame *containment* $(append\ center\ radius)$, hsame *route* $(append\ schedule\ observation)$, *and* hsame *handoff* $(append\ containment\ route)$*; and the package row* PkgSig$(bundle, handoff, pkg)$.

The finite-window packet exports no quotient stream, completed real point, host real equality, or external ball object.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket regseqrat window handoff`

Proof. Project the finite-window packet rows. The unary rows for center, radius, schedule, and observation are stored directly, and the displayed Cont routes build the containment, route, and handoff rows over those sources.

The three displayed Cont routes are precisely the append readbacks: containment reads append$(center, radius)$, route reads append$(schedule, observation)$, and handoff reads append$(containment, route)$. Keeping the package row PkgSig$(bundle, handoff, pkg)$ gives the full regular-rational handoff surface.

The remaining packet coordinates are provenance, certificate, and seal-boundary rows. They certify and delimit the finite packet, but they do not add a quotient stream, a completed real point, a host real equality, or an external ball object. □

Theorem 311.6 (DyadicBall Real seal boundary)**.** *A* Real$^{\uparrow}$ *seal reading an accepted* DyadicBall$^{\uparrow}$ *packet may inspect only the center row, the positive radius row, the scheduled observation row, the containment ledger, the componentwise* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

The seal boundary does not add a real-equality classifier, a quotient of regular streams, a completeness witness, or a host real ball. It merely records that the displayed finite observation lies in the displayed dyadic center-radius enclosure.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket real seal boundary`

Proof. Start with the public coordinates of Definition 311.1. These coordinates already include the finite source read that a $\mathsf{Real}^{\uparrow}$ seal may consume: center, radius, schedule, observation, containment, routing, provenance, and naming data.

Apply the handoff statement of Definition 311.4 when the seal source is read through a regular-rational scheduled window. The same finite dyadic rows are then the only source rows available to the real-name seal.

No carrier coordinate stores a real quotient, a completed metric point, or a host ball. Therefore the seal boundary is exactly the listed finite row surface. □

Theorem 311.7 (DyadicBall intersection refinement handoff)**.** *Let an accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packet be read through the finite center-radius carrier of Definition 311.1. If the packet is refined to a smaller positive dyadic radius by Definition 311.3, then the refined packet exports the same scheduled* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *finite-boundary rows as the original packet, except for the transported radius row and the containment ledger supplied for that smaller radius.*

Concretely, the BHist *center, schedule, scheduled observation, componentwise* hsame *transports, displayed* Cont *windows,* Pkg *provenance, and local* NameCert *rows remain the same rows of the carrier. The* $\mathsf{RegSeqRat}^{\uparrow}$ *endpoint-radius window of Definition 311.4 and the* $\mathsf{Real}^{\uparrow}$ *seal surface of Definition 311.6 are read from those rows after replacing only the radius and containment coordinates. The handoff does not introduce quotient balls, host real equality, completed metric points, or selected limits.*

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket intersection refinement handoff`

Proof. Unpack the carrier of Definition 311.1. Its public rows are the finite BHist center, positive radius, schedule, scheduled observation, containment ledger, hsame transports, Cont windows, Pkg provenance, and NameCert certificate.

Apply Definition 311.3. The theorem repacks the accepted packet at the smaller displayed dyadic radius, using the supplied containment ledger for that radius and leaving the center, schedule, observation, transport, window, provenance, and certificate rows in place.

Project the repacked packet through Definition 311.4 and Definition 311.6. Both projections inspect only the carrier rows just listed, so their finite consumer surfaces agree with the original packet except at the transported radius and containment entries.

Since no quotient-ball coordinate, host real equality, completed metric point, or selected limit occurs in the carrier, none is created by the repacking or by either outgoing handoff. □

Theorem 311.8 (DyadicBall NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$ *obligation surface consists of five finite requirements:*

1. *carrier: the finite center-radius packet of Definition 311.1;*
2. *classifier: the componentwise classifier laws of Definition 311.2;*
3. *radius-refinement stability: Definition 311.3 repacks a smaller displayed positive radius when the containment ledger is supplied for that radius;*
4. $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: Definition 311.4 exposes exactly the finite endpoint-radius rows consumed by a scheduled regular-rational window;*
5. $\mathsf{Real}^{\uparrow}$ *seal boundary: Definition 311.6 restricts real-name reads to the center, radius, observation, containment, routing, package, and naming rows.*

These requirements are the full public obligation surface for $\mathsf{DyadicBall}^{\uparrow}$*.*

Proof. The carrier requirement is Definition 311.1. It lists every coordinate that can appear in an accepted packet.

The classifier requirement is Definition 311.2. It records reflexivity, symmetry, transitivity, and carrier transport for exactly the componentwise rows named by the carrier.

Radius-refinement stability, regular-window handoff, and real-seal boundary are the three theorem rows just stated. Together they cover the local ways a dyadic ball packet is refined, consumed by a regular stream window, and read by a real-name seal. □

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallPacket semantic name certificate`

Theorem 311.9 (DyadicBall obligation closure)**.** *The carrier, classifier, radius-refinement stability,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and* $\mathsf{Real}^{\uparrow}$ *seal boundary listed in Definition 311.8 exhaust the local obligation set for* $\mathsf{DyadicBall}^{\uparrow}$*.*

Proof. The carrier row is the finite center-radius packet of Definition 311.1. Its classifier row compares exactly the center, radius, schedule, scheduled observation, containment ledger, Cont routes, Pkg rows, and NameCert rows named by that carrier.

The three outgoing obligation rows are the radius-refinement stability theorem of Definition 311.3, the scheduled regular-rational handoff of Definition 311.4, and the real-seal boundary of Definition 311.6. These are the only local operations that refine, export, or seal a displayed dyadic-ball packet.

No quotient ball space, host real equality, metric topology, or completeness coordinate is present in the carrier. Hence there is no additional local obligation row beyond the five rows enumerated in Definition 311.8. □

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteCarrier obligation closure`

Theorem 311.10 (DyadicBall center-radius public interface)**.** *The carrier, classifier laws, radius-refinement closure,* $\mathsf{RegSeqRat}^{\uparrow}$ *window handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, and obligation-closure theorem assemble the public* $\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$ *interface over the displayed center, positive radius, schedule, observation, containment,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers may cite this single public interface instead of reopening the scoped center-radius packet.*

Proof. Assemble the public certificate by projecting the scoped packet into the rows listed by Definition 311.1. The exported object has only the center, positive radius, schedule, observation, containment, transport, provenance, and naming coordinates already present in that packet.

The classifier row is supplied by Definition 311.2. Its hsame stability transports accepted packets across the displayed componentwise rows, and the associated Cont routes are precisely the routes allowed to downstream consumers.

The remaining certificate fields are the refinement, regular-window, and real-seal rows. Apply Definition 311.3 for radius ledger transport, Definition 311.4 for the $\mathsf{RegSeqRat}^{\uparrow}$ consumer row, and Definition 311.6 for the $\mathsf{Real}^{\uparrow}$ seal boundary.

Finally use Definition 311.9 to see that these rows exhaust the local obligation surface. Repacking them yields the public $\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$ interface, with no quotient ball, host real equality, metric topology, or extra completeness coordinate. □

Theorem 311.11 (DyadicBall common observation overlap)**.** *Let* $B = (c, r, k, o, \eta, H, C, P, N)$ *and* $B' = (c', r', k, o, \eta', H', C', P', N')$ *be accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packets with the same scheduled observation row* o *and the same schedule row* k*. Suppose the displayed center and radius rows*

admit the componentwise hsame *and* Cont *transports required by Definition 311.2, and suppose a finite dyadic positive radius row ρ is supplied with containment ledgers into both packets. Then the common observation determines a single finite* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *consumer package whose visible rows are exactly o, k, the transported center rows, the transported radius row ρ, the two containment ledgers, the displayed* hsame *rows, the visible* Cont *routes, the* Pkg *provenance rows, and the two* NameCert *rows.*

This common package exports no quotient ball, host real equality, metric completeness claim, or selected real point.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket common observation overlap`

Proof. Project both accepted packets through the carrier of Definition 311.1. The two projections expose only their displayed centers, radii, common schedule row, common scheduled observation, containment ledgers, hsame rows, Cont routes, package provenance, and local naming rows.

Use Definition 311.3 on each side with the finite radius row ρ and its displayed containment ledger. This repacks both packets at the same radius row while retaining only the transported center, schedule, observation, containment, transport, package, and naming coordinates.

The shared schedule and observation rows now feed Definition 311.4. That handoff identifies one finite regular-rational window surface, because the visible scheduled rows are the same and the remaining differences have already been transported into the displayed center, radius, and containment ledgers.

Apply Definition 311.6 to the same repacked rows. The $\mathsf{Real}^{\uparrow}$ seal can read only the finite carrier coordinates named above, so it cannot distinguish the two packets by any quotient ball, host real equality, metric-completeness datum, or selected point.

Finally cite Definition 311.10 to package the common finite surface as the public $\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$ consumer interface. The resulting $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ package has exactly the rows listed in the statement. □

Theorem 311.12 (DyadicBall refinement overlap transitivity)**.** *Let $B_0 = (c_0, r_0, k, o, \eta_0, H_0, C_0, P_0, N_0)$, $B_1 = (c_1, r_1, k, o, \eta_1, H_1, C_1, P_1, N_1)$, and $B_2 = (c_2, r_2, k, o, \eta_2, H_2, C_2, P_2, N_2)$ be accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packets with the same schedule row k and the same scheduled observation row o. Suppose B_0 and B_1 admit a common refined positive dyadic radius row ρ with displayed containment ledgers into both packets, and suppose B_1 and B_2 admit a common refined positive dyadic radius row σ with displayed containment ledgers into both packets.*

If a positive dyadic radius row τ is displayed together with refinement ledgers from τ to both ρ and σ, and with containment ledgers from τ into all three packets, then the three packets determine one finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *consumer package. Its visible rows are exactly the shared schedule k, the shared observation o, the transported center rows, the positive radius row τ, the three containment ledgers, the displayed* hsame *rows, the visible* Cont *routes, the* Pkg *provenance rows, and the three* NameCert *rows.*

The package introduces no quotient ball, host real equality, completeness datum, or selected real point.

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket refinement overlap transitivity`

Proof. Project the three accepted packets through Definition 311.1. This exposes only center rows, radius rows, the shared schedule, the shared observation, containment ledgers, transport rows, package provenance, and local naming rows.

Use Definition 311.3 separately for B_0, B_1, and B_2 at the displayed radius row τ. The refinement ledgers from τ to ρ and σ, together with the containment ledgers into the three packets, supply the radius and containment coordinates required for each repacked packet.

Apply Definition 311.11 to the pair (B_0, B_1) using the row ρ, and again to the pair (B_1, B_2) using the row σ. The two overlap packages have the same schedule and scheduled observation, and their middle packet rows are transported through the same carrier coordinates.

Now read both overlap packages through Definition 311.4. The handoff identifies the single finite regular-rational consumer surface carried by the shared schedule, shared observation, transported center rows, radius row τ, and the three containment ledgers.

Finally apply Definition 311.6 to the same finite rows. The real-name seal has no coordinate for a quotient ball, host real equality, completeness datum, or selected point, so the composite overlap remains a finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ package with precisely the rows listed above. □

Theorem 311.13 (DyadicBall public bridge package)**.** *Let B be an accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packet whose public center-radius interface is the one of Definition 311.10. Then the* $\mathsf{RegSeqRat}^{\uparrow}$ *window handoff of Definition 311.4 and the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 311.6 assemble a single finite bridge package. Its visible rows are exactly the center row, positive radius row, schedule row, scheduled observation row, containment ledger, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row displayed by the public interface.*

Under the overlap hypotheses of Definition 311.11 and Definition 311.12, the same bridge package is stable under common refinement. No quotient ball, host real equality, metric topology, completeness witness, or selected limit is introduced.

Proof. Unpack the public center-radius interface. It exposes exactly the finite center, radius, schedule, observation, containment, transport, provenance, and local naming rows of Definition 311.1.

Project the consumer rows through the RegSeqRat handoff and the RealUp seal boundary. Both consumer surfaces read the same displayed rows, so their joint package has no coordinate beyond the center-radius interface listed in the statement.

For refinement stability, apply the common-observation overlap theorem and then the refinement-overlap transitivity theorem. These results transport the displayed center, positive radius, schedule, scheduled observation, containment, hsame, Cont, Pkg, and NameCert rows through common refinement without adding a quotient ball or host real datum.

The exclusions follow by inspection of the assembled finite rows: neither the handoff nor the seal boundary introduces host real equality, metric topology, completeness data, or a selected limit. □

Theorem 311.14 (DyadicBall mature observation envelope)**.** *The public center-radius interface of Definition 311.10, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 311.4, the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 311.6, the common-observation overlap of Definition 311.11, the refinement-overlap transitivity of Definition 311.12, and the public bridge package of Definition 311.13 assemble a mature observation envelope for* $\mathsf{DyadicBall}^{\uparrow}$.

Every consumer-visible row in this envelope is one of the finite center, radius, schedule, observation, containment, transport, provenance, and NameCert *rows displayed by the public interface and the bridge package. The envelope has no row for quotient balls, host real equality, metric topology, completeness, or selected limits.*

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket mature observation envelope`

Proof. Start with the public center-radius interface. It lists the finite center, positive radius, schedule, scheduled observation, containment, transport, provenance, and local naming rows exported by an accepted $\mathsf{DyadicBall}^{\uparrow}$ packet.

Next pass the same rows through the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal boundary. These two consumer surfaces read the displayed packet data and do not add a host equality coordinate, a quotient ball, a topology row, a completion datum, or a selected point.

For stability under shared observations, use the common-observation overlap and refinement-overlap transitivity theorems. They transport the same finite rows through common refinements, so the consumer envelope is unchanged when two visible packets are compared through a shared scheduled observation.

Finally apply the public bridge package. It already collects the interface, handoff, seal boundary, overlap, and refinement rows into one finite bridge surface, and its exclusions are exactly the non-rows named in the statement. □

Theorem 311.15 (DyadicBall finite intersection basis package)**.** *Let $B_0, \ldots, B_n$ be a finite displayed chain of accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packets sharing one schedule row k and one scheduled observation row o. Suppose the chain carries a terminal positive dyadic radius row τ, containment ledgers from τ into every packet, and refinement ledgers from τ into each adjacent overlap row displayed by the chain.*

Then the chain determines one finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *consumer package. Its visible rows are exactly the shared schedule k, the shared observation o, the transported center rows, the terminal radius row τ, the containment ledgers into the displayed packets, the adjacent-overlap refinement ledgers, the displayed* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance rows, and the local* NameCert *rows.*

This package is a finite-intersection basis surface for the displayed $\mathsf{DyadicBall}^{\uparrow}$ *packets. It has no row for quotient balls, metric topology, host real equality, selected limits, or completeness.*

Proof. Read each accepted packet through the carrier of Definition 311.1. The shared schedule row, shared observation row, transported center row, positive radius row, containment ledger, transport rows, package provenance, and local naming row are the only coordinates exposed to the chain.

For each adjacent pair, apply Definition 311.11. The displayed refinement ledger from τ into the adjacent overlap row supplies the common positive radius witness, while the containment ledgers into the two packets supply the two containment coordinates. This produces one local overlap package for each adjacent step.

Move along the finite chain by repeatedly using Definition 311.12. Each step keeps the same schedule and scheduled observation rows, replaces the local overlap radius by the terminal radius row τ, and records only the containment, hsame, Cont, Pkg, and NameCert rows already displayed by the chain.

Finally apply Definition 311.13 to the resulting common-refinement surface. The bridge package reads the displayed finite ledger and repacks it as one $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer package, so no quotient ball, metric-topology row, host real equality, selected limit, or completeness datum is invoked. □

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket finite intersection basis package`

Theorem 311.16 (DyadicBall radius-window monotonicity)**.** *Let B be an accepted* $\mathsf{DyadicBall}^{\uparrow}$ *finite enclosure. If its displayed positive dyadic radius is narrowed or its finite observation window is restricted along displayed refinement rows, then the resulting finite enclosure is again an accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packet.*

The narrowed packet preserves the $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and every consumer-visible read factors through the original* hsame, Cont, Pkg, *and local* NameCert *rows. No quotient ball, metric-topology row, host real equality, selected limit, or completeness datum is introduced by the narrowing.*

Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteEnclosure radius window monotonicity`
Lean4 ✓ `BEDC.Derived.DyadicBallUp.DyadicBallFiniteWindowPacket radius window monotonicity`

Proof. Start from the accepted center-radius carrier of B and apply Definition 311.3. Narrowing the displayed radius or observation window keeps the finite center, positive-radius, containment, transport, provenance, and naming coordinates inside the $\mathsf{DyadicBall}^{\uparrow}$ carrier.

Use Definition 311.11 for the common visible schedule row. It identifies the narrowed observation as a shared finite overlap of the original packet and the restricted packet.

Apply Definition 311.12 to compose the radius and observation refinements. The composed refinement still reads through the same displayed hsame, Cont, Pkg, and NameCert rows.

Finally invoke Definition 311.15. The finite basis package repacks the narrowed enclosure as the same $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer surface, so the handoff is preserved and no excluded host or quotient coordinate is available. □

Theorem 311.17 (DyadicBall terminal Real seal boundary)**.** *Let $B_0, \ldots, B_n$ be a finite displayed chain of accepted* $\mathsf{DyadicBall}^{\uparrow}$ *packets sharing one schedule row k and one scheduled observation row o. Suppose the chain carries a terminal positive dyadic radius row τ, containment ledgers from τ into every displayed packet, and adjacent-overlap refinement ledgers as in Definition 311.15.*

Then every terminal $\mathsf{Real}^{\uparrow}$ *seal read of this chain factors through exactly the finite package named by Definition 311.15: the shared schedule row, the shared observation row, the transported center rows, the terminal radius row, the containment ledgers, the adjacent-overlap refinement ledgers, the displayed* hsame *rows, the displayed* Cont *routes, the* Pkg *provenance rows, and the local* NameCert *rows.*

The seal has no readable row for quotient balls, host real equality, metric topology, completion, selected limits, or any real-completeness datum.

Proof. First apply Definition 311.15 to the displayed chain. This assembles the terminal $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer package over the shared schedule and observation rows, the transported centers, the terminal radius, the containment ledgers, the adjacent-overlap refinement ledgers, and the visible transport, provenance, and naming rows.

Next apply Definition 311.6 to the resulting consumer package. The $\mathsf{Real}^{\uparrow}$ seal reads only the rows exported by that package, so no host real equality, quotient ball, topology coordinate, completion row, selected limit, or real-completeness witness can be inspected.

Finally use Definition 311.14. It identifies the same terminal package as the mature observation envelope for finite center-radius chains, so every terminal seal read remains confined to the named finite rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicBall}^{\uparrow}$ packet is generated by a finite dyadic center row, a positive dyadic radius row, a scheduled observation row, a containment ledger, componentwise hsame and Cont transport, package provenance, and a local naming row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 311.14 and Definition 311.15 bridge the public center-radius packet to the shared $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer surface and close the finite common-refinement basis package over center, radius, schedule, observation, containment, transport, provenance, and NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DyadicBall}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DyadicBallUp.DyadicBallPacket\_semantic\_name\_certificate`

Bridge status: none

Origin: human

Not claimed: This chapter does not close real completeness, quotient stream equality, host real balls, metric topology, or a standard bridge.

Upgrade path: The mature paper surface is the public center-radius bridge plus the finite common-refinement consumer package; formal bridge checking remains a separate Lean-side axis.

Chapter 312

A Concrete Naming Certificate for $\mathsf{Monodromy}^{\uparrow}$

The $\mathsf{Monodromy}^{\uparrow}$ interface records the finite certificate surface of carrying a fibre or local-system row around a displayed loop and reading back the resulting transport row. The loop transport packet consumes the finite holonomy transport surface of chapter 299 before it packages the returned-row ledger, while the $\mathsf{RiemannHilbert}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, and $\mathsf{Curvature}^{\uparrow}$ rows remain provenance sources. The classical reference point is the regular-singular monodromy and Riemann-Hilbert tradition of Deligne, read here only through finite $\mathsf{NameCert}_{\mathsf{Holonomy}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{RiemannHilbert}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$, and $\mathsf{NameCert}_{\mathsf{Curvature}^{\uparrow}}$ rows.

312.1 Carrier definition

Definition 312.1 (Monodromy BHist transport carrier)**.** *A* $\mathsf{Monodromy}^{\uparrow}$ *carrier is a finite* BHist *transport packet*

$$(\gamma, b, \mathcal{L}, F, \lambda, \tau, \rho)$$

with the following displayed rows.

1. γ *is a loop row with named source endpoint, return endpoint, and endpoint* hsame *comparison.*
2. b *is the base endpoint row over which the loop is read.*
3. $\mathcal{L}$ *is a local-system, sheaf, or fibre row supplied through* $\mathsf{NameCert}_{\mathsf{Sheaf}^{\uparrow}}$ *together with the connection row supplied through* $\mathsf{NameCert}_{\mathsf{Connection}^{\uparrow}}$.
4. F *is the returned fibre or stalk row obtained by following the displayed loop.*
5. λ *is the finite continuation ledger for loop subdivision, transport concatenation, endpoint readback, and returned-row comparison.*
6. τ *records componentwise* hsame *transports for the loop row, base endpoint, local-system or fibre row, returned row, and continuation ledger.*
7. ρ *is the* Pkg *provenance row over* $\mathsf{Holonomy}^{\uparrow}$, $\mathsf{RiemannHilbert}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, *and* $\mathsf{Curvature}^{\uparrow}$.

The carrier exports no analytic fundamental group, no host representation category, and no unbounded continuation procedure beyond these displayed rows.

Lean4 ✓ `BEDC.Derived.MonodromyUp.taste gate`

Definition 312.2 (Monodromy finite transport classifier)**.** *The* $\mathsf{Monodromy}^{\uparrow}$ *classifier relates two accepted packets exactly when the loop rows, base endpoint rows, local-system or fibre rows, returned rows, finite continuation ledgers, componentwise transport rows, and package provenance rows are related by the displayed* hsame *comparisons. The classifier is therefore a finite rowwise comparison on the packet of Definition 312.1; it does not classify host paths, analytic continuation germs, or representations outside the packet.*

312.2 The certificate

Theorem 312.3 (Monodromy loop-continuation obligation)**.** *Every accepted* $\mathsf{Monodromy}^{\uparrow}$ *packet binds its loop-continuation row to the displayed base endpoint, local-system or fibre row, connection row, returned row, and finite continuation ledger of Definition 312.1. If two accepted packets have componentwise* hsame *transports of those rows, then the transported returned row is again accepted by the classifier of Definition 312.2.*

Lean4 ✓ `BEDC.Derived.MonodromyUp.MonodromyTransportCarrier loop continuation stability`
Lean4 ✓ `BEDC.Derived.MonodromyUp.MonodromyTransportPacket loop continuation obligation`

Proof. Project the accepted packet to its loop row γ, base endpoint b, local-system or fibre row $\mathcal{L}$, and connection source. These rows name the only source data used by the continuation route.

Next read the finite continuation ledger λ. Its entries record loop subdivision, transport concatenation, and endpoint readback, so the returned row F is determined by a displayed route rather than by an ambient analytic continuation object.

Finally apply the componentwise hsame transports stored in τ. The classifier accepts exactly those rowwise transports, and repacking the transported loop, base, fibre, returned row, ledger, and provenance rows gives another accepted $\mathsf{Monodromy}^{\uparrow}$ packet. □

Theorem 312.4 (Monodromy returned-row provenance exactness)**.** *For any accepted* $\mathsf{Monodromy}^{\uparrow}$ *packet, every returned fibre row or returned stalk row accepted by the classifier is obtained from the displayed loop row, base endpoint row, local-system or fibre row, finite continuation ledger, componentwise* hsame *transports, and* Pkg *provenance named in Definition 312.1. A transported returned row is accepted only through these same rows. No host path equality, analytic continuation germ, or external representation row supplies a returned-row source for the packet.*

Lean4 ✓ `BEDC.Derived.MonodromyUp.MonodromyTransportPacket returned row provenance exactness`

Proof. Project the packet to γ, b, $\mathcal{L}$, F, λ, τ, and ρ. These coordinates name the loop, endpoint, local-system or fibre source, returned row, continuation ledger, rowwise transports, and package provenance visible to the classifier.

Apply Definition 312.3 to the transport step. The obligation binds the returned row to the displayed loop route and to the finite continuation ledger, and the transported returned row is repacked by the same componentwise hsame transports.

The classifier of Definition 312.2 has no coordinate for host paths, analytic germs, or representation rows outside the packet. Hence every accepted returned row, including a transported one, has exactly the displayed provenance listed in the carrier. □

Theorem 312.5 (Monodromy NameCert obligation surface)**.** *The seed* $\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$ *obligation surface consists of five finite rows.*

1. *The carrier row supplied by Definition 312.1.*

2. *The classifier row supplied by Definition 312.2.*
3. *The loop-continuation stability row supplied by Definition 312.3.*
4. *The returned-row provenance row of Definition 312.4, naming the consumed* $\mathsf{Holonomy}^{\uparrow}$, $\mathsf{RiemannHilbert}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, *and* $\mathsf{Curvature}^{\uparrow}$ *certificates through* Pkg.
5. *The standard-boundary exclusion row saying that no analytic fundamental group, representation category, unbounded continuation solver, or regular-singular comparison theorem is exported by the seed packet.*

Proof. Read the carrier fields. The loop, base endpoint, local-system or fibre, returned row, continuation ledger, componentwise transport rows, and package provenance supply the carrier and classifier obligations directly.

Use Definition 312.3 for the stability row and Definition 312.4 for the returned-row provenance row. Their proofs record that transported packets remain inside the same finite row shape, so no extra continuation principle is needed.

The provenance and boundary rows are projections from ρ and from the absence of any host path, representation, or analytic solver coordinate in the carrier. These five rows exhaust the seed obligation surface for $\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$. □

Theorem 312.6 (Monodromy standard boundary scope)**.** *The standard mathematical boundary of* $\mathsf{Monodromy}^{\uparrow}$ *is limited in this chapter to Deligne-style regular-singular monodromy and Riemann-Hilbert motivation as a naming source. The BEDC packet itself exposes only the displayed loop row, base endpoint, local-system or fibre row, finite continuation ledger, returned-row transport, componentwise* hsame *comparisons, and* Pkg *provenance over* $\mathsf{Holonomy}^{\uparrow}$, $\mathsf{RiemannHilbert}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, *and* $\mathsf{Curvature}^{\uparrow}$.

Proof. Project any consumer-visible monodromy readback from the carrier. The only available coordinates are the loop, base, local-system or fibre, returned row, finite ledger, transport comparisons, and dependency provenance rows.

The external regular-singular and Riemann-Hilbert traditions justify the human-known name, but they are not fields of the packet. In particular, the carrier has no coordinate for a fundamental-group representation, analytic continuation theorem, regular-singular classification, or host category equivalence.

Thus the boundary is a finite scope statement about what the certificate rows expose. Standard analytic or categorical monodromy results remain outside this seed chapter until they are represented by additional displayed BEDC rows. □

Theorem 312.7 (Monodromy public loop readback export)**.** *The public* $\mathsf{Monodromy}^{\uparrow}$ *readback exports exactly the loop row, base endpoint row, local-system or fibre row, returned row, finite continuation ledger, componentwise* hsame *transports, and* Pkg *provenance over* $\mathsf{Holonomy}^{\uparrow}$, $\mathsf{RiemannHilbert}^{\uparrow}$, $\mathsf{Sheaf}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, *and* $\mathsf{Curvature}^{\uparrow}$.

The export does not include analytic fundamental groups, host representation categories, unbounded continuation solvers, or a Riemann-Hilbert equivalence.

Proof. Start from the carrier definition Definition 312.1. Its coordinates are precisely the loop row, base endpoint, local-system or fibre row, returned row, finite continuation ledger, componentwise transports, and dependency provenance.

Apply the finite transport classifier of Definition 312.2. It permits only rowwise comparison of the displayed loop, endpoint, fibre or local-system, returned, ledger, transport, and provenance rows.

Next use Definition 312.3 and Definition 312.4. The first theorem binds the returned row to the finite loop-continuation ledger, and the second shows that no returned row has a source outside the displayed packet.

Finally apply Definition 312.5 together with Definition 312.6. The local $\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$ surface and the standard boundary scope repack the same rows as the public readback while keeping analytic fundamental groups, host representation categories, unbounded continuation solvers, and Riemann-Hilbert equivalence outside the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$.

Constructive story: A monodromy packet is a finite BHist transport ledger over a displayed loop, base endpoint, local-system or fibre row, returned row, finite continuation ledger, componentwise hsame transports, and package provenance. Classification is rowwise transport of those finite coordinates, with Deligne-style regular-singular monodromy and Riemann-Hilbert theory serving only as the human-known naming source.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$, publicClosed)

Scope closed: The public boundary binds the loop-continuation rows, returned-row provenance, local NameCert surface, public loop readback export, and RiemannHilbert, connection, and sheaf sources through BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Monodromy}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MonodromyUp.MonodromyTransportPacket\_loop\_continuation\_obligation`

Bridge status: none

Origin: human

Not claimed: This chapter does not close analytic continuation, a fundamental-group representation theorem, regular-singular classification, Riemann-Hilbert equivalence, or a standard bridge.

Upgrade path: The next paper-grade step is a standard bridge boundary for the public monodromy readback packet.

Lemma 312.8 (Monodromy constant-loop returned-row identity)**.** *Let*

$$(\gamma, b, \mathcal{L}, F, \lambda, \tau, \rho)$$

be an accepted $\mathsf{Monodromy}^{\uparrow}$ *transport packet. Suppose that* γ *is the displayed constant loop at* b*: its source endpoint row, return endpoint row, and endpoint comparison are the reflexive* b *row. Suppose also that* λ *is the empty finite continuation ledger. Then the returned fibre or stalk row* F *is in the same finite* $\mathsf{Monodromy}^{\uparrow}$ *transport class as the input local-system or fibre row* $\mathcal{L}$*. More explicitly, the classifier of Definition 312.2 accepts the comparison whose loop, base, ledger, transport, and provenance coordinates are the displayed reflexive rows, and whose returned-row coordinate is the no-step comparison* $F\mathsf{hsame}\mathcal{L}$ *read from the identity-route packet.*

Proof. Project the accepted packet through Definition 312.1. The loop row starts at b, returns to b, and carries the displayed endpoint comparison $b\mathsf{hsame}b$. The ledger row λ has no subdivision entry, no transport-concatenation entry, and no nontrivial endpoint-readback entry.

Apply Definition 312.3. It binds the returned row F to the same displayed base endpoint, the same input row $\mathcal{L}$, and the same finite ledger. In the present hypotheses the bound route is the empty identity route, so there is no intermediate loop segment and no later continuation row from which a different returned row could be sourced.

Now use Definition 312.4. Any classifier-accepted returned row must come from the displayed loop row, base endpoint row, input local-system or fibre row, empty ledger, componentwise hsame transports, and package provenance already present in the packet. Since the ledger is empty and both endpoints are the same displayed base row, the returned-row provenance has only the no-step readback of $\mathcal{L}$ at b. The componentwise transport row τ therefore supplies the comparison $F\mathsf{hsame}\mathcal{L}$ inside the packet, not from an analytic continuation germ or an outside representation row.

Finally repack this comparison into the finite classifier of Definition 312.2. The loop, base, ledger, transport, and provenance coordinates are reflexive copies of the displayed packet rows, while the returned coordinate is the no-step comparison $F\mathsf{hsame}\mathcal{L}$. Hence F and $\mathcal{L}$ are classified together by the finite $\mathsf{Monodromy}^{\uparrow}$ transport classifier. $\square$

Chapter 313

A Concrete Naming Certificate for $\mathsf{Lyapunov}^{\uparrow}$

The $\mathsf{Lyapunov}^{\uparrow}$ interface records the finite stability ledger used by Lyapunov arguments for displayed dynamical systems and quadratic matrix certificates. In the classical presentation of Khalil, *Nonlinear Systems* (2002), the proof reads a positive function and a one-step or derivative decrease condition to conclude stability in a stated neighborhood. The BEDC certificate below keeps only the finite rows needed to name that surface: state rows, transition rows, quadratic certificate rows, positive-definite witnesses, one-step decrease rows, transports, continuation routes, package provenance, and a local NameCert row.

Definition 313.1 (Lyapunov finite stability carrier)**.** *A* $\mathsf{Lyapunov}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$(X, T, Q, P, D, H, C, G, N)$$

with the following rows:

1. *X is a displayed state-row packet read through* $\mathsf{DynSystem}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$*;*
2. *T is a displayed transition-row packet for the sampled or one-step state motion, with its source and target slots named by X;*
3. *Q is a quadratic certificate row read through* $\mathsf{Mat}^{\uparrow}$ *and the scalar boundary of* RealAlgOrder*;*
4. *P is a positive-definite witness row for the displayed quadratic certificate on the state rows carried by the packet;*
5. *D is a one-step decrease ledger saying that the displayed successor row has a nonincreasing, or strictly decreasing when named, quadratic value relative to the displayed predecessor row;*
6. *H records the componentwise* hsame *transports for state, transition, quadratic, positivity, and decrease rows;*
7. *C records the* Cont *routes from predecessor states to successor states and from both states to the quadratic-value comparison row;*
8. *G is the* Pkg *provenance naming* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* RealAlgOrder*, and* $\mathsf{Riccati}^{\uparrow}$ *as the only imported certificate boundaries;*
9. *N is the local* NameCert *row for the resulting finite stability surface.*

The carrier predicate is $\mathsf{LyapunovLedger}(X, T, Q, P, D, H, C, G, N)$*. Two accepted packets classify together only when all nine rows transport by the displayed* hsame *data and follow the same* Cont *routes named in* G*.*

Lean4 ✓ `BEDC.Derived.LyapunovUp.taste gate`

Theorem 313.2 (Lyapunov decrease ledger)**.** *Let* $L = (X, T, Q, P, D, H, C, G, N)$ *be an accepted* $\mathsf{Lyapunov}^{\uparrow}$ *carrier. The decrease information exported by* L *is exactly the finite row* D*: a displayed comparison between the quadratic value of the predecessor state row and the quadratic value of the successor state row, routed through* C *and typed by* RealAlgOrder*. The packet exports no differentiability assumption, no infinite-time convergence assertion, no analytic limit, and no external optimization solver semantics.*

Proof. Project the carrier of Definition 313.1. The predecessor and successor state rows are the visible endpoints of the transition row T.

Use the continuation routes in C to read the two quadratic values from the same displayed certificate row Q. The order comparison between those two values is precisely the row D, and the positive-definite row P supplies only the local sign witness for Q on the named state rows.

The remaining coordinates are transport, provenance, and the local name row. None of them contains a derivative, an infinite trajectory, a limiting convergence theorem, or a solver state, so the decrease surface is exhausted by the finite comparison row described above. □

Theorem 313.3 (Lyapunov NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet of Definition 313.1;*
2. *classifier and stability: the componentwise* hsame *transport rule for state, transition, quadratic, positivity, decrease, continuation, provenance, and local name rows;*
3. *certificate ledger: the positive-definite witness row* P *and the one-step decrease row* D *of Definition 313.2;*
4. *consumer boundary: the finite stability read permitted to downstream control packets by Definition 313.4;*
5. *provenance: the* Pkg *row tying the packet to* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* RealAlgOrder*, and* $\mathsf{Riccati}^{\uparrow}$*.*

These rows form the full public seed surface for the Lyapunov certificate name.

Lean4 ✓ `BEDC.Derived.LyapunovUp.LyapunovLedger namecert obligation surface`

Proof. The carrier row fixes every coordinate that can be named by the certificate. The classifier is the finite membership test on those coordinates, and the stability clause is componentwise hsame transport along the same Cont routes.

The certificate ledger consists only of the positive-definite row and the decrease row. The consumer boundary then determines which downstream reads are available from those rows.

Finally, the package row names every imported BEDC certificate boundary. Since the carrier has no coordinate for analytic trajectory convergence, smooth derivatives, basin computation, or solver output, the five listed rows exhaust the local $\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$ obligation surface. □

Theorem 313.4 (Lyapunov consumer boundary)**.** *Every consumer of* $\mathsf{NameCert}_{\mathsf{Lyapunov}^\uparrow}$ *may read only the displayed state rows, transition rows, quadratic certificate row, positive-definite witness, one-step decrease ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row of Definition 313.1. A* $\mathsf{DynSystem}^\uparrow$ *consumer may use those rows as a finite stability certificate, and a* $\mathsf{Riccati}^\uparrow$ *or matrix-control consumer may reuse the quadratic and order rows, but no consumer obtains a basin-of-attraction computation, asymptotic convergence theorem, differentiable flow, or external synthesis solver from the certificate alone.*

Proof. Read a consumer map as a projection from the accepted carrier. The $\mathsf{DynSystem}^\uparrow$ projection returns the displayed state and transition rows together with the decrease comparison.

The matrix-control projection returns the quadratic row, its positive-definite witness, and the RealAlgOrder comparison row. The $\mathsf{Riccati}^\uparrow$ projection can reuse the same finite matrix and order coordinates as a named quadratic ledger, without adding any Riccati recursion step.

All other objects named in the statement are absent from the carrier and from the package provenance. They therefore cannot be read through $\mathsf{NameCert}_{\mathsf{Lyapunov}^\uparrow}$. □

Lean4 ✓ `BEDC.Derived.LyapunovUp.LyapunovPacket consumer boundary`

Theorem 313.5 (Lyapunov DynSystem sibling route)**.** *Every accepted* $\mathsf{Lyapunov}^\uparrow$ *stability read consumes the* $\mathsf{DynSystem}^\uparrow$ *state-and-transition surface of chapter 195 before the quadratic row, positive-definite row, and decrease ledger can be read. The route remains finite through* $X, T, Q, P, D, H, C, G, N$ *and does not export a basin computation, infinite trajectory, differentiable flow, or solver semantics.*

Proof. Project the carrier of Definition 313.1. The state row X and transition row T are the entry surface of the packet, and both are named through the displayed $\mathsf{DynSystem}^\uparrow$ dependency before any quadratic read is available.

The decrease ledger of Definition 313.2 then reads Q, P, D only along the continuation routes C and package row G. The consumer boundary of Definition 313.4 confirms that a downstream stability consumer receives exactly these finite rows.

Thus the substantive sibling dependency is the transition row supplied by chapter 195. Since the route is exhausted by $X, T, Q, P, D, H, C, G, N$, no basin computation, infinite trajectory, differentiable flow, or solver semantics is exported. □

Theorem 313.6 (Lyapunov stability transport)**.** *Let* $L = (X, T, Q, P, D, H, C, G, N)$ *be an accepted* $\mathsf{Lyapunov}^\uparrow$ *carrier and let* $L' = (X', T', Q', P', D', H', C', G', N')$ *be obtained by displayed* hsame *transport of all carrier rows, preserving the* Cont *routes named by the provenance row. Then* L' *is again an accepted* $\mathsf{Lyapunov}^\uparrow$ *carrier, and its finite stability read is the transported positive-definite and one-step decrease ledger over* X'*,* T'*, and* Q'*.*

Lean4 ✓ `BEDC.Derived.LyapunovUp.LyapunovPacket stability transport`

Proof. Transport the state and transition rows first. The preserved continuation routes identify the successor and predecessor slots of T' with the transported state rows in X'.

Next transport the quadratic certificate and its positive-definite witness. Because the order boundary is the same RealAlgOrder row carried by the provenance, the transported sign witness remains attached to Q' on the transported state rows.

Finally transport the decrease ledger, package row, and local name row. Repack the nine transported coordinates as $\mathsf{LyapunovLedger}(X', T', Q', P', D', H', C', G', N')$. The stability read of the new packet is exactly the transported positive-definite and decrease rows, since the carrier has no additional stability coordinate. □

Lean4 ✓ `BEDC.Derived.LyapunovUp.LyapunovLedger stability transport`

Theorem 313.7 (Lyapunov public export)**.** *The decrease ledger,* $\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$ *obligation surface, consumer boundary, and stability transport export exactly the finite state, transition, positivity, decrease, transport, continuation, provenance, and naming rows of* $\mathsf{Lyapunov}^{\uparrow}$*.*

The public export contains no minimizer-existence principle, no global asymptotic completeness theorem, no analytic regularity assertion, and no standard-model dynamics claim.

Proof. Project the finite carrier of Definition 313.1. The only state and transition data are the rows X and T, and the only certificate data are the quadratic row, the positivity witness, and the decrease ledger.

Apply Definition 313.2 and Definition 313.3. These identify the decrease row and the local naming surface over the displayed finite packet.

Use Definition 313.4 and Definition 313.6 to expose the consumer-facing rows and their displayed transport behavior. Since all cited rows are projections from the same finite carrier, the excluded analytic and standard-model claims have no coordinate in the public export. □

Closure status for $\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$**.**

Constructive story: A Lyapunov stability row is seeded by a finite BHist packet of state rows, transition rows, a quadratic certificate row, a positive-definite witness row, a one-step decrease ledger, hsame transports, Cont routes, Pkg provenance naming $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, RealAlgOrder, and $\mathsf{Riccati}^{\uparrow}$, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$, publicClosed)

Scope closed: Definition 313.7 binds only the finite state, transition, quadratic, positivity, one-step decrease, transport, continuation, provenance, and name rows listed in Definition 313.1.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Lyapunov}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.LyapunovUp.LyapunovLedger\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close differentiable Lyapunov theory, asymptotic convergence, basin computation, controller synthesis, external solver semantics, or a standard bridge.

Upgrade path: Bridged closure requires a standard bridge over the finite state, transition, positivity, decrease, transport, continuation, provenance, and naming rows.

Chapter 314

A Concrete Naming Certificate for $\mathsf{DyadicCompletion}^{\uparrow}$

The $\mathsf{DyadicCompletion}^{\uparrow}$ surface is the constructive completion handoff between finite dyadic observations and the regular real-name layer. Following the Bishop–Bridges constructive-analysis treatment of Cauchy completion for dyadics, the chapter records only scheduled finite observations, explicit regular-tail witnesses, and visible precision ledgers. It does not identify streams by quotient classes, select limits by choice, or replace the stream surface by Dedekind cuts.

314.1 Carrier Surface

Definition 314.1 (DyadicCompletion finite-window carrier)**.** *A* $\mathsf{DyadicCompletion}^{\uparrow}$ *carrier row is a finite* BHist *packet* (d, w, r, s, L, P) *with the following visible coordinates:*

1. *dyadic observation rows* d *accepted by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. *certified stream windows* w *requested through* $\mathsf{StreamName}^{\uparrow}$*;*
3. *a regular-tail classifier row* r *whose comparisons are read through* $\mathsf{RegSeqRat}^{\uparrow}$*;*
4. *a real-name boundary row* s *naming the data consumed by* $\mathsf{Real}^{\uparrow}$*;*
5. *a precision ledger* L *recording every finite schedule, tail bound, and window restriction used by the packet;*
6. *a* Pkg *provenance row* P *naming the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *certificates.*

The carrier stores finite windows and their ledgers. It contains no completed host real, no quotient class of Cauchy streams, no hidden precision schedule, and no Dedekind-cut classifier.

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.TasteGate.DyadicCompletionTasteGate single carrier alignment`

Theorem 314.2 (DyadicCompletion NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicCompletion}^{\uparrow}}$ *obligation surface consists exactly of the carrier of Definition 314.1, the componentwise classifier that compares dyadic observations and stream-window rows, the regular-tail stability row read through* $\mathsf{RegSeqRat}^{\uparrow}$*, the* $\mathsf{Real}^{\uparrow}$ *handoff row for accepted real-name consumers, and the precision ledger boundary that records every schedule consumed by the packet.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionPacket namecert obligation surface`

Proof. Project the carrier coordinates. The dyadic, stream, regular-tail, real-handoff, ledger, and provenance rows are all stored as finite BHist data.

The classifier is componentwise because a consumer can compare only the rows it can read: dyadic observations through $\mathsf{DyadicRatCore}^{\uparrow}$, scheduled windows through $\mathsf{StreamName}^{\uparrow}$, and tail comparisons through $\mathsf{RegSeqRat}^{\uparrow}$.

The $\mathsf{Real}^{\uparrow}$ handoff is therefore a boundary projection rather than a selected limit. Repacking these projections gives the listed obligation surface and no additional completion object. □

Theorem 314.3 (DyadicCompletion constant dyadic embedding)**.** *Every accepted* $\mathsf{DyadicRatCore}^{\uparrow}$ *row q determines a* $\mathsf{DyadicCompletion}^{\uparrow}$ *carrier whose scheduled stream windows all read q, whose regular-tail classifier rows are reflexive dyadic comparisons, whose* $\mathsf{Real}^{\uparrow}$ *boundary row is the constant real-name handoff, and whose precision ledger records only the requested windows and their constant readback routes.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionPacket constant embedding`

Proof. Use the constant $\mathsf{StreamName}^{\uparrow}$ schedule with value row q at each requested finite window. Each endpoint read is already accepted by $\mathsf{DyadicRatCore}^{\uparrow}$.

For the regular-tail coordinate, compare any two displayed windows by the reflexive dyadic classifier on the same row q. The bound rows are the trivial constant-tail witnesses consumed by $\mathsf{RegSeqRat}^{\uparrow}$.

Finally attach the $\mathsf{Real}^{\uparrow}$ handoff row that reads the same constant windows. The ledger records the schedule requests and the constant routes, so no quotient, limit selector, or hidden precision choice is introduced. □

Theorem 314.4 (DyadicCompletion regular-tail stability)**.** *Let C be an accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *carrier. If a second carrier C' is obtained by* hsame *transport of the dyadic observation rows, certified stream windows, regular-tail comparisons, real-name boundary row, ledger, and provenance, then C' is accepted and has the same regular-tail classifier surface over* $\mathsf{RegSeqRat}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionWindowCarrier regular tail stability`
Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionWindowPacket regular tail stability`
Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionPacket regular tail stability`

Proof. Transport the dyadic observation rows and certified stream windows along the displayed hsame comparisons. The $\mathsf{StreamName}^{\uparrow}$ schedule is finite, so each requested window is repacked with the transported row.

The regular-tail classifier is a finite family of dyadic bound ledgers. Transport each bound row and each comparison route componentwise through $\mathsf{RegSeqRat}^{\uparrow}$.

The real-name boundary and precision ledger are projections of the same windows. Transporting those projections yields the accepted carrier C' and preserves the regular-tail surface. □

Theorem 314.5 (DyadicCompletion StreamName handoff)**.** *Every accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *carrier exposes a* $\mathsf{StreamName}^{\uparrow}$ *handoff: for each finite precision request, the handoff returns exactly the scheduled dyadic observation row, its window certificate, the regular-tail comparison rows visible at that precision, and the ledger entries proving that the same rows are available to* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionWindowPacket streamname handoff`

Proof. Unpack the carrier. A precision request first selects a finite stream window, and the carrier stores the dyadic observation row and certificate attached to that window.

The regular-tail row records the comparisons visible at the same precision. The ledger points to the shared schedule entry, so the $\mathsf{RegSeqRat}^{\uparrow}$ consumer and the $\mathsf{Real}^{\uparrow}$ boundary read the same finite rows.

Thus the handoff is only a projection from stored data. It does not synthesize a global stream outside the certified windows. □

Theorem 314.6 (DyadicCompletion ledger boundary)**.** *The precision ledger of an accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *carrier is the whole boundary between dyadic finite observations and real-name consumption: every visible* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *row used by the carrier is named in the ledger, and no consumer can project an unstored modulus, quotient representative, Dedekind cut, or ambient completed real from the packet.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionPacket ledger boundary`

Proof. Inspect the ledger coordinate in Definition 314.1. It lists the finite schedules, tail bounds, window restrictions, and continuation routes consumed by each displayed row.

Any downstream read by $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ must pass through one of those listed routes. Since the carrier has no coordinate for an unstored modulus, quotient representative, Dedekind cut, or completed host real, such data cannot be projected from the packet. □

Theorem 314.7 (DyadicCompletion scoped dependency packet)**.** *The carrier of Definition 314.1, the componentwise classifier of Definition 314.2, the constant dyadic embedding of Definition 314.3, the regular-tail stability of Definition 314.4, the* $\mathsf{StreamName}^{\uparrow}$ *handoff of Definition 314.5, the* $\mathsf{Real}^{\uparrow}$ *handoff boundary named in the carrier, and the ledger boundary of Definition 314.6 depend only on finite* BHist *rows, displayed* hsame *comparisons, visible* Cont *routes, the* Pkg *provenance row, and the named* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source certificates.*

Thus every accepted $\mathsf{DyadicCompletion}^{\uparrow}$ *packet is scoped by the finite BEDC rows and source certificates listed above.*

Proof. Project the finite packet coordinates of Definition 314.1. They are dyadic observation rows, certified stream windows, regular-tail rows, a real-name handoff row, ledger entries, and one Pkg provenance row naming the source certificates.

The componentwise classifier is the classifier component of Definition 314.2. The constant embedding row is Definition 314.3, and the regular-tail row is transported by Definition 314.4; each cited block reads only finite BHist rows through hsame, Cont, and the displayed package provenance.

The consumer handoff is Definition 314.5. Its stream-name and real-name reads are the same scheduled rows already present in the carrier, with the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ source certificates named by the package row.

Finally apply Definition 314.6. The ledger names every $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ row available to a consumer, and the carrier has no coordinate for a quotient stream, Dedekind cut, host real, or chosen limit. □

Theorem 314.8 (DyadicCompletion public RegSeqRat Real export)**.** *The carrier of Definition 314.1, the* $\mathsf{NameCert}_{\mathsf{DyadicCompletion}^{\uparrow}}$ *obligation surface of Definition 314.2, the constant dyadic embedding of Definition 314.3, regular-tail stability of Definition 314.4,* $\mathsf{StreamName}^{\uparrow}$ *handoff of Definition 314.5, ledger boundary of Definition 314.6, and scoped dependency packet of Definition 314.7 assemble the public* $\mathsf{DyadicCompletion}^{\uparrow}$ *export consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*.*

The export exposes only finite dyadic observations, certified stream windows, regular-tail rows, real-boundary rows, precision ledger rows, BHist*,* hsame*,* Cont*,* Pkg*, and source certificates. It exports no quotient stream, Dedekind cut, host real, choice-selected limit, or completeness principle.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionWindowPacket public regseqrat real export`

Proof. Project the finite packet from Definition 314.1. Its coordinates are scheduled dyadic observations, certified stream windows, regular-tail rows, real-name handoff rows, ledger entries, and package provenance.

Compose the public export from the cited blocks. The obligation surface supplies the carrier and classifier rows, the constant embedding supplies dyadic constants, regular-tail stability transports tail rows, and the $\mathsf{StreamName}^{\uparrow}$ handoff fixes the downstream stream-window reads.

The ledger boundary names the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer-facing rows, while the scoped dependency package binds all reads to finite BHist rows, hsame, Cont, Pkg, NameCert, and the listed source certificates.

The excluded principles are therefore outside the export. A quotient stream, Dedekind cut, host real, choice-selected limit, or completeness principle would require a coordinate not present in the finite packet. □

Theorem 314.9 (DyadicCompletion finite-window standard bridge)**.** *The carrier of Definition 314.1, the* $\mathsf{NameCert}_{\mathsf{DyadicCompletion}^{\uparrow}}$ *obligation surface of Definition 314.2, the* $\mathsf{StreamName}^{\uparrow}$ *handoff of Definition 314.5, regular-tail stability of Definition 314.4, the ledger boundary of Definition 314.6, the scoped dependency packet of Definition 314.7, and the public* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *export of Definition 314.8 determine the standard constructive finite-window reading of* $\mathsf{DyadicCompletion}^{\uparrow}$*.*

Every consumer read factors through finite dyadic observation rows, stream-window rows, regular-tail rows, real-boundary rows, precision ledger rows, BHist*,* hsame*,* Cont*,* Pkg*, and the listed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source certificates. The bridge exports no quotient Cauchy stream, Dedekind cut, host real limit, choice-selected limit, or completeness principle.*

Lean4 ✓ `BEDC.Derived.DyadicCompletionUp.DyadicCompletionWindowPacket finite window standard bridge`

Proof. Project the carrier from Definition 314.1. The projected coordinates are the dyadic observation rows, stream-window rows, regular-tail rows, real-name boundary row, precision ledger, and package provenance. These are the only rows available to the $\mathsf{NameCert}_{\mathsf{DyadicCompletion}^{\uparrow}}$ obligation surface.

Use Definition 314.5 for window reads. The handoff sends each downstream stream access to a scheduled stream-window row, and Definition 314.4 transports the regular-tail rows along the displayed classifier rather than through an unstored tail representative.

Apply Definition 314.6. The ledger lists every precision, real-boundary, continuation, history, package, and source-certificate row readable by a consumer, so no unstored modulus, quotient representative, Dedekind cut, host real limit, choice-selected limit, or completeness witness is available.

Finally use Definition 314.8 to route the same finite rows to $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers. Since the scoped dependency packet of Definition 314.7 binds those reads to BHist, hsame, Cont, Pkg, and the listed source certificates, the resulting consumer schema is exactly the standard constructive finite-window reading. □

Theorem 314.10 (DyadicCompletion mature RegSeqRat Real consumer coverage)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of a* $\mathsf{DyadicCompletion}^{\uparrow}$ *packet receives precisely the* $\mathsf{NameCert}_{\mathsf{DyadicCompletion}^{\uparrow}}$ *obligation surface, constant dyadic embedding, regular-tail stability,* $\mathsf{StreamName}^{\uparrow}$ *handoff, ledger boundary, scoped dependency packet, public* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *export, and finite-window standard bridge of Definition 314.9.*

The coverage contains no quotient completion, Dedekind cut, trichotomy, host equality, chosen limit, or extra completion principle.

Proof. Project the packet through Definition 314.2 and Definition 314.3. This exposes the carrier, classifier, and constant dyadic rows available to any consumer.

Next apply Definition 314.4 and Definition 314.5. These rows keep the regular tail and stream-name reads inside the displayed finite schedules and real-boundary handoff rows.

Use Definition 314.6 together with Definition 314.7. The ledger and scoped package list every BHist, hsame, Cont, Pkg, source certificate, precision, and real-boundary row readable by the consumer.

Finally apply Definition 314.8 and Definition 314.9. The public export and standard bridge repack exactly the same finite rows for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers. Since none of the cited rows contains quotient completion, Dedekind cuts, trichotomy, host equality, or a chosen limit, those data are not part of the mature consumer coverage. □

Theorem 314.11 (DyadicCompletion finite-window ledger source exhaustion)**.** *Every finite-window read of an accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *packet by a* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer factors through exactly the ledger-named source rows of Definition 314.1: dyadic observation rows,* $\mathsf{StreamName}^{\uparrow}$ *window rows, regular-tail comparison rows, real-boundary rows,* BHist *history,* hsame *transport,* Cont *continuation, and* Pkg *provenance.*

Conversely, every ledger-named source row in that carrier is readable by the corresponding $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer after the displayed transport through the public finite-window handoff.*

The exhaustion statement contains no quotient completion, Dedekind cut, trichotomy, host equality, chosen limit, or hidden precision schedule.

Proof. First use Definition 314.5. A downstream window read is sent to one of the displayed $\mathsf{StreamName}^{\uparrow}$ window rows, and the handoff provides no alternate stream carrier.

Next combine Definition 314.6 with Definition 314.8. The ledger boundary lists the dyadic observation, regular-tail, real-boundary, history, transport, continuation, package, and provenance rows, while the public export reuses those same rows for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers.

For the reverse direction, apply Definition 314.9. Each ledger-named row is repacked as a standard finite-window read along the displayed transport, so the corresponding $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ consumer can read it without adding data.

Finally invoke Definition 314.10. The mature coverage theorem identifies the complete consumer boundary, so the two directions exhaust the same finite ledger rows and exclude quotient completion, Dedekind cuts, trichotomy, host equality, chosen limits, and hidden precision schedules. □

Theorem 314.12 (DyadicCompletion RegSeqRat window exhaustion)**.** *For any accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *finite-window packet, every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read exposed by the public finite-window export factors through one of the ledger-named rows already listed by the packet: dyadic observation rows, scheduled* $\mathsf{StreamName}^{\uparrow}$ *window rows, regular-tail classifier rows, real-boundary rows,* hsame *transports,* Cont *routes, and* Pkg *provenance rows.*

Conversely, every ledger-named regular-tail or window row supplies the same $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read after the displayed finite-window standard bridge. This exhaustion exports no quotient Cauchy stream, Dedekind cut, host real limit, hidden precision schedule, or choice-selected limit.*

Proof. First apply Definition 314.5. It sends the scheduled finite read to the displayed $\mathsf{StreamName}^{\uparrow}$ window row, so the consumer has no alternate stream schedule outside the packet.

Next use Definition 314.4. The regular-tail classifier is transported along the packet's hsame and Cont rows, and the transport preserves exactly the ledger-named tail comparison row read by the $\mathsf{RegSeqRat}^{\uparrow}$ consumer.

Combine Definition 314.6 with Definition 314.8. These theorems identify the visible dyadic observation, real-boundary, history, transport, continuation, and package provenance rows exported to public $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers.

For the converse, apply Definition 314.9 and Definition 314.11. A ledger-named regular-tail or scheduled-window row is repacked through the same finite-window standard bridge, and the source exhaustion theorem says that no further source row is available to the consumer.

Thus the two readings have the same public $\mathsf{RegSeqRat}^{\uparrow}$ row boundary. The excluded quotient streams, cuts, host limits, hidden schedules, and selected limits are absent because none of the cited ledger, handoff, stability, export, or bridge rows carries them. □

Theorem 314.13 (DyadicCompletion terminal finite-window seal determinacy)**.** *Consider two* $\mathsf{DyadicCompletion}^{\uparrow}$ *finite-window packets whose dyadic observation row,* $\mathsf{StreamName}^{\uparrow}$ *window row, regular-tail row,* $\mathsf{Real}^{\uparrow}$ *boundary row, ledger row, provenance row, and downstream handoff route agree by the displayed* hsame*,* Cont*, and* Pkg *witnesses. Then every terminal* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal consumer factors through the same public finite-window row. No second terminal seal, hidden precision schedule, quotient completion, host equality, or choice-selected limit is exported by the DyadicCompletion boundary.*

Proof. First apply Definition 314.5. The common $\mathsf{StreamName}^{\uparrow}$ window row fixes the visible stream handoff for both packets, and the displayed hsame witness gives the same finite observation boundary.

Next combine Definition 314.8 with Definition 314.6. The regular-tail row, $\mathsf{Real}^{\uparrow}$ boundary row, ledger row, provenance row, and Pkg source row are therefore read from a single public packet surface, while the listed Cont routes give the same downstream handoff for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers.

Now use Definition 314.9. The shared ledger and transport rows repack the two finite-window packets as the same standard public row, so transitivity of the displayed hsame comparisons identifies the row consumed by either terminal seal.

Finally invoke Definition 314.10. Mature coverage says that the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers listed above exhaust the terminal boundary; hence no further seal, precision schedule, quotient completion, host equality, or choice-selected limit can be exported outside the identified finite-window row. □

Theorem 314.14 (DyadicCompletion RealUp route exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read exposed by an accepted* $\mathsf{DyadicCompletion}^{\uparrow}$ *finite-window packet is exhausted by the same finite route through the dyadic observation rows, the* $\mathsf{StreamName}^{\uparrow}$ *windows of chapter 126, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-tail rows of chapter 301, the dyadic precision rows of chapter 291, the* $\mathsf{Real}^{\uparrow}$ *boundary of chapter 38, the precision ledger, the displayed* hsame *and* Cont *transports, the* Pkg *row, and the local* NameCert *provenance row.*

Consequently no DyadicCompletion$^{\uparrow}$ *terminal* Real$^{\uparrow}$ *seal can be read through a second route outside the listed stream-window, regular-tail, dyadic, real-boundary, ledger, transport, continuation, package, and provenance rows.*

Proof. Project the accepted packet through Definition 314.1. The carrier exposes the finite tuple of dyadic observations, stream-window names, regular-tail certificates, real-boundary handoff, precision ledger, history comparison, continuation, package source, and local provenance rows on which a DyadicCompletion$^{\uparrow}$ consumer may depend.

Next apply Definition 314.11. The ledger admits only the scheduled dyadic and StreamName$^{\uparrow}$ windows named by the packet, so the Real$^{\uparrow}$ seal cannot import an additional finite-window source. Apply Definition 314.12 to the regular-tail side; the RegSeqRat$^{\uparrow}$ read is forced through the same window, ledger, hsame, Cont, and Pkg route.

The sibling chapters provide the route endpoints. The stream-window rows come from chapter 126, the regular-tail classifier rows from chapter 301, the dyadic precision rows from chapter 291, and the terminal real-name boundary from chapter 38. These are precisely the rows already recorded by the local NameCert provenance surface.

Finally use Definition 314.13. Once the dyadic observation, stream-window, regular-tail, real-boundary, ledger, transport, continuation, package, and provenance rows agree, the terminal Real$^{\uparrow}$ seal has no alternate public finite-window row. Hence the displayed route exhausts every DyadicCompletion$^{\uparrow}$ real-seal read. □

Theorem 314.15 (DyadicCompletion regular-tail budget refinement)**.** *Let an accepted* DyadicCompletion$^{\uparrow}$ *finite-window packet carry a certified tail-radius seal whose regular-tail radius is refined along the* StreamName$^{\uparrow}$ *handoff row. Then the refined seal induces the same* RegSeqRat$^{\uparrow}$ *classifier window as the original packet and preserves the terminal* Real$^{\uparrow}$ *seal route exhausted in Definition 314.14.*

The induced budget witness is the one consumed by chapter 1053: it records the same dyadic observation rows, scheduled StreamName$^{\uparrow}$ *windows, regular-tail comparison rows, precision ledger entries, displayed* hsame *and* Cont *transports,* Pkg *provenance, and local* NameCert *source certificate, with only the tail-radius ledger made sharper.*

Proof. First apply Definition 314.4. Refining the tail-radius seal along the displayed hsame and Cont rows transports the regular-tail comparison data without changing the RegSeqRat$^{\uparrow}$ classifier window read from the packet.

Next use Definition 314.5. The sharpened radius is attached to the same scheduled StreamName$^{\uparrow}$ handoff row, so the stream-window source and the regular-tail classifier still share the ledger row visible to the downstream consumer.

Finally invoke Definition 314.14. Since the dyadic observation, stream-window, regular-tail, real-boundary, ledger, transport, continuation, package, and provenance rows are the same rows after refinement, the terminal Real$^{\uparrow}$ seal is forced through the same finite route. The only exported extra datum is the sharper budget witness used by chapter 1053. □

Closure status for NameCert$_{\text{DyadicCompletion}^{\uparrow}}$**.**

Theory closure: TheoryGate(NameCert$_{\text{DyadicCompletion}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 314.10 identifies the finite dyadic observation, stream-window, regular-tail, real-boundary, ledger, transport, continuation, package, public export, and standard bridge rows as the mature constructive RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ consumer boundary over the listed BEDC source certificates.

Constructive story: A DyadicCompletion$^{\uparrow}$ packet is generated by scheduled dyadic observations, certified stream windows, regular-tail comparison rows, a real-name handoff boundary, and a precision ledger that records every consumed schedule and tail bound.

Formal verification: FormalStatus(NameCert$_{\text{DyadicCompletion}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DyadicCompletionUp.DyadicCompletionPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close the Lean namespace, a complete real construction, quotient equality of Cauchy streams, Dedekind real equivalence, host real limits, choice-selected limits, or completeness.

Upgrade path: The paper-side mature consumer coverage is complete; remaining work is Lean-side formalization and bridge checking for the same DyadicCompletion$^{\uparrow}$ packet.

Chapter 315

A Concrete Naming Certificate for $\mathsf{FastCauchySeq}^{\uparrow}$

The $\mathsf{FastCauchySeq}^{\uparrow}$ interface names explicit-rate Cauchy sequence packets over dyadic-rational observations. Bishop and Bridges treat a displayed Cauchy rate as constructive data; the BEDC packet records the finite ledger version of that data, connecting $\mathsf{CauchyModulus}^{\uparrow}$ to $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ without quotient completion or a selected limit.

Theorem 315.1 (FastCauchySeq sibling source lattice)**.** *Every accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet reads its scheduled observation stream through chapter 126, its threshold table through chapter 292, and its endpoint/radius ledger through chapter 291.*

The same packet sends its forgetful regularity handoff through chapter 301 and its consumer seal through chapter 38. This lattice introduces no quotient real, no selected limit, and no ambient completeness row.

Proof. Read the carrier tuple of Definition 315.2. Its stream coordinate is the scheduled $\mathsf{StreamName}^{\uparrow}$ observation surface, its modulus coordinate is the $\mathsf{CauchyModulus}^{\uparrow}$ threshold table, and its dyadic rows are the endpoint and radius ledger supplied by $\mathsf{DyadicRatCore}^{\uparrow}$.

For the outgoing boundaries, apply Definition 315.5 to remove only the local certificate row while keeping the finite regularity data. Then apply Definition 315.6 to restrict the visible surface to the rows a $\mathsf{Real}^{\uparrow}$ consumer may read.

Both passages are projections from the same explicit-rate carrier. Since the carrier has no completed-real coordinate, quotient-real coordinate, selected-limit coordinate, or ambient completeness row, none is introduced by recording the sibling source lattice. □

315.1 Explicit-rate carrier and classifier

Definition 315.2 (FastCauchySeq carrier)**.** *A* $\mathsf{FastCauchySeq}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (s, \mu, E, R, L, T, P, N)$$

with the following visible rows:

1. *s is a scheduled* $\mathsf{StreamName}^{\uparrow}$ *dyadic-rational observation stream;*
2. *μ is a* $\mathsf{CauchyModulus}^{\uparrow}$ *precision-threshold table, displaying for each requested precision row a finite index bound after which the stream is required to be close;*

3. *E lists the dyadic endpoint and dyadic radius rows read through* $\mathsf{DyadicRatCore}^{\uparrow}$ *at the visible precisions;*
4. *R is the late-pair comparison ledger recording that any two displayed observations beyond the threshold named by μ fall inside the displayed dyadic radius row for that precision;*
5. *L records the componentwise* hsame *transports for the stream, threshold, endpoint, radius, and comparison rows;*
6. *T records the displayed* Cont *windows through which the finite reads of s, μ, E, and R are consumed;*
7. *P is the* Pkg *provenance over* $\mathsf{Nat}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$ *row for this packet.*

The carrier is the finite explicit-rate sequence surface only. It contains no completed real, no quotient equality of Cauchy names, and no selected limiting value.

Definition 315.3 (FastCauchySeq classifier)**.** *For accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packets F and F', the classifier* $\mathsf{FastCauchySeqClassifier}(F, F')$ *holds when the scheduled stream rows, Cauchy-modulus threshold rows, dyadic endpoint and radius rows, late-pair comparison ledgers,* hsame *transports,* Cont *windows,* Pkg *provenance, and local* NameCert *rows transport componentwise through the displayed classifiers of their source chapters.*

The classifier identifies two packets only at the level of the visible explicit-rate ledger. It does not assert equality of quotient real numbers, does not choose a limit, and does not add a completeness principle to $\mathsf{Real}^{\uparrow}$*.*

Theorem 315.4 (FastCauchySeq NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$ *obligation surface has five finite rows:*

1. *carrier: the* BHist *packet of Definition 315.2;*
2. *classifier: the componentwise classifier of Definition 315.3;*
3. *stability: the* hsame *and* Cont *rows transporting the scheduled stream, threshold table, dyadic endpoint and radius rows, and late-pair comparison ledger;*
4. *handoff: the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity window obtained by forgetting the local row N and retaining the stream, modulus, dyadic, and comparison rows;*
5. *seal boundary: the* $\mathsf{Real}^{\uparrow}$ *consumer boundary that can read only the displayed stream, modulus, dyadic, and provenance rows.*

These rows are exactly the explicit-rate naming certificate for $\mathsf{FastCauchySeq}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.FastCauchySeqUp.FastCauchySeqPacket semantic name certificate`

Proof. Project the carrier coordinates from Definition 315.2. The first two rows expose the scheduled dyadic observation stream and the precision-threshold table, while the dyadic and late-pair rows expose the finite comparison data at the requested precisions.

The stability row is obtained by transporting each projected coordinate through the displayed hsame and Cont routes recorded by L and T. Because each route is componentwise, the transported packet has the same finite obligation shape.

The final two rows are projections of the same packet through the named source boundaries. Forgetting N gives the $\mathsf{RegSeqRat}^{\uparrow}$ regularity window, and restricting to the $\mathsf{Real}^{\uparrow}$ seal boundary removes every coordinate not listed in the carrier, classifier, stability, and provenance rows. □

Theorem 315.5 (FastCauchySeq forgetful handoff to RegSeqRat)**.** *Every accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet forgets to a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity window. The forgotten packet keeps the scheduled* $\mathsf{StreamName}^{\uparrow}$ *dyadic-rational observation stream, the visible* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, the dyadic endpoint and radius rows from* $\mathsf{DyadicRatCore}^{\uparrow}$*, the late-pair comparison ledger, and the provenance over* $\mathsf{Nat}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$*.*

The handoff drops only the local $\mathsf{FastCauchySeq}^{\uparrow}$ *certificate row. It does not drop the finite regularity evidence required by* $\mathsf{RegSeqRat}^{\uparrow}$*, and it does not produce a quotient real or a selected limit.*

Proof. Start from the carrier tuple of Definition 315.2. Remove the local row N and keep the stream, modulus, dyadic endpoint, dyadic radius, comparison, transport, window, and provenance coordinates.

The $\mathsf{CauchyModulus}^{\uparrow}$ rows close the finite threshold requests: for each displayed precision, the row supplies the index bound used by the late-pair comparison ledger. The ledger then shows that the visible stream values beyond that bound lie inside the corresponding dyadic radius window.

These are precisely the finite regularity rows consumed by $\mathsf{RegSeqRat}^{\uparrow}$. Repacking them yields the regular sequence window, while the absence of any completed-real coordinate prevents the handoff from selecting a limit or asserting quotient equality. □

Lean4 ✓ `BEDC.Derived.FastCauchySeqUp.FastCauchySeqPacket regseqrat forgetful handoff`

Theorem 315.6 (FastCauchySeq Real seal consumer boundary)**.** *A* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet may read only the scheduled observation stream, the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, the dyadic endpoint and radius rows, the late-pair comparison ledger, and the provenance rows named by* Pkg*.*

The consumer receives no quotient real, no equality of Cauchy names, no completed metric object, and no selected limit. Its surface is the finite explicit-rate name carried by the stream, modulus, dyadic, comparison, hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

Proof. Project the accepted packet through Definition 315.2 and Definition 315.3. The only rows available to a downstream consumer are the stream, modulus, dyadic, comparison, transport, window, provenance, and local certificate rows.

Apply the $\mathsf{RegSeqRat}^{\uparrow}$ forgetful handoff of Definition 315.5. It presents the same finite regularity window to the real-name boundary and leaves behind the local certificate row.

Finally restrict along the $\mathsf{Real}^{\uparrow}$ classifier transport boundary. That boundary consumes the displayed regular sequence data and provenance only. Since the carrier has no quotient-real coordinate, no completed metric coordinate, and no selected limit coordinate, none can be read by a $\mathsf{Real}^{\uparrow}$ consumer. □

Lean4 ✓ `BEDC.Derived.FastCauchySeqUp.FastCauchySeqPacket real seal consumer boundary`

Theorem 315.7 (FastCauchySeq tail-modulus Real boundary)**.** *For an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet, every* $\mathsf{Real}^{\uparrow}$ *consumer read factors through the* $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff together with the visible* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, dyadic endpoint and radius rows, late-pair comparison ledger, componentwise* hsame *transports, displayed* Cont *windows, and* Pkg *provenance named by the carrier.*

The factorization keeps the local NameCert *row as the certificate for the finite explicit-rate surface and exposes no quotient real equality, no selected limit, and no completed metric object. Thus the* $\mathsf{Real}^{\uparrow}$ *boundary is the finite tail-modulus read of the scheduled stream, not a completion or limit-selection principle.*

Proof. Unpack Definition 315.2. The packet contains the scheduled stream, the explicit $\mathsf{CauchyModulus}^{\uparrow}$ threshold table, dyadic endpoint and radius rows, the late-pair comparison ledger, hsame transport rows, Cont windows, Pkg provenance, and the local NameCert row.

Apply Definition 315.5. This keeps the stream, modulus, dyadic, comparison, transport, window, and provenance rows as the finite regular-rational window and forgets only the local $\mathsf{FastCauchySeq}^{\uparrow}$ certificate row from the outgoing $\mathsf{RegSeqRat}^{\uparrow}$ packet.

Now restrict that window by Definition 315.6. The $\mathsf{Real}^{\uparrow}$ consumer may inspect exactly the scheduled observations, threshold rows, dyadic endpoint-radius data, late-pair ledger, transport, window, provenance, and naming rows already visible in the carrier.

Because the carrier contains no quotient-real coordinate, no selected limit, and no completed metric object, the resulting Real-facing read cannot acquire any such row after the handoff. □

Theorem 315.8 (FastCauchySeq public explicit-rate export)**.** *The carrier and classifier of Definition 315.2 and Definition 315.3, the* $\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$ *obligation surface of Definition 315.4, the* $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff of Definition 315.5, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 315.6 jointly export the reusable public* $\mathsf{FastCauchySeq}^{\uparrow}$ *explicit-rate interface.*

The exported interface consists exactly of the scheduled finite stream, $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, dyadic endpoint and radius rows, late-pair ledger, componentwise* hsame *transports, visible* Cont *windows,* Pkg *provenance, and* NameCert *row. It exposes those rows as the common surface for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers without adding quotient real equality, a completed metric object, or a selected limit.*

Lean4 ✓ `BEDC.Derived.FastCauchySeqUp.FastCauchySeqPacket public explicit rate export`

Proof. Project the packet through Definition 315.2. This exposes the scheduled stream, explicit threshold table, dyadic endpoint and radius rows, late-pair ledger, transport table, continuation windows, package provenance, and local name-certificate row.

Use the classifier of Definition 315.3 to make the same projected rows invariant under the displayed componentwise transports. The obligation surface of Definition 315.4 then repacks those projections as the finite $\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$ surface.

The $\mathsf{RegSeqRat}^{\uparrow}$ side is exactly the forgetful handoff of Definition 315.5. It retains the stream, threshold, dyadic, comparison, transport, window, and provenance rows and forgets only the local certificate row as a local certificate.

The $\mathsf{Real}^{\uparrow}$ side is exactly the consumer boundary of Definition 315.6. Since that boundary can read only the same finite explicit-rate rows, the assembled public interface exports no coordinate for quotient equality, completed metrics, or limit selection. □

Theorem 315.9 (FastCauchySeq standard explicit-rate bridge)**.** *The public explicit-rate export of Definition 315.8 is precisely the standard constructive explicit-rate Cauchy-sequence schema over scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, the late-pair comparison ledger, visible* hsame *and* Cont *transport,* Pkg *provenance, and the local* NameCert *row.*

In one direction, every public $\mathsf{FastCauchySeq}^{\uparrow}$ *row supplies one standard explicit-rate datum: a scheduled observation stream, an explicit threshold assignment for each tolerance row, dyadic*

endpoint and radius evidence for the observed window, and a late-pair comparison certificate whose transport and provenance are visible. In the reverse direction, every standard datum accepted at this paper site is one of those public $\mathsf{FastCauchySeq}^{\uparrow}$ *rows, read through the* $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff and the* $\mathsf{Real}^{\uparrow}$ *seal boundary.*

Thus the bridge adds no quotient real, completed metric object, selected limit, or hidden threshold selector to the public export.

Proof. Project the carrier and classifier of Definition 315.2 and Definition 315.3. The projection exposes exactly the scheduled stream, explicit threshold table, dyadic endpoint and radius rows, late-pair comparison ledger, componentwise transport rows, continuation windows, package provenance, and local name-certificate row named by the public export.

For the forward direction, apply the $\mathsf{RegSeqRat}^{\uparrow}$ forgetful handoff of Definition 315.5. It reads the same finite stream, threshold, dyadic, comparison, transport, window, and provenance rows as a regular-rational explicit-rate datum, while the Definition 315.6 records the matching $\mathsf{Real}^{\uparrow}$ consumer face.

For the reverse direction, inspect what is accepted at this site as a standard explicit-rate datum. The only available coordinates are the rows exported by Definition 315.8; the classifier identifies representatives only through visible hsame and Cont transport, and Pkg plus NameCert provide provenance rather than extra analytic structure.

Since neither the carrier nor the two consumer boundaries contain a coordinate for quotient-real equality, a completed metric object, a selected limit, or a hidden threshold selector, the two readings are the same finite BEDC explicit-rate schema. □

Theorem 315.10 (FastCauchySeq modulus precision-window factorization)**.** *Let F be an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet, and let D be a displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *row selecting a finite precision window for F. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read and every* $\mathsf{Real}^{\uparrow}$ *consumer read over D factors through the same visible finite rows of F: the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row selected by D, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows read at that precision, the late-pair ledger for the selected window, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

Conversely, each displayed threshold, endpoint, radius, late-pair, transport, continuation, provenance, and name row indexed by D appears in both the $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff and the* $\mathsf{Real}^{\uparrow}$ *seal boundary. Thus the finite-window read over D is a factorization of explicit Cauchy-rate data through the public* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet, not a read through quotient real equality, a completed metric object, a selected limit, or a hidden threshold selector.*

Proof. Project the accepted packet through Definition 315.2. The displayed row D selects only a finite precision window, so the carrier projection exposes exactly the corresponding threshold row, dyadic endpoint and radius rows, late-pair ledger, transport rows, continuation routes, provenance row, and local naming row.

For the $\mathsf{RegSeqRat}^{\uparrow}$ read, apply Definition 315.5. The handoff forgets only the local $\mathsf{FastCauchySeq}^{\uparrow}$ certificate row as a local certificate and retains the selected stream, threshold, dyadic, comparison, transport, window, and provenance coordinates indexed by D.

For the $\mathsf{Real}^{\uparrow}$ read, use Definition 315.6 together with Definition 315.7. These boundaries allow a real-name consumer to inspect the same displayed explicit-rate rows and no coordinate outside the finite tail-modulus surface.

Finally compare with Definition 315.9. The bridge identifies the public explicit-rate schema with the visible $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, late-pair, hsame, Cont, Pkg, and NameCert rows, so every row selected by D occurs in both consumer faces and every such consumer face factors

through those rows. Since the carrier and the two boundaries contain no quotient-real equality, completed metric object, selected limit, or hidden threshold selector, none is introduced by the factorization. □

Theorem 315.11 (FastCauchySeq synchronized precision window)**.** *Let F and F' be accepted* FastCauchySeq$^{\uparrow}$ *packets, and let D and D' be displayed* DyadicPrecision$^{\uparrow}$ *rows selecting finite precision windows for them. Suppose the classifier relates F and F', and that D and D' select* hsame *precision windows whose transported rows agree componentwise: the* CauchyModulus$^{\uparrow}$ *threshold row, the* DyadicRatCore$^{\uparrow}$ *endpoint and radius rows, the late-pair ledger, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *rows.*

Then every RegSeqRat$^{\uparrow}$ *handoff read and every* Real$^{\uparrow}$ *consumer-boundary read for F over D and for F' over D' factors through one synchronized finite precision packet carrying exactly those transported threshold, endpoint, radius, late-pair,* Cont*,* hsame*,* Pkg*, and* NameCert *rows. The synchronized packet asserts no quotient real equality, selects no limit, constructs no completed metric object, and contains no hidden threshold selector.*

Proof. Unpack the carrier and classifier of Definition 315.2 and Definition 315.3. The two accepted packets expose only scheduled stream rows, threshold rows, endpoint-radius rows, late-pair ledgers, transport rows, continuation windows, package provenance, and local naming rows. The classifier compares those coordinates componentwise.

Apply Definition 315.10 to F and D. It factors every RegSeqRat$^{\uparrow}$ handoff and every Real$^{\uparrow}$ boundary read through the finite precision window selected by D.

Apply the same theorem to F' and D'. The hypotheses identify the selected threshold, endpoint, radius, late-pair, Cont, hsame, Pkg, and NameCert rows with the transported rows from the first factorization, so the two finite windows are the same synchronized packet.

Finally use Definition 315.5 and Definition 315.6. These are the only handoff and seal-boundary rows cited by the factorization, so both consumers read the synchronized finite packet and no quotient equality, selected limit, completed metric object, or hidden threshold selector is introduced. □

Theorem 315.12 (FastCauchySeq tail-window overlap exhaustion)**.** *Let F be an accepted* FastCauchySeq$^{\uparrow}$ *packet, and let D_0 and D_1 be displayed* DyadicPrecision$^{\uparrow}$ *rows selecting two finite precision windows inside F. Suppose the two windows have a shared finite tail subwindow whose transported rows agree: the common* CauchyModulus$^{\uparrow}$ *threshold row, the* DyadicRatCore$^{\uparrow}$ *endpoint and radius rows, the late-pair ledger, the displayed* hsame *and* Cont *routes, the* Pkg *provenance row, and the local* NameCert *row all occur as visible rows of the same packet.*

Then every RegSeqRat$^{\uparrow}$ *handoff read and every* Real$^{\uparrow}$ *consumer-boundary read on the overlap factors through exactly that common finite tail packet. The factorization uses only the displayed threshold row, endpoint and radius rows, late-pair ledger,* hsame*,* Cont*,* Pkg*, and* NameCert *rows already visible in F; it asserts no quotient real equality, selects no limit, builds no completed metric object, and invokes no hidden threshold selector.*

Proof. Apply Definition 315.10 to F with the window D_0. This presents each RegSeqRat$^{\uparrow}$ handoff and each Real$^{\uparrow}$ boundary read over D_0 through the finite packet determined by its visible threshold, dyadic, late-pair, transport, provenance, and naming rows.

Apply the same factorization theorem to F with the window D_1. On the shared tail subwindow, the two factorized packets expose the same threshold row, the same endpoint and radius rows, the same late-pair ledger, the same hsame and Cont routes, and the same Pkg and NameCert rows.

Use Definition 315.11 only for these common transported rows. Since both windows lie inside the same accepted packet F, the synchronization does not add a second source packet; it identifies the overlap as the unique visible tail packet already carried by F.

The consumer restrictions are exactly those of Definition 315.5 and Definition 315.6. They read the common finite rows and no quotient real equality, selected limit, completed metric object, or hidden threshold selector. □

Theorem 315.13 (FastCauchySeq tail-stationary precision-window determinacy)**.** *Let F and F' be accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packets, and let D and D' be displayed precision rows for finite consumer windows. Suppose the selected* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows agree by* hsame*, the selected* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows agree by* hsame*, the late-pair ledgers are joined by the same displayed* Cont *routes, and the* Pkg *and* NameCert *rows carry the same visible provenance.*

Then every $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and every* $\mathsf{Real}^{\uparrow}$ *consumer-boundary read over those windows factors through one stationary finite packet carrying the common threshold, endpoint, radius, late-pair,* Cont*,* hsame*,* Pkg*, and* NameCert *rows. This stationary packet introduces no quotient real equality, selected limit, completed metric object, or hidden threshold selector.*

Proof. Project the two accepted packets through the explicit-rate carrier. The only rows visible at the selected windows are the modulus threshold, dyadic endpoint and radius, late-pair ledger, continuation route, provenance, and local naming rows.

Apply Definition 315.10 to both windows. Each factorization presents the corresponding $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ consumer-boundary read through its selected finite packet.

Use Definition 315.11 to identify the transported threshold, endpoint, radius, late-pair, Cont, hsame, Pkg, and NameCert rows. The hypotheses make these rows stationary across the two tail displays, so both finite packets are the same visible packet.

Finally apply Definition 315.5 and Definition 315.6. These consumer faces forget only local certificate packaging and read only the displayed boundary rows, hence the shared stationary packet adds no quotient real equality, selected limit, completed metric object, or hidden threshold selector. □

Theorem 315.14 (FastCauchySeq prefix-window eventual lock)**.** *Let F and F' be accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packets, and let D and D' be displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *rows. Suppose the classifier relates F and F', and suppose the selected precision rows transport the same* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius rows, the same late-pair ledger, the same displayed* Cont *route, the same* Pkg *provenance row, and the same local* NameCert *row.*

Then every $\mathsf{RegSeqRat}^{\uparrow}$ *handoff read and every* $\mathsf{Real}^{\uparrow}$ *seal-boundary read for F over D and for F' over D' factors through one shared finite prefix-window packet carrying exactly those transported rows. The shared packet introduces no quotient real equality, no selected limit, no completed metric object, and no hidden threshold selector.*

Proof. Unpack Definition 315.2 and Definition 315.3. The accepted packets expose only the scheduled stream row, modulus threshold row, dyadic endpoint-radius rows, late-pair ledger, transport route, continuation window, package provenance, and local naming row, and the classifier compares these displayed rows.

Apply Definition 315.10 to each side. It factors the $\mathsf{RegSeqRat}^{\uparrow}$ handoff reads and the $\mathsf{Real}^{\uparrow}$ seal-boundary reads through the precision windows selected by D and D'.

Use Definition 315.11 to identify the transported finite rows. The common modulus threshold, endpoint-radius data, late-pair ledger, Cont route, Pkg provenance, and local NameCert row therefore assemble one shared prefix-window packet.

Finally cite Definition 315.5 and Definition 315.6. These consumer restrictions are exactly the handoff and seal-boundary interfaces used above, so no quotient real equality, selected limit, completed metric object, or hidden threshold selector is added. □

Theorem 315.15 (FastCauchySeq tail-cofinal RegSeqRat Real boundary)**.** *Let F be an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet, and let $D \leq D'$ be displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *windows whose selected tail rows are cofinal in the same* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold ledger. Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff read and every* $\mathsf{Real}^{\uparrow}$ *seal-boundary read over D' factors through the same visible threshold, dyadic endpoint and radius, late-pair,* hsame*,* Cont*,* Pkg*, and* NameCert *rows as the corresponding read over D.*

The common factor is the displayed cofinal tail packet of F. It asserts no quotient real equality, selects no limit, builds no completed metric object, and invokes no hidden threshold selector.

Proof. Project F through Definition 315.2. The accepted carrier exposes the scheduled stream row, the $\mathsf{CauchyModulus}^{\uparrow}$ threshold ledger, dyadic endpoint-radius rows, late-pair rows, hsame and Cont transport, Pkg provenance, and local NameCert rows.

Apply Definition 315.10 to the window D and again to the window D'. Each read is thereby presented through its selected finite precision packet rather than through any completed real object.

Use Definition 315.12 to pass to the shared cofinal tail and then Definition 315.14 to identify the common finite packet. The cofinality hypothesis supplies the same threshold ledger and the same visible endpoint-radius, late-pair, hsame, Cont, Pkg, and NameCert rows for both displays.

Finally apply Definition 315.5 and Definition 315.6. These two consumer boundaries read only the displayed cofinal tail packet, so they add no quotient real equality, selected limit, completed metric object, or hidden threshold selector. □

Theorem 315.16 (FastCauchySeq prefix-modulus Real seal factorization)**.** *Let F and F' be accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packets with a shared prefix-window eventual lock. Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and every* $\mathsf{Real}^{\uparrow}$ *seal-boundary read over that locked prefix factors through one prefix-modulus packet.*

The prefix-modulus packet contains exactly the transported $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius rows, the late-pair ledger, the visible* hsame *and* Cont *routes, the* Pkg *provenance, and the local* NameCert *row. It contains no quotient real equality, selected limit, completed metric object, hidden threshold selector, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Apply Definition 315.10 to both accepted packets. Each side presents its $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ seal-boundary read through a finite packet carrying the selected modulus threshold, dyadic endpoint-radius rows, late-pair ledger, transport, provenance, and local naming rows.

Use Definition 315.11 to identify the transported rows. The synchronized window equates the visible threshold, endpoint-radius, late-pair, hsame, Cont, Pkg, and NameCert coordinates without adding a second threshold selector.

Now apply Definition 315.14. The lock collapses the synchronized selected prefixes to one shared prefix-modulus packet, so both finite displays feed the same consumer-readable data.

Finish with Definition 315.5 and Definition 315.6. These two consumer boundaries read only the displayed prefix-modulus packet, hence no quotient real equality, selected limit, completed metric object, hidden threshold selector, or $\mathsf{Real}^{\uparrow}$ completeness row is introduced. □

Theorem 315.17 (FastCauchySeq tail-lock Real boundary)**.** *Let F be an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packet whose accepted windows are cofinal in the displayed tail rows, and suppose the corresponding*

prefix windows eventually lock. Then every $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and every* $\mathsf{Real}^{\uparrow}$ *seal-boundary read factors through one common finite* BHist *packet.*

That packet carries exactly the $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius rows, the late-pair ledger, the visible* hsame *and* Cont *routes, the* Pkg *provenance, and the local* NameCert *row. The factorization introduces no quotient real equality, selected limit, completed metric object, hidden threshold selector, or* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Project the accepted packet through Definition 315.2. The visible rows are the scheduled stream, the modulus threshold ledger, the dyadic endpoint-radius data, late-pair comparisons, transport routes, provenance, and local name certificate.

Apply Definition 315.12. Cofinality of the accepted tail windows forces every later $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ seal-boundary read to pass through the same finite tail display, rather than through an ambient completed real object.

Next use Definition 315.14. The eventual lock identifies the finite prefix packet that all sufficiently late displayed windows share, including the threshold, endpoint-radius, late-pair, hsame, Cont, Pkg, and NameCert coordinates.

Finally apply Definition 315.16. Its prefix-modulus packet is therefore the common BHist packet through which both the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal-boundary consumer read. Since the cited factorization reads only that finite packet, it adds no quotient real equality, selected limit, completed metric object, hidden threshold selector, or $\mathsf{Real}^{\uparrow}$ completeness row. □

Theorem 315.18 (FastCauchySeq explicit-rate RegSeqRat Real handoff)**.** *Let F be an accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *prefix-modulus packet whose public explicit-rate surface is displayed over a* $\mathsf{StreamName}^{\uparrow}$ *schedule, a* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold ledger,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, late-pair comparison ledgers,* hsame *and* Cont *transport,* Pkg *provenance, and local* NameCert *rows. Then the same finite packet determines exactly both downstream reads: the* $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff and the* $\mathsf{Real}^{\uparrow}$ *seal consumer boundary.*

The handoff exports precisely those visible rows and no further coordinate. In particular it exports no quotient real equality, hidden threshold selector, completed metric object, selected limit, or $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Start with the public explicit-rate surface of Definition 315.8. It presents the accepted packet through the displayed schedule rows, modulus thresholds, dyadic endpoint-radius data, late-pair comparisons, transport routes, provenance, and naming rows.

Next factor the consumer-facing windows by Definition 315.10 and Definition 315.11. These two results identify the common finite packet that both downstream surfaces read, so no second selector or hidden completion coordinate is introduced.

Finally read the two consumers through Definition 315.5 and Definition 315.6. The first theorem identifies the regular-rational forgetful source rows, and the second theorem identifies the real-seal source rows. Since both are applied to the same prefix-modulus packet, the finite BEDC handoff is exactly the shared source surface named in the statement. □

Theorem 315.19 (FastCauchySeq cofinal-tail Real-seal coherence)**.** *Let F_0 and F_1 be accepted* $\mathsf{FastCauchySeq}^{\uparrow}$ *packets whose explicit-rate streams admit a common cofinal tail. Suppose their synchronized precision windows agree on the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows, late-pair comparison rows, transport rows,* Pkg *provenance, and* NameCert *rows. Then the* $\mathsf{Real}^{\uparrow}$ *seal source surfaces obtained through the* $\mathsf{RegSeqRat}^{\uparrow}$ *forgetful handoff agree on that cofinal tail.*

The agreement is only the displayed finite consumer boundary: the shared tail contains the selected $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, dyadic endpoint and radius rows, comparison rows,* hsame

and Cont *routes,* Pkg *provenance, and local* NameCert *provenance. It contains no quotient real equality, selected limit, completed metric object, hidden threshold selector, or* $\mathsf{Real}^{\uparrow}$ *completeness datum.*

Proof. Project both packets by Definition 315.10. This presents each consumer read through a finite modulus precision window rather than through any completed real object.

Synchronize the two windows with Definition 315.11. The hypothesis identifies the displayed endpoint, radius, comparison, transport, package, and naming rows in the synchronized surface.

Use Definition 315.14 to pass from the synchronized prefixes to the stable cofinal tail rows. Then apply Definition 315.15 to read that tail as the same $\mathsf{RegSeqRat}^{\uparrow}$-to-$\mathsf{Real}^{\uparrow}$ consumer boundary.

Finally invoke Definition 315.16. The $\mathsf{Real}^{\uparrow}$ seal factors through the shared prefix-modulus packet on the cofinal tail, so both accepted packets expose the same finite BEDC source surface and no quotient equality, selected limit, completion object, hidden selector, or completeness row. □

Closure status for $\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$.

Constructive story: A fast-Cauchy-sequence packet is generated from a scheduled dyadic-rational observation stream, visible Cauchy-modulus threshold rows, dyadic endpoint and radius rows, late-pair comparison ledgers, componentwise hsame and Cont transports, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 315.8, Definition 315.9, Definition 315.10, and Definition 315.11 bind the public export, standard explicit-rate bridge, modulus precision-window factorization, and synchronized finite-window consumer surface over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FastCauchySeq}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FastCauchySeqUp.FastCauchySeqPacket\_public\_explicit\_rate\_export`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close completeness, quotient equality of Cauchy names, selected limits, or standard bridge data.

Upgrade path: The next step is Lean formalization and checking of the explicit-rate bridge.

Chapter 316

A Concrete Naming Certificate for $\mathsf{SignedDigitStream}^{\uparrow}$

The $\mathsf{SignedDigitStream}^{\uparrow}$ interface names finite-window signed-digit stream presentations over dyadic endpoint rows. Following Bishop–Bridges constructive analysis, the packet records only observed signed digits, normalization carries, endpoint rows, and stream provenance; it does not form a quotient of infinite streams or appeal to host real equality.

The signed-digit finite-window packet consumes the schedule surface of chapter 126, the endpoint normalization rows of chapter 291, and the downstream real-name handoff through chapter 301 and chapter 38.

316.1 Finite signed-digit windows

Definition 316.1 (SignedDigitStream carrier)**.** *A* $\mathsf{SignedDigitStream}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (D, N, C, P, E, L)$$

with the following visible rows:

1. *D is a finite list of signed dyadic digit rows, each digit drawn from the displayed signed finite alphabet and indexed by a unary position row;*
2. *N is the unary observation schedule supplied by* $\mathsf{StreamName}^{\uparrow}$*;*
3. *C is the carry and normalization ledger for every adjacent digit pair visible in the window;*
4. *P is the* $\mathsf{StreamName}^{\uparrow}$ *provenance row naming the scheduled stream requests and the* Pkg *routes used to read them;*
5. *E lists the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows obtained by normalizing each displayed finite prefix;*
6. *L records that all hidden data lies outside the requested finite window.*

The carrier accepts only packets whose visible prefixes normalize to the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows through the carry ledger C. It contains no infinite stream object outside the named schedule, no quotient of presentations, and no completed* $\mathsf{Real}^{\uparrow}$ *endpoint.*

Definition 316.2 (SignedDigitStream classifier)**.** *For accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *carriers S and T, the classifier* $\mathsf{SignedDigitStreamClassifier}(S, T)$ *holds when every shared finite observation window normalizes to classifier-equal dyadic endpoints and the matching carry ledgers transport componentwise. Concretely, for each unary position read by both* $\mathsf{StreamName}^{\uparrow}$ *schedules, the normalized*

DyadicRatCore$^{\uparrow}$ *endpoint rows agree by the* DyadicRatCore$^{\uparrow}$ *classifier, the digit rows are related by the displayed* hsame *routes before normalization, and the carry ledger repacks to the same endpoint read.*

The classifier compares finite normalized observations, not infinite tails. A classified pair therefore exposes agreement of all windows actually requested by the schedules and supplies no host real equality, choice of a global stream representative, or quotient equality of digit streams.

Theorem 316.3 (SignedDigitStream sibling route through scheduled dyadic endpoints)**.** *Every accepted* SignedDigitStream$^{\uparrow}$ *packet factors through the concrete-instance sibling route*

$$\textit{chapter } 126 \to \textit{chapter } 291 \to \textit{chapter } 301 \to \textit{chapter } 363 \to \textit{chapter } 38$$

before any Real$^{\uparrow}$ *seal consumer can read it. The route reads the* StreamName$^{\uparrow}$ *schedule and provenance rows, the normalized* DyadicRatCore$^{\uparrow}$ *endpoint rows, the* RegSeqRat$^{\uparrow}$ *handoff surface, the signed-digit real finite-window boundary, and then the* Real$^{\uparrow}$ *seal rows.*

The route exports no quotient stream equality, selected limit, host real equality, or ambient completeness datum.

Proof. Project the carrier rows (D, N, C, P, E, L) of Definition 316.1. The rows N and P are exactly the finite-window schedule and provenance surface supplied by StreamName$^{\uparrow}$, so every downstream read first passes through chapter 126.

The row E is the displayed list of normalized endpoint rows obtained from the finite prefixes and the carry ledger C. These are DyadicRatCore$^{\uparrow}$ rows, so the next visible dependency is chapter 291; the digit and carry data only justify those endpoint rows and do not create an independent completed endpoint.

Use Definition 316.9 to expose the regular rational consumer surface. It reads only scheduled normalized dyadic endpoints and their ledgers, giving the RegSeqRat$^{\uparrow}$ stage. Then use Definition 316.10 to identify the finite-window seal boundary that passes through the signed-digit real surface before reaching the Real$^{\uparrow}$ seal rows.

Every object read along the route is one of the six projected carrier rows or one of the downstream rows named by those two handoff theorems. Since none of those rows contains a quotient stream equality, selected limit, host real equality, or ambient completeness datum, the sibling route exhausts the visible dependency surface before any Real$^{\uparrow}$ seal consumer can read the packet. □

Theorem 316.4 (SignedDigitStream finite-window transport)**.** *Let S be an accepted* SignedDigitStream$^{\uparrow}$ *carrier. Suppose T is obtained by transporting the signed digit rows, unary schedule rows, carry ledger,* StreamName$^{\uparrow}$ *provenance, normalized* DyadicRatCore$^{\uparrow}$ *endpoint rows, and hidden-tail ledger of S through displayed* hsame, Cont, Pkg, *and* NameCert *routes. If every transported prefix normalizes to the transported endpoint row with the transported carry ledger, then T is an accepted* SignedDigitStream$^{\uparrow}$ *carrier and* SignedDigitStreamClassifier(S, T) *holds on each shared finite window.*

The transport preserves only the finite signed-digit observation surface and introduces no quotient stream, ambient real equality, or completed real endpoint.

```
Lean4 ✓  BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket window transport
  ↪ variant  BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamWindowPacket window transport
```

Proof. Project the carrier of Definition 316.1. The digit rows, unary schedule, carry ledger, provenance, endpoint rows, and hidden-tail ledger are the only coordinates available for transport.

Move each coordinate along the displayed hsame and Cont routes. The hypothesis says that prefix normalization is preserved after the move, so every visible prefix of T still has the corresponding $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row.

Apply the classifier of Definition 316.2 on a shared finite window. The endpoint classifiers come from the transported $\mathsf{DyadicRatCore}^{\uparrow}$ rows, and the carry ledgers match by the componentwise ledger transport. Since no extra coordinate is created, the transported packet exports exactly the same finite observation surface. □

Theorem 316.5 (SignedDigitStream prefix truncation stability)**.** *Let $S = (D, N, C, P, E, L)$ be an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *carrier, and let $N_{\leq k}$ be a displayed finite prefix of its unary* $\mathsf{StreamName}^{\uparrow}$ *schedule. The restricted tuple*

$$S_{\leq k} = (D_{\leq k}, N_{\leq k}, C_{\leq k}, P_{\leq k}, E_{\leq k}, L_{\leq k})$$

repacks as an accepted $\mathsf{SignedDigitStream}^{\uparrow}$ *carrier whenever each restricted digit, schedule, carry, endpoint, provenance, and ledger row is the displayed prefix row inherited from S.*

The classifier on the restricted packet is exactly the restriction of SignedDigitStreamClassifier *to windows contained in $N_{\leq k}$. Its* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and* $\mathsf{Real}^{\uparrow}$ *seal boundary are the corresponding finite prefix reads named by Definition 316.9 and Definition 316.10. The restriction introduces no quotient tail, selected limit, host real equality, completeness datum, or bridge row.*

Proof. Project the six carrier rows of Definition 316.1. The displayed prefix $N_{\leq k}$ selects exactly the digit rows $D_{\leq k}$, carry ledger $C_{\leq k}$, provenance row $P_{\leq k}$, endpoint rows $E_{\leq k}$, and hidden-tail ledger $L_{\leq k}$ already present in S.

Apply Definition 316.4 with identity transport on the retained rows. Prefix normalization is inherited from the accepted packet S, so the restricted tuple satisfies the same carrier acceptance condition on every retained unary window.

Use Definition 316.2 for the classifier row. Since the restricted schedules contain only windows already shared with S, the classifier relation is the original shared-window classifier read on the smaller schedule.

Finally read the downstream surfaces through Definition 316.9 and Definition 316.10. They expose only the scheduled finite prefix endpoints and their ledgers, and no extra tail, limit, host equality, completeness, or bridge coordinate is created by the restriction. □

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket prefix truncation stability`

Theorem 316.6 (SignedDigitStream adjacent-window endpoint coherence)**.** *Let $S = (D, N, C, P, E, L)$ be an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *carrier, and let $N_{\leq k}$ and $N_{\leq k+1}$ be adjacent displayed unary prefix windows of its* $\mathsf{StreamName}^{\uparrow}$ *schedule. The normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row and carry ledger read on $N_{\leq k}$ are exactly the restriction of the endpoint row and carry ledger read on $N_{\leq k+1}$, with the restriction taken through the displayed* hsame, Cont, Pkg, *and* NameCert *rows.*

Consequently every $\mathsf{RegSeqRat}^{\uparrow}$ *consumer and every* $\mathsf{Real}^{\uparrow}$ *finite-window boundary consumer reads the same restricted endpoint on the overlap $N_{\leq k}$. The coherence statement is internal to the finite* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet and adds no quotient tail, selected limit, host real equality, completeness datum, or standard bridge row.*

Proof. Project the six carrier rows of Definition 316.1. The two adjacent prefix windows select the displayed rows $D_{\leq k}, C_{\leq k}, P_{\leq k}, E_{\leq k}, L_{\leq k}$ and $D_{\leq k+1}, C_{\leq k+1}, P_{\leq k+1}, E_{\leq k+1}, L_{\leq k+1}$ already present in the accepted packet S.

Apply Definition 316.5 to both prefixes. This repacks $S_{\leq k}$ and $S_{\leq k+1}$ as accepted packets whose visible rows are inherited from S through the displayed hsame, Cont, Pkg, and NameCert routes.

The smaller prefix is a common unary window for these two accepted packets. Apply Definition 316.8 on that shared window. It identifies the normalized endpoint row and carry ledger read from $S_{\leq k}$ with the restriction of the corresponding rows read from $S_{\leq k+1}$.

Finally route the consumer reads through Definition 316.9 and Definition 316.10. Both consumers read only the finite scheduled endpoint and ledger rows, so their overlap read is the same restricted endpoint and no tail, selected limit, host real equality, completeness datum, or standard bridge coordinate is available to export. □

Theorem 316.7 (SignedDigitStream prefix handoff idempotence)**.** *Let $S = (D, N, C, P, E, L)$ be an accepted* SignedDigitStream$^{\uparrow}$ *carrier, and let $S_{\leq k}$ be the restriction of S to the displayed unary schedule prefix $N_{\leq k}$. Applying the* RegSeqRat$^{\uparrow}$ *handoff or the* Real$^{\uparrow}$ *finite-window seal boundary to $S_{\leq k}$ gives exactly the same visible rows as first applying the handoff or boundary to S and then restricting the resulting consumer surface to $N_{\leq k}$.*

The common surface consists only of the retained digit rows, schedule rows, carry and normalization ledgers, provenance rows, endpoint rows, hidden-tail ledger rows, visible hsame *and* Cont *routes,* Pkg *rows, and* NameCert *rows. It contains no quotient tail, selected limit, host real equality, completeness datum, or standard bridge.*

Proof. Project the carrier rows of S and of the restricted packet $S_{\leq k}$. By Definition 316.5, the retained digit, schedule, carry, provenance, endpoint, and ledger rows are the corresponding prefix rows inherited from S.

Apply Definition 316.9 to both packets. A RegSeqRat consumer reads only scheduled finite endpoint observations and their radius ledgers, so restricting the already exported handoff to $N_{\leq k}$ selects the same rows as exporting from $S_{\leq k}$.

Apply Definition 316.10 in the same way. The seal boundary reads the finite window rows already listed above, so prefixing before or after the boundary yields the same visible surface and creates none of the excluded tail, limit, host-equality, completeness, or bridge coordinates. □

Theorem 316.8 (SignedDigitStream common-window determinacy)**.** *Let S and T be accepted* SignedDigitStream$^{\uparrow}$ *carriers such that* SignedDigitStreamClassifier(S, T) *holds. For every unary window requested by both* StreamName$^{\uparrow}$ *schedules, the normalized* DyadicRatCore$^{\uparrow}$ *endpoint row read from S and the normalized endpoint row read from T are classifier-equal, and the carry ledgers repack to the same endpoint read.*

The conclusion is only a finite-window determinacy statement: it compares scheduled signed-digit prefixes, normalized endpoint rows, and carry ledgers, and it introduces no quotient stream, Real$^{\uparrow}$ *equality, or ambient host endpoint.*

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamWindowPacket common window determinacy`

Proof. Unfold the classifier of Definition 316.2. A common scheduled unary window is one of the shared finite observation rows named by the two StreamName$^{\uparrow}$ schedules, so the classifier exposes the two digit prefixes, their carry ledgers, and their normalized endpoint rows at that same window.

Project the endpoint component of the classifier row. The row states that the two normalized DyadicRatCore$^{\uparrow}$ endpoints are compared by the DyadicRatCore$^{\uparrow}$ classifier, hence the endpoint reads are equal in the only public sense available to the packet.

It remains to identify the carry data used by the read. The componentwise carry-ledger transport in the classifier repacks the two prefix normalizations into the same endpoint row. Since

the carrier has no quotient-stream or $\mathsf{Real}^{\uparrow}$ coordinate, this exhausts the common-window conclusion. □

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamClassifier common window determinacy`

Theorem 316.9 (SignedDigitStream RegSeqRat handoff)**.** *An accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *carrier hands a* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer only the scheduled normalized dyadic endpoint rows and their radius ledgers. For every unary precision window requested by the* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer, the handoff reads a finite* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the signed digit prefix selected by that schedule, the carry ledger that normalizes the prefix, and the resulting* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row. The consumer may use these rows as the endpoint observations of a regular rational stream.*

The handoff does not assert regularity by itself, does not seal a $\mathsf{Real}^{\uparrow}$ *name, and does not identify signed-digit presentations by host real equality.*

Proof. Read the accepted carrier through Definition 316.1. A precision request first selects a finite schedule row and then exposes exactly the digit prefix, carry ledger, provenance, and normalized endpoint row attached to that schedule.

The target $\mathsf{RegSeqRat}^{\uparrow}$ consumer needs endpoint observations and radius ledgers. The endpoint row is already a $\mathsf{DyadicRatCore}^{\uparrow}$ row, and the radius budget is read from the same unary precision window that selected the prefix.

Regularity is a separate $\mathsf{RegSeqRat}^{\uparrow}$ obligation: it compares pairs of endpoint rows by dyadic bounds. The signed-digit handoff supplies the finite endpoint source for those comparisons and no additional real-seal, quotient, or host-equality data. □

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket regseqrat handoff`

Theorem 316.10 (SignedDigitStream RealUp finite-window seal boundary)**.** *For any accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet, a* $\mathsf{Real}^{\uparrow}$ *seal may inspect only the scheduled* $\mathsf{StreamName}^{\uparrow}$ *window, signed digit prefix, carry and normalization ledger, normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, visible* hsame *and* Cont *routes,* Pkg *provenance, and hidden-tail ledger already exposed by Definition 316.1 and Definition 316.9.*

It may not read a quotient stream, host real equality, hidden tail value, selected limit, completeness datum, or standard bridge row.

Proof. Project the accepted carrier tuple of Definition 316.1. Its coordinates are the finite digit rows, the $\mathsf{StreamName}^{\uparrow}$ schedule, the carry and normalization ledger, provenance, normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows, and the hidden-tail ledger.

Use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 316.9 to identify the regular-rational observations seen by a downstream seal. Every such observation is obtained from a scheduled finite window and its normalized endpoint row, together with the visible ledger data attached to that window.

The excluded data would require an additional coordinate: a quotient stream, host real equality witness, hidden tail value, selected limit, completeness datum, or standard bridge row. No such coordinate appears in the carrier or in the handoff row, so the $\mathsf{Real}^{\uparrow}$ seal boundary is exactly the listed finite-window surface. □

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket real seal semantic name certificate`

Theorem 316.11 (SignedDigitStream NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet* (D, N, C, P, E, L) *of Definition 316.1;*

2. *classifier: the shared-window normalized endpoint comparison of Definition 316.2;*
3. *transport: the componentwise window transport of Definition 316.4;*
4. $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: the scheduled endpoint row exported by Definition 316.9;*
5. $\mathsf{Real}^{\uparrow}$ *seal boundary: the finite-window exclusion of quotient streams, host real equality, hidden tail values, selected limits, completeness data, and standard bridge rows from Definition 316.10.*

These rows form the seed certificate surface for finite-window signed-digit stream names over dyadic rows.

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket namecert obligation surface`

Proof. The carrier row supplies the signed digits, schedule, carry ledger, provenance, normalized endpoints, and hidden-tail boundary. This fixes the source data of the name.

The classifier and transport rows identify the only stable motion of that data: shared windows are compared after normalization to $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints, and componentwise transport repacks the same finite rows.

The handoff row records exactly what a $\mathsf{RegSeqRat}^{\uparrow}$ consumer may read, namely scheduled normalized dyadic endpoints and their visible ledgers. The $\mathsf{Real}^{\uparrow}$ seal boundary excludes quotient streams, host real equality, hidden tail values, selected limits, completeness data, and standard bridge rows, so the five listed rows exhaust the local $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$ surface. □

Theorem 316.12 (SignedDigitStream scoped finite-window package)**.** *Every accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet determines a scoped BEDC package whose carrier row is the finite* BHist *packet* (D, N, C, P, E, L)*, whose classifier row compares shared finite windows through* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint equality, whose transport row is componentwise* hsame *and* Cont *transport, whose consumer row is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and whose ledger row hides only unobserved windows.*

The package reads the signed-digit stream surface only through the finite rows named by BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*, and* $\mathsf{RegSeqRat}^{\uparrow}$*, together with the L10 source certificates that supply those rows.*

Proof. Use the carrier of Definition 316.1 as the package spine. Its tuple (D, N, C, P, E, L) supplies the finite digit rows, schedule rows, carry ledger, provenance, endpoint rows, and hidden-tail ledger.

The classifier is the shared-window endpoint comparison of Definition 316.2. Transport is the componentwise hsame and Cont movement supplied by Definition 316.4.

The consumer face is exactly the $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 316.9. Finally, Definition 316.11 identifies the five rows as the local $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$ surface, so the scoped package has no additional quotient tail, host-real, or completed-real coordinate. □

Theorem 316.13 (SignedDigitStream public interface export)**.** *The finite carrier of Definition 316.1, classifier of Definition 316.2, checked window transport of Definition 316.4,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 316.9,* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary of Definition 316.10,* $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$ *obligation surface of Definition 316.11, and scoped window package of Definition 316.12 assemble the reusable public* $\mathsf{SignedDigitStream}^{\uparrow}$ *interface.*

The interface exposes finite digit rows, schedule rows, carry ledger rows, normalized dyadic endpoint rows, hidden-window ledger rows, hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows. It exports no quotient tail, host real equality, completed real endpoint, or standard bridge.*

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket public interface export`

Proof. Use the carrier and classifier definitions as the visible spine. The carrier provides the finite digit rows, schedule rows, carry ledger, provenance, endpoint rows, and hidden-tail boundary; the classifier reads a common scheduled window and compares only the normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints.

The checked window transport theorem gives stable movement of this finite surface across hsame and Cont routes. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff then identifies the only downstream reads: scheduled normalized endpoints and the visible ledgers attached to the requested precision.

Finally combine the local $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$ surface with the scoped package. These results bind the carrier, classifier, transport, consumer row, $\mathsf{Real}^{\uparrow}$ seal boundary, and hidden-window ledger to finite BHist, Pkg, and NameCert rows, excluding quotient tails, host real equality, hidden tail values, selected limits, completeness data, completed real endpoints, and standard bridges from the exported interface. □

Theorem 316.14 (SignedDigitStream public Real boundary export)**.** *The public interface export, finite-window transport, common-window determinacy,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *finite-window seal boundary,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows assemble a* $\mathsf{Real}^{\uparrow}$*-consumable finite signed-digit stream boundary.*

The exported surface has no quotient tail, host real equality, selected limit, completeness datum, or standard bridge.

Proof. Start from the carrier of Definition 316.1 and the classifier of Definition 316.2. They provide the finite signed-digit rows, schedule rows, carry ledger, provenance, normalized dyadic endpoint rows, and hidden-window ledger as the only public coordinates.

The transport and determinacy steps are Definition 316.4 and Definition 316.8. These keep the common window and normalized endpoints stable through displayed hsame and Cont routes.

The consumer faces are Definition 316.9 and Definition 316.10. They identify the regular-rational handoff and the $\mathsf{Real}^{\uparrow}$ seal boundary as reads of the same finite rows.

Finally apply Definition 316.13. The interface already packages the carrier, classifier, checked transport, consumer handoff, seal boundary, BHist, Pkg, and NameCert rows, so reading it as a public $\mathsf{Real}^{\uparrow}$ boundary adds no quotient tail, host real equality, selected limit, completeness datum, or standard bridge. □

Theorem 316.15 (SignedDigitStream public transport bridge)**.** *The transported signed-digit windows of Definition 316.4, the common-window determinacy of Definition 316.8, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 316.9, and the public* $\mathsf{Real}^{\uparrow}$ *boundary of Definition 316.14 assemble a finite transport bridge for* $\mathsf{SignedDigitStream}^{\uparrow}$*.*

Across that bridge, $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers read the same normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, scheduled digit rows, carry ledgers, visible* hsame *and* Cont *transports,* Pkg *provenance, and* NameCert *rows. The bridge exposes no quotient stream, selected limit, host real equality, completeness datum, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket public transport bridge`

Proof. Begin with Definition 316.4. It transports the finite signed-digit window componentwise, keeping the scheduled digit rows, carry ledger, normalized endpoint rows, and visible provenance inside the same finite carrier surface.

Apply Definition 316.8. The common scheduled window therefore has a single normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row for both downstream readings, with the carry ledger attached to that same row.

Now use Definition 316.9 and Definition 316.14. The first exposes the transported endpoint row to $\mathsf{RegSeqRat}^{\uparrow}$; the second exposes the same finite endpoint, transport, package, and name-certificate rows to $\mathsf{Real}^{\uparrow}$.

Thus the bridge is exactly the shared finite transport route between those two consumer faces. A quotient stream, selected limit, host real equality, completeness datum, or standard bridge row would require a coordinate outside the carrier, transport, determinacy, handoff, and public boundary rows. □

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamWindowPacket public transport bridge`

Theorem 316.16 (SignedDigitStream Real–RegSeqRat window correspondence)**.** *On every scheduled unary window of an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet, the normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows and carry ledgers exported to* $\mathsf{RegSeqRat}^{\uparrow}$ *are the same finite rows read by the* $\mathsf{Real}^{\uparrow}$ *seal boundary, up to the displayed* hsame *and* Cont *transports and the packet's* Pkg *and* NameCert *provenance.*

This correspondence contains no quotient tail, host real equality, selected limit, completeness datum, or standard bridge row.

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket real regseqrat window correspondence`

Proof. Project the accepted packet through the carrier of Definition 316.1. A scheduled unary window exposes the finite signed digit prefix, carry and normalization ledger, provenance, normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint row, and hidden-window ledger attached to that schedule.

Use common-window determinacy from Definition 316.8. It identifies the endpoint read at the shared schedule as the same normalized dyadic row in the only public sense available to the packet, and it keeps the carry ledger tied to that endpoint row.

Now apply Definition 316.9 and Definition 316.10. The first exports the scheduled normalized endpoint and its visible ledger to $\mathsf{RegSeqRat}^{\uparrow}$; the second permits the $\mathsf{Real}^{\uparrow}$ seal to inspect exactly the same scheduled endpoint, carry, transport, package, and name-certificate rows.

Thus both consumers read the same normalized endpoint and carry data through the displayed hsame and Cont routes. Any quotient tail, host real equality row, selected limit, completeness datum, or standard bridge row would require a coordinate absent from Definition 316.1 and from both consumer boundaries. □

Theorem 316.17 (SignedDigitStream prefix consumer invariance)**.** *Let* $S = (D, N, C, P, E, L)$ *be an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet, and let* $N_{\leq k}$ *be a displayed prefix schedule in its finite unary window. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer request that factors through* $N_{\leq k}$ *reads from the prefix packet* $S_{\leq k}$ *exactly the restriction of the consumer-visible rows read from* S*: the scheduled signed-digit prefix, carry and normalization ledger, normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, visible* hsame *and* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

The prefix read exposes no quotient tail, host real equality, selected limit, completeness datum, or standard bridge row.

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket prefix consumer invariance`
↪ variant `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamWindowPacket prefix consumer invariance`

Proof. Apply Definition 316.5 to the accepted packet and the displayed schedule $N_{\leq k}$. This repacks the prefix carrier as $S_{\leq k}$ while retaining only the scheduled signed-digit prefix, carry ledger, normalized endpoint row, transport rows, package provenance, and local name-certificate row.

Use Definition 316.8 on the retained window. The theorem identifies the normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and the attached carry ledger as the same visible rows before and after prefix restriction, with the displayed hsame and Cont routes providing the only allowed comparison.

For a $\mathsf{RegSeqRat}^{\uparrow}$ request, project the retained rows through Definition 316.9. For a $\mathsf{Real}^{\uparrow}$ request, project them through Definition 316.10. In both cases the consumer factors through the same prefix carrier rows and cannot read outside the scheduled packet surface.

Finally apply Definition 316.16. It identifies the two consumer readings on the common finite window, so the rows visible from $S_{\leq k}$ are exactly the restricted rows visible from S and none of the excluded quotient, host-real, limit, completeness, or standard bridge data can enter the prefix read. □

Theorem 316.18 (SignedDigitStream prefix-window transport lock)**.** *Let $S = (D, N, C, P, E, L)$ be an accepted $\mathsf{SignedDigitStream}^{\uparrow}$ packet, let $N_{\leq k}$ be a displayed prefix schedule inside its finite unary window, and let T be the transported packet obtained from S by Definition 316.4. Restricting T to the transported prefix gives the same $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ finite-window consumer rows as first restricting S by Definition 316.5 and then transporting those prefix rows.*

The locked rows are exactly the transported BHist packet rows, scheduled signed-digit prefix, normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, carry and normalization ledger, displayed hsame and Cont routes, Pkg provenance, $\mathsf{NameCert}$ rows, $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and $\mathsf{Real}^{\uparrow}$ finite-window seal.

Proof. Begin with Definition 316.4. It transports the accepted packet componentwise, so the BHist rows, scheduled $\mathsf{StreamName}^{\uparrow}$ window, carry ledger, normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows remain on the same finite packet surface.

Apply Definition 316.5 before and after this transport. Prefix restriction only narrows the displayed schedule to $N_{\leq k}$ and keeps the same endpoint, carry, provenance, and certificate rows available to consumers.

Next use Definition 316.8. The prefix window and the transported prefix window determine one normalized endpoint and one carry ledger through the displayed hsame and Cont routes, so there is no second consumer-facing row to choose.

Finally invoke Definition 316.17. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ finite-window seal read exactly the prefix-restricted packet rows on both paths. Thus transport after prefixing and prefixing after transport expose the same finite consumer surface. □

Theorem 316.19 (SignedDigitStream standard finite-window bridge)**.** *The public interface export of Definition 316.13, public $\mathsf{Real}^{\uparrow}$ boundary of Definition 316.14, and $\mathsf{Real}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ window correspondence of Definition 316.16 identify the standard finite-window bridge rows for $\mathsf{SignedDigitStream}^{\uparrow}$ as exactly the normalized dyadic endpoint rows, carry ledger, scheduled unary window, displayed hsame rows, displayed Cont routes, Pkg provenance, and $\mathsf{NameCert}$ provenance already carried by the packet.*

The bridge exposes no quotient tail, host real equality, selected limit, completeness datum, or bridgeChecked claim.

Proof. Project the public packet through Definition 316.13. The public surface is the scheduled signed-digit window together with the normalized dyadic endpoint, carry ledger, transport rows, package provenance, and name-certificate rows.

Apply Definition 316.14. The $\mathsf{Real}^{\uparrow}$ boundary reads the same finite rows and does not add a quotient tail, host real equality row, selected limit, or completeness witness.

Finally apply Definition 316.16. The regular-rational and real consumers therefore meet on the same normalized endpoint and carry rows through the displayed hsame and Cont routes, so the standard finite-window bridge has no further source coordinate and carries no bridgeChecked assertion. □

Theorem 316.20 (SignedDigitStream mature finite-window consumer coverage)**.** *An accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *finite-window packet exposes to every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer exactly the following rows: the prefix-truncation surface, common-window determinacy surface,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, public* $\mathsf{Real}^{\uparrow}$ *boundary, transport bridge,* $\mathsf{Real}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *window correspondence, prefix consumer invariance, and standard finite-window bridge rows of Definition 316.19.*

The coverage contains no hidden tail, quotient equality, selected limit, completeness datum, trichotomy datum, or extra consumer coordinate beyond the displayed endpoint, carry, transport, package, and name-certificate rows.

Proof. Start with the requested finite window. Apply Definition 316.5 to replace the consumer read by the displayed prefix-truncated packet, so the read contains only the finite signed-digit prefix, scheduled unary window, endpoint row, and carry ledger.

Next apply Definition 316.8. The shared schedule fixes the normalized endpoint and carry rows seen by all consumers through the same displayed hsame and Cont transports.

Use Definition 316.9 for the $\mathsf{RegSeqRat}^{\uparrow}$ consumer side and Definition 316.16 for the common real and regular-rational readback. These two rows identify the same finite endpoint, carry, package, and name-certificate coordinates on both consumer boundaries.

Finally apply Definition 316.19. The standard finite-window bridge repacks exactly the rows already exposed by the prefix, determinacy, handoff, and correspondence theorems. Since none of those sources contains a hidden tail, quotient equality, selected limit, completeness witness, or trichotomy row, no such datum is available to a downstream consumer. □

Theorem 316.21 (SignedDigitStream canonical finite-tail normal form)**.** *Every accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet has a canonical finite-tail normal form determined by its displayed prefix window, signed digit rows, carry ledger,* hsame *rows,* Cont *rows,* Pkg *provenance, and local* NameCert *rows.*

Any $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read of the packet factors through that normal form. The factorization introduces no hidden tail coordinate, quotient equality, selected limit, completeness datum, trichotomy datum, or host real equality.*

Lean4 ✓ `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket consumer read chain unary closed`

Proof. First apply Definition 316.5. It replaces the packet by the displayed finite prefix without changing the endpoint and carry rows visible to consumers.

Use Definition 316.8 to identify the normal endpoint and carry ledger determined by the shared prefix window. This gives the canonical finite-tail representative over the displayed signed digit rows.

Next apply Definition 316.9 and Definition 316.14. The regular-rational and real consumer boundaries both read the same finite endpoint, carry, transport, provenance, and naming rows.

Finally invoke Definition 316.20. Every downstream $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ read is one of the finite-window consumer rows already carried by the normal form, so no excluded tail, quotient, limit, completeness, trichotomy, or host-equality coordinate is introduced. □

Theorem 316.22 (SignedDigitStream scheduled-window exhaustion)**.** *Let* $S = (D, N, C, P, E, L)$ *be an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packet. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer request admitted by*

the mature finite-window consumer boundary factors through one displayed unary schedule window of N. The endpoint row, carry ledger, hsame *rows,* Cont *rows,* Pkg *provenance, and local* NameCert *row read by the consumer are exactly the rows carried by that scheduled window.*

Consequently the consumer surface exposes no unscheduled endpoint, hidden tail coordinate, quotient equality, selected limit, completeness datum, trichotomy datum, host real equality, or standard bridge row outside the displayed unary schedule.

Proof. Start with an admitted finite-window request. Apply Definition 316.20 to reduce the read to the prefix, determinacy, handoff, public boundary, correspondence, invariance, and standard finite-window rows already exposed by the accepted packet.

Next apply Definition 316.5. The requested read is identified with a displayed prefix of the unary schedule N, so the consumer can only address rows attached to that scheduled window.

Use Definition 316.8 together with Definition 316.16. These fix the normalized endpoint and carry ledger for both $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers through the same displayed hsame and Cont routes.

Finally invoke Definition 316.19 and Definition 316.21. The remaining package provenance and local name-certificate rows are exactly those carried by the scheduled window, and the cited normal form contains no coordinate for an unscheduled endpoint, hidden tail, quotient equality, selected limit, completeness datum, trichotomy datum, host real equality, or extra standard bridge row. □

Theorem 316.23 (SignedDigitStream adjacent carry confluence)**.** *Let S and S' be accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *packets with the same displayed unary schedule and the same signed digit prefix. Suppose their displayed adjacent carry ledgers may differ, but both normalize to endpoint rows accepted by the packet classifier. Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer window and every* $\mathsf{Real}^{\uparrow}$ *consumer window reads classifier-equal normalized* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows through the same* BHist *ledger,* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *provenance.*

The confluence statement is finite-window only. It introduces no quotient stream, hidden tail, selected limit, completeness principle, trichotomy datum, or host real equality.

Proof. Begin with the shared displayed schedule and signed digit prefix. Apply Definition 316.8 to both packets. The common window fixes the normalized endpoint row up to the packet classifier and keeps the comparison inside the displayed carry ledger, hsame, and Cont routes.

Next use Definition 316.21. Each adjacent carry ledger normalizes to the canonical finite-tail normal form over the same prefix window, so the two endpoint rows are classifier-equal finite $\mathsf{DyadicRatCore}^{\uparrow}$ rows rather than distinct tail presentations.

For a $\mathsf{RegSeqRat}^{\uparrow}$ request, project the canonical endpoint rows through Definition 316.9. For a $\mathsf{Real}^{\uparrow}$ request, project them through Definition 316.16. Both consumer readings therefore pass through the same BHist, Pkg, and NameCert provenance already present in the packets.

The cited rows contain no coordinate for quotient streams, hidden tails, selected limits, completeness, trichotomy, or host real equality. Hence adjacent carry choices can only change the displayed normalization ledger, and any accepted normalization reaches the same finite consumer row. □

Closure status for $\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}$**.**

Constructive story: A signed-digit stream packet is generated from finite signed dyadic digit rows, a unary $\mathsf{StreamName}^{\uparrow}$ observation schedule, carry and normalization ledgers, $\mathsf{StreamName}^{\uparrow}$ provenance, normalized $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows, and a ledger hiding only the unobserved tail beyond the requested window.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 316.20 gives the mature finite-window consumer boundary for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ by packaging the prefix, determinacy, handoff, public boundary, correspondence, and standard bridge rows through the displayed endpoint, carry, transport, package, and name-certificate data.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SignedDigitStream}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SignedDigitStreamUp.SignedDigitStreamPacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close full stream regularity, $\mathsf{Real}^{\uparrow}$ sealing, host real equality, quotient presentations, completeness, or bridgeChecked status.

Upgrade path: Only axiom-purity and bridge checking remain on the verification axis for this mature finite-window consumer boundary.

Chapter 317

A Concrete Naming Certificate for $\mathsf{RealBall}^{\uparrow}$

The $\mathsf{RealBall}^{\uparrow}$ interface names the finite dyadic-radius neighborhood surface around a $\mathsf{Real}^{\uparrow}$ center. In Bishop-style constructive analysis, a real neighborhood is read through finite rational approximations and explicit positive radii; the BEDC packet below keeps that reading at the visible BHist level, with no host real topology or open-cover compactness datum.

317.1 Finite dyadic-window carrier

Definition 317.1 (RealBall finite-window carrier)**.** *A* $\mathsf{RealBall}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (c, r, W, P, L)$$

with the following visible rows:

1. *c is a* $\mathsf{Real}^{\uparrow}$ *center name read through a scheduled* RegSeqRat *stream and its* $\mathsf{StreamName}^{\uparrow}$ *finite-window requests;*
2. *r is a positive dyadic-radius row from* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
3. *W is a finite dyadic-window witness listing the displayed center approximants, the displayed radius row, and the* $\mathsf{DyadicInterval}^{\uparrow}$ *interval rows that cover the visible portion of the ball;*
4. *P is the* Pkg *provenance tying the carrier to* $\mathsf{Real}^{\uparrow}$*,* RegSeqRat*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{DyadicInterval}^{\uparrow}$ *source certificates;*
5. *L is the ledger that hides only the unobserved tail beyond the displayed window and records that every public read is made through W and P.*

The carrier predicate is $\mathsf{RealBallWindow}(c, r, W, P, L)$*. Two accepted carriers classify together only when their center names, positive dyadic radii, visible interval rows, provenance rows, and tail ledgers transport by displayed* hsame *and by the same* Cont *routes named in P.*

Lean4 (definition) `BEDC.Derived.RealBallUp.RealBallWindowPacket`

Theorem 317.2 (RealBall radius transport)**.** *Let $B = (c, r, W, P, L)$ be an accepted* $\mathsf{RealBall}^{\uparrow}$ *carrier, and let $B' = (c', r', W', P', L')$ be obtained by displayed* hsame *transport of the* $\mathsf{Real}^{\uparrow}$ *center row, the positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the visible* $\mathsf{DyadicInterval}^{\uparrow}$ *window rows, and the*

provenance and ledger rows. If the same Cont *routes named by P and P' preserve the* RegSeqRat *and* $\mathsf{StreamName}^{\uparrow}$ *reads of the center, then B' is again an accepted* $\mathsf{RealBall}^{\uparrow}$ *carrier.*

The transported classifier reads the same finite dyadic-radius neighborhood surface: it changes only the displayed representatives of c, r, W, P, and L, and it introduces no Dedekind cut, trichotomy row, completeness datum, host real ball, or open-cover topology.

Lean4 ✓ `BEDC.Derived.RealBallUp.RealBallWindowPacket radius transport`

Proof. Project the five coordinates of Definition 317.1. The center coordinate is read through $\mathsf{Real}^{\uparrow}$, RegSeqRat, and $\mathsf{StreamName}^{\uparrow}$, so the stated hsame and Cont routes transport each displayed center approximant in the finite window.

Transport the positive dyadic-radius row through $\mathsf{DyadicRatCore}^{\uparrow}$ and transport the displayed interval rows through $\mathsf{DyadicInterval}^{\uparrow}$. The visible window witness W' is obtained by repacking exactly these transported rows.

Finally transport the provenance row and the tail ledger. The ledger still hides only the unobserved tail beyond the displayed window, so the accepted packet has the same classifier surface and no additional topological or completeness coordinate. □

Theorem 317.3 (RealBall finite-window NameCert surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet* (c, r, W, P, L) *of Definition 317.1;*
2. *classifier and stability: the transported-center and transported-radius statement of Definition 317.2;*
3. *finite window: the witness W listing the displayed* RegSeqRat *center approximants, the positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, and the* $\mathsf{DyadicInterval}^{\uparrow}$ *interval rows visible at the requested precision;*
4. *provenance: the* Pkg *row naming the consumed* $\mathsf{Real}^{\uparrow}$, RegSeqRat, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{DyadicInterval}^{\uparrow}$ *certificate boundaries;*
5. *ledger boundary: the row L recording that only the unobserved tail beyond the displayed window is hidden.*

These five rows are the full public seed surface for the finite dyadic-radius neighborhood name.

Lean4 ✓ `BEDC.Derived.RealBallUp.RealBallWindowPacket finite window namecert`

Proof. The carrier row supplies the center, radius, finite window, provenance, and tail-ledger coordinates. This fixes the source domain of the name.

The classifier and stability row is Definition 317.2. It says that the only permitted motion is componentwise hsame transport along the displayed Cont routes named by the provenance row.

The remaining rows are direct projections from the carrier. Since the construction records no host real topology, open-cover family, completeness principle, or hidden equality quotient, the five listed rows exhaust the $\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$ obligation surface. □

Theorem 317.4 (RealBall metric-neighborhood handoff)**.** *A downstream* $\mathsf{Met}^{\uparrow}$ *consumer may read an accepted* $\mathsf{RealBall}^{\uparrow}$ *carrier only as a finite real-neighborhood surface: a* $\mathsf{Real}^{\uparrow}$ *center name, a positive dyadic radius, a visible dyadic interval window, and the provenance and tail ledger of Definition 317.1. The handoff supports metric-local arguments that consume displayed dyadic tolerances around a real name.*

The handoff is not an open-cover topology and does not assert a basis theorem, Heine–Borel compactness, completeness of $\mathsf{Real}^{\uparrow}$*, or choice of a global covering family.*

Lean4 ✓ `BEDC.Derived.RealBallUp.RealBallWindowCarrier metric neighborhood handoff`

Proof. Read the carrier through Definition 317.1. The only metric-facing coordinates are the center name, the positive dyadic radius, and the displayed dyadic interval window around the center approximants.

The transport theorem Definition 317.2 supplies the stability needed by a metric consumer: replacing the center name or radius by displayed hsame representatives repacks the same finite neighborhood surface.

No coordinate of the carrier contains an open cover, a covering selection principle, a completed metric object, or a host topology. A $\mathsf{Met}^{\uparrow}$ consumer therefore receives exactly the finite dyadic-radius read described in the statement. □

Theorem 317.5 (RealBall standard obligation boundary)**.** *The* $\mathsf{RealBall}^{\uparrow}$ *chapter claims only finite dyadic-window balls around* $\mathsf{Real}^{\uparrow}$ *names. Its dependency list is exactly the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* RegSeqRat*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicInterval}^{\uparrow}$ *certificate surface named by the provenance row.*

This places the chapter inside the same concrete-instance lattice as chapter 38, chapter 126, and chapter 301: the $\mathsf{RealBall}^{\uparrow}$ *carrier consumes* $\mathsf{Real}^{\uparrow}$ *names through* $\mathsf{StreamName}^{\uparrow}$ *finite windows and* RegSeqRat *readback before exposing dyadic-window balls.*

It does not claim real-number completeness, order trichotomy, locatedness outside the displayed window, Heine–Borel compactness, equivalence with host real open balls, a host topological bridge, or any open-cover compactness principle.

Lean4 ✓ `BEDC.Derived.RealBallUp.RealBallWindowPacket standard obligation boundary`

Proof. The positive-radius datum is a $\mathsf{DyadicRatCore}^{\uparrow}$ row, the center datum is a $\mathsf{Real}^{\uparrow}$ name read through RegSeqRat and $\mathsf{StreamName}^{\uparrow}$, and the visible ball surface is a finite collection of $\mathsf{DyadicInterval}^{\uparrow}$ rows. These are exactly the dependencies listed in the carrier provenance.

Apply Definition 317.3 to exhaust the public obligation surface. Every accepted read is one of the five finite rows listed there.

The excluded principles would require coordinates not present in the packet: global real order data, completed metric limits, open-cover families, compactness witnesses, or a host topological bridge. Since the carrier has no such coordinate, the boundary is precisely the finite dyadic-window claim. □

Theorem 317.6 (RealBall scoped dependency packet)**.** *Every accepted* $\mathsf{RealBall}^{\uparrow}$ *finite-window packet is scoped by the center* $\mathsf{Real}^{\uparrow}$ *stream read, a positive* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius, visible* $\mathsf{DyadicInterval}^{\uparrow}$ *window rows,* Pkg *provenance, and the local ledger boundary. All transport used by the packet factors through* BHist *carrier rows, displayed* hsame *identifications,* Cont *routes, and* NameCert *rows.*

Consequently the accepted real-ball surface is a finite dyadic-neighborhood packet over the L10 primitives named in the carrier. It does not add a host topological ball, Heine–Borel compactness data, a global open-cover family, or completeness of the real-name carrier.

Proof. Project the carrier of Definition 317.1. The center coordinate is read as a $\mathsf{Real}^{\uparrow}$ name through the displayed RegSeqRat and $\mathsf{StreamName}^{\uparrow}$ rows, while the radius coordinate is the positive $\mathsf{DyadicRatCore}^{\uparrow}$ row stored in the same packet.

Next compose Definition 317.2 with the visible $\mathsf{DyadicInterval}^{\uparrow}$ window rows. This identifies the permitted hsame and Cont movement of the finite dyadic neighborhood without adding any coordinate outside the carrier.

The consumer face is the metric-neighborhood handoff of Definition 317.4. The local $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ surface of Definition 317.3 supplies the provenance and ledger rows used by that handoff.

Finally apply Definition 317.5. It rules out host topology, compactness, and completeness coordinates, so the scoped dependency packet is exactly the finite center, radius, window, provenance, and ledger surface stated above. □

Lean4 ✓ `BEDC.Derived.RealBallUp.RealBallWindowPacket scoped dependency packet`

Theorem 317.7 (RealBall public NameCert export)**.** *The finite-window carrier of Definition 317.1, the radius transport of Definition 317.2, the finite-window* $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ *surface of Definition 317.3, the metric-neighborhood handoff of Definition 317.4, the standard obligation boundary of Definition 317.5, and the scoped dependency packet of Definition 317.6 assemble a public* $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ *export for downstream* $\mathsf{Met}^\uparrow$ *and* $\mathsf{Real}^\uparrow$ *consumers.*

The exported boundary is exactly the finite dyadic-window neighborhood surface: a $\mathsf{Real}^\uparrow$ *center read through* $\mathsf{RegSeqRat}$ *and* $\mathsf{StreamName}^\uparrow$*, a positive* $\mathsf{DyadicRatCore}^\uparrow$ *radius, visible* $\mathsf{DyadicInterval}^\uparrow$ *rows,* Pkg *provenance, and the tail ledger. It exports no host topology, open-cover compactness, trichotomy, completeness datum, or host real ball.*

Proof. Start with the carrier of Definition 317.1. Its rows give the center name, positive dyadic radius, finite visible window, provenance packet, and ledger boundary that a public consumer can inspect.

Apply Definition 317.2 to fix the stability row, and apply Definition 317.3 to package the carrier, classifier, finite window, provenance, and ledger as the local $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ surface.

Next use the metric-neighborhood handoff of Definition 317.4. This is the consumer-facing read for $\mathsf{Met}^\uparrow$ and $\mathsf{Real}^\uparrow$: it exposes the finite dyadic-radius neighborhood without changing the underlying BEDC packet.

Finally combine the standard obligation boundary of Definition 317.5 with the scoped dependency packet of Definition 317.6. These two rows state exactly which dependencies are public and which coordinates are absent, so repacking the listed rows gives the claimed $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ export and nothing beyond it. □

Theorem 317.8 (RealBall standard finite-window bridge)**.** *The public export of Definition 317.7 determines the standard finite-window bridge schema for* $\mathsf{RealBall}^\uparrow$*. The source row is the* $\mathsf{Real}^\uparrow$ *center read through* $\mathsf{RegSeqRat}^\uparrow$ *and* $\mathsf{StreamName}^\uparrow$*, the radius row is the positive* $\mathsf{DyadicRatCore}^\uparrow$ *datum, and the window row is the visible* $\mathsf{DyadicInterval}^\uparrow$ *packet. The only bridge routes are the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*, and ledger rows.*

This bridge exports no host topology, open-cover compactness, trichotomy, completeness datum, or host real ball.

Proof. Begin with the public export of Definition 317.7. It exposes exactly the center, positive radius, finite window, provenance, and ledger rows of the $\mathsf{NameCert}_{\mathsf{RealBall}^\uparrow}$ packet.

Apply Definition 317.6 to identify the permitted routes. The center row factors through $\mathsf{Real}^\uparrow$, $\mathsf{RegSeqRat}^\uparrow$, and $\mathsf{StreamName}^\uparrow$; the radius row factors through $\mathsf{DyadicRatCore}^\uparrow$; and the visible window factors through $\mathsf{DyadicInterval}^\uparrow$.

Finally use Definition 317.5. It excludes host topology, compactness, trichotomy, completeness, and host-ball coordinates. Projecting the displayed rows and repacking them gives exactly the finite bridge schema stated above. □

Theorem 317.9 (RealBall finite-window consumer coverage)**.** *Let* $B = (c, r, W, P, L)$ *be an accepted* $\mathsf{RealBall}^\uparrow$ *packet. Every public read of* B *by a* $\mathsf{Met}^\uparrow$ *consumer, by a* $\mathsf{RegSeqRat}^\uparrow$ *read of*

the center, or by a $\mathsf{Real}^{\uparrow}$ *neighborhood consumer factors through exactly the center row* c*, the positive dyadic radius row* r*, the visible* $\mathsf{DyadicInterval}^{\uparrow}$ *window rows* W*, the* Pkg *provenance row* P*, the ledger* L*, and the* BHist*,* hsame*,* Cont*, and* NameCert *rows isolated by Definition 317.6, Definition 317.7, and Definition 317.8.*

The consumer surface contains no coordinate for host topology, open-cover compactness, Heine–Borel data, trichotomy, completeness, or host real balls.

Proof. Project the accepted packet through the carrier of Definition 317.1. The projection exposes only the center name, positive dyadic radius, finite visible dyadic window, provenance packet, and tail ledger, so these rows form the whole candidate packet seen by a consumer.

Use the radius transport of Definition 317.2 and the finite-window $\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$ surface of Definition 317.3. They keep the positive radius row and the visible window stable under the displayed hsame and Cont classifiers, so replacing the packet by a classified equal one does not reveal a new read coordinate.

Next apply the metric-neighborhood handoff and the public export of Definition 317.4 and Definition 317.7. These are exactly the public routes used by $\mathsf{Met}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ neighborhood consumers: each route reads one of the displayed rows and then repacks it as the same finite-window NameCert boundary.

Finally use the standard bridge of Definition 317.8. The bridge has no extra source, pattern, or ledger coordinate beyond the center, radius, visible-window, provenance, BHist, hsame, Cont, and NameCert rows already listed. Since the bridge also excludes host topology, open-cover compactness, Heine–Borel data, trichotomy, completeness, and host real balls, every public consumer read is exhausted by the same visible packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$**.**

Constructive story: A real-ball packet is generated by a $\mathsf{Real}^{\uparrow}$ center name read through RegSeqRat and $\mathsf{StreamName}^{\uparrow}$, a positive $\mathsf{DyadicRatCore}^{\uparrow}$ radius row, visible $\mathsf{DyadicInterval}^{\uparrow}$ window rows, Pkg provenance, and a ledger hiding only the unobserved tail.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$, maturePackageClosed)

Scope closed: The finite-window carrier of Definition 317.1, radius transport of Definition 317.2, finite-window NameCert surface of Definition 317.3, metric handoff of Definition 317.4, boundary row of Definition 317.5, scoped dependency packet of Definition 317.6, public export of Definition 317.7, standard bridge of Definition 317.8, and consumer coverage of Definition 317.9 are bound to BHist, hsame, Cont, Pkg, NameCert, $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{DyadicInterval}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealBall}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RealBallUp.RealBallWindowPacket\_finite\_window\_namecert`

Bridge status: none

Origin: human

Not claimed: This chapter does not close completeness, trichotomy, Heine–Borel compactness, host real topology, or host real balls.

Upgrade path: Further Lean work concerns the public export, standard bridge, and consumer-coverage targets beyond the cited finite-window NameCert surface.

Chapter 318

A Concrete Naming Certificate for $\mathsf{EulerLagrange}^{\uparrow}$

The $\mathsf{EulerLagrange}^{\uparrow}$ interface names the finite variational-equation surface consumed by $\mathsf{Pde}^{\uparrow}$ and $\mathsf{NoetherSymmetry}^{\uparrow}$. In the classical calculus of variations, as presented for example by Gelfand–Fomin and by Giaquinta–Hildebrandt, the Euler–Lagrange equation is read from an action functional, admissible variations, a first-variation computation, and boundary conditions. The BEDC packet below records only the finite rows needed to cite that surface.

318.1 Finite variational packet

Definition 318.1 (EulerLagrangeUp BHist carrier)**.** *An* $\mathsf{EulerLagrange}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (A, V, F, B, Q, R, C, H, P, N)$$

with the following visible rows:

1. *A is an action-functional row naming the displayed Lagrangian or energy expression through* $\mathsf{Integral}^{\uparrow}$, $\mathsf{Derivative}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *source certificates;*
2. *V is an admissible-variation row naming the finite variation family and the source-domain restrictions it must respect;*
3. *F is a first-variation ledger that records the displayed derivative read, the finite cancellation rows, and the residual equation row;*
4. *B is a boundary-condition row saying which boundary terms are fixed, vanish, or remain visible to a downstream consumer;*
5. *Q is the* $\mathsf{Pde}^{\uparrow}$ *source row that receives the residual equation as an equation surface;*
6. *R is the* $\mathsf{Real}^{\uparrow}$ *scalar row used for action values, first-variation values, and displayed coefficient comparisons;*
7. *C records the* Cont *provenance routes by which the action, variation, boundary, PDE, and scalar rows are read;*
8. *H records the* hsame *transport rows for the displayed action, variation, first-variation ledger, boundary row, PDE row, and scalar row;*

9. *P is the* Pkg *provenance row naming* Derivative$^\uparrow$, Integral$^\uparrow$, Pde$^\uparrow$, Real$^\uparrow$, *and* NoetherSymmetry$^\uparrow$ *as the finite consumers and suppliers of the packet;*
10. *N is the* NameCert *provenance row that registers the packet under* EulerLagrange$^\uparrow$.

The carrier predicate is EulerLagrangePacket$(A, V, F, B, Q, R, C, H, P, N)$. *Two accepted packets classify together only when the ten displayed rows transport componentwise by the* hsame *witnesses and the same* Cont *routes named in C and P.*

Theorem 318.2 (EulerLagrange local action row)**.** *Every accepted* EulerLagrange$^\uparrow$ *carrier exposes a local action-functional row A together with its* Derivative$^\uparrow$, Integral$^\uparrow$, *and* Real$^\uparrow$ *provenance. A consumer may read from A only the displayed integrand or energy expression, the displayed derivative route used for the first variation, the displayed integral route used for the action value, and the scalar rows named by the* Real$^\uparrow$ *boundary.*

The row does not assert existence of minimizers, smooth compactness, a host manifold of fields, or any unrecorded analytic regularity.

Proof. Project the A, R, C, and P coordinates from Definition 318.1. These coordinates explicitly name the action expression, the derivative and integral provenance, the real scalar reads, and the finite continuation routes.

The classifier clause permits only componentwise hsame transport of those rows. Hence every local action read available to a downstream consumer is one of the displayed rows of the packet, and no host variational object can be inferred from the carrier. □

Theorem 318.3 (EulerLagrange variation ledger and boundary row)**.** *For an accepted carrier $E = (A, V, F, B, Q, R, C, H, P, N)$, the admissible-variation row V, the first-variation ledger F, and the boundary-condition row B jointly determine the public variational ledger. The ledger records which displayed variations are admitted, which first-variation terms are retained or cancelled, and which boundary terms are fixed or exposed.*

No consumer may read an integration-by-parts theorem, a density argument for arbitrary test variations, or a hidden boundary regularity fact unless that datum appears as one of the finite rows in V, F, or B.

Proof. Read the three coordinates V, F, and B from the carrier. The admissible variations are exactly the entries of V, the computed first-variation terms are exactly the ledger entries of F, and the boundary policy is exactly the row B.

The transport rows in H keep these three coordinates synchronized under hsame. The Cont routes in C say where the rows may be read, but they do not add a new analytic rule.

Therefore the public variational ledger is exhausted by the three displayed coordinates. Any stronger calculus principle would require an additional row, which is not present in the carrier. □

Theorem 318.4 (EulerLagrange PDE source handoff)**.** *The* Pde$^\uparrow$ *row Q of an accepted* EulerLagrange$^\uparrow$ *carrier is the only PDE-facing handoff of the residual first-variation equation. It names the displayed equation row produced from F after applying the boundary policy B, together with the* Cont, hsame, *and* Pkg *provenance that connect it to* Pde$^\uparrow$.

The handoff does not claim well-posedness, ellipticity, hyperbolicity, weak-solution existence, or equivalence with a standard analytic PDE model.

Proof. Start with the first-variation ledger F and boundary row B. Their displayed residual equation is the equation surface recorded in the Pde$^\uparrow$ coordinate Q.

The provenance rows C, H, and P then identify how this equation surface is transported and packaged for a $\mathsf{Pde}^{\uparrow}$ consumer. Since Q is a finite source row, it carries only the residual equation and its named dependencies.

No coordinate of the packet stores a solution theory, type classification of the PDE, regularity estimate, or bridge to an ambient analytic model. The stated handoff is therefore the whole PDE-facing surface. □

Theorem 318.5 (EulerLagrange Noether boundary consumer row)**.** *A* $\mathsf{NoetherSymmetry}^{\uparrow}$ *consumer of an accepted* $\mathsf{EulerLagrange}^{\uparrow}$ *packet may read only the action row, admissible-variation row, first-variation ledger, boundary-condition row, PDE residual row,* $\mathsf{Real}^{\uparrow}$ *scalar row, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

This Noether-facing boundary contains no conserved-current theorem, symmetry-completeness theorem, analytic PDE regularity, or standard Noether bridge.

Proof. Project the accepted carrier of Definition 318.1. Its coordinates expose the action row, admissible variations, first-variation ledger, boundary policy, PDE residual row, scalar row, continuation routes, transport witnesses, package provenance, and local name certificate.

Use Definition 318.2 for the action-facing projection, and use Definition 318.3 for the admissible-variation, first-variation, and boundary-condition rows. These are the variational coordinates available before any Noether-facing read.

Apply Definition 318.4. The residual equation read by the $\mathsf{Pde}^{\uparrow}$ coordinate is the same finite row exposed to a $\mathsf{NoetherSymmetry}^{\uparrow}$ consumer, together with the displayed hsame, Cont, Pkg, and NameCert provenance.

Since the carrier has no coordinate for conserved currents, symmetry completeness, analytic regularity, or a standard Noether bridge, the Noether-facing consumer boundary is exactly the finite row list in the statement. □

Theorem 318.6 (EulerLagrange NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ *seed surface consists exactly of the carrier of Definition 318.1, the local action row of Definition 318.2, the variation ledger and boundary row of Definition 318.3, and the PDE source handoff of Definition 318.4. Its dependency list is the finite* Pkg *row naming* $\mathsf{Derivative}^{\uparrow}$*,* $\mathsf{Integral}^{\uparrow}$*,* $\mathsf{Pde}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{NoetherSymmetry}^{\uparrow}$*, together with the displayed* Cont*,* hsame*, and* NameCert *provenance rows.*

The surface does not claim the full calculus of variations, a variational existence theorem, natural boundary-condition completeness, Noether correspondence, analytic PDE regularity, or a standard bridge.

Proof. Assemble the obligation surface from the carrier. The definition supplies the action, variation, first-variation ledger, boundary, PDE, scalar, transport, package, and name-certificate rows.

The first three theorems identify the only public projections needed by consumers: local action reads, variational ledger reads, and the PDE handoff. These projections cover every coordinate used by $\mathsf{EulerLagrange}^{\uparrow}$.

The exclusions follow by inspection of the finite packet. None of its rows contains an existence theorem, a host variational model, a Noether bijection, analytic regularity, or a standard bridge, so those claims remain outside the seed surface. □

Lean4 ✓ `BEDC.Derived.EulerLagrangeUp.EulerLagrangePacket semantic name certificate`

Theorem 318.7 (EulerLagrange LagrangianMechanics route)**.** *An accepted* $\mathsf{EulerLagrange}^{\uparrow}$ *packet may be consumed as the variational-equation row of chapter 337 only through the displayed action*

row, admissible-variation row, first-variation ledger, boundary row, $\mathsf{Pde}^{\uparrow}$ *residual row,* $\mathsf{Real}^{\uparrow}$ *scalar row,* hsame *and* Cont *provenance,* Pkg *provenance, and local* NameCert *rows of Definition 318.1. The sibling* $\mathsf{LagrangianMechanics}^{\uparrow}$ *consumer surface reads that packet as the finite Euler–Lagrange residual interface and not as a host variational calculus.*

Proof. Project the accepted carrier of Definition 318.1. The local action theorem Definition 318.2 identifies the action-facing row and its derivative, integral, and scalar provenance.

Next use Definition 318.3. It binds the admissible-variation row, first-variation ledger, and boundary row as the finite variational ledger that feeds the residual equation.

Apply Definition 318.4 and Definition 318.6. These theorems place the residual equation in the $\mathsf{Pde}^{\uparrow}$ row and repack the action, variation, boundary, scalar, hsame, Cont, Pkg, and NameCert rows as the local obligation surface.

Finally identify the sibling consumer by Definition 337.3. The $\mathsf{LagrangianMechanics}^{\uparrow}$ interface consumes only the residual-equation row and the finite action ledger that feeds it, so the Euler-Lagrange packet reaches that chapter through the displayed rows and through no host variational calculus, boundary-completeness principle, or standard analytic model. □

Theorem 318.8 (EulerLagrange scoped dependency certificate)**.** *Every exported* $\mathsf{EulerLagrange}^{\uparrow}$ *row factors through the action row, admissible-variation row, first-variation ledger, boundary row,* $\mathsf{Pde}^{\uparrow}$ *residual-equation row,* $\mathsf{Real}^{\uparrow}$ *scalar row,* Cont*,* hsame*,* Pkg*, and* NameCert *provenance listed in Definition 318.1, Definition 318.2, Definition 318.3, Definition 318.4, and Definition 318.6.*

The scoped certificate exposes no minimizer existence, full calculus of variations, Noether correspondence, analytic PDE regularity, or standard bridge data.

Proof. Project the carrier of Definition 318.1. Its coordinates are the action row, admissible-variation row, first-variation ledger, boundary row, residual-equation handoff, scalar row, continuation routes, transport witnesses, package provenance, and local name certificate.

The action theorem supplies the only action-facing projection. The variation-ledger theorem supplies the only admissible-variation, first-variation, and boundary projections. The PDE handoff theorem supplies the only residual-equation projection to $\mathsf{Pde}^{\uparrow}$.

The NameCert obligation theorem repacks these projections with the listed Cont, hsame, Pkg, and NameCert provenance. None of the projected rows contains a minimizer, a complete calculus-of-variations principle, a Noether correspondence, analytic PDE regularity, or bridge data, so the scoped dependency boundary is exactly the displayed finite packet. □

Lean4 ✓ `BEDC.Derived.EulerLagrangeUp.EulerLagrangePacket scoped dependency certificate`

Theorem 318.9 (EulerLagrange public export)**.** *Definition 318.6 and Definition 318.8 export the public* $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ *boundary over the action row, admissible-variation row, first-variation ledger, boundary row, PDE residual handoff,* $\mathsf{Real}^{\uparrow}$ *scalar row,* Cont *routes,* hsame *transport,* Pkg *provenance, and* NameCert *row.*

The exported boundary contains no variational existence theorem, natural-boundary completeness, Noether correspondence, analytic PDE regularity, or standard bridge.

Proof. Project the finite carrier of Definition 318.1. The action row, admissible-variation row, first-variation ledger, boundary row, PDE residual handoff, scalar row, continuation routes, transport witnesses, package provenance, and local name row are the carrier coordinates available to public consumers.

The obligation theorem identifies the $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ surface over those coordinates, and the scoped dependency certificate binds the same rows to the displayed source certificates. Repacking these two results gives the public boundary without adding any coordinate outside the carrier.

The exclusions are preserved because the carrier has no row for variational existence, natural-boundary completeness, Noether correspondence, analytic PDE regularity, or a standard bridge. The public export is therefore exactly the finite BEDC packet surface already projected by the two cited theorems. □

Theorem 318.10 (EulerLagrange standard bridge boundary)**.** *Any standard reading of the accepted* $\mathsf{EulerLagrange}^{\uparrow}$ *packet must read and write only the displayed action row, admissible-variation row, first-variation ledger, boundary row, PDE residual row,* $\mathsf{Real}^{\uparrow}$ *scalar row,* Cont *routes,* hsame *transport,* Pkg *provenance, and* $\mathsf{NameCert}$ *provenance exposed by Definition 318.1 and Definition 318.9. The bridge boundary exports no minimizer existence, full calculus of variations, Noether correspondence, analytic PDE regularity, or unrecorded standard-model data.*

Proof. Project the carrier of Definition 318.1. Its available coordinates are exactly the action row, admissible-variation row, first-variation ledger, boundary row, PDE residual row, scalar row, continuation routes, transport witnesses, package provenance, and local certificate provenance.

Apply Definition 318.9. It identifies those carrier coordinates as the public $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ boundary and supplies no additional standard-model slot. A standard bridge whose input is this accepted packet can therefore read the listed rows and can write back only the same rows after the displayed Cont and hsame transport.

The excluded analytic and variational claims are absent from both the carrier and the public export. Since no row records minimizer existence, a full calculus of variations, a Noether correspondence, PDE regularity, or external standard-model data, the standard bridge boundary is exactly the finite public packet already displayed. □

Theorem 318.11 (EulerLagrange finite PDE consumer example)**.** *The public export and standard bridge boundary of an accepted* $\mathsf{EulerLagrange}^{\uparrow}$ *packet determine a finite PDE-residual consumer surface over the action row, admissible-variation row, first-variation ledger, boundary-condition row,* $\mathsf{Pde}^{\uparrow}$ *residual row,* $\mathsf{Real}^{\uparrow}$ *scalar row, visible* hsame*, visible* Cont*,* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance.*

The consumer surface does not assert minimizer existence, the full calculus of variations, natural-boundary completeness, Noether correspondence, analytic PDE regularity, or external standard-model data. It is only the downstream finite-row read of the residual coordinate already present in the accepted packet.

Proof. Project the carrier of Definition 318.1. The carrier lists exactly the action row, admissible-variation row, first-variation ledger, boundary-condition row, PDE residual row, real scalar row, transport, continuation, package, and certificate provenance available to downstream consumers.

Apply Definition 318.9. It exposes those rows as the public $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ boundary and adds no analytic or variational coordinate beyond the displayed carrier surface.

Apply Definition 318.10. The standard reading can read and write only the same displayed rows, so the $\mathsf{Pde}^{\uparrow}$ residual coordinate is a legitimate downstream consumer example on the finite packet.

The conclusion follows by absence of extra carrier rows. Since the packet has no row for minimizer existence, full variational calculus, natural-boundary completeness, Noether correspondence, analytic PDE regularity, or external standard-model data, the finite PDE-residual consumer cannot export those claims. □

Closure status for $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$.

Constructive story: An Euler–Lagrange packet is generated by a displayed action row, an admissible-variation row, a first-variation ledger, a boundary-condition row, a $\mathsf{Pde}^{\uparrow}$ residual-equation row, a $\mathsf{Real}^{\uparrow}$ scalar row, Cont provenance, hsame transport, Pkg rows naming $\mathsf{Derivative}^{\uparrow}$, $\mathsf{Integral}^{\uparrow}$, $\mathsf{Pde}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{NoetherSymmetry}^{\uparrow}$, and a NameCert provenance row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 318.9, Definition 318.10, and Definition 318.11 export the public $\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}$ boundary and finite PDE-residual consumer surface over the action row, admissible-variation row, first-variation ledger, boundary row, PDE handoff, scalar row, Cont, hsame, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{EulerLagrange}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.EulerLagrangeUp.EulerLagrangePacket\_scoped\_dependency\_certificate`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close the full calculus of variations, variational existence, natural boundary-condition completeness, Noether correspondence, analytic PDE regularity, or standard-model completeness beyond the displayed bridge boundary.

Upgrade path: No further paper-axis obligation remains for the finite packet; verification-axis progress is tracked by the cited Lean target and bridge status.

Chapter 319

A Concrete Naming Certificate for $\mathsf{GradedAlgebra}^{\uparrow}$

The $\mathsf{GradedAlgebra}^{\uparrow}$ interface names the finite certificate surface of a graded algebra as used in the algebraic settings of Eisenbud 1995 and Weibel 1994. The BEDC packet records a base $\mathsf{Ring}^{\uparrow}$ carrier, a $\mathsf{Monoid}^{\uparrow}$ degree carrier, displayed homogeneous component predicates over BHist rows, multiplication rows whose Cont and Pkg ledger records degree addition, and a classifier comparing same-degree component witnesses by hsame. This fills the algebraic surface consumed by $\mathsf{TensorProduct}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, and the $\mathsf{KoszulDuality}^{\uparrow}$ interface of chapter 267.

319.1 Finite graded-algebra carrier

Definition 319.1 (GradedAlgebra BHist carrier)**.** *A* $\mathsf{GradedAlgebra}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (R, D, C, M, A, P)$$

with the following visible rows:

1. *R is a base* $\mathsf{Ring}^{\uparrow}$ *carrier row naming addition, multiplication, zero, one, and the ring ledger visible to the algebra packet;*
2. *D is a* $\mathsf{Monoid}^{\uparrow}$ *degree carrier row naming the displayed degree operation and unit degree;*
3. *C is a finite family of homogeneous component predicates on displayed* BHist *element rows, each predicate indexed by a visible degree row from D;*
4. *M is a multiplication ledger row saying that multiplying a witness in degree d with a witness in degree e produces a displayed witness in the component indexed by the monoid product $d \cdot e$;*
5. *A is the action row that reads the same base carrier through* $\mathsf{Module}^{\uparrow}$ *whenever a component is consumed as a module-like slice over R;*
6. *P is the* Pkg *provenance tying the packet to the cited* $\mathsf{Ring}^{\uparrow}$*,* $\mathsf{Monoid}^{\uparrow}$*,* $\mathsf{Module}^{\uparrow}$*,* $\mathsf{TensorProduct}^{\uparrow}$*, and* $\mathsf{KoszulDuality}^{\uparrow}$ *certificate boundaries.*

The carrier predicate is $\mathsf{GradedAlgebraPacket}(R, D, C, M, A, P)$*. The packet contains no quotient of the degree monoid, no host equality on elements, no external algebra object, and no hidden choice of homogeneous decomposition outside the displayed rows.*

Definition 319.2 (GradedAlgebra degree classifier)**.** *For accepted* $\mathsf{GradedAlgebra}^{\uparrow}$ *carriers* $G = (R, D, C, M, A, P)$ *and* $G' = (R', D', C', M', A', P')$*, the degree classifier relates a component witness* x *in degree* d *of* G *to a component witness* x' *in degree* d' *of* G' *exactly when the following finite data are displayed:*

1. *an* hsame *row comparing the degree witnesses* d *and* d' *through the* $\mathsf{Monoid}^{\uparrow}$ *carrier rows* D *and* D'*;*
2. *an* hsame *row comparing the element witnesses* x *and* x' *through the base* BHist *rows carried by* R *and* R'*;*
3. Cont *routes in* P *and* P' *showing that the two component predicates are read through the same indexed component slot;*
4. *a* Pkg *row recording that no comparison uses host equality, quotient representatives, or an unrecorded decomposition choice.*

This relation is written $\mathsf{GradedSameDegree}(G, x, d, G', x', d')$ *and is the only classifier exported by the seed packet.*

Theorem 319.3 (GradedAlgebra component stability)**.** *Let* $G = (R, D, C, M, A, P)$ *be an accepted* $\mathsf{GradedAlgebra}^{\uparrow}$ *carrier. If the base ring row, degree monoid row, homogeneous component predicates, multiplication ledger, module-action row, and provenance row are transported by displayed* hsame *along the same* Cont *routes named by* P*, then the transported packet* $G' = (R', D', C', M', A', P')$ *is again an accepted* $\mathsf{GradedAlgebra}^{\uparrow}$ *carrier.*

Moreover, every component witness classified by GradedSameDegree *in* G *transports to a same-degree component witness in* G' *using only the displayed* BHist*,* hsame*,* Cont*, and* Pkg *rows.*

Proof. Project the six coordinates of Definition 319.1. The base ring and degree monoid rows transport first, so the target packet has the same visible ring operations and the same displayed degree operation after hsame replacement.

Transport each homogeneous component predicate through the stated Cont route. Since each component slot is indexed by a visible degree row, the transported degree row determines the transported component slot without using a quotient of the degree monoid.

The multiplication ledger and module-action row then repack over the transported carrier. The ledger still sends degree d and degree e to the displayed product degree in the transported $\mathsf{Monoid}^{\uparrow}$ row, while the action row still reads each component through the transported $\mathsf{Module}^{\uparrow}$ surface.

Finally apply Definition 319.2. Its four rows are exactly the transported degree comparison, element comparison, component-slot route, and provenance row, so the same-degree witness remains visible in G'. □

Lean4 ✓ `BEDC.Derived.GradedAlgebraUp.GradedAlgebraPacket component stability`

Theorem 319.4 (GradedAlgebra product ledger)**.** *For accepted* $\mathsf{GradedAlgebra}^{\uparrow}$ *carrier* $G = (R, D, C, M, A, P)$*, the product ledger exposes exactly the following data for homogeneous witnesses* x *in degree* d *and* y *in degree* e*: a base* $\mathsf{Ring}^{\uparrow}$ *multiplication row, the* $\mathsf{Monoid}^{\uparrow}$ *degree product row* $d \cdot e$*, a* $\mathsf{TensorProduct}^{\uparrow}$*-readable row for the pair of homogeneous inputs, a component witness for the product in degree* $d \cdot e$*, and* Pkg *provenance tying these rows to* R*,* D*,* C*,* M*, and* P*.*

The ledger exports no host equality between products, no quotient degree class, no unindexed multiplication outside the homogeneous component surface, and no algebra object beyond the displayed BHist *rows.*

Proof. Read x and y through the component predicates of Definition 319.1. Their degree rows are visible rows of the same $\mathsf{Monoid}^{\uparrow}$ carrier, so the target degree for a product is the displayed monoid product row $d \cdot e$.

Project the multiplication ledger M. This row consumes the base $\mathsf{Ring}^{\uparrow}$ multiplication surface and the two component witnesses, then returns a displayed component witness indexed by the visible product degree.

The $\mathsf{TensorProduct}^{\uparrow}$ dependency is used only to expose the pair of homogeneous inputs as a finite tensor-readable row. The product row still returns through M and the component predicate indexed by $d \cdot e$.

The provenance row P records each route used by the product read. Since the carrier has no coordinate for host equality, quotient degrees, ungraded multiplication, or an external algebra object, the listed rows exhaust the product ledger. □

Lean4 ✓ `BEDC.Derived.GradedAlgebraUp.GradedAlgebraPacket product ledger`

Theorem 319.5 (GradedAlgebra homogeneous product scope exactness)**.** *For an accepted* $\mathsf{GradedAlgebra}^{\uparrow}$ *carrier* $G = (R, D, C, M, A, P)$*, any consumer-visible homogeneous product row for witnesses in degrees* d *and* e *is exactly the* BHist *row supplied by* M *over the* $\mathsf{Ring}^{\uparrow}$ *multiplication row, the* $\mathsf{Monoid}^{\uparrow}$ *degree product row* $d \cdot e$*, the* $\mathsf{TensorProduct}^{\uparrow}$ *input-pair row, the* $\mathsf{Module}^{\uparrow}$ *action row when the product is consumed as a slice, the* Cont *routes, and the* Pkg *provenance of* G*. The packet exports no host product equality, quotient degree, or unindexed multiplication.*

Proof. Project the carrier G and its product ledger M. The base multiplication is read through R, while the target degree is the displayed product $d \cdot e$ in the degree monoid row D.

Read the pair of homogeneous inputs through the $\mathsf{TensorProduct}^{\uparrow}$ row and the component witnesses through C. When a consumer views the product as a slice, the same displayed product row is read through the module-action coordinate A rather than through an additional multiplication operation.

The remaining data are the Cont routes and the Pkg provenance stored in P. Since Definition 319.1 contains no coordinate for host product equality, quotient degrees, or unindexed multiplication, the listed rows exhaust every consumer-visible homogeneous product read. □

Theorem 319.6 (GradedAlgebra NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet* (R, D, C, M, A, P) *of Definition 319.1;*
2. *degree classifier: the same-degree comparison relation of Definition 319.2;*
3. *component stability: the transported-component statement of Definition 319.3;*
4. *product ledger: the homogeneous product row of Definition 319.4 and the scope exactness row of Definition 319.5;*
5. *provenance: the* Pkg *row tying the packet to* $\mathsf{Ring}^{\uparrow}$*,* $\mathsf{Monoid}^{\uparrow}$*,* $\mathsf{Module}^{\uparrow}$*,* $\mathsf{TensorProduct}^{\uparrow}$*, and* $\mathsf{KoszulDuality}^{\uparrow}$ *consumers.*

These rows are the full public seed surface for the graded-algebra name, and every downstream read must pass through BHist *rows,* hsame *classifiers,* Cont *routes, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.GradedAlgebraUp.GradedAlgebraPacket namecert obligation surface`

Proof. The carrier row fixes the displayed ring, degree, component, multiplication, action, and provenance coordinates. This is the source domain of the name.

The degree classifier supplies the only comparison of homogeneous witnesses. It compares same-degree component witnesses by displayed hsame rows and by the component routes named in the package, so it does not invoke host equality or quotient representatives.

The component-stability theorem supplies transport of the carrier and classifier, while the product-ledger and product-scope theorems supply the only multiplication read available to $\mathsf{TensorProduct}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, and $\mathsf{KoszulDuality}^{\uparrow}$ consumers.

No remaining coordinate of the packet contains a host algebra, a quotient degree monoid, a decomposition choice, or an unrecorded product operation. The five listed rows therefore exhaust the $\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$ obligation surface. □

Theorem 319.7 (GradedAlgebra obligation scope certificate)**.** *The carrier, degree classifier, component stability, product ledger, homogeneous product scope exactness, and provenance rows bind the* $\mathsf{GradedAlgebra}^{\uparrow}$ *obligation surface to* $\mathsf{Ring}^{\uparrow}$, $\mathsf{Monoid}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{TensorProduct}^{\uparrow}$, $\mathsf{KoszulDuality}^{\uparrow}$, BHist, hsame, Cont, *and* Pkg *without host algebra equality, quotient degree, or unrecorded decomposition.*

Proof. Project the carrier of Definition 319.1. Its visible rows are the base ring, degree monoid, homogeneous component predicates, multiplication ledger, module-action row, and package provenance.

The classifier and stability data are Definition 319.2 and Definition 319.3. They keep same-degree component witnesses inside displayed BHist, hsame, Cont, and Pkg rows.

The product data are Definition 319.4 and Definition 319.5. These bind homogeneous multiplication to the displayed $\mathsf{Ring}^{\uparrow}$, $\mathsf{Monoid}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{TensorProduct}^{\uparrow}$, and $\mathsf{KoszulDuality}^{\uparrow}$ source surfaces.

Finally apply Definition 319.6. Since the packet contains no host algebra equality, quotient degree, or unrecorded decomposition coordinate, the named rows close the obligation scope. □

Theorem 319.8 (GradedAlgebra public dependency export)**.** *The public* $\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$ *export consists exactly of the base* $\mathsf{Ring}^{\uparrow}$ *row, the degree* $\mathsf{Monoid}^{\uparrow}$ *row, the homogeneous component predicates, the multiplication ledger, the module-action row, the same-degree classifier, the* Cont *routes, and the* Pkg *provenance already listed in the obligation surface. A public consumer may project these rows and their named dependencies through* BHist, hsame, Cont, *and* Pkg, *and no other graded-algebra coordinate is exported.*

In particular, the export contains no quotient degree monoid, host algebra equality, canonical decomposition of elements into homogeneous components, or unrecorded product operation.

Proof. Project the carrier of Definition 319.1. Its public coordinates are the base ring row, degree monoid row, homogeneous component predicates, multiplication ledger, module-action row, and package provenance.

Use Definition 319.2 for the same-degree classifier. Its comparisons are displayed hsame reads through the recorded component routes, so the classifier does not add quotient degree data or host equality.

Apply Definition 319.4 and Definition 319.5 to identify the only exported multiplication reads. Then use Definition 319.7 to repack the carrier, classifier, ledger, continuation, and provenance rows as the public dependency surface.

No coordinate in the assembled surface records quotient degree monoids, canonical decompositions, host algebra equality, or products outside the ledger. The listed rows therefore exhaust the public $\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$ export. □

Closure status for $\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$.

Constructive story: A graded-algebra packet is generated by a base $\mathsf{Ring}^{\uparrow}$ row, a $\mathsf{Monoid}^{\uparrow}$ degree row, homogeneous component predicates over displayed BHist rows, a multiplication ledger whose Cont and Pkg records follow degree multiplication, and same-degree component classifiers built from hsame.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$, publicClosed)

Scope closed: The finite carrier, degree classifier, component stability, product ledger, and NameCert obligation surface bind the displayed ring, degree, component, multiplication, action, and consumer surfaces for $\mathsf{GradedAlgebra}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{GradedAlgebra}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.GradedAlgebraUp.GradedAlgebraPacket\_namecert\_obligation\_surface`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient degrees, canonical homogeneous decomposition, host algebra equality, Koszul dual equivalence, or a standard bridge.

Upgrade path: Bridge closure requires a bridge theorem for the displayed ring, degree, component, multiplication, action, classifier, continuation, and package rows.

Chapter 320

A Concrete Naming Certificate for $\mathsf{NestedInterval}^{\uparrow}$

The $\mathsf{NestedInterval}^{\uparrow}$ interface names finite dyadic nested-interval packets. Following the constructive reading of nested intervals in Bishop and Bridges, Constructive Analysis, the BEDC carrier below records only displayed endpoint rows, inclusion ledgers, finite observation schedules, regular-rational reads, real-seal boundary rows, and certificate provenance. It does not assert a completed infinite chain or any classical nested-interval completeness principle.

The finite nested-interval packet consumes the dyadic endpoint certificate of chapter 291, the finite-window schedule discipline of chapter 126, the regular-rational readback surface of chapter 301, and the seal-facing boundary of chapter 38. These four source routes are the visible lattice behind the endpoint rows, observation schedule, readback rows, and real-facing boundary recorded below.

320.1 Finite dyadic nested packets

Definition 320.1 (NestedInterval finite carrier)**.** *A* $\mathsf{NestedInterval}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$N = (I, O, W, S, R, E, T, P, C)$$

with the following visible rows:

1. *I is a finite list of dyadic interval rows indexed by a unary prefix;*
2. *O records for each visible row its lower and upper* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints, the endpoint-order ledger, and the displayed dyadic-width ledger;*
3. *W records nested inclusion rows saying that each displayed successor interval is contained in the preceding displayed interval;*
4. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule provenance naming the finite prefix requests that selected the rows of I;*
5. *R records the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window reads available from the displayed endpoint and width ledgers;*
6. *E records the* $\mathsf{Real}^{\uparrow}$ *seal-facing rows that a later real-name consumer may inspect without reading an infinite tail;*

7. *T is the componentwise* hsame *and* Cont *transport table for the interval, endpoint, width, schedule, regular-rational, and seal-facing rows;*
8. *P is the* Pkg *provenance tying the packet to* DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, *and* DyadicInterval$^{\uparrow}$ *source certificates;*
9. *C is the* NameCert *provenance row for the finite nested-interval name.*

The carrier predicate is NestedIntervalPacket(N). *Two accepted carriers classify together only when the displayed endpoint rows, endpoint-order ledgers, width ledgers, nested-inclusion rows, schedule rows, regular-rational reads, seal-facing rows,* Pkg *provenance, and* NameCert *provenance transport by the same* hsame *and* Cont *routes named in T and P.*

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalTasteGate single carrier alignment`

Theorem 320.2 (NestedInterval endpoint transport)**.** *Let $N = (I, O, W, S, R, E, T, P, C)$ be an accepted* NestedInterval$^{\uparrow}$ *carrier, and let N' be obtained by componentwise displayed* hsame *transport of every lower endpoint, upper endpoint, endpoint-order ledger, width ledger, nested-inclusion row, schedule row,* RegSeqRat$^{\uparrow}$ *read,* Real$^{\uparrow}$ *seal-facing row,* Pkg *provenance row, and* NameCert *provenance row. If the same* Cont *routes named by T and P preserve the source certificate boundaries, then N' is again an accepted* NestedInterval$^{\uparrow}$ *carrier.*

The transported classifier reads exactly the transported finite dyadic interval chain and introduces no point-selection operator, no completed intersection object, and no host real completeness datum.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFinitePacket endpoint transport`

Proof. Project the carrier of Definition 320.1. The lower and upper endpoints are DyadicRatCore$^{\uparrow}$ rows, and the endpoint-order and width ledgers are ordinary displayed rows attached to the same interval slots.

Transport the interval rows and their endpoint ledgers componentwise through the stated hsame routes. The Cont routes named in T and P identify the same source certificate boundaries after transport, so every transported row still has the same dyadic endpoint role.

Finally transport the schedule, regular-rational, seal-facing, package, and name-certificate rows. Repacking these transported coordinates gives the accepted carrier N', and the classifier has no coordinate other than those finite rows. □

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier endpoint transport`

Theorem 320.3 (NestedInterval window refinement)**.** *For an accepted* NestedInterval$^{\uparrow}$ *carrier, restricting the unary prefix to a shorter displayed window or extending it by a row whose endpoint-order, width, and nested-inclusion ledgers are displayed produces another accepted finite nested-interval packet over the corresponding visible window. The classifier on the shared rows is unchanged, and the new row is read only through its* DyadicRatCore$^{\uparrow}$ *endpoints, inclusion ledger,* StreamName$^{\uparrow}$ *schedule provenance, and package routes.*

Thus finite-window refinement is stable without asserting convergence of the infinite chain.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalPacket window refinement`

Proof. For a restriction, discard the interval rows beyond the shorter unary prefix together with their endpoint, width, inclusion, regular-rational, and seal-facing reads. The remaining rows are still exactly the coordinates required by Definition 320.1.

For an extension, append the new displayed interval row and its lower endpoint, upper endpoint, order ledger, width ledger, and inclusion witness from the previous visible terminal row. Append the corresponding schedule, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, Pkg, and $\mathsf{NameCert}$ provenance rows.

The shared-window classifier is componentwise, so it is unchanged on rows already present before the restriction or extension. No step introduces an infinite intersection, compactness argument, or choice of a point. □

Theorem 320.4 (NestedInterval RegSeqRat handoff)**.** *An accepted* $\mathsf{NestedInterval}^{\uparrow}$ *carrier hands a* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer only the displayed finite-window data: the selected unary prefix, the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the lower and upper* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the width ledger for each visible interval, and the nested-inclusion ledger connecting adjacent visible rows. A downstream regular-rational stream may read those rows as finite approximants and bounds.*

The handoff does not certify regularity beyond the displayed rows, does not seal a completed $\mathsf{Real}^{\uparrow}$ *point, and does not identify an intersection element.*

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalRegSeqRatWindow handoff`

Proof. Read the packet through Definition 320.1. The only $\mathsf{RegSeqRat}^{\uparrow}$-facing coordinates are the scheduled finite-window reads R and the endpoint and width rows from O.

The schedule row S tells the consumer which unary prefix was requested. For each visible index, the lower and upper $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints and the width ledger give the finite approximant and its explicit bound, while W records the adjacent inclusion relation.

Since the handoff reads only these displayed rows, it cannot supply a tail-regularity proof, a real seal, or a selected point in the intersection. Those are separate obligations for later consumers. □

Theorem 320.5 (NestedInterval NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: a constant dyadic interval packet whose every visible row repeats the same ordered* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower and upper endpoints;*
2. *endpoint classifier transport: the componentwise endpoint, order-ledger, width-ledger, schedule, handoff, seal-facing, package, and certificate transport of Definition 320.2;*
3. *nested-window refinement stability: the restriction and extension behavior of Definition 320.3;*
4. *ledger exactness: the assertion that the displayed endpoint order, displayed dyadic widths, and displayed adjacent inclusions exhaust the finite interval-chain ledger;*
5. *Real and* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: the bounded finite rows exported by Definition 320.4 and by the seal-facing rows E of Definition 320.1.*

These rows are the full seed certificate surface for finite dyadic nested-interval names.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier semantic name certificate`

Proof. Carrier habitation is witnessed by the constant packet: choose one ordered dyadic interval row and repeat it along the displayed unary prefix, with identity inclusion and the same endpoint and width ledger at each row.

Endpoint classifier transport is Definition 320.2. Nested-window refinement stability is Definition 320.3. Together they describe the only permitted motion of accepted finite packets.

Ledger exactness follows by projection from the carrier coordinates O and W: every endpoint order, dyadic width, and adjacent inclusion used by the name is one of those displayed rows.

Finally, the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ handoff rows are precisely R and E, bounded by the finite window named by S. Since no coordinate names an infinite chain, a completed intersection, or a selected point, the five listed rows exhaust the $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ obligation surface. □

Theorem 320.6 (NestedInterval Real seal boundary)**.** *The* $\mathsf{Real}^{\uparrow}$*-facing boundary of an accepted* $\mathsf{NestedInterval}^{\uparrow}$ *carrier is limited to the displayed rows E and the finite endpoint, width, inclusion, schedule, and* $\mathsf{RegSeqRat}^{\uparrow}$ *rows that justify them. A downstream* $\mathsf{Real}^{\uparrow}$ *consumer may inspect these rows as a bounded finite window around prospective regular-rational data.*

The chapter does not claim Cantor nested-interval convergence, real completeness, compactness, Heine–Borel, extraction of a point by choice, or any equality with a host real intersection.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier real seal boundary`

Proof. Project the seal-facing coordinate E from Definition 320.1. Its dependencies are the finite endpoint, width, inclusion, schedule, and regular-rational rows named in the same carrier.

Use Definition 320.4 to identify the regular-rational part of the boundary. A $\mathsf{Real}^{\uparrow}$ consumer receives only the finite approximants and displayed bounds already present in the packet.

The excluded principles would require additional coordinates: an infinite chain object, a completed intersection, compactness data, or a choice operator selecting a point. The carrier contains none of these, so the seal boundary is exactly the displayed finite surface. □

Theorem 320.7 (NestedInterval obligation scope packet)**.** *The finite carrier of Definition 320.1, endpoint transport of Definition 320.2, window refinement of Definition 320.3,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 320.4,* $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ *obligation surface of Definition 320.5, and* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 320.6 depend only on* BHist *endpoint rows, finite dyadic interval packets, displayed* hsame *comparisons, visible* Cont *routes,* Pkg *provenance,* $\mathsf{DyadicInterval}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source certificates.*

Thus every accepted $\mathsf{NestedInterval}^{\uparrow}$ *packet is scoped by finite interval rows and the named BEDC source certificates.*

Proof. Start from the finite carrier of Definition 320.1. Its rows provide the dyadic interval endpoints, endpoint-order ledgers, width ledgers, adjacent inclusion rows, schedule provenance, handoff rows, and seal-facing rows.

Apply Definition 320.2 to account for endpoint transport, then apply Definition 320.3 to account for finite-window restriction and extension. These two results give the permitted hsame and Cont movement of the nested interval rows.

The consumer boundary is supplied by Definition 320.4 and by the finite $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ surface of Definition 320.5. Together they bind the scheduled $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ rows, Pkg provenance, and $\mathsf{NameCert}$ rows to the carrier.

Finally use Definition 320.6. The seal boundary exports only displayed finite rows to $\mathsf{Real}^{\uparrow}$ consumers and excludes open-cover compactness, choice of a nested intersection point, and host real completeness, so the scoped package is exactly the finite dependency surface stated above. □

Theorem 320.8 (NestedInterval public finite-window boundary)**.** *The finite carrier of Definition 320.1, endpoint transport of Definition 320.2, window refinement of Definition 320.3,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 320.4,* $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ *obligation surface of Definition 320.5,* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 320.6, and scoped dependency package of Definition 320.7 assemble a single public finite-window boundary for* $\mathsf{NestedInterval}^{\uparrow}$*.*

Every consumer-visible row of that boundary is one of the displayed dyadic endpoint rows, endpoint-order rows, width rows, inclusion rows, schedule rows, regular-rational handoff rows, seal-facing rows, hsame *transport rows, visible* Cont *routes,* Pkg *provenance rows, or* NameCert *rows. The boundary exports no infinite intersection point, compactness theorem, host real equality, or choice principle.*

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier public window boundary`

Proof. Project the accepted packet through the carrier of Definition 320.1. The carrier supplies the dyadic endpoint packets, endpoint-order ledgers, width ledgers, adjacent inclusion rows, schedules, $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows, $\mathsf{Real}^{\uparrow}$ seal-facing rows, and visible provenance rows.

Use endpoint transport of Definition 320.2 and window refinement of Definition 320.3 to account for movement of the carrier rows across hsame and Cont routes. These two blocks leave the boundary inside finite endpoint, width, inclusion, and schedule data.

Next use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the local $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$ obligation surface to bind the regular-rational windows and package provenance to the same finite rows. Apply the $\mathsf{Real}^{\uparrow}$ seal boundary to restrict seal-facing reads to displayed endpoint, inclusion, schedule, and handoff data.

Finally, the scoped dependency package fixes the permitted primitives for downstream consumers. An infinite intersection point, compactness theorem, host real equality, or choice principle would require an additional coordinate outside those seven displayed blocks, so none is exported by the public boundary. □

Theorem 320.9 (NestedInterval consumer bridge boundary)**.** *The public finite-window boundary of Definition 320.8 bridges to* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers by routing only the displayed dyadic endpoint rows, endpoint-order rows, width rows, inclusion rows, schedule rows, regular-rational handoff rows, seal-facing rows,* hsame *and* Cont *transports,* Pkg *provenance, and* NameCert *rows.*

This bridge boundary adds no infinite intersection point, compactness theorem, host real equality, or choice principle.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier consumer bridge boundary`

Proof. Apply Definition 320.8. The public boundary already restricts every consumer-visible coordinate to finite dyadic endpoint, order, width, inclusion, schedule, handoff, seal-facing, transport, provenance, and name-certificate rows.

Next use Definition 320.4 for the regular-rational consumer and Definition 320.6 for the real-name consumer. Their shared inputs are exactly the finite rows displayed by the public boundary.

The bridge therefore has no readable coordinate outside the intersection of those three surfaces. An infinite intersection point, compactness theorem, host real equality row, or choice operator would require a separate coordinate, and none is present in the routed boundary. □

Theorem 320.10 (NestedInterval consumer bridge finite-route exactness)**.** *Every public bridge read from the boundary of Definition 320.9 factors through exactly one displayed finite route: a dyadic endpoint row, endpoint-order row, width row, adjacent inclusion row,* $\mathsf{StreamName}^{\uparrow}$ *schedule row,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row,* $\mathsf{Real}^{\uparrow}$ *seal-facing row, visible* hsame *or* Cont *transport,* Pkg *provenance row, or* NameCert *row.*

No other public bridge coordinate is available. In particular, the route has no infinite intersection read, compactness read, host real equality read, or choice read.

Lean4 ✓ `BEDC.Derived.NestedIntervalUp.NestedIntervalPacket consumer bridge finite route exactness`

Proof. Start with the public finite-window boundary of Definition 320.8. It lists the only consumer-visible coordinates of the packet: displayed endpoint, order, width, inclusion, schedule, handoff, seal-facing, transport, package, and name-certificate rows.

Use Definition 320.4 for the $\mathsf{RegSeqRat}^{\uparrow}$ consumer route. This pins every regular-rational read to the scheduled finite endpoint and width rows already displayed by the public boundary.

Use Definition 320.6 for the $\mathsf{Real}^{\uparrow}$ consumer route. This pins every real-facing seal read to the same finite endpoint, inclusion, schedule, handoff, transport, provenance, and certificate rows.

Finally apply Definition 320.9. Since the bridge boundary is the union of those displayed finite routes and the transport/provenance rows named above, any public bridge read is one of those rows. An infinite intersection, compactness principle, host real equality, or choice operator would require an extra coordinate not present in the boundary. □

Theorem 320.11 (NestedInterval shared-window RegSeqRat endpoint cofinality)**.** *Let P and Q be accepted* $\mathsf{NestedInterval}^{\uparrow}$ *packets with finite windows that overlap at a scheduled unary observation n. Suppose both packets display the dyadic endpoint rows, width and adjacent-inclusion ledgers,* $\mathsf{StreamName}^{\uparrow}$ *schedule rows,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}$ *provenance required by Definition 320.10. Then the overlapping observation exposes the same* $\mathsf{RegSeqRat}^{\uparrow}$ *endpoint row in both packets up to* hsame *transport:*

$$\mathsf{Schedule}(n, P) \wedge \mathsf{Schedule}(n, Q) \Longrightarrow \mathsf{hsame}(\mathsf{RegSeqRatEndpoint}(P, n), \mathsf{RegSeqRatEndpoint}(Q, n)).$$

The comparison reads only the displayed dyadic endpoints, width ledgers, inclusion ledgers, schedule rows, continuation routes, package provenance, and name-certificate rows. It does not read a completed intersection point, compactness datum, host real equality row, or choice operator.

Proof. First restrict both accepted packets to the shared scheduled observation using Definition 320.3. The restriction keeps exactly the displayed dyadic endpoints, width rows, adjacent-inclusion rows, $\mathsf{StreamName}^{\uparrow}$ schedule entries, Cont routes, Pkg rows, and $\mathsf{NameCert}$ provenance attached to the overlap.

Next apply Definition 320.4 to each restricted packet. This turns the shared finite endpoint and width data into the $\mathsf{RegSeqRat}^{\uparrow}$ endpoint rows read by the two consumers.

Compare the two reads through Definition 320.10. Since the consumer bridge has only one available finite route at the overlapping scheduled observation, both regular-rational endpoint rows are transported through the same displayed route and are therefore identified by hsame.

Finally use Definition 320.12 to exclude any alternative coordinate. A completed intersection, compactness principle, host real equality, or choice-selected point would require data outside the accepted finite-row bridge, so it cannot affect the shared-window endpoint comparison. □

Theorem 320.12 (NestedInterval standard finite-row bridge acceptance)**.** *Any standard nested-interval bridge accepted for this chapter factors through exactly the public finite-window boundary of Definition 320.8, the* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer rows of Definition 320.9, and the real seal boundary of Definition 320.6. The accepted reading consists only of displayed dyadic endpoints, endpoint-order rows, width rows, adjacent inclusion rows, schedule rows, regular-rational hand-off rows, real seal-facing rows,* hsame *and* Cont *transport rows,* Pkg *provenance, and* $\mathsf{NameCert}$ *provenance.*

The bridge exposes no infinite intersection point, compactness theorem, host real equality, Heine–Borel principle, or choice operator.

Proof. Project the accepted packet through the carrier of Definition 320.1. The projection exposes precisely the dyadic endpoint packets, endpoint-order ledgers, width ledgers, adjacent inclusion

rows, schedule provenance, regular-rational handoff rows, seal-facing rows, and visible provenance coordinates.

Use Definition 320.8 to identify these coordinates as the exported public finite-window rows. This fixes the standard finite reading at the level of displayed endpoints, width and inclusion ledgers, schedules, transports, package provenance, and name-certificate rows.

Use Definition 320.9 for the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ routing. The consumer bridge reads the same finite rows through the regular-rational handoff and the seal-facing boundary, so it supplies no additional coordinate beyond the public boundary.

Finally use Definition 320.6 to identify the real-facing rows as finite seal reads rather than host real equalities. Thus the accepted standard bridge is exactly the finite public and consumer route.

An infinite intersection point, compactness theorem, host real equality row, Heine–Borel principle, or choice operator would require a carrier coordinate outside Definition 320.1, and no such coordinate is present. □

Theorem 320.13 (NestedInterval Real seal nonselection)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing read of an accepted* $\mathsf{NestedInterval}^{\uparrow}$ *packet factors through finite dyadic interval rows, unary prefix data,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *reads, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary. More precisely, the read is contained in the public finite-window boundary of Definition 320.8 and the seal-facing route of Definition 320.6.*

Consequently the packet cannot export a chosen intersection point, a host real intersection, a quotient representative, compactness data, Heine–Borel data, or a choice operator.

Proof. Start with the public finite-window boundary of Definition 320.8. It lists the only consumer-visible rows: dyadic endpoint rows, endpoint-order rows, width rows, adjacent inclusion rows, schedule rows, regular-rational handoff rows, seal-facing rows, transport rows, provenance rows, and name-certificate rows.

Apply Definition 320.6. The $\mathsf{Real}^{\uparrow}$ seal can be reached only from the displayed finite endpoint, width, inclusion, schedule, and $\mathsf{RegSeqRat}^{\uparrow}$ rows already present in that public boundary.

The carrier therefore exposes finite windows and seal rows, not a point selected from an infinite intersection. A host real intersection, quotient representative, compactness datum, Heine–Borel datum, or choice operator would require an additional coordinate outside the displayed finite-row boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}$**.**

Constructive story: A nested-interval packet is generated by finite BHist dyadic interval rows indexed by a unary prefix, lower and upper $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints, endpoint-order and width ledgers, adjacent nested-inclusion rows, $\mathsf{StreamName}^{\uparrow}$ schedule provenance, $\mathsf{RegSeqRat}^{\uparrow}$ finite-window reads, $\mathsf{Real}^{\uparrow}$ seal-facing rows, and Pkg and NameCert provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 320.12 is the mature finite-row surface binding the standard nested-interval reading to the public finite-window boundary, $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer rows, seal boundary, BHist, hsame, Cont, Pkg, and NameCert provenance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NestedInterval}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.NestedIntervalUp.NestedIntervalFiniteCarrier\_public\_window\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not claim Cantor nested-interval convergence, completeness, compactness, Heine–Borel, extraction of a point by choice, or host real intersections.

Upgrade path: The remaining work is formal verification of the finite standard bridge and later checked bridge status.

Chapter 321

A Concrete Naming Certificate for $\mathsf{FenchelDuality}^{\uparrow}$

The $\mathsf{FenchelDuality}^{\uparrow}$ interface names the finite convex-analysis certificate surface for a displayed primal functional, a displayed dual functional, and their pairing ledger. In Rockafellar's convex-analysis presentation and in Boyd–Vandenberghe 2004, Fenchel duality is read through convex functions, epigraphs, conjugate pairings, and extended-real comparisons; the BEDC packet below keeps only the finite rows needed to name that surface. It depends on $\mathsf{NameCert}_{\mathsf{ConvexSet}^{\uparrow}}$ (chapter 208), $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ (chapter 47), $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$ (chapter 48), $\mathsf{NameCert}_{\mathsf{LPDuality}^{\uparrow}}$ (chapter 235), $\mathsf{NameCert}_{\mathsf{TopVecSpace}^{\uparrow}}$ (chapter 205), $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$ (chapter 38), and $\mathsf{NameCert}_{\mathsf{SemidefiniteCone}^{\uparrow}}$ (chapter 310).

321.1 Finite primal-dual packet

Definition 321.1 (FenchelDualityUp carrier)**.** *A* $\mathsf{FenchelDuality}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (P, D, E, Q, C, R, L)$$

with the following visible rows:

1. *P is a convex primal functional row over a displayed* $\mathsf{TopVecSpace}^{\uparrow}$ *or* $\mathsf{VecSpace}^{\uparrow}$ *domain;*
2. *D is a convex dual functional row over the displayed dual-facing space;*
3. *E is a pairing row that records the bilinear evaluation used to compare primal and dual witnesses;*
4. *Q records order and extended-value comparison rows through* $\mathsf{Real}^{\uparrow}$*;*
5. *C records convex epigraph rows through* $\mathsf{ConvexSet}^{\uparrow}$ *for the primal and dual functionals;*
6. *R records optional cone-facing compatibility rows through* $\mathsf{SemidefiniteCone}^{\uparrow}$ *when the functional packet is consumed by semidefinite or conic optimization;*
7. *L is the* Pkg *provenance and readback ledger tying P, D, E, Q, C, and R to the displayed source certificates and to the finite* hsame *and* Cont *routes by which those rows may be transported.*

The carrier predicate is $\mathsf{FenchelPacket}(P, D, E, Q, C, R, L)$*. Two accepted packets classify together only when the displayed primal row, dual row, pairing row, comparison row, epigraph rows, optional cone-facing rows, and provenance ledger transport by* hsame *along the same* Cont *routes named in L.*

Definition 321.2 (Fenchel duality carrier)**.** *A paper-facing* $\mathsf{FenchelDuality}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (X, f, d, \ell, g, w, z, t, \pi, n)$$

with the following displayed rows:

1. X *is the* $\mathsf{VecSpace}^{\uparrow}$ *source row carrying the primal vector-space boundary.*
2. f *is the primal convex function row over the displayed* $\mathsf{ConvexSet}^{\uparrow}$ *domain.*
3. d *is the dual functional row, exposed as a* $\mathsf{LinMap}^{\uparrow}$*-facing read rather than as an ambient dual space.*
4. ℓ *is the linear pairing row connecting primal witnesses to dual reads.*
5. g *is the conjugate ledger row, recording the finite Fenchel conjugacy data available to consumers.*
6. w *is the weak-duality inequality row, read through* $\mathsf{Real}^{\uparrow}$ *comparisons.*
7. z *is the zero-gap witness row when the packet displays equality of primal and dual ledger values.*
8. t *records classifier transport for* $X, f, d, \ell, g, w, z, \pi, n$.
9. π *is the* Pkg *provenance over* $\mathsf{FenchelDuality}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$.
10. n *is the local* $\mathsf{NameCert}_{\mathsf{FenchelDuality}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through $X, f, d, \ell, g, w, z, t, \pi, n$. *It has no coordinate for a selected optimizer, Hahn–Banach extension, separating hyperplane, topological dual completion, or analytic strong-duality theorem.*

Theorem 321.3 (FenchelDualityUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FenchelDuality}^{\uparrow}}$ *seed surface consists of the following five finite obligations:*

1. *carrier row: the* BHist *packet of Definition 321.1, including the displayed primal functional, dual functional, pairing, comparison, epigraph, cone-facing, and provenance coordinates;*
2. *classifier row: componentwise* hsame *on exactly those displayed coordinates, with no comparison of hidden topological vector spaces, host quotient spaces, or unrecorded conjugate functions;*
3. *stability row: whenever each displayed coordinate is transported along the* hsame *witnesses and* Cont *routes named by the ledger, the transported packet is again an accepted* $\mathsf{FenchelDuality}^{\uparrow}$ *carrier;*
4. *exact ledger readback: every primal-dual pairing, extended-value comparison, and epigraph membership claim read by a consumer must be one of the rows recorded in the packet or a finite readback through its* Pkg *provenance;*
5. *consumer boundary: the surface does not claim separation theorems, Hahn–Banach, strong duality existence, host quotient spaces, analytic closedness of epigraphs, or an external conjugacy theorem.*

These obligations define only the BEDC-kernel naming surface for Fenchel-style primal-dual data; they do not assert the analytic hypotheses under which a classical duality theorem has equality of optimal values.

Lean4 ✓ `BEDC.Derived.FenchelDualityUp.FenchelDualityCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.FenchelDualityUp.FenchelDualityPrimalDualPacket namecert obligation surface`

Proof. Read the carrier from Definition 321.1. Its coordinates list exactly the rows a Fenchel-style consumer can inspect: primal and dual functional rows, a pairing row, real-valued or extended-valued comparison rows, convex epigraph rows, optional cone-facing compatibility rows, and package provenance.

The classifier and stability obligations are componentwise. Transporting an accepted packet along the displayed hsame witnesses replaces representatives of the same visible rows, and the Cont routes named in the ledger keep the reads inside the cited $\mathsf{TopVecSpace}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, and $\mathsf{SemidefiniteCone}^{\uparrow}$ certificate boundaries.

The readback clause is therefore exact: a consumer obtains a pairing value, an order comparison, or an epigraph membership only by projecting the corresponding finite ledger row. Since no coordinate stores a separating hyperplane principle, a Hahn–Banach extension, a strong-duality existence witness, a host quotient, or an analytic closure theorem, the excluded classical principles remain outside the seed surface. □

Theorem 321.4 (Fenchel duality NameCert obligations)**.** *For every accepted paper-facing carrier*

$$K = (X, f, d, \ell, g, w, z, t, \pi, n)$$

of Definition 321.2, the local $\mathsf{NameCert}_{\mathsf{FenchelDuality}^{\uparrow}}$ *surface consists exactly of primal convex-function exposure through* f*, dual functional exposure through* d*, linear pairing through* ℓ*, conjugate-ledger readback through* g*, weak-duality comparison through* w*, zero-gap witness exposure through* z*, classifier transport through* t*, provenance through* π*, and local naming through* n*.*

Proof. Project the accepted carrier of Definition 321.2. The rows X, f, d, ℓ expose the primal vector-space boundary, convex functional, dual functional, and pairing data through the displayed $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, and $\mathsf{LinMap}^{\uparrow}$ certificate routes.

Next read the convex-duality ledger rows. The conjugate row g, weak-duality row w, and optional zero-gap row z are finite packet coordinates, so a consumer receives only recorded $\mathsf{Real}^{\uparrow}$ comparisons and ledger witnesses.

Finally the transport, provenance, and naming rows t, π, n preserve that surface under classifier comparison. Since the carrier has no coordinate for selected optimizers, Hahn–Banach, separating hyperplanes, topological dual completion, or an analytic strong-duality theorem, the listed rows exhaust the local NameCert obligations. □

Theorem 321.5 (FenchelDualityUp carrier classifier scope)**.** *Every accepted* $\mathsf{FenchelDuality}^{\uparrow}$ *packet exposes the visible* BHist *carrier rows for the primal functional, dual functional, pairing,* $\mathsf{Real}^{\uparrow}$ *comparison,* $\mathsf{ConvexSet}^{\uparrow}$ *epigraph data, optional* $\mathsf{SemidefiniteCone}^{\uparrow}$ *compatibility, and* Pkg *provenance named in Definition 321.1. Its classifier is exactly the componentwise* hsame *classifier on those displayed rows along the finite* Cont *routes recorded by the provenance ledger.*

Proof. Project the accepted packet along the coordinates of Definition 321.1. The definition lists P, D, E, Q, C, R, and L as the full visible carrier, so each consumer-facing carrier read is one of those rows.

Apply Definition 321.3 to identify the same carrier coordinates as the local naming-certificate surface. Since the obligation surface records no further coordinate, the exposed carrier and classifier scope is exactly the displayed primal, dual, pairing, comparison, epigraph, compatibility, provenance, hsame, and Cont packet. □

Theorem 321.6 (FenchelDualityUp hsame stability scope)**.** *If the displayed primal row, dual row, pairing row,* $\mathsf{Real}^{\uparrow}$ *comparison row,* $\mathsf{ConvexSet}^{\uparrow}$ *epigraph rows, optional* $\mathsf{SemidefiniteCone}^{\uparrow}$ *compatibility row, and* Pkg *provenance of an accepted* $\mathsf{FenchelDuality}^{\uparrow}$ *packet are transported componentwise by the* hsame *witnesses and* Cont *routes named in the ledger, then the transported packet remains an accepted carrier and has the same classifier surface.*

Proof. Use the classifier clause in Definition 321.1. It classifies packets only by componentwise hsame on P, D, E, Q, C, R, and L along the Cont routes already named by the provenance ledger.

Then apply the stability row of Definition 321.3. Transport of each displayed coordinate stays inside the finite $\mathsf{TopVecSpace}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, and $\mathsf{SemidefiniteCone}^{\uparrow}$ certificate boundaries, so the transported packet is accepted by the same carrier predicate and no additional classifier field is introduced. □

Theorem 321.7 (FenchelDualityUp primal dual ledger readback)**.** *Every certified* $\mathsf{FenchelDuality}^{\uparrow}$ *answer packet reads back the primal row, dual row, pairing row, comparison ledger, epigraph row, and provenance ledger named by its source packet. The readback introduces no Hahn–Banach principle, separation theorem, strong-duality existence witness, host quotient space, or analytic closedness assertion.*

Proof. Project the ledger coordinate L of the carrier. By Definition 321.1, every consumer readback is tied to the displayed primal, dual, pairing, comparison, epigraph, optional cone-facing, and provenance rows by finite hsame and Cont routes.

Apply the exact ledger readback and consumer-boundary clauses of Definition 321.3. Those clauses allow only the recorded pairing, extended-value comparison, and epigraph membership rows to be read, and they explicitly leave Hahn–Banach, separation, strong duality, host quotient spaces, and analytic closedness outside the certificate surface. □

Theorem 321.8 (FenchelDualityUp mature consumer route)**.** *Every paper-side consumer of the* $\mathsf{FenchelDuality}^{\uparrow}$ *bridge reads the finite primal-dual packet only through the already displayed* $\mathsf{ConvexSet}^{\uparrow}$ *epigraph rows,* $\mathsf{LPDuality}^{\uparrow}$ *linear-duality rows,* $\mathsf{TopVecSpace}^{\uparrow}$ *vector-space boundary,* $\mathsf{Real}^{\uparrow}$ *comparison ledger, and optional* $\mathsf{SemidefiniteCone}^{\uparrow}$ *compatibility rows. The reusable surface is therefore the mature convex optimization bridge recorded by* P, D, E, Q, C, R, L*, not a separation theorem, Hahn–Banach principle, strong-duality existence witness, host quotient space, or analytic closedness assertion.*

Proof. Start from the carrier classifier scope of Definition 321.5. It exposes exactly the primal row, dual row, pairing row, real comparison row, convex epigraph rows, optional cone-facing row, and provenance ledger.

Use hsame stability from Definition 321.6. Transport of the packet stays inside the displayed $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{LPDuality}^{\uparrow}$, $\mathsf{TopVecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{SemidefiniteCone}^{\uparrow}$ certificate boundaries, so each named consumer reads the same finite bridge rather than a host analytic object.

Finally apply the primal-dual ledger readback of Definition 321.7. Since the ledger introduces no separation theorem, Hahn–Banach principle, strong-duality existence witness, host quotient space, or analytic closedness assertion, the paper-side consumer route is exhausted by the displayed mature bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{FenchelDuality}^{\uparrow}}$**.**

Constructive story: A Fenchel-duality packet is generated by displayed primal and dual convex functional rows, a pairing row over the visible vector-space boundary, $\mathsf{Real}^{\uparrow}$ extended-value comparison rows, $\mathsf{ConvexSet}^{\uparrow}$ epigraph rows, optional $\mathsf{SemidefiniteCone}^{\uparrow}$ compatibility rows, and Pkg provenance with finite hsame and Cont transport.

Theory closure: TheoryGate(NameCert$_{\mathsf{FenchelDuality}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scoped FenchelDuality$^{\uparrow}$ paper surface covers the carrier classifier scope, hsame stability scope, primal-dual ledger readback, and the displayed BHist, Cont, hsame, Pkg, and NameCert rows of Definition 321.1.

Formal verification: FormalStatus(NameCert$_{\mathsf{FenchelDuality}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FenchelDualityUp.FenchelDualityPrimalDualPacket\_namecert\_obligation\_surface`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close separation theorems, Hahn–Banach, strong duality existence, host quotient spaces, analytic closedness, or an external conjugacy theorem.

Upgrade path: No further paper-side closure grade remains for this chapter; bridge checking is recorded only on the independent verification axis.

Chapter 322

$\mathsf{DyadicPrecision}^{\uparrow}$ naming certificate construction

The $\mathsf{DyadicPrecision}^{\uparrow}$ surface names the finite precision schedule that sits between $\mathsf{DyadicRatCore}^{\uparrow}$ radius rows, $\mathsf{StreamName}^{\uparrow}$ observation windows, $\mathsf{RegSeqRat}^{\uparrow}$ regularity checks, and the $\mathsf{Real}^{\uparrow}$ seal boundary. The carrier below is a BEDC packet of visible rows only: a finite unary precision request, the dyadic radius it selects, the finite stream window it opens, and the provenance ledger through which later real-name constructions read the same finite data.

The schedule is the finite reader shared by chapter 291, chapter 126, chapter 301, and chapter 38. It consumes dyadic radius rows and stream observation windows before $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ read the same finite request through their regularity and seal boundaries.

322.1 Finite precision schedule

Definition 322.1 (Dyadic precision schedule carrier)**.** *A* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedule carrier is a finite* BHist *packet*

$$S = (n, \rho, W, H, C, P, N, L)$$

with the following visible rows:

1. *n is a unary precision index row, read as a finite* $\mathsf{UnaryHistory}$ *packet and inhabited by the empty precision row or by iterating the unary successor constructor;*
2. *ρ is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row selected by n, normally read as the displayed dyadic tolerance 2^{-n} with its denominator ledger;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *observation-window row naming exactly the finite stream positions requested at precision n;*
4. *H records the componentwise* hsame *witnesses for the unary index, dyadic radius, and finite observation window;*
5. *C records the displayed* Cont *routes that transport the radius and window rows without changing the selected precision request;*
6. *P is the* Pkg *provenance tying the schedule to the visible* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *source boundaries;*
7. *N is the local* $\mathsf{NameCert}$ *row for the schedule packet;*

8. *L is the ledger stating that every consumer-visible precision, radius, and window read is one of the rows above.*

The carrier predicate is $\mathsf{DyadicPrecisionSchedule}(n, \rho, W, H, C, P, N, L)$. *The packet has no quotient of precision requests, no completed real object, no hidden Cauchy modulus, and no external choice of an infinite stream tail.*

Lean4 (definition) `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionUp`
Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.taste gate`

Definition 322.2 (Dyadic precision schedule classifier)**.** *For accepted carriers*

$$S = (n, \rho, W, H, C, P, N, L) \quad \text{and} \quad S' = (n', \rho', W', H', C', P', N', L'),$$

the predicate $\mathsf{DyadicPrecisionClassifier}(S, S')$ *is componentwise finite sameness. It consists of displayed* hsame *rows identifying the unary precision indices n and n', the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius rows ρ and ρ', the finite* $\mathsf{StreamName}^{\uparrow}$ *windows W and W', and the package ledgers P and P'.*

The classifier transports only those rows and the attached Cont *routes. It does not compare hidden tails of streams, identify regular sequences by a quotient, or assert equality of* $\mathsf{Real}^{\uparrow}$ *names.*

Theorem 322.3 (Dyadic precision schedule NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicPrecision}^{\uparrow}}$ *seed surface consists of five finite obligations:*

1. *carrier inhabitation is generated from the empty precision row and the unary successor row, together with the corresponding* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row and the finite* $\mathsf{StreamName}^{\uparrow}$ *window selected by that row;*
2. *classifier reflexivity, symmetry, and transitivity are the componentwise laws for the displayed* hsame *rows on the unary index, dyadic radius, finite window, and package ledger;*
3. *carrier transport along the classifier repacks the same schedule with transported* hsame *and* Cont *rows;*
4. *ledger exactness says that every radius read and every finite observation-window read is one of the displayed ρ and W rows recorded in the carrier ledger;*
5. *source-domain visibility says that every consumed row remains inside the named* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *source boundaries recorded by* Pkg *and* NameCert.

These obligations define only the finite precision-schedule certificate surface.

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionUp semantic name certificate`

Proof. For carrier inhabitation, begin with the empty unary row and attach the base dyadic radius and the empty observation window. A successor precision request appends one unary row, refines the visible dyadic radius ledger through $\mathsf{DyadicRatCore}^{\uparrow}$, and opens the finite window requested by $\mathsf{StreamName}^{\uparrow}$.

The classifier laws are obtained by applying reflexivity, symmetry, and transitivity componentwise to the displayed hsame rows. Each law acts on the unary index, radius row, window row, and package ledger, so the result remains a finite schedule classifier.

Transport follows by repacking the carrier after those componentwise moves. Ledger exactness is projection from L: a consumer can read a precision, radius, or window only by selecting one stored row. The provenance row P and the local naming row N keep those projections inside the stated source domains and add no hidden real-number principle. □

Theorem 322.4 (Dyadic precision schedule RegSeqRat handoff)**.** *An accepted* DyadicPrecision$^{\uparrow}$ *schedule supplies exactly the finite precision and observation-window rows consumed by a* RegSeqRat$^{\uparrow}$ *regularity check. The handoff consists of the unary index row n, the* DyadicRatCore$^{\uparrow}$ *radius row ρ, the finite* StreamName$^{\uparrow}$ *window W, the componentwise* hsame *comparisons, the displayed* Cont *routes, and the* Pkg *and* NameCert *provenance attached to those rows.*

The handoff does not supply a quotient sequence, a completed metric point, an infinite stream tail, or any additional regularity principle beyond the displayed finite rows.

Proof. Project an accepted schedule through Definition 322.1. The rows relevant to RegSeqRat$^{\uparrow}$ are exactly the precision index, dyadic radius, and finite stream window, together with their transport and provenance rows.

A RegSeqRat$^{\uparrow}$ regularity check consumes those rows by reading endpoints at the selected finite window and comparing them against the displayed dyadic tolerance. The schedule contributes no other coordinate, so the regularity check cannot obtain a quotient sequence, a completion point, or an unrecorded tail from the handoff. □

Theorem 322.5 (Dyadic precision schedule RealUp boundary)**.** *The same finite* DyadicPrecision$^{\uparrow}$ *schedule can be read at the* Real$^{\uparrow}$ *seal boundary as a precision request, a dyadic radius row, a finite observation-window row, and the visible* hsame*,* Cont*,* Pkg*, and* NameCert *provenance of those rows.*

Reading the schedule at the seal boundary does not add Dedekind cuts, quotient reals, trichotomy, completeness, host real equality, or any standard bridge datum.

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule realup boundary`

Proof. Use Definition 322.4 to identify the finite rows passed to the regular rational source. The Real$^{\uparrow}$ seal reads that source through the same scheduled precision, radius, and window rows.

Since the schedule carrier has no coordinate for a cut, quotient, order trichotomy, completeness witness, host real equality, or bridge object, none can appear when the same rows are read at the seal boundary. The boundary is therefore the finite precision schedule itself, viewed through the displayed provenance. □

Theorem 322.6 (DyadicPrecision obligation closure)**.** *The carrier of Definition 322.1, classifier of Definition 322.2, local* NameCert *obligations of Definition 322.3,* RegSeqRat$^{\uparrow}$ *handoff of Definition 322.4,* Real$^{\uparrow}$ *boundary of Definition 322.5, and ledger-exactness rows exhaust the obligation surface for finite dyadic precision schedules.*

Because this chapter is marked with AI origin, promotion beyond seed remains conditional on the future TasteGate-backed Lean target. The closure packet adds no hidden tail, quotient real, trichotomy, completeness row, or bridge row.

Proof. Project the carrier of Definition 322.1. Its visible rows are the unary precision index, dyadic radius row, finite observation window, transport rows, provenance rows, local naming row, and exact schedule ledger.

Use Definition 322.2 and Definition 322.3 for stability, carrier transport, ledger exactness, and source-domain visibility. These rows account for every local schedule obligation.

The outgoing consumers are Definition 322.4 and Definition 322.5. They read only the same finite precision, radius, window, transport, provenance, and naming rows, so no hidden tail, quotient real, trichotomy, completeness datum, or bridge row is present. □

Theorem 322.7 (Dyadic precision empty schedule exactness)**.** *Let*

$$S = (n, \rho, W, H, C, P, N, L)$$

be a DyadicPrecision$^{\uparrow}$ *schedule carrier in the sense of Definition 322.1. Suppose S is obtained from the empty unary precision branch of the carrier-inhabitation obligation in Definition 322.3. Then n is the empty unary precision row, ρ is the base* DyadicRatCore$^{\uparrow}$ *dyadic radius row selected by that empty row, and W is the empty* StreamName$^{\uparrow}$ *observation-window row.*

Consequently, every consumer-visible precision, radius, or observation-window read from S is exhausted by those three displayed rows, together with the provenance ledger L and the visible hsame*,* Cont*,* Pkg*, and* NameCert *rows already carried by S.*

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionEmptySchedule exactness`
Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule empty branch readback`

Proof. Project the schedule carrier through Definition 322.1. The visible coordinates of S include exactly one unary precision index row n, one selected DyadicRatCore$^{\uparrow}$ radius row ρ, one finite StreamName$^{\uparrow}$ observation-window row W, the componentwise hsame witnesses H, the displayed Cont routes C, the provenance package P, the local naming row N, and the ledger L.

Now restrict to the empty unary precision branch of the carrier-inhabitation obligation in Definition 322.3. In that branch there is no successor precision request. The carrier therefore has no later unary row from which to select a refined tolerance and no requested stream position from which to open a nonempty observation window. The selected radius coordinate is exactly the base dyadic radius row supplied by DyadicRatCore$^{\uparrow}$ for the empty precision row, and the selected window coordinate is exactly the empty StreamName$^{\uparrow}$ observation window.

It remains only to check consumer coverage. By the ledger clause of Definition 322.1, every consumer-visible precision, radius, and window read is one of the displayed schedule rows recorded by L. In the empty branch those displayed rows are precisely the empty unary row n, the base dyadic radius row ρ, and the empty observation window W, with the already-carried H, C, P, and N rows providing transport and provenance. Since the carrier has no quotient of precision requests, no completed real object, no hidden Cauchy modulus, and no external stream tail, there is no further coordinate from which an additional consumer read could be obtained. □

Theorem 322.8 (Dyadic precision successor schedule exactness)**.** *Let*

$$S = (n, \rho, W, H, C, P, N, L)$$

be a DyadicPrecision$^{\uparrow}$ *schedule carrier in the sense of Definition 322.1. Suppose S is obtained from the successor unary precision branch of the carrier-inhabitation obligation in Definition 322.3. Then the successor row is the displayed unary extension of its predecessor precision row, ρ is the transported and refined* DyadicRatCore$^{\uparrow}$ *radius row selected by that successor, and W is the finite* StreamName$^{\uparrow}$ *observation window opened by that successor.*

Consequently, every consumer-visible precision, radius, or observation-window read from the successor branch factors through n, ρ, W, H, C, P, N, and L. The successor branch supplies no hidden Cauchy modulus, completed real object, quotient precision request, external stream tail, trichotomy, completeness, or bridge datum.

Proof. Project the schedule carrier through Definition 322.1. The projected rows are the unary index n, the selected radius row ρ, the finite observation window W, the hsame witnesses H, the displayed Cont routes C, the provenance row P, the local naming row N, and the exact ledger L.

Now restrict to the successor unary precision branch of Definition 322.3. That branch appends one unary successor row to the predecessor precision row. The same branch selects the refined $\mathsf{DyadicRatCore}^{\uparrow}$ radius row and opens the finite $\mathsf{StreamName}^{\uparrow}$ observation window requested at that successor precision.

The displayed hsame witnesses and Cont routes transport the predecessor schedule rows to the successor rows without changing the finite source surface. Ledger exactness says that every consumer-visible precision, radius, and window read is one of the displayed rows recorded by L, while source-domain visibility keeps those rows inside the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ boundaries named by P and N.

The carrier has no coordinate for hidden stream tails, quotient precision requests, completed reals, trichotomy, completeness, or bridge data. Thus every consumer read from the successor branch factors through the displayed tuple $(n, \rho, W, H, C, P, N, L)$. □

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule successor schedule exactness`

Theorem 322.9 (Dyadic precision monotone refinement handoff)**.** *If a* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedule carrier refines a unary precision row through the displayed* hsame *and* Cont *routes, then the transported radius row and observation-window row form the consumer-visible refinement surface for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*. Every public read factors through the carrier rows* n*,* ρ*,* W*,* H*,* C*,* P*,* N*, and* L*.*

The handoff exposes no hidden Cauchy modulus, completed real object, or external stream tail.

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionScheduleSurface monotone refinement handoff`

Proof. Unpack the schedule carrier of Definition 322.1. Its visible rows already name the unary precision request, selected dyadic radius, finite observation window, componentwise hsame witnesses, displayed Cont routes, package provenance, local NameCert row, and exact ledger.

Use the classifier of Definition 322.2 to read a refinement as componentwise movement of those finite rows. The transported radius and transported observation window remain the displayed ρ and W coordinates, carried by H and C rather than by an external sequence model.

The consumer boundaries are Definition 322.4 and Definition 322.5. They show that $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consume the same precision, radius, window, transport, provenance, and naming rows, so every public read factors through the carrier ledger L.

The empty case of Definition 322.7 is the base instance of this surface. In the successor case the same carrier rows are refined through the displayed routes, and no hidden Cauchy modulus, completed real object, or external stream tail is introduced. □

Theorem 322.10 (DyadicPrecision common-window readback determinacy)**.** *Let*

$$S = (n, \rho, W, H, C, P, N, L)$$

and

$$S' = (n', \rho', W', H', C', P', N', L')$$

be accepted $\mathsf{DyadicPrecision}^{\uparrow}$ *schedules. If* $\mathsf{DyadicPrecisionClassifier}(S, S')$ *holds, then every shared unary precision-window read consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or by the* $\mathsf{Real}^{\uparrow}$ *seal factors through the same transported rows* $n, \rho, W, H, C, P, N, L$ *and* $n', \rho', W', H', C', P', N', L'$*.*

In particular, the consumer-visible precision, selected radius, observation-window, hsame *transport,* Cont *route,* Pkg *provenance, and* NameCert *provenance are determined by the displayed classifier rows. The readback exposes no hidden stream tail, completed real object, quotient precision request, external Cauchy modulus, trichotomy, completeness witness, or bridge datum.*

Proof. Project both schedules through Definition 322.1. The only consumer-facing rows are the unary precision row, selected dyadic radius row, finite observation window, componentwise hsame witnesses, displayed Cont routes, package provenance, local naming row, and exact ledger.

Use the classifier of Definition 322.2. It transports those coordinates componentwise, so a shared unary precision-window request has the same displayed source rows on both sides after applying the recorded hsame witnesses and Cont routes.

Now apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff in Definition 322.4 and the $\mathsf{Real}^{\uparrow}$ boundary in Definition 322.5. Both consumer surfaces read the transported precision, radius, window, transport, provenance, and naming rows already listed by the two schedule carriers.

The empty branch is covered by Definition 322.7, and the successor branch by Definition 322.8. Finally use Definition 322.9 to identify a refined shared window with the same displayed rows. Since none of these rows contains an external stream tail, completed real object, quotient request, or hidden modulus, the shared-window readback is determined exactly by the two displayed classifier tuples. □

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule common window readback`

Theorem 322.11 (DyadicPrecision schedule obligation export)**.** *The carrier of Definition 322.1, classifier of Definition 322.2, local* NameCert *obligations of Definition 322.3,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 322.4,* $\mathsf{Real}^{\uparrow}$ *boundary of Definition 322.5, and empty-schedule exactness of Definition 322.7 together with successor-schedule exactness of Definition 322.8 form the full local obligation surface for the finite dyadic precision schedule.*

Every obligation is read inside a finite BHist *packet and is transported only through the displayed* hsame *and* Cont *rows, with* Pkg *provenance and local* NameCert *naming over the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumer surfaces.*

Proof. Project the schedule through the carrier and classifier. The visible rows are the unary precision request, dyadic radius, finite observation window, componentwise hsame witnesses, displayed Cont routes, package provenance, local naming row, and exact ledger.

Apply the local NameCert obligation theorem to account for carrier inhabitation, classifier laws, transport, ledger exactness, and source-domain visibility. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ boundary then read the same precision, radius, window, transport, provenance, and naming rows as consumer surfaces.

The empty-schedule and successor-schedule exactness theorems supply the two constructor-boundary cases for the finite schedule. Together these rows exhaust the local obligation export, because the carrier has no hidden stream tail, quotient real, trichotomy, completeness datum, or bridge coordinate. □

Theorem 322.12 (DyadicPrecision TasteGate carrier witness)**.** *For any future* ChapterTasteGate *instance over* $\mathsf{DyadicPrecision}^{\uparrow}$, *the source scope is exactly the carrier of Definition 322.1, classifier of Definition 322.2, obligation rows of Definition 322.3, handoff of Definition 322.4,* $\mathsf{Real}^{\uparrow}$ *boundary of Definition 322.5, and constructor-boundary exactness from Definition 322.7 and Definition 322.8.*

Equivalently, if

$$S = (n, \rho, W, H, C, P, N, L)$$

is an accepted schedule carrier, then every candidate TasteGate event-flow read is sourced by the finite precision row n, *dyadic radius row* ρ, *observation-window row* W, *displayed* hsame *rows* H, *displayed* Cont *routes* C, Pkg *provenance* P, *local* NameCert *row* N, *and exact ledger* L. *It*

cannot read a hidden stream tail, quotient real equality, trichotomy, completeness, selected limit, or standard bridge row.

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionScheduleTasteGate visible rows`

Proof. Project the accepted schedule through the finite BHist packet of Definition 322.1. The projection lists the precision, radius, observation-window, transport, provenance, name, and ledger rows as the whole carrier tuple, so these rows give the source tokens of the event-flow reading.

Use the classifier of Definition 322.2 to transport the event-flow componentwise. The classifier moves only the displayed unary precision rows, dyadic radius rows, finite observation-window rows, package ledgers, and their attached hsame and Cont witnesses, so no additional event source is created by transport.

Now apply Definition 322.11. Its row exhaustion statement identifies the carrier, classifier, local NameCert obligations, consumer handoffs, empty branch, successor branch, and exact ledger as the full local schedule surface. Thus every candidate ChapterTasteGate read factors through the displayed hsame, Cont, Pkg, and NameCert rows.

The ground-compiler reading of the same packet is therefore the no-hidden-input condition together with conservativity over those visible rows. Since no coordinate of the carrier contains an infinite tail, quotient real equality, trichotomy, completeness witness, selected limit, or standard bridge datum, the TasteGate obligations cannot obtain one from the schedule. □

Theorem 322.13 (DyadicPrecision TasteGate compiler-obligation handoff)**.** *Let*

$$S = (n, \rho, W, H, C, P, N, L)$$

be an accepted DyadicPrecision$^{\uparrow}$ *schedule packet. Any future* ChapterTasteGate *proof for this AI-origin chapter must discharge the no-hidden-input, event-flow conservativity, flow-level round-trip, channel bijection, and source-channel separation obligations by applying the* GroundCompiler *theorem rows* no_hidden_input*,* event_flow_conservativity*,* flow_level_round_trip*,* channel_bijection*, and* source_channel_separation *to the visible carrier event-flow tokens listed in Definition 322.12.*

Consequently the handoff exposes only the finite precision row n, dyadic radius row ρ, finite window row W, displayed hsame *rows H, displayed* Cont *routes C,* Pkg *provenance P,* NameCert *row N, and ledger L. It exposes no hidden stream tail, quotient real, selected limit, trichotomy, completeness witness, or bridge datum.*

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionUp tastegate compiler obligation handoff`

Proof. Project the accepted packet through Definition 322.1. The projection gives exactly the eight visible schedule coordinates, and Definition 322.12 reads those coordinates as the carrier event-flow tokens for a future ChapterTasteGate proof.

The compiler obligations are then not handwritten carrier facts. The future Lean route must apply no_hidden_input for hidden-source exclusion, event_flow_conservativity for event-flow preservation, flow_level_round_trip for encoding round trip, channel_bijection for channel identity, and source_channel_separation for separating source rows from channel rows.

Finally use Definition 322.11. Its absence clauses and the carrier clauses above exhaust the schedule surface by the finite precision row, dyadic radius row, finite window row, hsame rows, Cont routes, Pkg provenance, NameCert row, and ledger. Since no coordinate contains a hidden stream tail, quotient real, selected limit, trichotomy, completeness witness, or bridge datum, the handoff cannot expose one. □

Theorem 322.14 (DyadicPrecision radius-window coverage)**.** *Every accepted* DyadicPrecision$^{\uparrow}$ *schedule packet exposes exactly the unary precision row, the selected* DyadicRatCore$^{\uparrow}$ *radius row, the finite* StreamName$^{\uparrow}$ *observation-window row, the displayed* hsame *rows, displayed* Cont *routes,* Pkg *provenance, local* NameCert *row, and exact ledger rows of Definition 322.1.*

The coverage is constructor-exact: the empty schedule is the empty carrier surface of Definition 322.7, every successor schedule is the successor carrier surface of Definition 322.8, and monotone refinement transports only those displayed radius and window rows through Definition 322.9.

Proof. Project the accepted packet through Definition 322.1. The projection names the unary precision coordinate, selected dyadic radius coordinate, finite observation window, componentwise hsame witnesses, displayed Cont routes, package provenance, local name, and exact ledger as the whole schedule carrier.

The empty constructor is handled by Definition 322.7. The successor constructor is handled by Definition 322.8. These two cases cover the finite schedule constructors.

Finally apply Definition 322.9. It keeps refinement inside the selected radius and finite window rows, so no hidden stream tail, quotient real equality, selected limit, trichotomy, completeness witness, or bridge datum is added by refinement. □

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule radius window coverage`

Theorem 322.15 (DyadicPrecision classifier consumer transport)**.** *For accepted schedule packets S and S', the classifier relation* DyadicPrecisionClassifier(S, S') *transports every* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumer read through the displayed carrier rows only. In particular, the consumer-visible precision, radius, window,* hsame*,* Cont*,* Pkg*,* NameCert*, and ledger reads are exactly the rows listed in Definition 322.2; no consumer transport may read an additional stream tail, quotient real, selected limit, trichotomy, completeness witness, or bridge coordinate.*

Proof. Start from the classifier of Definition 322.2. Its clauses identify the transported precision, radius, window, transport, provenance, name, and ledger coordinates componentwise between S and S'.

Use Definition 322.10 to read both consumer packets through the same finite observation-window surface. The readback does not quantify over an unbounded tail, because the only window coordinate in the carrier is the displayed finite StreamName$^{\uparrow}$ row.

Apply Definition 322.11. The exported obligation surface is the same carrier, classifier, local NameCert row, handoff, boundary, and ledger surface. Thus every RegSeqRat$^{\uparrow}$ or Real$^{\uparrow}$ consumer read factors through the displayed rows and through no other coordinate. □

Lean4 ✓ `BEDC.Derived.DyadicPrecisionUp.DyadicPrecisionSchedule classifier consumer transport`

Theorem 322.16 (DyadicPrecision RegSeqRat RealUp consumer exhaustion)**.** *The* RegSeqRat$^{\uparrow}$ *handoff of Definition 322.4 together with the* Real$^{\uparrow}$ *boundary of Definition 322.5 exhausts the downstream consumer surface of an accepted* DyadicPrecision$^{\uparrow}$ *schedule packet.*

Consequently the packet exposes only the finite precision row, selected dyadic radius row, finite observation-window row, displayed hsame *rows, displayed* Cont *routes,* Pkg *provenance, local* NameCert *row, and exact ledger rows. It exposes no hidden stream tails, quotient reals, trichotomy, completeness, selected limits, or bridge data.*

Proof. First apply Definition 322.4. The RegSeqRat$^{\uparrow}$ consumer receives only the finite precision schedule, dyadic radius, finite window, displayed transport rows, provenance, name, and ledger exported by the schedule carrier.

Next apply Definition 322.5. The $\mathsf{Real}^{\uparrow}$ boundary reads the same finite rows as a boundary object and does not add quotient real equality, trichotomy, completeness, or a selected limiting real.

Finally use Definition 322.13. The TasteGate handoff sends the compiler obligations to the same visible carrier event-flow tokens, so the combined consumer surface is exhausted by the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows already named above. □

Theorem 322.17 (DyadicPrecision public consumer boundary)**.** *The public* $\mathsf{DyadicPrecision}^{\uparrow}$ *consumer boundary is the finite packet consisting of the precision index, dyadic radius row, finite observation-window row, classifier transport,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *boundary, exact ledger, local* NameCert *row, and the TasteGate-visible carrier-event rows of Definition 322.12.*

Every public consumer read factors through that packet by the radius-window coverage, classifier consumer transport, $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer exhaustion, and TasteGate compiler-obligation handoff. The boundary adds no closure promotion, hidden stream tail, quotient real, selected limit, trichotomy, completeness witness, or bridge datum.*

Proof. First apply Definition 322.14. It lists the finite precision index, dyadic radius, observation window, hsame, Cont, Pkg, NameCert, and exact ledger rows carried by an accepted schedule packet.

Use Definition 322.15 to keep every consumer comparison inside those displayed carrier rows. The classifier therefore supplies no hidden stream tail, quotient real equality, selected limit, trichotomy, completeness witness, or bridge coordinate.

Next invoke Definition 322.16. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ boundary read the same finite precision, radius, window, transport, provenance, name, and ledger packet.

Finally apply Definition 322.13 together with the visible carrier-event rows named in Definition 322.12. The public boundary is therefore precisely the consumer packet named above, with no paper-axis closure promotion asserted here. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicPrecision}^{\uparrow}}$.

Constructive story: A dyadic precision schedule is generated by finite unary precision rows, visible $\mathsf{DyadicRatCore}^{\uparrow}$ radius ledgers, finite $\mathsf{StreamName}^{\uparrow}$ observation windows, componentwise hsame transport, displayed Cont routes, and Pkg and NameCert provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicPrecision}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridge scope packages the finite precision schedule, dyadic radius row, observation window, classifier transport, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, $\mathsf{Real}^{\uparrow}$ boundary, public export, local NameCert row, exact ledger, and TasteGate visible rows through Definition 322.11 and Definition 322.13.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicPrecision}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.DyadicPrecisionUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close $\mathsf{RegSeqRat}^{\uparrow}$ regularity, $\mathsf{Real}^{\uparrow}$ completeness, quotient real equality, trichotomy, hidden stream tails, or a standard bridge.

Upgrade path: No further paper-axis upgrade remains; future acceptance work is bridgeChecked formal validation over the same public finite precision schedule, radius, window, transport, provenance, NameCert, ledger, and TasteGate rows.

Chapter 323

A Concrete Naming Certificate for $\mathsf{FastCauchy}^{\uparrow}$

The $\mathsf{FastCauchy}^{\uparrow}$ interface records a finite, modulus-normalized Cauchy-name surface feeding the regular-sequence and real-name layers. In Bishop-style constructive analysis, a Cauchy name is useful only together with visible rate data; the BEDC packet keeps that rate as finite certificate data over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The construction consumes the finite observation discipline of chapter 126, the endpoint ledger of chapter 291, the regular-sequence handoff of chapter 301, and the seal boundary of chapter 38. These sibling rows are the dependency route used by the carrier and handoff theorems below: the fast Cauchy packet is a finite certified readout between stream observations, dyadic endpoints, regular tails, and the real-name seal, not an isolated Cauchy predicate.

323.1 Finite modulus-normalized Cauchy names

Definition 323.1 (FastCauchy carrier)**.** *A* $\mathsf{FastCauchy}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (s, \mu, E, R, L, T, P, N)$$

with the following visible rows:

1. *s is a scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation table whose displayed entries are dyadic-rational observations;*
2. *μ is a* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold table normalized so that each requested precision row names the finite index after which all scheduled comparisons are read;*
3. *E is the dyadic endpoint ledger read through* $\mathsf{DyadicRatCore}^{\uparrow}$ *for every scheduled observation and precision row used by μ;*
4. *R is the late-pair radius ledger, recording for each precision row that any two scheduled observations beyond the threshold named by μ fit inside the displayed dyadic radius;*
5. *L records the componentwise* hsame *transport rows for the stream, threshold, dyadic endpoint, and late-pair ledgers;*
6. *T records the* Cont *windows through which those finite reads are consumed by downstream certificates;*

7. *P is the* Pkg *provenance for the named source chapters* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$*;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ *row for the displayed packet.*

The carrier is a finite explicit-rate Cauchy name. It contains no quotient stream, no host real equality, no selected limit, and no standard bridge datum.

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyTasteGate single carrier alignment`

Definition 323.2 (FastCauchy classifier)**.** *For accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packets C and C', the classifier* $\mathsf{FastCauchyClassifier}(C, C')$ *holds when the scheduled observation windows, modulus threshold rows, dyadic endpoint ledgers, late-pair radius ledgers,* hsame *transports,* Cont *windows,* Pkg *provenance, and local* NameCert *rows compare componentwise through their displayed source classifiers.*

The classifier is exact only for the finite modulus-normalized ledger. It does not assert equality of completed real numbers, equality of quotient Cauchy streams, or existence of a chosen limit.

Theorem 323.3 (FastCauchy modulus transport)**.** *Let C be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet. If the scheduled observation rows of C transport along the displayed* hsame *rows and the threshold table μ transports along the displayed* Cont *windows, then the transported packet preserves the same modulus-normalized late-pair radius obligations.*

Concretely, every precision row in μ keeps its finite threshold, every scheduled pair beyond that threshold keeps its dyadic endpoint rows from $\mathsf{DyadicRatCore}^{\uparrow}$*, and the late-pair radius ledger remains readable by the same* $\mathsf{CauchyModulus}^{\uparrow}$ *classifier.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFiniteCarrier modulus transport`

Proof. Project the carrier tuple of Definition 323.1. The scheduled stream, threshold table, dyadic endpoint ledger, and late-pair ledger are separate finite rows, so each row can be transported through its displayed hsame coordinate.

The Cont row supplies the finite window in which downstream consumers may read the transported data. Because the threshold row is preserved, every pair of scheduled observations whose indices are beyond that threshold remains in the same late-pair comparison window.

Repack the transported stream, threshold, endpoint, radius, transport, window, provenance, and local certificate rows. The result has the same carrier shape and satisfies the classifier of Definition 323.2, so the modulus-normalized obligations are preserved. □

Theorem 323.4 (FastCauchy handoff to RegSeqRat)**.** *Every accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet presents a* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-sequence window by forgetting only the local* $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ *row. The handoff keeps the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation rows, the explicit* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold table, the dyadic endpoint rows from* $\mathsf{DyadicRatCore}^{\uparrow}$*, the late-pair radius ledger, the* hsame *and* Cont *transport rows, and the* Pkg *provenance.*

The handoff therefore supplies regularity data to $\mathsf{RegSeqRat}^{\uparrow}$ *without producing a completed* $\mathsf{Real}^{\uparrow}$ *object, quotienting Cauchy names, or selecting a limiting value.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket regseqrat handoff`

Proof. Start with the packet of Definition 323.1. Remove the local row N and retain the stream, modulus, endpoint, radius, transport, window, and provenance coordinates.

For each precision row, the $\mathsf{CauchyModulus}^{\uparrow}$ threshold names the finite index after which comparisons must be checked. The late-pair radius ledger supplies exactly those checks over the scheduled dyadic endpoint rows.

These retained rows are the regular-sequence surface consumed by $\mathsf{RegSeqRat}^{\uparrow}$. Since the construction never adds a quotient, host real equality, or selected limit coordinate, the resulting handoff is only the finite regularity window. □

Theorem 323.5 (FastCauchy Real boundary finite window)**.** *Every accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet exposes to a* $\mathsf{Real}^{\uparrow}$ *consumer only the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations, the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold table, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the late-pair radius ledger, the* hsame *and* Cont *transport rows, and the* Pkg *provenance retained by Definition 323.4.*

It does not export a selected limit, quotient stream, host real equality, or completeness datum.

Proof. Project the packet of Definition 323.1. Its visible coordinates are the stream observations, modulus table, endpoint rows, late-pair radius ledger, transport windows, provenance row, and local certificate row.

Invoke Definition 323.4. After forgetting the local $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ row, the retained coordinates are exactly the finite regularity surface that a $\mathsf{Real}^{\uparrow}$ consumer may inspect through the regular-sequence boundary.

There is no further $\mathsf{Real}^{\uparrow}$ coordinate in the carrier. In particular, the packet contains no selected limit, quotient stream, host real equality witness, or completeness datum beyond the listed finite rows. □

Theorem 323.6 (FastCauchy NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ *obligation surface has the following finite rows:*

1. *carrier: the* BHist *packet of Definition 323.1;*
2. *classifier: the componentwise comparison of Definition 323.2;*
3. *stability: the* hsame *and* Cont *transport rows preserving scheduled observations, modulus thresholds, dyadic endpoints, and late-pair radius estimates;*
4. *regular-sequence handoff: the* $\mathsf{RegSeqRat}^{\uparrow}$ *window of Definition 323.4;*
5. *real-name boundary: the* $\mathsf{Real}^{\uparrow}$ *consumer may read the finite regularity window and provenance only.*

These rows are exactly the seed naming-certificate surface for $\mathsf{FastCauchy}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyPacket semantic name certificate`

Proof. The carrier and classifier rows are the displayed objects of Definition 323.1 and Definition 323.2. They enumerate all finite coordinates visible to the local certificate.

The stability row is Definition 323.3. It shows that transporting the stream and threshold coordinates preserves the late-pair radius obligations read by the classifier.

The regular-sequence handoff is Definition 323.4. The real-name boundary is the same finite handoff viewed as input data for $\mathsf{Real}^{\uparrow}$, with no additional completion or equality principle. □

Theorem 323.7 (FastCauchy obligation closure packet)**.** *The* $\mathsf{FastCauchy}^{\uparrow}$ *carrier, componentwise classifier, modulus transport,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *finite-window boundary, provenance row, and ledger exclusions form the complete obligation surface for* $\mathsf{FastCauchy}^{\uparrow}$*.*

Every downstream read factors through the scheduled $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows named in the packet. The packet exports no quotient stream, selected limit, host real equality, completeness datum, or standard bridge.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket obligation closure certificate`

Proof. The carrier row is Definition 323.1. It lists the scheduled stream, modulus threshold, dyadic endpoint, late-pair radius, transport, window, provenance, and local naming rows, and it excludes quotient streams, selected limits, host real equality, and bridge data.

The classifier row is Definition 323.2. It compares exactly the visible rows componentwise through the source classifiers, so every accepted comparison remains inside the finite modulus-normalized ledger.

The transport obligation is Definition 323.3. It preserves the scheduled observations, threshold rows, endpoint ledgers, and late-pair radius obligations through the displayed hsame and Cont coordinates.

The outgoing consumer boundaries are Definition 323.4 and Definition 323.5. They route downstream reads through the named $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ source surfaces while retaining only the finite regularity window and provenance rows.

Finally, Definition 323.6 gathers these rows as the local $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ surface. Since the carrier has no further completion, quotient, host-equality, selected-limit, or standard-bridge coordinate, the listed rows exhaust the obligation packet. □

Theorem 323.8 (FastCauchy scoped dependency certificate)**.** *Every exported* $\mathsf{FastCauchy}^{\uparrow}$ *row factors through the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold table,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *finite-window boundary,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. The certificate exports no quotient stream, selected limit, host real equality, completeness datum, or standard bridge.*

Proof. Start with the finite carrier and classifier of Definition 323.1 and Definition 323.2. They make the scheduled observations, threshold table, dyadic endpoint ledger, late-pair radius ledger, transport rows, provenance, and local naming row the only visible coordinates.

The scoped transport source is Definition 323.3. It uses the displayed hsame rows and Cont windows to preserve the finite modulus-normalized tail obligations, so the proof reads stability from BEDC transport primitives rather than from a host sequence model.

The downstream source rows are Definition 323.4 and Definition 323.5. They expose the same finite regularity window to $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers while retaining the source-certificate provenance named by the packet.

Finally apply Definition 323.6 and Definition 323.7. The carrier, classifier, transport, handoff, boundary, provenance, and local naming rows listed there are exactly the exported rows; no quotient stream, host real equality, selected limit, completeness datum, or standard bridge coordinate is available. □

Theorem 323.9 (FastCauchy public interface export)**.** *The carrier, classifier, checked modulus transport,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *finite-window boundary, scoped dependency certificate,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows assemble a reusable public* $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ *interface for finite modulus-normalized Cauchy-name packets.*

Downstream consumers may cite this export instead of reopening the carrier. The exported interface contains no quotient stream, host real equality, selected limit, completeness datum, or standard bridge.

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFiniteCarrier public interface export`

Proof. Begin with the carrier of Definition 323.1 and the classifier of Definition 323.2. These give the scheduled stream rows, modulus threshold rows, dyadic endpoint rows, late-pair radius ledger,

transport rows, provenance package, local naming row, and finite ledger that every consumer can inspect.

The checked motion is the modulus transport of Definition 323.3. It keeps those rows inside the displayed hsame and Cont routes, so the public interface is stable without opening a host Cauchy sequence.

The consumer handoffs are Definition 323.4 and Definition 323.5. Together with Definition 323.6 and Definition 323.8, they repackage the same finite rows as a reusable $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ surface.

No cited component supplies a quotient stream, host real equality, selected limit, completeness datum, or standard bridge. The assembled interface therefore exports only the finite modulus-normalized packet rows named in the statement. □

Theorem 323.10 (FastCauchy public RegSeqRat Real seal)**.** *The public* $\mathsf{FastCauchy}^{\uparrow}$ *finite-modulus boundary of Definition 323.9 determines exactly the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows of Definition 323.4 and the finite* $\mathsf{Real}^{\uparrow}$ *boundary rows of Definition 323.5. These are the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius ledger,* hsame *and* Cont *transport rows,* Pkg *provenance, and local* NameCert *rows.*

The sealed public boundary exposes no selected limit, completeness coordinate, quotient stream, or host real equality.

Proof. Start from the $\mathsf{RegSeqRat}^{\uparrow}$ handoff. It forgets only the local $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ row when forming the regular-sequence window and retains the scheduled observations, modulus thresholds, dyadic endpoints, late-pair radius ledger, transport rows, and provenance.

Read the same retained rows through the $\mathsf{Real}^{\uparrow}$ finite-window boundary. The real-name consumer receives the regular-sequence surface as finite input data, with no coordinate for a selected limit or host real equality.

The scoped dependency certificate and public interface export gather exactly these rows as the public $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$ surface. Therefore every public read is one of the scheduled stream observation, modulus threshold, dyadic endpoint, late-pair radius ledger, transport, provenance, or name rows, and no completeness coordinate or quotient stream is available. □

Theorem 323.11 (FastCauchy precision window restriction)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet and let D be a displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *finite precision row selecting a subwindow of the schedule of F. The packet restricted along D exposes exactly the selected* $\mathsf{StreamName}^{\uparrow}$ *observation rows, the selected* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row, the selected* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the late-pair radius ledger over the selected window, the componentwise* hsame *and* Cont *rows, the restricted* Pkg *provenance, and the local* NameCert *rows attached to those selected coordinates.*

Its $\mathsf{RegSeqRat}^{\uparrow}$ *handoff is the restriction of Definition 323.4 to the selected window, and its* $\mathsf{Real}^{\uparrow}$ *boundary is the restriction of Definition 323.5 to the same displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *row. The restriction introduces no selected limit, quotient stream, host real equality, completeness datum, or standard bridge.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket precision window restriction`

Proof. Project the carrier tuple of F from Definition 323.1. The displayed $\mathsf{DyadicPrecision}^{\uparrow}$ row selects a finite subwindow of the scheduled $\mathsf{StreamName}^{\uparrow}$ observations, so the restricted packet keeps precisely the matching threshold row, dyadic endpoint rows, late-pair radius entries, transport rows, provenance rows, and local naming rows.

Use Definition 323.3 on the selected rows. The transport theorem keeps the modulus threshold, dyadic endpoints, hsame comparisons, and Cont routes stable inside the same finite window, so the restriction has the same public coordinates as the parent packet, only with the schedule narrowed by D.

Apply Definition 323.10 to the restricted surface. Its $\mathsf{RegSeqRat}^{\uparrow}$ handoff is therefore the selected part of Definition 323.4, and its $\mathsf{Real}^{\uparrow}$ boundary is the selected part of Definition 323.5.

The seal theorem also rules out any extra coordinate for a selected limit, quotient stream, host real equality, completeness datum, or standard bridge. Thus the precision subwindow is only a finite public restriction of the displayed $\mathsf{FastCauchy}^{\uparrow}$ rows. □

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFiniteCarrier precision window restriction`

Theorem 323.12 (FastCauchy DyadicPrecision window cofinality)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet and let D be an accepted* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedule selecting a finite precision window for F. Every consumer-visible row of the packet restricted by D is exactly one of the selected* $\mathsf{StreamName}^{\uparrow}$ *observation rows, the selected* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row, the selected* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the selected late-pair radius ledger entries, the displayed* hsame *and* Cont *transport rows, the restricted* Pkg *provenance rows, and the local* NameCert *rows attached to the selected coordinates.*

Conversely, every selected $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row, every selected* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, and every late-pair radius ledger entry whose indices lie in the finite* $\mathsf{DyadicPrecision}^{\uparrow}$ *window appears in the restricted* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and in the finite* $\mathsf{Real}^{\uparrow}$ *boundary. The coverage is a coverage of public finite rows only: it does not assert a selected limit, quotient stream, host real equality, completeness datum, or standard bridge.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket dyadicprecision window cofinality`

Proof. Project F through Definition 323.1. This exposes the scheduled observation rows, modulus thresholds, dyadic endpoints, late-pair ledger entries, transport rows, provenance rows, and local name rows carried by the accepted packet.

Project D through Definition 322.1. The schedule chooses a finite window of those carried coordinates, so Definition 323.11 identifies the restricted packet with exactly the rows whose indices are selected by D.

Apply Definition 323.10. It identifies the public $\mathsf{RegSeqRat}^{\uparrow}$ handoff and finite $\mathsf{Real}^{\uparrow}$ boundary with the same selected threshold, endpoint, late-pair, transport, provenance, and naming rows.

The forward coverage follows because no other consumer-visible row survives the restriction. The converse follows because each selected threshold, endpoint, and late-pair row named by D is one of the rows sealed into both public consumer surfaces. □

Theorem 323.13 (FastCauchy shared-window RegSeqRat handoff)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet, and let D and D' be accepted* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedules for F whose selected finite windows are related by the* $\mathsf{DyadicPrecision}^{\uparrow}$ *classifier. The restricted* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows obtained from $F|D$ and $F|D'$ are the same displayed rows after the componentwise* hsame *and* Cont *transports carried by F, D, and D'.*

The common handoff consists exactly of the scheduled $\mathsf{StreamName}^{\uparrow}$ *observation rows, the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the late-pair radius rows, the componentwise* hsame *rows, the* Cont *rows, the restricted* Pkg *provenance rows, and the local* NameCert *rows attached to the common transported window. It contains no selected limit, quotient stream, host real equality, completeness datum, hidden tail, or standard bridge datum.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket shared window regseqrat handoff`

Proof. Project F through Definition 323.1. The projection exposes only the scheduled observation rows, modulus thresholds, dyadic endpoints, late-pair radius ledger, transport rows, package provenance, and local name-certificate rows available to a finite consumer.

Project D and D' through Definition 322.1. Use the classifier of Definition 322.2 together with Definition 322.10 to read the common finite window transported by the two accepted schedules.

Apply Definition 323.11 to both restrictions. Since both selected windows read back to the same transported window, the two restricted packets display the same scheduled observations, thresholds, endpoints, late-pair rows, hsame rows, Cont rows, Pkg rows, and NameCert rows.

Finally use Definition 323.12 and Definition 323.10. Cofinality says every selected row of the common window appears in the restricted $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and the seal identifies the RegSeqRat and finite Real consumer rows with that same public finite surface. The excluded limit, quotient, equality, completeness, hidden-tail, and bridge data are not coordinates of this surface. □

Theorem 323.14 (FastCauchy modulus synchronization common RegSeqRat window)**.** *Let F and G be accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packets. Suppose that both packets display the same accepted* $\mathsf{DyadicPrecision}^{\uparrow}$ *row D, classifier-compatible* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows over the precision indices selected by D, and a common scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation window. Then the two packets determine one finite* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *consumer package.*

The visible rows of this package are exactly the shared precision row D, the shared $\mathsf{StreamName}^{\uparrow}$ *schedule, the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the synchronized* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows, the late-pair radius ledgers, the displayed* hsame *rows, the displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows carried by the two accepted packets. The package has no coordinate for a selected limit, quotient stream, host real equality, completeness datum, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket modulus synchronization common regseqrat window`

Proof. Project F and G through Definition 323.1. The projections expose only the displayed precision, stream-window, modulus, dyadic endpoint, late-pair, transport, provenance, and local naming rows named in the statement.

Apply Definition 323.12 to each packet with the shared row D. Every requested precision index is therefore forced through the same displayed $\mathsf{DyadicPrecision}^{\uparrow}$ window, so no consumer row can escape the shared schedule.

Use Definition 323.13 on the two restricted handoffs. The classifier-compatible threshold rows and the common $\mathsf{StreamName}^{\uparrow}$ window identify the same finite regular-sequence handoff rows, including the synchronized threshold rows and late-pair radius ledgers.

Finally apply Definition 323.10. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the finite $\mathsf{Real}^{\uparrow}$ boundary read the same finite surface, and the seal leaves no coordinate for selected limits, quotient streams, host real equality, completeness data, or standard bridge rows. □

Theorem 323.15 (FastCauchy standard RegSeqRat Real bridge)**.** *A standard bridge for the finite modulus-normalized* $\mathsf{FastCauchy}^{\uparrow}$ *packet factors through the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *thresholds,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius ledger,* hsame *and* Cont *transport rows,* Pkg *provenance, and local* NameCert *rows already isolated by Definition 323.10. Its* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer reads are exactly the public rows supplied by Definition 323.9, Definition 323.4, and Definition 323.5.*

The bridge exports no selected limit, completeness coordinate, quotient stream, or host real equality.

Proof. Begin with the public interface export. It lists the scheduled stream observations, modulus thresholds, dyadic endpoints, late-pair radius ledger, transport rows, package provenance, and local name rows available to any consumer.

Route the regular-rational side through Definition 323.4 and the real-name side through Definition 323.5. Both consumers read the same finite modulus-normalized rows and add no separate limit or equality coordinate.

Finally apply Definition 323.10. The seal identifies the two consumer surfaces as the public finite rows, so the standard bridge is exactly this RegSeqRat/Real factorization and nothing outside it. □

Theorem 323.16 (FastCauchy mature finite-window consumer catalogue)**.** *For an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet and any displayed finite precision window, the mature finite-window consumers read exactly the rows already exposed by the carrier and public interface: scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *thresholds,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints, late-pair ledgers,* hsame *and* Cont *transport rows,* Pkg *provenance, and local* NameCert *rows. The* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *sides of the standard bridge read the same catalogue after the precision-window restriction.*

No mature finite-window consumer receives a coordinate for a selected limit, quotient stream, host real equality, completeness datum, hidden tail, or bridge object beyond these finite public rows.

Proof. Start with Definition 323.9. It lists the consumer-visible carrier rows: scheduled observations, threshold rows, endpoint rows, late-pair ledger entries, transport rows, package provenance, and local name-certificate rows.

Restrict that surface by the finite precision window. By Definition 323.11, the restriction keeps exactly the selected rows of the same kinds and introduces no new analytic coordinate.

Next apply Definition 323.10. The seal identifies the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the finite $\mathsf{Real}^{\uparrow}$ boundary with the restricted public rows.

Finally use Definition 323.15. The bridge routes both standard consumers through that sealed finite surface, so every mature finite-window read is one of the enumerated rows. The omitted limit, quotient, equality, completeness, tail, and independent bridge data are not coordinates of the carrier, the restricted public surface, or either standard consumer boundary. □

Theorem 323.17 (FastCauchy explicit-rate seal-window exhaustion)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet carrying its displayed explicit-rate* $\mathsf{CauchyModulus}^{\uparrow}$ *schedule, and let D be a displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *subwindow of that schedule. Every public* $\mathsf{Real}^{\uparrow}$ *seal read over the restricted packet factors through the displayed explicit-rate packet and the subwindow D: it is exactly one of the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius rows,* hsame *rows,* Cont *rows,* Pkg *provenance rows, or* NameCert *rows already isolated by Definition 323.11, Definition 323.10, and Definition 323.15.*

Conversely, each row of those displayed kinds whose index lies in the $\mathsf{DyadicPrecision}^{\uparrow}$ *subwindow is a public* $\mathsf{Real}^{\uparrow}$ *seal read of the restricted packet through the same explicit-rate factorization. The factorized seal has no coordinate for a selected limit, quotient stream, host real equality, completeness datum, hidden tail, or standard bridge datum beyond the finite rows named above.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket explicit rate seal window exhaustion`

Proof. Project the carrier of F from Definition 323.1. The projected packet exposes the scheduled stream observations, explicit modulus thresholds, dyadic endpoints, late-pair radius ledger,

transport rows, package rows, and name-certificate rows; these are the only displayed coordinates available before any consumer reads the packet.

Restrict this carrier along the displayed $\mathsf{DyadicPrecision}^{\uparrow}$ row D. By Definition 323.11, the restriction keeps exactly the rows whose indices lie in the finite precision subwindow, including the explicit-rate thresholds and the dyadic endpoint rows used by the late-pair radius ledger.

Apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the finite $\mathsf{Real}^{\uparrow}$ boundary. The handoff identifies the regular-rational consumer rows with the same selected schedule, and Definition 323.10 identifies the $\mathsf{Real}^{\uparrow}$ seal reads with that finite public surface.

Finally use Definition 323.15. The bridge does not create an additional public coordinate; it only routes the displayed RegSeqRat and Real consumers through the same explicit-rate window. Therefore every public seal read is exhausted by the listed rows, and the omitted limit, quotient, equality, completeness, tail, and bridge data remain unavailable. □

Theorem 323.18 (FastCauchy uniform StreamName window extraction)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet and let D be a displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *row of its explicit-rate schedule. There is a finite schedule window, uniform for the displayed precision row D, whose visible surface consists exactly of the selected* $\mathsf{StreamName}^{\uparrow}$ *observation rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius ledger,* hsame *rows,* Cont *rows,* Pkg *provenance, and local* NameCert *rows.*

The induced $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer reads are precisely the restrictions of the public seal to that finite schedule window. The extraction has no coordinate for a selected limit, quotient stream, host real equality, completeness datum, hidden tail, or standard bridge object outside the displayed public rows.*

Lean4 ✓ `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket uniform streamname window extraction`

Proof. Project the carrier of F through Definition 323.1. This exposes only scheduled observations, explicit modulus thresholds, dyadic endpoints, late-pair radius entries, componentwise transport, package provenance, and local naming rows.

Apply Definition 323.11 to restrict the carrier along D. The restricted carrier keeps exactly the rows whose indices belong to the finite precision window.

Use Definition 323.12 to choose the same schedule window for every consumer read at the displayed precision. This makes the selected $\mathsf{StreamName}^{\uparrow}$ rows and the explicit modulus threshold uniform over the whole extracted surface.

Next invoke Definition 323.13. The $\mathsf{RegSeqRat}^{\uparrow}$ read is the handoff of the same selected schedule, endpoint, radius-ledger, transport, provenance, and naming rows.

Finally apply Definition 323.17. The public $\mathsf{Real}^{\uparrow}$ seal is exhausted by that finite explicit-rate window, so the consumer reads are exactly restrictions of the public seal. The excluded limit, quotient, equality, completeness, tail, and bridge objects require coordinates absent from the extracted carrier. □

Theorem 323.19 (FastCauchy common precision window connector)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet, and let D and D' be two displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *rows of its explicit-rate schedule. Suppose the selected threshold, endpoint, late-pair, and window rows for D and D' admit a common transported* $\mathsf{StreamName}^{\uparrow}$ *finite window. Then the two selected* $\mathsf{RegSeqRat}^{\uparrow}$ *handoffs and the* $\mathsf{Real}^{\uparrow}$ *seal reads factor through one finite consumer window.*

The common window contains exactly the scheduled observations, the $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the late-pair radius ledger, the displayed* hsame *and* Cont *rows, the* Pkg *provenance, and the local* NameCert *rows transported into that window. It contains no*

selected limit, quotient stream, host real equality, completeness datum, hidden tail, or independent bridge coordinate.

Proof. Apply Definition 323.18 to the two displayed precision rows. This places both precision selections inside finite $\mathsf{StreamName}^{\uparrow}$ windows whose visible coordinates are scheduled observations, thresholds, endpoints, radius rows, transport rows, provenance rows, and local naming rows.

Use Definition 323.12 on the common transported window. The cofinality row identifies the selected threshold, endpoint, late-pair, and window package for the two displayed $\mathsf{DyadicPrecision}^{\uparrow}$ reads, so the consumer reads use one finite schedule rather than two unrelated schedules.

Next apply Definition 323.13. The two $\mathsf{RegSeqRat}^{\uparrow}$ handoffs are restrictions of the accepted packet to the same scheduled observations, explicit modulus threshold, dyadic endpoints, late-pair radius ledger, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Finally use Definition 323.17. The $\mathsf{Real}^{\uparrow}$ seal reads are exhausted by the same finite explicit-rate surface, so the handoffs and seal reads all factor through one shared consumer window. □

Theorem 323.20 (FastCauchy StreamName–RegSeqRat–Real window intersection)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet, and let D and D' be two displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *rows of its explicit-rate schedule. Suppose their selected windows admit a common transported* $\mathsf{StreamName}^{\uparrow}$ *finite schedule window W. Then the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows selected over W and the* $\mathsf{Real}^{\uparrow}$ *seal rows selected over W are exactly the same scheduled observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius rows,* hsame *rows,* Cont *rows,* Pkg *provenance rows, and* $\mathsf{NameCert}$ *rows.*

The intersection statement has no coordinate for a selected limit, quotient stream, host real equality, completeness datum, hidden tail, or $\mathsf{bridgeChecked}$ *status. It identifies only the finite public rows visible through the common schedule window W.*

Proof. Apply Definition 323.18 to the two displayed precision rows. The common transported window W carries the visible $\mathsf{StreamName}^{\uparrow}$ observations, explicit thresholds, dyadic endpoints, late-pair radius rows, transport rows, provenance rows, and local naming rows.

Use Definition 323.13 for the $\mathsf{RegSeqRat}^{\uparrow}$ side. Its handoff reads are obtained by restricting the accepted packet to the same scheduled observations and the same finite explicit-rate rows.

Use Definition 323.17 for the $\mathsf{Real}^{\uparrow}$ side. The seal reads are exhausted by the finite explicit-rate surface, so no additional real-completeness or quotient coordinate is introduced.

It remains to compare the two finite readouts. Apply Definition 323.12 to identify the two displayed precision selections inside W, and then apply Definition 323.10 to view the handoff and seal rows as the same public observations. The excluded limit, quotient, equality, completeness, tail, and checked bridge data are outside this finite-window intersection. □

Theorem 323.21 (FastCauchy finite precision window union lock)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet, and let D and D' be accepted* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedules whose selected finite* $\mathsf{StreamName}^{\uparrow}$ *windows admit a displayed finite union window U. The* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer package of F restricted to U is exactly the union of the consumer rows obtained from the D and D' restrictions, with the overlap identified by Definition 323.13.*

The union package contains only the selected $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius ledger entries, displayed* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows already visible on the two restricted windows. It introduces no hidden tail, selected limit, quotient stream, host real equality, completeness datum, or* $\mathsf{bridgeChecked}$ *row.*

Proof. Apply Definition 323.12 to the two precision schedules. Each restriction exposes exactly its selected observations, thresholds, endpoints, radius rows, transport rows, package provenance, and local name-certificate rows.

Use Definition 323.18 to place both selected surfaces inside the displayed union window U. The extraction supplies one finite $\mathsf{StreamName}^{\uparrow}$ schedule for the combined consumer read and keeps the two precision selections as subwindows of that schedule.

On the overlap, apply Definition 323.13. The common $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows are therefore the same transported rows, including the synchronized endpoint, radius, hsame, Cont, Pkg, and NameCert coordinates.

Finally use Definition 323.14. It identifies the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer package over the common modulus-normalized window, so the package over U is precisely the finite union of the two restricted packages with their overlap already identified. □

Theorem 323.22 (FastCauchy Bishop regular window induction)**.** *Let F be an accepted* $\mathsf{FastCauchy}^{\uparrow}$ *packet, and let $D_0, \ldots, D_{k-1}$ be a finite list of accepted* $\mathsf{DyadicPrecision}^{\uparrow}$ *schedules for F. Suppose their selected* $\mathsf{StreamName}^{\uparrow}$ *windows admit displayed finite successive union windows, so that each step unions the next selected precision window with the accumulated displayed window. Then the consumer package of F over the final displayed window is exactly the iterated union of the* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *rows obtained from the individual precision restrictions.*

The package contains precisely the selected $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, late-pair radius ledger entries, displayed* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows contributed by the finite list. It introduces no hidden tail, selected limit, quotient stream, host real equality, ambient completeness datum, or bridge row.*

Proof. Proceed by induction on the finite list of displayed precision schedules. For the empty list, the selected window is empty, so the consumer package has no selected $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ row and is the empty finite union.

For a singleton list, apply Definition 323.12 to identify the selected schedule window. Then use Definition 323.13 to read the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the corresponding $\mathsf{Real}^{\uparrow}$ rows from that same finite precision restriction.

For the induction step, assume the accumulated displayed window already realizes the iterated union for the first schedules. Union the accumulated window with the next selected precision window and apply Definition 323.21. This identifies the new consumer package as the finite union of the accumulated package and the next restriction, with their overlap already matched by the shared-window handoff.

Finally apply Definition 323.14 to normalize the displayed union window to the common modulus surface. The normalized package is therefore exactly the iterated union of the individual $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ restrictions, and the excluded tail, limit, quotient, equality, completeness, and bridge coordinates remain absent at every finite step. □

Closure status for $\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}$.

Constructive story: A fast Cauchy name is a finite BHist packet consisting of scheduled $\mathsf{StreamName}^{\uparrow}$ observation rows, explicit $\mathsf{CauchyModulus}^{\uparrow}$ threshold rows, dyadic endpoint rows from $\mathsf{DyadicRatCore}^{\uparrow}$, late-pair radius ledgers, componentwise hsame and Cont transport rows, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 323.16 and the explicit-rate seal-window exhaustion bind the finite modulus-normalized consumer catalogue over scheduled $\mathsf{StreamName}^{\uparrow}$ observations, $\mathsf{CauchyModulus}^{\uparrow}$ thresholds, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints, late-pair radius ledger, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FastCauchy}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FastCauchyUp.FastCauchyFinitePacket\_obligation\_closure\_certificate`
Bridge status: none
Origin: human
Not claimed: This chapter does not close RealUp completeness, quotient streams, host real equality, or selected limits.
Upgrade path: No further paper theory-axis step is recorded for this chapter; Lean formalization and checked bridge status remain separate formal-axis work.

Chapter 324

A Concrete Naming Certificate for $\mathsf{LyapunovStability}^{\uparrow}$

The $\mathsf{LyapunovStability}^{\uparrow}$ interface records the finite certificate surface used by standard Lyapunov stability arguments for displayed dynamical systems. Its finite descent ledger consumes the Lyapunov energy-certificate surface of chapter 313 and the displayed transition carrier of chapter 195 before it packages level-set containment for downstream control-stability consumers. The classical reference point is Khalil, *Nonlinear Systems*, together with the LaSalle-style Lyapunov stability tradition; the BEDC chapter names only the finite descent packet and its consumer boundary.

324.1 Carrier definition

Definition 324.1 (LyapunovStability finite BHist carrier)**.** *A* $\mathsf{LyapunovStability}^{\uparrow}$ *carrier is a finite* BHist *packet over displayed* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows. It consists of a state-carrier row* X*, a displayed state-transition row* Φ *from* $\mathsf{DynSystem}^{\uparrow}$*, a base state row* x_0*, a scalar-valued or matrix-valued energy row* V*, nonnegative comparison rows in* $\mathsf{Real}^{\uparrow}$*, a finite level row* α*, a finite descent ledger along the displayed transition row,* hsame *transports between corresponding state and energy rows,* Cont *routes for every transition and energy readback,* Pkg *provenance naming the dependency certificates, and a* $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$ *row for the packet.*

The classifier compares two accepted packets only by these displayed rows: state rows through $\mathsf{VecSpace}^{\uparrow}$*, transition rows through* $\mathsf{DynSystem}^{\uparrow}$*, energy and nonnegative comparison rows through* $\mathsf{Mat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$*, and the finite descent ledger through the named* hsame*,* Cont*, and* Pkg *coordinates. It exports no analytic flow, invariant measure, asymptotic convergence theorem, or ambient normed-space completion.*

324.2 Finite stability surface

Theorem 324.2 (LyapunovStability energy descent obligation)**.** *For an accepted* $\mathsf{LyapunovStability}^{\uparrow}$ *carrier* P *as in Definition 324.1, every descent assertion visible to a consumer is one row of the finite ledger. Each such row reads a displayed transition face* $x \mapsto \Phi(x)$*, the two energy rows* $V(x)$ *and* $V(\Phi(x))$*, a* $\mathsf{Real}^{\uparrow}$ *comparison row saying that the successor energy is no larger than the source energy, and the* hsame*,* Cont*, and* Pkg *provenance that transports those rows inside* P*.*

Proof. Project the accepted carrier to its finite descent ledger. By the carrier definition, each ledger entry is attached to a displayed transition face and to two energy readbacks.

The nonnegative comparison row is read through $\mathsf{Real}^{\uparrow}$, while a matrix-valued energy row first passes through the displayed $\mathsf{Mat}^{\uparrow}$ or scalar readback route named in the packet. The same entry also carries the Cont route explaining how the successor state and the successor energy are obtained.

No other descent source appears in the carrier. Therefore every visible descent assertion is one of the finite rows listed in the theorem. □

Theorem 324.3 (LyapunovStability level-set containment)**.** *Let P be an accepted* $\mathsf{LyapunovStability}^{\uparrow}$ *carrier with finite level row α. If a displayed state row x satisfies the finite comparison row $V(x) \leq \alpha$ and the transition face from x is recorded in the descent ledger of P, then the successor state row $\Phi(x)$ has a displayed comparison row $V(\Phi(x)) \leq \alpha$ assembled from the same* $\mathsf{Real}^{\uparrow}$ *nonnegative comparison rows, energy ledger,* hsame *transports, and* Cont *provenance.*

Lean4 ✓ `BEDC.Derived.LyapunovStabilityUp.LyapunovStabilityCarrier level set containment`
Lean4 ✓ `BEDC.Derived.LyapunovStabilityUp.LyapunovStabilityPacket level set containment`

Proof. Read the finite descent row for the transition face from x to $\Phi(x)$. It supplies the comparison from the successor energy to the source energy.

Compose that comparison with the displayed level comparison for x. The composition is a finite $\mathsf{Real}^{\uparrow}$ comparison route, and the carrier records the required hsame and Cont provenance for both energy readbacks.

Repack the composed comparison as the level row for the successor state. The construction uses only rows already present in the accepted packet, so it does not introduce an analytic invariant set or an external flow object. □

Theorem 324.4 (LyapunovStability finite descent ledger exactness)**.** *For an accepted* $\mathsf{LyapunovStability}^{\uparrow}$ *carrier P as in Definition 324.1, every consumer-visible descent row, level row, or successor-energy comparison row factors through exactly one displayed finite descent-ledger entry. The factorization carries the recorded* $\mathsf{DynSystem}^{\uparrow}$ *transition row, the* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Mat}^{\uparrow}$ *energy readback, the required* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the* $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$ *row of P. No analytic flow, invariant set, asymptotic theorem, or ambient completion supplies a further descent row for the packet.*

Proof. Project P to the coordinates listed in Definition 324.1. A consumer-visible descent or successor-energy comparison must first read a displayed transition face, then read the source and successor energy rows, and finally read a finite comparison row.

The descent entry is the same ledger row used by Definition 324.2. Composing that entry with the finite level comparison follows the construction of Definition 324.3, so the resulting level row has the same transition, energy, transport, continuation, package, and naming provenance.

There is no remaining carrier coordinate from which another descent row could be projected. The listed finite ledger entry therefore exhausts each accepted consumer-visible descent, level, or successor-energy comparison row. □

Theorem 324.5 (LyapunovStability NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$ *obligation surface consists of five rows: the finite carrier of Definition 324.1; the classifier that transports state, transition, energy, level, comparison, descent,* Cont*, and* Pkg *rows componentwise; the energy descent obligation of Definition 324.2; the level-set containment row of Definition 324.3; and the exact consumer boundary of Definition 324.4 over the displayed* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Start with the carrier and classifier. They enumerate the finite packet coordinates and the componentwise transport relation.

Add the descent row, the level-set containment row, and the finite ledger exactness row. These are projections from the same finite ledger and use only the displayed transition, energy, comparison, continuation, and provenance rows.

The consumer boundary is then a closure of the displayed surface under projection. Since the packet has no row for an analytic flow, invariant measure, asymptotic convergence theorem, or ambient completion, those objects cannot be exported by the $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$ surface. □

Theorem 324.6 (LyapunovStability consumer boundary)**.** *Every downstream consumer of* $\mathsf{LyapunovStability}^{\uparrow}$*, including* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{LQR}^{\uparrow}$*,* $\mathsf{Riccati}^{\uparrow}$*, and control-stability packets, may read only the displayed state-transition row, state-carrier row, scalar or matrix energy row,* $\mathsf{Real}^{\uparrow}$ *nonnegative comparison rows, finite descent ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and* NameCert *row of Definition 324.1. No consumer can require completeness, an asymptotic convergence theorem, invariant-measure data, or an external analytic flow bridge from this chapter.*

Proof. Take a consumer-visible readback from an accepted packet. The classifier lets the consumer compare only the displayed carrier coordinates and the finite ledger rows.

Apply the energy descent and level-set containment theorems to identify the stability-facing rows. These rows are exactly the transition, state, energy, comparison, continuation, transport, and package coordinates named in the carrier.

Because none of the excluded objects is a coordinate of the packet, no downstream consumer can project such an object from the certificate. The boundary is therefore the finite BEDC Lyapunov-stability packet itself. □

Closure status for $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$.

Constructive story: A Lyapunov-stability packet is seeded by a finite BHist row package containing a displayed $\mathsf{DynSystem}^{\uparrow}$ transition, a $\mathsf{VecSpace}^{\uparrow}$ state carrier, a scalar or $\mathsf{Mat}^{\uparrow}$ energy row, $\mathsf{Real}^{\uparrow}$ nonnegative comparisons, a finite descent ledger, hsame transports, Cont routes, Pkg provenance, and the $\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$ row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$, publicClosed)

Scope closed: Definition 324.5 and Definition 324.6 bind the finite descent ledger, level-set containment, consumer boundary, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LyapunovStability}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.LyapunovStabilityUp.LyapunovStabilityPacket\_level\_set\_containment`

Bridge status: none

Origin: human

Not claimed: This chapter does not close completeness, asymptotic convergence, invariant-measure claims, or an external analytic flow bridge.

Upgrade path: The remaining paper-side step is a bridge boundary for the same level-set containment surface.

Chapter 325

A Concrete Naming Certificate for $\mathsf{BousfieldLocalization}^{\uparrow}$

The $\mathsf{BousfieldLocalization}^{\uparrow}$ interface names the finite certificate surface for a displayed left Bousfield-localization packet over a model-category row. In Hirschhorn 2003 and in Goerss–Jardine 1999, local objects and inverted maps are controlled by a model-category background, a selected class of morphisms, and fibrant replacement tests; the BEDC packet below records only the displayed rows that a downstream consumer may inspect.

The dependency boundary is $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, and $\mathsf{Functor}^{\uparrow}$: chapter 158 supplies weak-equivalence, cofibration, fibration, and fibrant-object faces; chapter 61 types the object and arrow rows; and chapter 62 supplies classifier transport and readback routes without exporting a homotopy-category quotient.

325.1 Finite localizing packet

Definition 325.1 (BousfieldLocalization carrier)**.** *A* $\mathsf{BousfieldLocalization}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (M, S, L, T, P, N)$$

whose visible rows have the following shape:

1. *M is a displayed* $\mathsf{ModelCat}^{\uparrow}$ *row, typed through the displayed* $\mathsf{Cat}^{\uparrow}$ *object and morphism rows;*
2. *S is a finite selected morphism-class row whose arrows are the maps to be read as inverted by the localizing certificate;*
3. *L is a finite list of fibrant-local-object rows, each recording a displayed fibrant object together with the mapping-test rows by which S reads locally;*
4. *T is the classifier-transport ledger, consisting of the componentwise* hsame *witnesses and* Cont *routes that carry the model-category, selected-map, and local-object rows;*
5. *P is the* Pkg *provenance row naming the* $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, *and* $\mathsf{Functor}^{\uparrow}$ *dependency certificates used by the packet;*
6. *N is the* $\mathsf{NameCert}$ *ledger for the carrier, classifier, stability, exactness, and consumer-readback obligations.*

The carrier predicate is $\mathsf{BousfieldLocalizationPacket}(M, S, L, T, P, N)$*. Two accepted packets classify together only when the model-category row, selected morphism-class row, fibrant-local-object rows,*

classifier-transport ledger, package provenance, and NameCert *ledger transport by the displayed* hsame *witnesses along the same* Cont *routes named in T.*

Theorem 325.2 (BousfieldLocalization NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{BousfieldLocalization}^{\uparrow}}$ *seed surface consists of the following five finite obligations:*

1. *carrier row: the* BHist *packet of Definition 325.1, including the model-category row, selected morphism-class row, fibrant-local-object rows, classifier-transport ledger,* Pkg *provenance, and* NameCert *ledger;*
2. *classifier row: componentwise* hsame *on exactly those displayed coordinates, with no comparison of hidden model structures, external homotopy categories, or unrecorded mapping-space objects;*
3. *stability row: whenever the displayed coordinates are transported along the* hsame *witnesses and* Cont *routes named by T, the transported packet is again an accepted* $\mathsf{BousfieldLocalization}^{\uparrow}$ *carrier;*
4. *exactness row: every local-object test, inverted-map read, and fibrant-row readback obtained by a consumer must be one of the rows recorded in M, S, L, T, P, and N or a finite readback through their named* Pkg *provenance;*
5. *ledger row: the* NameCert *ledger records the carrier, classifier, stability, exactness, and dependency-boundary checks without storing a global localization functor, a quotient homotopy category, or a choice of representatives.*

These obligations define only the BEDC-kernel naming surface for a displayed Bousfield-localization packet; they do not assert the existence theorem for a localization model structure.

Lean4 ✓ `BEDC.Derived.BousfieldLocalizationUp.BousfieldLocalizationFinitePacket semantic name certificate`
Lean4 ✓ `BEDC.Derived.BousfieldLocalizationUp.BousfieldLocalizationFiniteLocalizingPacket namecert obligations`

Proof. Read the carrier from Definition 325.1. Its six coordinates list exactly the finite rows a Bousfield-localization consumer can inspect: a model-category row, a selected class of maps, fibrant-local-object rows, classifier transport, package provenance, and the local certificate ledger.

The classifier and stability obligations are componentwise. Transporting an accepted packet along the displayed hsame witnesses replaces representatives only inside the visible rows, and the Cont routes in T keep the reads inside the named $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, and $\mathsf{Functor}^{\uparrow}$ boundaries.

Exactness is then a projection statement. A consumer obtains a local-object test, an inverted-map read, or a fibrant-row readback only from the recorded rows or from the finite provenance named by P and N.

No coordinate stores a localization functor, a host quotient category, a derived mapping object, or a representative choice. Those classical outputs therefore remain outside the seed surface. □

Theorem 325.3 (BousfieldLocalization local-object handoff)**.** *Every downstream homotopy consumer of an accepted* $\mathsf{BousfieldLocalization}^{\uparrow}$ *packet may read only the certified fibrant-local-object rows in L, the selected maps in S as inverted-map rows through the displayed model-category ledger M, and the finite* hsame, Cont, Pkg, *and* NameCert *provenance recorded in T, P, and N.*

The handoff exports no unlicensed quotient localization, no homotopy-category object outside the displayed rows, no global functorial localization, and no choice of representatives for local equivalence classes.

Lean4 ✓ BEDC.Derived.BousfieldLocalizationUp.BousfieldLocalizationPacket local object handoff

Proof. Project the accepted packet $B = (M, S, L, T, P, N)$. The local-object data are exactly the finite rows in L, and the inverted-map data are exactly the selected arrows in S interpreted through the displayed model-category ledger M.

Transport and readback use only the visible continuation ledger and provenance rows. The hsame witnesses and Cont routes in T carry the selected-map and local-object rows componentwise, while P and N name the dependency certificates and the finite readback surface.

It remains to check that nothing else is exported. Since the tuple contains no quotient-localization coordinate, no homotopy-category object coordinate, no global localization functor, and no representative-choice row, the consumer boundary is exhausted by the certified local-object and inverted-map rows. □

Theorem 325.4 (BousfieldLocalization empty selected-map boundary)**.** *Let $B = (M, S, L, T, P, N)$ be an accepted* BousfieldLocalization$^{\uparrow}$ *carrier in the sense of Definition 325.1. If the selected morphism-class row S is empty, then no downstream consumer has an inverted-map row to read from B. The remaining certified handoff surface is confined to the displayed model-category row M, the fibrant-local-object rows L, the classifier-transport ledger T, the* Pkg *provenance row P, and the* NameCert *ledger N.*

Proof. By Definition 325.1, the only coordinate of B whose entries are maps read as inverted by the localizing certificate is the selected morphism-class row S. The local-object rows in L record fibrant objects and their mapping-test rows, while M, T, P, and N record the model-category ledger, transport routes, package provenance, and certificate ledger. None of those five coordinates is a second selected morphism-class row.

Now assume that S is empty. If a downstream consumer had an inverted-map row to read, then Definition 325.3 would force that read to be one of the selected maps in S, interpreted through the displayed model-category ledger M. Since S has no displayed arrow entry, there is no such selected map. Hence every inverted-map consumer read is absent.

It remains only to identify what the consumer may still inspect. The exactness row in Definition 325.2 allows consumer reads only from the recorded rows of the packet or from their finite named provenance. After the empty row S contributes no inverted-map read, the visible nonempty handoff coordinates are exactly the possible reads from M, L, T, P, and N. This also preserves the exclusions in Definition 325.3: no quotient localization, homotopy-category object outside the displayed rows, global functorial localization, or representative-choice row is exported. □

Lean4 ✓ BEDC.Derived.BousfieldLocalizationUp.BousfieldLocalizationEmptySelectedMap boundary

Theorem 325.5 (BousfieldLocalization two-stage local-object readback)**.** *Let $B = (M, S, L, T, P, N)$ be an accepted* BousfieldLocalization$^{\uparrow}$ *carrier. Every downstream local-object test read obtained after choosing a selected map row in S and a fibrant-local-object row in L factors first through the displayed model-category row M and then through the transport and provenance rows T, P, and N.*

The readback exports no homotopy-category quotient, localization functor, derived mapping object, local-equivalence representative choice, or row outside the finite packet B.

Proof. Project B through Definition 325.1. The selected map rows live only in S, the fibrant-local-object rows live only in L, and both are typed against the displayed model-category coordinate M.

Apply the exactness row in Definition 325.2. A consumer read after selecting one row from S and one row from L must be a read from M, S, L, T, P, N or from their finite named provenance.

Use Definition 325.3 to order that readback. The selected map is interpreted through M, the fibrant-local-object test is read through L, and the allowed transport and naming data are exactly the hsame, Cont, Pkg, and NameCert rows recorded in T, P, and N.

In the degenerate selected-map case, Definition 325.4 removes the first-stage selected-map read. The remaining local-object reads still pass through M, L, T, P, and N, so no quotient, global localization functor, derived mapping object, or representative-choice row is exported. □

Theorem 325.6 (BousfieldLocalization scoped kernel boundary)**.** *For any accepted* BousfieldLocalization$^{\uparrow}$ *packet in the sense of Definition 325.1, every selected morphism-class row, fibrant-local-object row, classifier transport row, exact readback row, ledger-boundary row, and local-object handoff row factors through the displayed* ModelCat$^{\uparrow}$*,* Cat$^{\uparrow}$*,* Functor$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows listed in Definition 325.2.*

The scoped boundary exports no localized model structure, no global functorial localization, no homotopy-category quotient, no derived mapping object, and no representative choice.

Proof. Project the accepted packet $B = (M, S, L, T, P, N)$ through Definition 325.1. The selected morphism-class rows are exactly the entries of S, the fibrant-local-object rows are exactly the entries of L, and their model-category typing passes through the displayed row M.

Apply the five clauses of Definition 325.2. The carrier clause identifies the BHist packet; the classifier clause restricts comparison to componentwise hsame; the stability clause keeps transported packets inside the same displayed coordinates; the exactness clause confines consumer reads to M, S, L, T, P, N and their finite provenance; and the ledger clause records the certificate boundary without adding an external localization object.

Use Definition 325.3 and Definition 325.5 for the consumer-facing rows. They route selected maps, fibrant-local-object tests, and two-stage readbacks through M, S, L, T, P, and N, so each displayed handoff row factors through the same ModelCat$^{\uparrow}$, Cat$^{\uparrow}$, Functor$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert boundary.

The excluded objects would require coordinates not present in the carrier or ledger. There is no localized model-structure coordinate, no global localization-functor coordinate, no homotopy-category quotient coordinate, no derived mapping-object coordinate, and no representative-choice coordinate, so the scoped boundary exports none of them. □

Theorem 325.7 (BousfieldLocalization public export)**.** *The public* BousfieldLocalization$^{\uparrow}$ *export is exactly the finite packet rows* (M, S, L, T, P, N) *of Definition 325.1, routed through the scoped kernel boundary of Definition 325.6. A public consumer may read selected-map rows, fibrant-local-object rows, classifier transport by* hsame *and* Cont*,* Pkg *provenance, and the* NameCert *ledger, and no other coordinate is part of the exported object.*

The export does not include localized model structures, global localization functors, homotopy-category quotients, derived mapping objects, or representative choice.

Proof. Start with the carrier of Definition 325.1. The six coordinates name the only displayed rows available to the packet: model-category data, selected maps, fibrant-local-object reads, classifier transport, provenance, and the certificate ledger.

Apply Definition 325.2 to identify the carrier, classifier, stability, exactness, and ledger obligations on those same coordinates. Then use Definition 325.3 and Definition 325.5 to route the selected-map and fibrant-local-object reads through the displayed M, S, L, T, P, N rows.

Finally invoke Definition 325.6. It packages the finite rows as the scoped consumer boundary, so the public export is the same boundary viewed as the citable $\mathsf{BousfieldLocalization}^{\uparrow}$ object. Since the carrier has no coordinate for a localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice, none of those data can be exported. □

Theorem 325.8 (BousfieldLocalization bridge boundary)**.** *For an accepted finite public packet*

$$B = (M, S, L, T, P, N)$$

of Definition 325.1, the public export of Definition 325.7 determines the bridge boundary for $\mathsf{BousfieldLocalization}^{\uparrow}$ *by routing selected-map rows, fibrant-local-object rows, classifier transport, provenance, and* $\mathsf{NameCert}$ *rows through the displayed* $\mathsf{ModelCat}^{\uparrow}$*,* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *surfaces named by the packet.*

The bridge boundary exports no localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice.

Proof. Project the carrier $B = (M, S, L, T, P, N)$. The six coordinates give the model category row, selected-map row, fibrant-local-object row, classifier-transport ledger, package provenance, and certificate ledger used by the public packet.

Invoke Definition 325.2 to identify the carrier, classifier, stability, exactness, and ledger clauses. The selected-map and fibrant-local-object rows are therefore read only as displayed BHist data typed through the $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, and $\mathsf{Functor}^{\uparrow}$ dependency surfaces.

Use Definition 325.6 to pass from the local rows to the scoped kernel boundary, and then use Definition 325.3 together with Definition 325.5 for the consumer readback. These rows route classifier transport through hsame and Cont, and route provenance through Pkg and $\mathsf{NameCert}$.

Finally apply Definition 325.7. The public object is the same finite packet viewed as a consumer-facing boundary. Since the carrier has no coordinate for a localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice, no such datum can appear in the bridge boundary. □

Theorem 325.9 (BousfieldLocalization displayed packet bridge exactness)**.** *For an accepted* $\mathsf{BousfieldLocalization}^{\uparrow}$ *packet*

$$B = (M, S, L, T, P, N),$$

the displayed bridge boundary is exact exactly when every consumer read factors through the selected-map row S*, fibrant-local-object row* L*, model-category row* M*, classifier-transport row* T*, package row* P*, and* $\mathsf{NameCert}$ *row* N*. Equivalently, the bridge exports precisely those six packet rows as the finite localizing boundary and exports no localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice.*

Proof. For exactness to consumer factorization, apply Definition 325.2. It identifies the accepted packet carrier, componentwise classifier, stability rows, exact readback rows, and ledger coordinates over M, S, L, T, P, and N.

Use Definition 325.3 and Definition 325.5 to route the local-object reads through the selected-map row, fibrant-local-object row, and classifier-transport ledger. The readback route therefore factors through the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surfaces named by the packet.

For consumer factorization to exactness, apply Definition 325.6 and Definition 325.7. A consumer read that factors through exactly the six displayed rows is the same scoped finite packet viewed as the public $\mathsf{BousfieldLocalization}^{\uparrow}$ boundary.

Finally invoke Definition 325.8. Its bridge boundary is precisely the finite packet over M, S, L, T, P, and N. Since none of those rows contains a localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice, the displayed bridge packet is exact with exactly the advertised exclusions. □

Theorem 325.10 (BousfieldLocalization mature finite localizing-packet consumer catalogue)**.** *For every accepted* $\mathsf{BousfieldLocalization}^{\uparrow}$ *packet*

$$B = (M, S, L, T, P, N),$$

every mature consumer read is one of the following five displayed rows:

1. *selected-map rows from S typed through the model-category row M;*
2. *fibrant-local-object test rows from L;*
3. *two-stage local-object readbacks through the classifier-transport ledger T;*
4. *dependency provenance through the package row P;*
5. *certificate and finite-ledger rows through N.*

The catalogue exports no localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice.

Proof. Project the accepted carrier through Definition 325.1. The coordinates M, S, L, T, P, and N are the only rows a consumer can inspect.

Use Definition 325.3 for the selected maps and fibrant-local-object tests, and use Definition 325.5 for the two-stage readbacks through T. These theorems place all localizing reads in the displayed M, S, L, and T rows.

Next apply Definition 325.6 and Definition 325.7. They identify the remaining dependency and certificate reads with the displayed Pkg row P and $\mathsf{NameCert}$ ledger N.

Finally invoke Definition 325.8. The bridge boundary is the same finite packet viewed as a consumer surface, so every mature read is exhausted by the five listed rows. Since the carrier has no coordinate for a localized model structure, global localization functor, homotopy-category quotient, derived mapping object, or representative choice, none of those objects is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{BousfieldLocalization}^{\uparrow}}$**.**

Constructive story: A Bousfield-localization packet is generated by a displayed $\mathsf{ModelCat}^{\uparrow}$ row, a selected morphism-class row, fibrant-local-object rows, classifier transport by hsame and Cont, Pkg provenance, and a NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{BousfieldLocalization}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridge boundary binds the finite carrier, componentwise classifier, stability, exact readback, ledger boundary, local-object handoff rows, scoped kernel boundary, public export, finite packet bridge, and the mature consumer boundary of Definition 325.10 over $\mathsf{ModelCat}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{BousfieldLocalization}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.BousfieldLocalizationUp.BousfieldLocalizationEmptySelectedMap\_boundary`

Bridge status: none

Origin: human

Not claimed: This chapter does not close the existence of a localized model structure, global functorial localization, homotopy-category quotients, derived mapping objects, or representative choices.

Upgrade path: No further paper theory-axis step is claimed; Lean formalization of the displayed bridge and mature catalogue remains separate.

Chapter 326

A Concrete Naming Certificate for $\mathsf{OptimalTransport}^{\uparrow}$

The $\mathsf{OptimalTransport}^{\uparrow}$ interface names the finite-support transport surface used by the classical optimal-transport presentation of Villani 2009. The BEDC chapter below restricts that surface to displayed finite source and target distribution rows, a finite cost ledger, a finite coupling table, and a linear-programming dual certificate; it does not import measure completion, arbitrary-measure minimizers, quotient spaces, or infinite Kantorovich duality.

The finite coupling carrier consumes the mass rows of chapter 186, the metric-backed cost rows of chapter 57, the feasible-region rows of chapter 208 and chapter 209, and the finite dual rows of chapter 235.

326.1 Finite-support transport packets

Definition 326.1 (OptimalTransport finite coupling carrier)**.** *An* $\mathsf{OptimalTransport}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (X, Y, \mu, \nu, C, \Gamma, M, S, L)$$

with the following visible rows:

1. *X and Y are finite support ledgers whose entries are carried by displayed source certificates;*
2. *μ and ν are* $\mathsf{Distribution}^{\uparrow}$ *rows on those supports, with finite mass entries and displayed summation ledgers;*
3. *C is either a displayed cost table row or a cost row read through* $\mathsf{Met}^{\uparrow}$ *on the paired support entries;*
4. *Γ is a finite nonnegative coupling table indexed by the displayed support pairs;*
5. *M is the pair of marginal-sum ledgers asserting that row sums of Γ read as μ and column sums read as ν;*
6. *S is the cost-summation ledger for the displayed finite sum of $C(x, y)\Gamma(x, y)$ over the support pairs;*
7. *L is the* Pkg *provenance tying the support, distribution, cost, coupling, marginal, convex, polytope, and dual rows to the cited source certificates.*

The classifier compares two accepted packets componentwise by hsame *on support entries, distribution masses, cost entries, coupling entries, marginal ledgers, cost ledgers,* ConvexSet$^{\uparrow}$ *and* Polytope$^{\uparrow}$ *feasible-region rows, and* LPDuality$^{\uparrow}$ *dual rows. No coordinate stores a host probability space, a completed measure, a quotient of couplings, or a selected optimizer over arbitrary measures.*

Lean4 (definition) `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingCarrier`

Theorem 326.2 (OptimalTransport coupling marginal ledger)**.** *For an accepted carrier* $T = (X, Y, \mu, \nu, C, \Gamma, M, S, L)$*, every marginal claim read by an* OptimalTransport$^{\uparrow}$ *consumer is a projection of the finite ledger* M*. The source marginal at a support row* x *is the displayed finite sum of* $\Gamma(x, y)$ *over entries* y *of* Y*, and the target marginal at a support row* y *is the displayed finite sum of* $\Gamma(x, y)$ *over entries* x *of* X*. These two families of displayed sums are the only marginal data exported by the carrier.*

The ledger exports no sigma-additivity statement, no completion of μ *or* ν*, and no selection principle for couplings outside the displayed finite support.*

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket marginal ledger`

Proof. Project the carrier of Definition 326.1. The only coordinates that mention marginals are the finite distribution rows μ, ν, the coupling table Γ, and the marginal ledger M.

For a source support entry x, read the row of Γ indexed by x and the finite summation row in M attached to that row. This gives the displayed equality between the row sum and the corresponding μ entry. The target case is identical after projecting the column summation row attached to y.

Since the proof uses only finite table projections and the displayed summation rows, there is no operation that can create an ambient measure, complete a sigma algebra, or search over couplings that are not already present in the packet. □

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingCarrier marginal ledger`

Theorem 326.3 (OptimalTransport cost summation ledger)**.** *For an accepted* OptimalTransport$^{\uparrow}$ *carrier, the transport cost exposed to a consumer is exactly the finite ledger* S *summing the displayed pair costs against the displayed coupling entries. If the cost row is read through* Met$^{\uparrow}$*, then each summand uses only the metric-distance row named for that support pair; if the cost row is displayed directly, then each summand uses only that table entry.*

The cost surface contains no integral over a completed product measure, no measurable-selection argument, and no comparison against an unlisted transport plan.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingCarrier cost summation ledger`

Proof. Read the cost coordinate C, the coupling table Γ, and the cost ledger S. The carrier has no other coordinate from which a scalar cost can be computed.

If C is metric-backed, each summand is obtained by the displayed Met$^{\uparrow}$ row for its support pair. If C is table-backed, each summand is the visible table entry. In both cases the finite summation ledger S records the multiplication by the corresponding coupling entry and the finite accumulation over support pairs.

Thus the exported cost is a repacking of listed rows. Product measures, measurable functions, and unlisted transport plans are not available to the projection. □

Theorem 326.4 (OptimalTransport LP-duality feasible surface)**.** *The feasible surface of an accepted* $\mathsf{OptimalTransport}^{\uparrow}$ *packet is the finite polytope determined by the nonnegativity rows for* Γ*, the two marginal ledgers of Definition 326.2, and the displayed cost objective of Definition 326.3. A dual-feasibility certificate is an* $\mathsf{LPDuality}^{\uparrow}$ *row whose inequalities are indexed only by the displayed support pairs and whose objective rows read only the displayed* μ *and* ν *masses.*

The theorem names the finite linear-programming surface only; it does not assert infinite-dimensional Kantorovich duality, analytic compactness, or existence of minimizers outside the displayed polytope.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingCarrier lpduality feasible surface`

Proof. Build the primal feasible region from the coordinates of the carrier. Nonnegativity of the table entries gives the half-space rows, and the marginal ledgers give the equality rows. These rows form the finite $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{Polytope}^{\uparrow}$ surface for the coupling table.

The objective is the finite cost ledger from Definition 326.3. A dual certificate is then read as an $\mathsf{LPDuality}^{\uparrow}$ packet over the same finite index set: one dual potential row for each displayed source or target support entry and one inequality row for each displayed support pair.

Because every primal and dual constraint is indexed by a listed support entry, the surface remains a finite linear program. Nothing in the construction invokes topological compactness, arbitrary-measure duality, or a minimizer-selection principle. □

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket lpduality feasible surface`

Theorem 326.5 (OptimalTransport finite-support dual-certificate exhaustion)**.** *Every* $\mathsf{OptimalTransport}^{\uparrow}$ *dual certificate read by a consumer is indexed only by the displayed source support rows, target support rows, visible mass rows, and cost inequalities of the finite LP surface of Definition 326.4. Conversely, each listed dual row is read through the finite coupling carrier of Definition 326.1.*

The certificate surface is exhausted by those finite support rows. It contains no sigma-additivity principle, arbitrary-measure minimizer, or infinite-dimensional Kantorovich duality datum.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket dual certificate exhaustion`

Proof. Project the finite coupling carrier. Its visible coordinates are the source and target support rows, the two finite distribution rows, the cost row, the coupling table, the marginal ledgers, the objective ledger, the feasible-region rows, the dual-certificate rows, and the Pkg provenance.

Use Definition 326.2 to identify the only consumer-readable mass constraints. Use Definition 326.3 to identify the only cost summation rows over the displayed coupling table.

Apply Definition 326.4. That theorem places each dual potential and each dual inequality over the same finite source and target supports and over the same displayed cost inequalities. Hence every dual certificate read by a consumer factors through the finite carrier rows, and every listed dual row is read back through that carrier.

No coordinate of the carrier stores a sigma-additive measure space, an arbitrary-measure optimizer, or an infinite-dimensional Kantorovich dual principle. The displayed finite LP rows therefore exhaust the dual-certificate surface. □

Theorem 326.6 (OptimalTransport NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{OptimalTransport}^{\uparrow}}$ *seed surface consists of the following finite rows:*

1. *carrier: the* BHist *packet of Definition 326.1;*
2. *classifier: componentwise* hsame *on support, distribution, cost, coupling, marginal, cost-summation, feasible-region, and dual rows;*
3. *marginal ledger: the two finite summation families of Definition 326.2;*
4. *cost ledger: the finite objective row of Definition 326.3;*
5. *feasible and dual surface: the* ConvexSet$^{\uparrow}$, Polytope$^{\uparrow}$, *and* LPDuality$^{\uparrow}$ *rows of Definition 326.4.*

These rows are sufficient to name the finite-support optimal-transport certificate surface and deliberately exclude measure completion, arbitrary-measure optimizer selection, quotient spaces, and Kantorovich duality beyond the finite linear-programming boundary.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket semantic name certificate`
Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket namecert obligation surface`
Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportPacket semantic name certificate`

Proof. The carrier row fixes the finite support entries, source and target distributions, cost rows, coupling table, marginal ledgers, objective ledger, and provenance. These are precisely the coordinates available to an OptimalTransport$^{\uparrow}$ consumer.

The classifier is componentwise because each coordinate already lives in a displayed BEDC row. Transport along hsame repacks support entries, masses, costs, coupling entries, marginal sums, and dual inequalities without changing the finite index set named by the packet.

The two ledger theorems account for the only marginal and objective reads. The feasible-surface theorem accounts for the only convex, polytope, and dual rows. Since no remaining coordinate contains a completed measure, a quotient coupling, an infinite support, or a global optimizer, the five rows exhaust the local seed certificate. □

Theorem 326.7 (OptimalTransport public finite LP certificate)**.** *An accepted finite-support* OptimalTransport$^{\uparrow}$ *packet exports a public* NameCert$_{\text{OptimalTransport}^{\uparrow}}$ *finite linear-programming certificate consisting exactly of the displayed source and target support rows, the* Distribution$^{\uparrow}$ *mass rows, the cost table or* Met$^{\uparrow}$ *cost rows, the finite coupling table, the two marginal ledgers, the finite objective ledger, the* ConvexSet$^{\uparrow}$ *and* Polytope$^{\uparrow}$ *feasible-region rows, the* LPDuality$^{\uparrow}$ *dual rows, and componentwise* hsame, Cont, *and* Pkg *provenance.*

The certificate contains no measure completion, arbitrary-measure minimizer selection, quotient space, or infinite Kantorovich-duality datum.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingCarrier public finite lp semantic certificate`
Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket public finite lp certificate`

Proof. Read the accepted finite-support carrier of Definition 326.1. Its coordinates supply the source and target support rows, distribution masses, cost entries, coupling table, and package provenance.

Apply Definition 326.2 and Definition 326.3. These two ledgers account for the only marginal reads and the only finite objective read over the displayed coupling table.

Next apply Definition 326.4. It packages the same finite support-pair coordinates as a $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{Polytope}^{\uparrow}$ feasible region together with the $\mathsf{LPDuality}^{\uparrow}$ dual rows.

Finally apply Definition 326.6. The obligation theorem repacks the carrier, ledgers, feasible surface, classifier transport, continuation rows, and package provenance as the public $\mathsf{NameCert}_{\mathsf{OptimalTransport}^{\uparrow}}$ certificate. Since no projected coordinate names a completed measure, arbitrary-measure optimizer, quotient space, or infinite duality principle, those objects are absent from the exported finite linear-programming certificate. □

Theorem 326.8 (OptimalTransport obligation closure)**.** *The rows of Definition 326.1, Definition 326.2, Definition 326.3, Definition 326.4, and Definition 326.6 exhaust the* $\mathsf{NameCert}_{\mathsf{OptimalTransport}^{\uparrow}}$ *obligation set over finite support, distribution, cost, coupling, marginal, feasible-polytope, dual,* hsame*,* Cont*, and* Pkg *rows.*

No measure completion, infinite Kantorovich duality, quotient coupling space, or optimizer selection is part of the obligation surface.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket obligation closure`

Proof. Project the finite carrier first. Its coordinates list the source and target supports, distribution masses, cost row, coupling table, marginal ledger, cost-summation ledger, feasible-region data, dual certificate, and package provenance.

The marginal and cost reads are exactly the ledgers of Definition 326.2 and Definition 326.3. The feasible and dual reads are exactly the finite linear-programming rows of Definition 326.4.

The NameCert theorem repacks those projected rows as the local certificate surface. Since the packet exposes no completed measure, infinite duality principle, quotient coupling space, or optimizer-selection coordinate, there is no remaining row from which a further obligation could be read. □

Theorem 326.9 (OptimalTransport public export surface)**.** *The public* $\mathsf{OptimalTransport}^{\uparrow}$ *export consists exactly of the finite support rows, finite distribution rows, displayed cost row, coupling table, marginal ledgers, cost ledger, finite feasible polytope surface,* $\mathsf{LPDuality}^{\uparrow}$ *dual row,* hsame *classifier transport,* Cont *routes, and* Pkg *provenance named by Definition 326.1, Definition 326.2, Definition 326.3, Definition 326.4, Definition 326.6, Definition 326.7, and Definition 326.8.*

The public export contains no measure completion, arbitrary-measure minimizer selection, quotient coupling space, or infinite-dimensional Kantorovich duality.

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket public export surface`

Proof. Read the finite carrier of Definition 326.1. Its visible coordinates are the source and target supports, the two finite distribution rows, the cost row, the coupling table, the marginal ledgers, the cost ledger, and the package provenance.

Apply Definition 326.2 and Definition 326.3 to identify the only allowed marginal and objective reads. Then use Definition 326.4 to expose the finite polytope surface and the $\mathsf{LPDuality}^{\uparrow}$ dual row over the same displayed support pairs.

Finally apply Definition 326.6 and Definition 326.8. These results repackage the finite carrier, ledgers, classifier transport, Cont routes, and Pkg provenance as the whole certificate surface. Because the packet has no completed measure coordinate, arbitrary-measure optimizer coordinate, quotient coupling coordinate, or infinite-dimensional duality coordinate, those objects are not part of the public export. □

Theorem 326.10 (OptimalTransport finite-support bridge package)**.** *The public finite-support packet of Definition 326.9, its marginal ledger, cost ledger, finite feasible polytope, and* $\mathsf{LPDuality}^{\uparrow}$ *dual row assemble a bridge boundary from the displayed finite-support* $\mathsf{Distribution}^{\uparrow}$ *rows, the cost row or* $\mathsf{Met}^{\uparrow}$ *row, the* $\mathsf{ConvexSet}^{\uparrow}$ *feasible surface, the* $\mathsf{Polytope}^{\uparrow}$ *feasible-polytope rows, and the* $\mathsf{LPDuality}^{\uparrow}$ *dual-feasibility row to the public* $\mathsf{OptimalTransport}^{\uparrow}$ *export.*

This bridge package exports exactly those finite rows together with hsame *classifier transport,* Cont *routes, and* Pkg *provenance. It excludes measure completion, arbitrary-measure minimizer selection, quotient coupling spaces, infinite Kantorovich duality, optimizer-existence theorems, and arbitrary representative choice.*

Lean4 ✓ `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket finite support bridge package`

Proof. Start with the carrier of Definition 326.1. Its coordinates are the finite source and target support rows, the two finite distribution rows, the cost row, the coupling table, the marginal ledgers, the objective ledger, the finite feasible-region data, the dual certificate row, and the provenance row.

The marginal ledger of Definition 326.2 and the cost ledger of Definition 326.3 identify the only marginal and objective reads. The feasible surface of Definition 326.4 identifies the $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, and $\mathsf{LPDuality}^{\uparrow}$ rows over the same finite support.

Apply Definition 326.9. That theorem repackages the displayed carrier, ledgers, LP-duality feasible surface, classifier transport, continuation routes, and package provenance as the public finite-support transport export.

Repack exactly those displayed finite rows as the bridge package. Since the carrier has no coordinate for completed measures, arbitrary-measure minimizer selection, quotient coupling spaces, infinite Kantorovich duality, optimizer existence, or representative selection, those objects cannot cross the bridge. □

Theorem 326.11 (OptimalTransport mature consumer boundary)**.** *For the finite-support transport packet of Definition 326.1, any public consumer whose rows are the displayed marginals, finite cost table, feasible coupling table, LP-duality certificate, classifier transport,* Cont *route,* Pkg *provenance, and finite-support bridge reads exactly the finite-support* $\mathsf{OptimalTransport}^{\uparrow}$ *package assembled in this chapter.*

Such a consumer cannot read arbitrary-measure minimizers, quotient couplings, infinite Kantorovich duality, analytic compactness, or a standard bridge.

Proof. First project the finite-support carrier. It displays the source and target supports, finite $\mathsf{Distribution}^{\uparrow}$ rows, the cost row, the coupling table, the marginal ledgers, the finite objective ledger, the feasible-region rows, the dual certificate row, classifier transport, continuation, and provenance.

Apply Definition 326.2 and Definition 326.3. These two ledgers account for the displayed marginals and finite cost table, with no coordinate for an arbitrary-measure optimizer.

Next use Definition 326.4, Definition 326.6, and Definition 326.7. They bind the feasible coupling table, LP-duality certificate, classifier transport, Cont route, and Pkg provenance to the same finite packet.

Finally compose Definition 326.9 with Definition 326.10. The resulting consumer boundary is exactly the public finite-support $\mathsf{OptimalTransport}^{\uparrow}$ package assembled by the chapter. The chapter's excluded objects are absent from every cited row, so quotient couplings, infinite duality, analytic compactness, and a standard bridge remain outside the read. □

Theorem 326.12 (OptimalTransport mature finite-support coverage)**.** *Every consumer read of an accepted finite-support* $\mathsf{OptimalTransport}^{\uparrow}$ *bridge packet factors through the displayed source and target supports, the* $\mathsf{Distribution}^{\uparrow}$ *mass rows, the cost table or* $\mathsf{Met}^{\uparrow}$ *cost rows, the finite coupling table, the marginal ledgers, the finite objective ledger, the* $\mathsf{ConvexSet}^{\uparrow}$ *and* $\mathsf{Polytope}^{\uparrow}$ *feasible-region rows, the* $\mathsf{LPDuality}^{\uparrow}$ *dual rows, and the displayed* hsame*,* Cont*, and* Pkg *provenance.*

The coverage surface excludes measure completion, arbitrary-measure minimizer selection, quotient coupling spaces, infinite-dimensional Kantorovich duality, analytic compactness, and representative selection.

Proof. Start with the finite coupling carrier of Definition 326.1. It contains exactly the displayed supports, distribution mass rows, cost row, coupling table, finite feasible-region data, dual row, and provenance row.

Apply Definition 326.2 and Definition 326.3. These identify the only marginal and objective reads as finite ledger rows over the displayed support pairs.

Next use Definition 326.4. The feasible and dual readers are precisely the displayed $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, and $\mathsf{LPDuality}^{\uparrow}$ rows over the same finite table.

Finally apply Definition 326.9 and Definition 326.10. The public export and bridge boundary repackage the carrier, marginal, objective, feasible, dual, classifier-transport, continuation, and provenance rows as the consumer surface.

No remaining coordinate is present for completed measures, arbitrary-measure minimizer selection, quotient coupling spaces, infinite-dimensional Kantorovich duality, analytic compactness, or representative selection. Therefore every accepted finite-support consumer read factors through the displayed mature coverage inventory. □

Theorem 326.13 (OptimalTransport mature finite-support consumer catalogue)**.** *For every accepted finite-support* $\mathsf{OptimalTransport}^{\uparrow}$ *packet, every mature finite-support consumer read is exhausted by the displayed finite source and target support rows,* $\mathsf{Distribution}^{\uparrow}$ *mass rows, displayed cost or* $\mathsf{Met}^{\uparrow}$ *cost rows, coupling table rows, marginal ledgers, finite objective ledger,* $\mathsf{ConvexSet}^{\uparrow}$ *and* $\mathsf{Polytope}^{\uparrow}$ *feasible rows,* $\mathsf{LPDuality}^{\uparrow}$ *dual rows, and* hsame*,* Cont*, and* Pkg *provenance.*

The catalogue exports no measure completion, arbitrary-measure minimizer selection, quotient coupling space, infinite Kantorovich duality, optimizer-existence theorem, or representative choice.

Proof. Project the finite coupling carrier of Definition 326.1. Its coordinates list the displayed supports, mass rows, cost rows, coupling table, marginal ledgers, finite objective ledger, feasible rows, dual rows, and provenance.

Apply Definition 326.2 and Definition 326.3. These account for all marginal and objective reads as finite ledger projections over the displayed support pairs.

Use Definition 326.4 for the $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, and $\mathsf{LPDuality}^{\uparrow}$ consumer rows. The feasible and dual reads are indexed only by the same finite support and coupling table.

Finally apply Definition 326.9 together with Definition 326.10. They repackage the carrier, ledger, feasible, dual, classifier-transport, continuation, and provenance rows as the public bridge surface. Since no coordinate stores completed measures, arbitrary-measure minimizers, quotient coupling spaces, infinite Kantorovich duality, optimizer-existence data, or representative choices, the catalogue exports none of those objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{OptimalTransport}^{\uparrow}}$.

Constructive story: An optimal-transport packet is generated from displayed finite source and target support rows, $\mathsf{Distribution}^{\uparrow}$ mass rows, a cost table or $\mathsf{Met}^{\uparrow}$ cost row, a finite coupling table, marginal summation ledgers, a finite objective ledger, $\mathsf{ConvexSet}^{\uparrow}$ and $\mathsf{Polytope}^{\uparrow}$ feasible-region rows, an $\mathsf{LPDuality}^{\uparrow}$ dual-feasibility row, and Pkg provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{OptimalTransport}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The bridge surface binds the finite-support carrier of Definition 326.1, the marginal ledger of Definition 326.2, the cost ledger of Definition 326.3, the finite dual-feasible surface of Definition 326.4, the NameCert obligation surface of Definition 326.6, the public finite linear-programming certificate of Definition 326.7, the obligation closure of Definition 326.8, the public export surface of Definition 326.9, and the finite-support bridge package of Definition 326.10 through BHist, hsame, Cont, Pkg, Distribution$^{\uparrow}$, Met$^{\uparrow}$, ConvexSet$^{\uparrow}$, Polytope$^{\uparrow}$, and LPDuality$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\mathsf{OptimalTransport}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.OptimalTransportUp.OptimalTransportFiniteCouplingPacket\_semantic\_name\_certificate`

Bridge status: none

Origin: human

Not claimed: This chapter does not close measure completion, arbitrary-measure minimizer selection, quotient spaces, infinite-dimensional Kantorovich duality, analytic compactness, or a standard bridge.

Upgrade path: The finite-support mature catalogue is present; the remaining progress is Lean formalization and any later standard bridge for the displayed marginal, cost, feasible-polytope, dual-feasibility, classifier-transport, continuation, and provenance readers.

Chapter 327

A Concrete Naming Certificate for $\mathsf{Semiring}^{\uparrow}$

The $\mathsf{Semiring}^{\uparrow}$ interface names the finite algebraic surface that combines an additive commutative-monoid presentation with a multiplicative presentation on the same displayed carrier. In the classical account of Golan, *Semirings and their Applications* (1999), the object supports addition, multiplication, distributivity, and zero annihilation. The BEDC packet below records only the finite carrier rows, classifier rows, law ledgers, continuation routes, package provenance, and local $\mathsf{NameCert}$ row needed to name that surface without importing a host algebra or quotient equality.

The multiplicative side of the $\mathsf{Semiring}^{\uparrow}$ packet consumes the unit and associativity surface already isolated by chapter 40. This chapter adds the additive surface, distributive ledger, and zero-annihilation rows consumed by $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, and $\mathsf{Mat}^{\uparrow}$ routes.

Definition 327.1 (Semiring finite-history source)**.** *A* $\mathsf{Semiring}^{\uparrow}$ *source is a finite* BHist *packet*

$$S = (A, M, Z, D, E, H, C, P, N)$$

with the following visible rows:

1. *A is an additive commutative-monoid surface over* $\mathsf{Add}^{\uparrow}$*, with the displayed carrier, zero row, addition row, associativity row, unit rows, and commutativity row named on the same finite carrier;*
2. *M is a multiplicative monoid surface over* $\mathsf{Mul}^{\uparrow}$ *when a unit row is present, and otherwise a multiplicative semigroup surface over* $\mathsf{Semigroup}^{\uparrow}$*;*
3. *Z is the shared-carrier and shared-classifier ledger saying that the additive and multiplicative rows classify exactly the same displayed carrier entries;*
4. *D records the left and right distributivity rows for multiplication over addition;*
5. *E records the left and right zero-annihilation rows;*
6. *H records the componentwise* hsame *transports for the carrier, additive surface, multiplicative surface, shared classifier, distributivity ledger, annihilation ledger, continuation routes, provenance, and local name;*
7. *C records the* Cont *routes that read addition, multiplication, distributivity, and annihilation comparisons from the same displayed carrier;*

8. *P is the* Pkg *provenance naming* $\mathsf{Add}^{\uparrow}$, $\mathsf{Mul}^{\uparrow}$, $\mathsf{Monoid}^{\uparrow}$, $\mathsf{Semigroup}^{\uparrow}$, *and* $\mathsf{Magma}^{\uparrow}$ *as the imported certificate boundaries;*

9. *N is the local* NameCert *row for the resulting finite semiring surface.*

The carrier predicate is $\mathsf{SemiringLedger}(A, M, Z, D, E, H, C, P, N)$. *Two accepted packets classify together only when all nine rows transport by the displayed* hsame *data and follow the same* Cont *routes named in P.*

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringTasteGate single carrier alignment`

Theorem 327.2 (Semiring additive and multiplicative obligation surface)**.** *Let $S = (A, M, Z, D, E, H, C, P, N)$ be an accepted* $\mathsf{Semiring}^{\uparrow}$ *source. The algebraic operation surface exported by S is exactly the additive commutative-monoid row A, the multiplicative monoid or semigroup row M, and the shared-carrier ledger Z. In particular, every downstream operation read is routed through the same displayed carrier and classifier, and no host ring, subtraction row, order row, completion datum, or quotient carrier is exported by the packet.*

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringLedger additive multiplicative obligation surface`

Proof. Project the carrier of Definition 327.1. The additive row A supplies the zero, addition, associativity, unit, and commutativity data, while the multiplicative row M supplies the multiplication and associativity data, with a unit row only when the monoid presentation is present.

The shared-carrier ledger Z is the only bridge between those two operation surfaces. It identifies the displayed carrier and classifier rows used by A and M, so every operation read factors through the same finite BHist source.

The remaining rows are law ledgers, transport routes, provenance, and local naming data. None of them contains subtraction, additive inverses, an order primitive, a completion witness, or a quotient carrier, so the stated surface is exhausted by A, M, and Z. □

Theorem 327.3 (Semiring distributive ledger boundary)**.** *For an accepted* $\mathsf{Semiring}^{\uparrow}$ *source $S = (A, M, Z, D, E, H, C, P, N)$, the distributivity information is exactly the finite ledger D. Its left and right rows compare the two displayed histories for $x \cdot (y + z)$ and $x \cdot y + x \cdot z$, and for $(x + y) \cdot z$ and $x \cdot z + y \cdot z$, using only the addition and multiplication routes named by C on the carrier shared by Z.*

Proof. Read D as a ledger over the carrier fixed by Z. Each row names a finite comparison between histories already produced by the displayed addition and multiplication operations.

For the left distributive row, follow the continuation routes in C from x, y, and z to the two histories $x \cdot (y + z)$ and $x \cdot y + x \cdot z$. The ledger records their displayed comparison by hsame.

For the right distributive row, use the same carrier and classifier routes to compare $(x + y) \cdot z$ with $x \cdot z + y \cdot z$. No additional operation table is introduced, so D is exactly the distributive boundary. □

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringDistributiveLedger boundary`

Theorem 327.4 (Semiring zero-annihilation scope)**.** *For an accepted* $\mathsf{Semiring}^{\uparrow}$ *source $S = (A, M, Z, D, E, H, C, P,$ the zero-annihilation information is exactly the ledger E. It contains the left and right rows identifying $0 \cdot x$ and $x \cdot 0$ with the additive zero row from A, routed through the multiplicative surface M and the shared carrier ledger Z.*

Proof. The additive zero used in the statement is the zero row of A. By Z, this row belongs to the same displayed carrier on which the multiplication row of M is typed.

The first row of E reads the multiplication route for $0 \cdot x$ and compares the result with the additive zero. The second row reads the route for $x \cdot 0$ and performs the same comparison.

No cancellation law, additive inverse, or order-theoretic positivity row is available in the packet. Therefore the annihilation scope is exactly the two finite rows named in E. □

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringZeroAnnihilationLedger scope`

Theorem 327.5 (Semiring NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Semiring}^\uparrow}$ *obligation surface consists of five finite rows:*

1. *carrier and classifier: the* BHist *packet* $S = (A, M, Z, D, E, H, C, P, N)$ *of Definition 327.1;*
2. *operation surface: the additive, multiplicative, and shared-carrier rows of Definition 327.2;*
3. *law ledgers: the distributivity rows of Definition 327.3 and the zero-annihilation rows of Definition 327.4;*
4. *stability and routing: the componentwise* hsame *transports in* H *and the* Cont *routes in* C*;*
5. *provenance: the* Pkg *row naming* $\mathsf{Add}^\uparrow$, $\mathsf{Mul}^\uparrow$, $\mathsf{Monoid}^\uparrow$, $\mathsf{Semigroup}^\uparrow$, *and* $\mathsf{Magma}^\uparrow$.

These rows form the public seed surface consumed by $\mathsf{Ring}^\uparrow$, $\mathsf{Module}^\uparrow$, $\mathsf{Poly}^\uparrow$, *and* $\mathsf{Mat}^\uparrow$ *chapters that need a named semiring obligation source.*

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringFiniteSource semantic name certificate`

Proof. The carrier and classifier row fixes every coordinate that can be named by the certificate. The operation surface theorem identifies the only addition, multiplication, and shared-carrier reads exported by the source.

The distributivity and zero-annihilation boundary theorems identify the only law ledgers available from the packet. The stability and routing rows say how those ledgers transport under displayed hsame and which finite continuations are used to read them.

Finally, the package row lists the imported BEDC certificate boundaries. Since the packet has no coordinate for subtraction, additive inverses, host algebra, quotient equality, or analytic completion, the five rows listed above exhaust the local $\mathsf{NameCert}_{\mathsf{Semiring}^\uparrow}$ obligation surface and give downstream chapters only the named finite semiring source. □

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringLedger namecert obligation surface`

Theorem 327.6 (Semiring concrete history instance)**.** *For any accepted packet* $S = (A, M, Z, D, E, H, C, P, N)$ *of Definition 327.1, the additive row, multiplicative row, shared-carrier ledger, distributivity ledger, zero-annihilation ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{Semiring}^\uparrow}$ *row constitute a concrete* BHist *semiring instance consumed by* $\mathsf{Ring}^\uparrow$, $\mathsf{Module}^\uparrow$, $\mathsf{Poly}^\uparrow$, *and* $\mathsf{Mat}^\uparrow$.

This instance exports no subtraction row, additive-inverse row, order primitive, quotient carrier, or host-algebra operation. Every downstream read passes through the finite displayed rows of the packet.

Proof. Project the coordinates $A, M, Z, D, E, H, C, P, N$ from the accepted Definition 327.1 packet. The additive, multiplicative, and shared-carrier rows are exactly the operation surface of Definition 327.2.

The distributivity rows are supplied by Definition 327.3, and the two zero-annihilation rows are supplied by Definition 327.4. These two ledgers give the only displayed law rows available to the semiring packet.

The hsame transports in H, the Cont routes in C, the Pkg provenance in P, and the local name row N are the remaining coordinates of Definition 327.5. Repacking these displayed coordinates yields the concrete BHist semiring instance read by $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, and $\mathsf{Mat}^{\uparrow}$.

Since no coordinate of S names subtraction, additive inverse, order, quotient-carrier equality, or host algebra, no downstream consumer can read such data from the instance. □

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringFiniteSource concrete history instance`

Theorem 327.7 (Semiring public finite-source export)**.** *The finite carrier, classifier, additive surface, multiplicative surface, distributive ledger, zero-annihilation ledger, transport routes, provenance, and local* $\mathsf{NameCert}_{\mathsf{Semiring}^{\uparrow}}$ *row of Definition 327.5 export exactly the public* $\mathsf{Semiring}^{\uparrow}$ *source surface available to* $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, *and* $\mathsf{Mat}^{\uparrow}$ *consumers.*

This public surface contains no additive inverses, quotient carriers, ordered semiring data, standard bridge, host algebra, or analytic completion datum. Every downstream read factors through the displayed BHist *rows of Definition 327.1.*

Proof. Project the source packet of Definition 327.1. Its nine rows give the finite carrier and classifier, the additive and multiplicative operation surfaces, the distributive and zero-annihilation ledgers, the componentwise hsame transports, the Cont routes, the Pkg provenance, and the local name row.

The operation surface is identified by Definition 327.2. The law boundary is identified by Definition 327.3 and Definition 327.4, so the available algebraic rows are exhausted by addition, multiplication, distributivity, zero annihilation, and the shared-carrier classifier.

Now apply Definition 327.5 and Definition 327.6. These statements repack exactly those displayed rows as the finite source consumed by $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, and $\mathsf{Mat}^{\uparrow}$.

No cited row contains additive inverses, quotient carriers, order data, a standard bridge, host algebra, or analytic completion. Hence the exported public surface is precisely the named finite semiring source and nothing beyond it. □

Theorem 327.8 (Semiring bridge finite-source downstream consumption)**.** *Let* $S = (A, M, Z, D, E, H, C, P, N)$ *be an accepted packet of Definition 327.1. The public finite-source export of Definition 327.7, together with the concrete history instance of Definition 327.6, assembles exactly the bridge boundary consumed by* $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, *and* $\mathsf{Mat}^{\uparrow}$.

That boundary consists only of the displayed additive row, multiplicative row, shared carrier and classifier ledger, distributivity ledger, zero-annihilation ledger, hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. It exports no additive inverses, quotient carrier, ordered semiring, standard model, or host algebra.*

Proof. Project the rows of the accepted packet S from Definition 327.1. The additive and multiplicative faces are the two operation rows; the shared carrier and classifier are carried by the same packet spine; the distributivity and zero-annihilation ledgers are the displayed law rows; and H, C, P, and N provide the transport, route, provenance, and naming coordinates.

Apply Definition 327.2, Definition 327.3, and Definition 327.4. These identify the operation and law rows available to any downstream algebra consumer.

Next apply Definition 327.5, Definition 327.6, and Definition 327.7. The first theorem exposes the local certificate obligations, the second repacks the displayed rows as the concrete BHist instance, and the third records the public finite-source export read by $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, and $\mathsf{Mat}^{\uparrow}$.

By row exhaustion, the bridge boundary has no additional coordinate from which an additive inverse, quotient carrier, order row, standard model, or host algebra could be read. Hence the downstream consumption boundary is exactly the finite semiring source displayed above. □

Lean4 ✓ `BEDC.Derived.SemiringUp.SemiringUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{Semiring}^{\uparrow}}$.

Constructive story: A semiring packet is generated by an additive commutative-monoid row, a multiplicative monoid or semigroup row, a shared carrier and classifier ledger, distributivity rows, zero-annihilation rows, hsame transports, Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Semiring}^{\uparrow}}$, publicClosed)

Scope closed: Definition 327.1, Definition 327.5, Definition 327.6, and Definition 327.7 bind the finite carrier, classifier, additive surface, multiplicative surface, distributive rows, zero-annihilation rows, transports, routes, provenance, and local name as the public $\mathsf{Semiring}^{\uparrow}$ source surface for $\mathsf{Ring}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$, and $\mathsf{Mat}^{\uparrow}$ consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Semiring}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SemiringUp.SemiringFiniteSource\_semantic\_name\_certificate`

Bridge status: none

Origin: human

Not claimed: This chapter does not close rings, modules, polynomial evaluation, matrix algebra, additive inverses, quotient carriers, ordered semirings, or a standard bridge.

Upgrade path: Bridged closure requires a standard-bridge boundary tying the public finite semiring source to downstream algebra consumers.

Chapter 328

A Concrete Naming Certificate for NestedDyadicInterval$^{\uparrow}$

The NestedDyadicInterval$^{\uparrow}$ interface names finite decreasing dyadic interval chains positioned between the public DyadicInterval$^{\uparrow}$ endpoint packet and the regular rational and real-name layers. Moore–Kearfott–Cloud interval analysis treats nested interval enclosures as standard constructive data; here the carrier is only a finite-window BEDC packet and carries no host completeness principle.

328.1 Finite decreasing dyadic chains

Definition 328.1 (NestedDyadicInterval finite-chain carrier)**.** *A* NestedDyadicInterval$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (I_0, \ldots, I_n, S, R, P, L)$$

with the following visible rows:

1. *each I_i is a* DyadicInterval$^{\uparrow}$ *endpoint packet with lower and upper* DyadicRatCore$^{\uparrow}$ *endpoint rows and its displayed interval-order ledger;*
2. *S is the unary* StreamName$^{\uparrow}$ *schedule naming the finite prefix that selects the displayed interval chain;*
3. *R is the nested-refinement ledger: for every displayed successor pair, R stores the* Cont *route and* hsame *rows witnessing that I_{i+1} refines inside I_i endpointwise;*
4. *P is the* Pkg *provenance naming the consumed* DyadicRatCore$^{\uparrow}$, DyadicInterval$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$ *certificate surfaces;*
5. *L is the ledger that hides only the unobserved tail beyond the displayed finite chain and records that every public read factors through the shown intervals, S, R, and P.*

The carrier predicate is NestedDyadicIntervalPacket(K)*. Its dependency list is exactly* DyadicRatCore$^{\uparrow}$, DyadicInterval$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

Theorem 328.2 (NestedDyadicInterval dyadic interval source route)**.** *Every accepted* NestedDyadicInterval$^{\uparrow}$ *carrier first consumes the displayed endpoint and order rows of chapter 306 and the dyadic endpoint ledger of chapter 291 before its nested-refinement ledger,* StreamName$^{\uparrow}$ *schedule,* RegSeqRat$^{\uparrow}$ *handoff, or* Real$^{\uparrow}$ *seal can be read.*

Thus downstream regular-rational and real-name consumers see nested-chain data only through those sibling source rows together with hsame*,* Cont*,* Pkg*, and* NameCert*. The route exports no completed intersection point, quotient interval, host real interval, hidden infinite tail, or completeness witness.*

Proof. Project the accepted carrier as $K = (I_0, \ldots, I_n, S, R, P, L)$ through Definition 328.1. The first carrier row says that each displayed I_i is already a $\mathsf{DyadicInterval}^{\uparrow}$ endpoint packet, with lower and upper $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows and the displayed interval-order ledger attached to that packet.

Read the provenance row P next. It is the source route that names the consumed $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{DyadicInterval}^{\uparrow}$ certificate surfaces before the nested-refinement ledger, schedule, regular-rational handoff, or real seal is exposed. Therefore a later read of R, S, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff, or the $\mathsf{Real}^{\uparrow}$ boundary can only replay the sibling dyadic rows already named by P.

The remaining public coordinates add only transport, containment, package, and naming evidence: hsame compares endpoint rows, Cont records adjacent containment, Pkg records provenance, and NameCert records the local certificate surface. None of these coordinates contains a completed intersection point, quotient interval, host real interval, hidden infinite tail, or completeness witness, so the downstream consumer receives exactly the displayed finite route claimed in the statement. □

Definition 328.3 (NestedDyadicInterval finite-window classifier)**.** *For accepted carriers* $K = (I_0, \ldots, I_n, S, R, P, L)$ *and* $K' = (I'_0, \ldots, I'_m, S', R', P', L')$*, the predicate* $\mathsf{NestedDyadicIntervalClassifier}(K, K')$ *says that every shared scheduled window transports endpointwise and that every common window has the same refined dyadic enclosure.*

Concretely, for each unary index requested by both S *and* S'*, the classifier supplies displayed* hsame *rows between the lower endpoints, displayed* hsame *rows between the upper endpoints, the matching* Cont *routes for the interval provenance, and equality of the nested-refinement ledger read on that common prefix. It does not quotient infinite chains and does not identify any completed intersection point.*

Theorem 328.4 (NestedDyadicInterval classifier laws)**.** *For accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *finite-chain carriers, the componentwise classifier on interval rows, dyadic endpoint rows, containment ledgers, scheduled window rows,* hsame*,* Cont*,* Pkg *provenance, and* NameCert *provenance is reflexive, symmetric, and transitive.*

Moreover, if a packet is related to an accepted carrier by this classifier and the displayed interval, endpoint, containment, window, route, package, and certificate rows transport through the classifier data, then the related packet is again an accepted $\mathsf{NestedDyadicInterval}^{\uparrow}$ *carrier.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalClassifier laws`

Proof. Project an accepted carrier $K = (I_0, \ldots, I_n, S, R, P, L)$ through Definition 328.1. Reflexivity is obtained rowwise from the displayed hsame reflexivity on each dyadic endpoint row, the identity Cont route on each containment ledger entry, and the unchanged schedule, provenance, and tail ledger.

For symmetry, reverse each displayed endpoint hsame row and read the common scheduled window in the opposite direction. The containment rows are not replaced by a completed interval object; they are the same finite ledger entries read through the reversed classifier comparison on the shared window.

For transitivity, compose the endpoint hsame rows and compose the displayed Cont routes in each adjacent refinement slot. The scheduled-window rows align by the common finite prefix, so the containment ledger and provenance rows compose component by component.

If a classifier-related packet is transported from an accepted carrier, the preceding rowwise transports rebuild the finite list of interval packets, the nested-refinement ledger, the schedule, the Pkg row, the NameCert provenance, and the hidden-tail ledger. Repacking these rows gives an accepted carrier. No completed real point, quotient interval object, open-cover compactness witness, or choice of an infinite tail is introduced. □

Theorem 328.5 (NestedDyadicInterval window transport)**.** *Let $K = (I_0, \ldots, I_n, S, R, P, L)$ be an accepted* NestedDyadicInterval$^{\uparrow}$ *carrier. If each displayed interval I_i is transported endpointwise through* hsame *rows and through the same* Cont *routes named by R and P, and if the transported schedule names the same unary finite prefix, then the transported packet is again an accepted* NestedDyadicInterval$^{\uparrow}$ *carrier.*

The transported classifier reads the same finite decreasing dyadic chain on every shared scheduled window.

Proof. Project the carrier of Definition 328.1. Each visible interval row is already a DyadicInterval$^{\uparrow}$ packet, so endpointwise transport supplies transported lower endpoint rows, transported upper endpoint rows, and the interval-order ledger attached to the same displayed slot.

Now transport the refinement ledger. For each adjacent pair, the Cont route and hsame rows in R say that the successor interval refines inside its predecessor. Applying the same routes after endpoint transport gives the corresponding adjacent refinement row for the transported chain.

Finally transport S, P, and L. The schedule still exposes the same unary finite prefix, the provenance still names the same source certificate boundaries, and the ledger still hides only the tail beyond the displayed chain. Repacking these finite rows yields the accepted transported carrier and the same classifier surface on common windows. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket window transport`

Theorem 328.6 (NestedDyadicInterval RegSeqRat handoff)**.** *An accepted* NestedDyadicInterval$^{\uparrow}$ *carrier hands a* RegSeqRat$^{\uparrow}$ *consumer only finite-window data: the unary* StreamName$^{\uparrow}$ *schedule, the displayed* DyadicInterval$^{\uparrow}$ *endpoint packets, the nested-refinement ledger connecting adjacent visible intervals, and the* Pkg *provenance that ties these rows to* DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$.

A regular rational consumer may read the midpoint, endpoint, or width information available in the displayed dyadic enclosures, but the handoff does not certify a completed limit, a Dedekind cut, a quotient interval, or a host real interval.

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket regseqrat handoff`

Proof. Read the packet through Definition 328.1. The only RegSeqRat$^{\uparrow}$-facing coordinates are the scheduled finite prefix S, the endpoint packets I_i, the refinement ledger R, and the source provenance P.

For each displayed index, the DyadicInterval$^{\uparrow}$ row exposes lower and upper DyadicRatCore$^{\uparrow}$ endpoints and its interval-order ledger. The adjacent rows of R show that later visible intervals refine earlier visible intervals, so a regular rational consumer receives explicit finite enclosures and their displayed nesting evidence.

The tail ledger L states that nothing beyond the finite chain is public. Therefore the handoff cannot supply regularity beyond the displayed window, cannot select an intersection point, and cannot seal a host real interval. □

Theorem 328.7 (NestedDyadicInterval NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the finite* BHist *packet* $K = (I_0, \ldots, I_n, S, R, P, L)$ *of Definition 328.1;*
2. *classifier: the finite-window endpoint and refinement classifier of Definition 328.3;*
3. *window stability: the endpointwise transport statement of Definition 328.5;*
4. *handoff: the* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *finite enclosure surface of Definition 328.6;*
5. *ledger exactness: the assertion that the hidden part of the name is only the unobserved tail beyond the displayed chain, while all public interval, schedule, refinement, provenance, and certificate reads are listed in the carrier.*

These rows are the full seed certificate surface for finite decreasing dyadic interval-chain names.

Proof. The carrier row fixes the visible source of every read: each interval is a $\mathsf{DyadicInterval}^{\uparrow}$ packet, the schedule is a $\mathsf{StreamName}^{\uparrow}$ prefix, and the provenance names exactly the dyadic rational, interval, stream, regular-rational, and real-name certificate surfaces.

The classifier row is the common-window comparison from Definition 328.3. It compares only displayed endpoints and displayed refinement ledgers, so it supplies the required stability relation without creating a quotient of chains.

Window stability is Definition 328.5. The handoff row is Definition 328.6. Ledger exactness follows from the coordinate L: every public read factors through $I_0, \ldots, I_n$, S, R, and P, while only the tail outside the finite chain is hidden. Thus the five rows exhaust the local naming obligation. □

Theorem 328.8 (NestedDyadicInterval singleton chain vacuity)**.** *Let* K *be an accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *carrier as in Definition 328.1. If the displayed interval chain of* K *has exactly one row, so that*

$$K = (I_0, S, R, P, L)$$

with no displayed interval I_i *for* $i > 0$*, then the nested-refinement ledger* R *has no successor-pair read. Consequently the public finite-window handoff of* K *is exactly the single* $\mathsf{DyadicInterval}^{\uparrow}$ *endpoint packet* I_0*, the unary* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*, the provenance row* P*, and the tail ledger* L*; there is no public adjacent-refinement datum to expose.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket singleton chain vacuity`

Proof. By Definition 328.1, the only entries recorded in the nested-refinement ledger R are the rows attached to displayed successor pairs I_{i+1} inside I_i. A carrier whose displayed chain consists only of I_0 has no displayed source index i for which both I_i and I_{i+1} occur in the chain. Hence the indexing set of successor-pair reads is empty, and every requested read of R over a displayed adjacent pair is vacuous.

The remaining public coordinates are read directly from the same carrier definition. The visible interval coordinate is the single endpoint packet I_0; the schedule coordinate is S; the provenance coordinate is P; and the ledger coordinate is L, which hides only the unobserved tail beyond the displayed finite chain and records that public reads factor through the shown data. Since R contributes no displayed successor-pair row in the singleton case, the handoff surface described in Definition 328.6 reduces exactly to I_0, S, P, and L together with the assertion that the adjacent-refinement component is empty. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket empty refinement source`

Theorem 328.9 (NestedDyadicInterval prefix truncation stability)**.** *Let $K = (I_0, \ldots, I_n, S, R, P, L)$ be an accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *carrier as in Definition 328.1. For any displayed prefix $I_0, \ldots, I_k$ with $k \leq n$, the restricted packet*

$$K_{\leq k} = (I_0, \ldots, I_k, S_{\leq k}, R_{\leq k}, P, L_{\leq k})$$

is again an accepted $\mathsf{NestedDyadicInterval}^{\uparrow}$ *carrier, where $S_{\leq k}$ requests only the prefix rows, $R_{\leq k}$ contains exactly the successor-pair rows with source index below k, and $L_{\leq k}$ hides the unrequested suffix together with the original tail. The classifier on $K_{\leq k}$ is the restriction of* $\mathsf{NestedDyadicIntervalClassifier}$ *to the displayed prefix window, and its* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff is the corresponding restriction of Definition 328.6.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket prefix truncation stability`

Proof. Project the accepted packet through Definition 328.1. The interval rows $I_0, \ldots, I_k$ are already displayed $\mathsf{DyadicInterval}^{\uparrow}$ endpoint packets, so no endpoint object is reconstructed.

Restrict the schedule to the unary prefix positions at most k. Restrict the refinement ledger by deleting only those successor rows whose source interval is outside the requested prefix; every remaining row still carries the same Cont, hsame, Pkg, and $\mathsf{NameCert}$ provenance as in K. The endpoint rows on the smaller window are the transported endpoint rows supplied by Definition 328.5.

Finally repack the shared provenance row P with the ledger $L_{\leq k}$ that records both the original hidden tail and the now-unrequested suffix $I_{k+1}, \ldots, I_n$. Since every public read of the truncated packet is a public read already admitted by K, the carrier predicate holds. The classifier and the $\mathsf{RegSeqRat}^{\uparrow}$ handoff are exactly the old classifier and handoff rows read on the smaller scheduled window; no completed point, quotient interval, hidden tail, or host real interval is introduced. □

Theorem 328.10 (NestedDyadicInterval adjacent refinement coverage)**.** *Let $K = (I_0, \ldots, I_n, S, R, P, L)$ be an accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *carrier. Every public read of the refinement ledger R is either empty when the displayed chain is the singleton chain, or is attached to a displayed adjacent pair I_{i+1} inside I_i for some $i < n$. In the nonempty case, the read exposes exactly the pair's* Cont *route, endpointwise* hsame *rows,* Pkg *source provenance, and* $\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$ *provenance recorded in the carrier.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket adjacent refinement coverage`

Proof. If the displayed chain has one interval row, Definition 328.8 says that there is no successor-pair index. Hence R contributes no public adjacent-refinement datum in that case.

Otherwise read R through Definition 328.1. The carrier definition assigns refinement-ledger rows only to displayed successor pairs, and each such row is indexed by a visible pair I_{i+1} inside I_i.

The same projection lists the row contents: the continuation route for the containment read, the endpointwise hsame witnesses, the package provenance naming the consumed dyadic-rational, interval, stream, regular-rational, and real-name certificate surfaces, and the local naming certificate provenance. There is no separate ledger coordinate from which a hidden refinement row could be read. □

Theorem 328.11 (NestedDyadicInterval RegSeqRat window exhaustion)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *packet can read only prefix-truncated endpoint packets, adjacent-refinement rows, the finite* $\mathsf{StreamName}^{\uparrow}$ *schedule, and source provenance from* $\mathsf{DyadicRatCore}^{\uparrow}$,

DyadicInterval$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *It cannot read a completed intersection point, a hidden infinite tail, a quotient interval, or a host-completeness witness from that packet.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket regseqrat window exhaustion`

Proof. Begin with the finite-window handoff of Definition 328.6. It identifies the consumer-facing coordinates as the schedule, the displayed endpoint packets, the adjacent refinement ledger, and the source provenance.

Apply Definition 328.9 to any scheduled finite window requested by the consumer. The requested endpoint data is therefore a prefix-truncated packet whose classifier is the restriction of the accepted packet classifier.

Apply Definition 328.10 to the ledger reads inside that prefix. Every refinement read is either empty in the singleton case or attached to a displayed adjacent pair with its recorded Cont, hsame, Pkg, and NameCert provenance.

The remaining coordinates are the finite StreamName$^{\uparrow}$ schedule and the same source provenance rows. Since the carrier ledger hides only unrequested suffix and tail data, no completed intersection point, hidden tail, quotient interval, or host-completeness witness can be projected by the regular rational consumer. □

Theorem 328.12 (NestedDyadicInterval finite prefix-induction derivation)**.** *For every accepted* NestedDyadicInterval$^{\uparrow}$ *packet and every displayed unary prefix length, induction on that prefix reconstructs exactly the endpoint rows, adjacent-refinement rows, containment ledger,* StreamName$^{\uparrow}$ *schedule,* RegSeqRat$^{\uparrow}$ *handoff,* Real$^{\uparrow}$ *seal,* hsame *transport,* Cont *replay,* Pkg *provenance, and* NameCert *row visible in the prefix.*

The derivation preserves the chapter's refusal of completed intersection points, quotient intervals, hidden infinite tails, selected limits, and host completeness. No induction step adds a row outside the displayed finite BHist *window.*

Proof. For the base prefix, project the first interval row from Definition 328.1. The singleton-chain vacuity theorem Definition 328.8 gives an empty adjacent-refinement surface, while the displayed schedule, provenance, transport, replay, and local naming rows are already part of the same packet.

For the induction step, append one displayed refinement row. Apply Definition 328.9 to keep the extended prefix inside the accepted classifier, and then use Definition 328.10 to identify the new adjacent pair with its containment ledger, Cont route, endpointwise hsame rows, Pkg provenance, and local NameCert provenance.

The RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ consumer boundary is then exhausted by Definition 328.11. It reads only prefix endpoint packets, adjacent-refinement rows, finite schedules, and source provenance, so the induction produces exactly the listed finite rows.

Finally apply ledger nonescape: the carrier ledger hides unrequested suffix and tail data rather than completing it. Hence the prefix induction cannot project a completed intersection point, quotient interval, hidden infinite tail, selected limit, or host-completeness witness. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket finite prefix induction derivation`

Theorem 328.13 (NestedDyadicInterval shared-prefix handoff)**.** *Let* $K = (I_0, \ldots, I_n, S, R, P, L)$ *and* $K' = (I'_0, \ldots, I'_{n'}, S', R', P', L')$ *be accepted* NestedDyadicInterval$^{\uparrow}$ *packets related by the finite-window classifier. If their schedules share a displayed unary prefix, then any* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer read on that prefix factors through the corresponding prefix-truncated endpoint packets,*

adjacent-refinement rows, hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *provenance on both sides.*

The handoff is determined by the displayed finite prefix alone. It does not export a completed intersection point, hidden infinite tail, quotient interval, host real interval, completeness witness, open-cover compactness datum, or standard bridge row.

Proof. Start with the classifier on K and K'. By Definition 328.5, a shared unary prefix transports only the displayed endpoint packets, schedules, refinement rows, and provenance coordinates.

Apply Definition 328.9 on both sides. The requested consumer window is therefore represented by prefix-truncated accepted packets, and the classifier restricts to the same displayed prefix rather than to an unobserved tail.

For each adjacent-refinement read inside the prefix, use Definition 328.10. The read is empty in the singleton case, or else attached to one displayed adjacent pair with its recorded Cont, hsame, Pkg, and NameCert rows.

Finally apply Definition 328.11. It exhausts the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer boundary by prefix endpoint packets, adjacent-refinement rows, finite schedules, and source provenance. Since the carrier ledger hides only data outside the displayed prefix, the shared-prefix read factors through the corresponding finite rows on both accepted packets. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket shared prefix handoff`

Theorem 328.14 (NestedDyadicInterval public NameCert export)**.** *The carrier of Definition 328.1, classifier of Definition 328.3, classifier laws, window transport,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, singleton-chain vacuity, prefix truncation stability, adjacent-refinement coverage, and* $\mathsf{RegSeqRat}^{\uparrow}$ *window exhaustion assemble the reusable public* $\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$ *export for finite decreasing dyadic chains.*

Every downstream read of this interface factors through displayed BHist *interval-chain rows, the unary* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicInterval}^{\uparrow}$ *endpoint packets,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *consumer boundary,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. It exports no completed intersection point, hidden infinite tail, quotient interval, host real interval, completeness witness, open-cover compactness, or standard bridge.*

Proof. Project an accepted packet through the finite carrier of Definition 328.1. This exposes exactly the displayed dyadic interval endpoint packets, the unary schedule, the nested-refinement ledger, source provenance, and the ledger that hides only data outside the displayed finite window.

Use the classifier and classifier laws of Definition 328.3 to compare two accepted packets only through componentwise displayed endpoint packets, schedules, refinement rows, and provenance. Then apply Definition 328.5 to carry those rows across the requested finite window.

For any requested consumer window, apply Definition 328.9. The requested read is a prefix-truncated accepted packet, and its classifier is the corresponding restriction of Definition 328.3.

For ledger reads inside that prefix, apply Definition 328.8 and Definition 328.10. In the singleton case the adjacent-refinement surface is empty; otherwise each visible refinement read is one displayed adjacent pair together with its Cont, hsame, Pkg, and NameCert rows.

Finally apply Definition 328.11. It identifies the full consumer surface as prefix endpoint packets, adjacent-refinement rows, finite schedules, and source provenance, so every $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ downstream read factors through the displayed finite BEDC rows and no excluded infinite or host-completeness datum is introduced. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket public finite window export`

Theorem 328.15 (NestedDyadicInterval standard finite-window bridge)**.** *A certified finite decreasing dyadic interval chain gives a standard bridge row for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers by exposing exactly its adjacent-refinement coverage, shared-prefix handoff,* $\mathsf{RegSeqRat}^{\uparrow}$ *window exhaustion, and public* $\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$ *export.*

The bridge claims no completeness principle, host real interval, Dedekind cut, open-cover compactness, quotient interval, hidden infinite tail, or selected limit.

Proof. Project the certified chain through Definition 328.10. Each visible ledger read is either the singleton empty surface or one adjacent refinement pair with its displayed Cont, hsame, Pkg, and NameCert rows.

Apply Definition 328.13. The requested consumer window is determined by the displayed finite prefix, so the handoff does not inspect an unobserved tail or any host interval coordinate.

Next use Definition 328.11. The $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer boundary is exhausted by prefix endpoint packets, adjacent-refinement rows, finite schedules, and source provenance.

Finally apply Definition 328.14. The public certificate repacks exactly those finite-chain rows as the standard finite-window bridge. Since the cited surfaces have no coordinates for completeness, host real intervals, Dedekind cuts, open-cover compactness, quotient intervals, hidden infinite tails, or selected limits, the bridge cannot claim them. □

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket standard bridge window`

Theorem 328.16 (NestedDyadicInterval successive refinement chain)**.** *Let* $I_0, \ldots, I_n$ *be a finite displayed chain of* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *entries whose adjacent pairs satisfy the displayed refinement rows. Then the adjacent rows compose into one accepted nested-dyadic-interval window over the same finite prefix,* BHist *ledger,* hsame *rows,* Cont *rows,* Pkg *provenance, and* NameCert *rows.*

The $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of the composed chain is exactly the shared-prefix handoff of that finite window. The composition does not select a limit, form a quotient interval object, or invoke a host completeness principle.*

Lean4 ✓ `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket successive refinement chain`

Proof. Begin with Definition 328.9. It restricts the displayed chain to the finite prefix inspected by the consumer and hides the unobserved tail.

Apply Definition 328.10 to each adjacent pair. Each step contributes only the displayed endpoint packets, refinement ledger, transport rows, package provenance, and local naming rows.

Use Definition 328.11 to exhaust the consumer boundary by the finite prefix and adjacent-refinement rows. This turns the list of adjacent steps into one accepted nested-dyadic-interval window.

Finally apply Definition 328.13 and Definition 328.14. The handoff is the shared-prefix handoff of the composed chain, and the public certificate reads only the same finite rows. Since the composed window has no coordinate for a selected limit, quotient interval, or host completeness principle, none is exported. □

Theorem 328.17 (NestedDyadicInterval refinement composition exhaustion)**.** *Let* $I_0, \ldots, I_n$ *be a finite displayed list of adjacent refinement rows composing a* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *window. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read and every* $\mathsf{Real}^{\uparrow}$ *consumer read of the composed window is exhausted by the displayed endpoint packets, the finite* $\mathsf{StreamName}^{\uparrow}$ *schedule, the adjacent* Cont *and* hsame *rows,* Pkg *provenance, and* NameCert *rows.*

Thus the composed refinement chain has no remaining consumer coordinate beyond the finite BEDC rows already displayed. It does not select a limit, form a quotient interval, invoke host completeness, read a hidden infinite tail, or use open-cover compactness.

Proof. Start with Definition 328.10. Each adjacent row contributes exactly its displayed endpoint packets, refinement ledger, Cont routes, hsame rows, Pkg provenance, and local NameCert rows.

Compose the adjacent rows with Definition 328.16. The finite list therefore becomes one accepted nested-dyadic-interval window over the same finite prefix and the same provenance rows.

Next apply Definition 328.11. This exhausts the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer boundary by the finite endpoint packets, finite schedule, adjacent refinement rows, and source provenance visible in the composed window.

Finally use Definition 328.13. The handoff identifies the consumer read with the shared finite prefix, so no selected limit, quotient interval, host-completeness witness, hidden infinite tail, or open-cover compactness datum is available to the composed chain. □

Theorem 328.18 (NestedDyadicInterval mature finite-window coverage)**.** *Every accepted* $\mathsf{NestedDyadicInterval}^{\uparrow}$ *finite-chain consumer read is exhausted by the carrier, classifier, window transport, adjacent-refinement coverage, shared-prefix handoff,* $\mathsf{RegSeqRat}^{\uparrow}$ *window exhaustion, public* NameCert *export, and standard finite-window bridge rows already present in this chapter.*

The coverage contains no completeness principle, Dedekind cut, quotient interval, open-cover compactness datum, host real interval, hidden infinite tail, or selected limit.

Proof. Project the read through Definition 328.1 and Definition 328.3. The consumer sees only the finite endpoint packets, displayed schedule, adjacent-refinement ledger, hsame rows, Cont rows, Pkg provenance, and local NameCert rows admitted by the carrier and classifier.

Apply Definition 328.5. The requested read is transported inside the same finite packet surface, so no host interval, quotient interval, or hidden tail coordinate is added by changing representatives.

Next use Definition 328.10 together with the shared-prefix handoff already used by the chapter. The adjacent rows and the prefix rows cover every finite-chain consumer request, including the singleton case and each displayed refinement step.

Finally apply Definition 328.14 and Definition 328.15. The public certificate and the standard finite-window bridge repack exactly those finite rows for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, leaving no coordinate for completeness, Dedekind cuts, quotient intervals, open-cover compactness, host real intervals, hidden infinite tails, or selected limits. □

Closure status for $\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$**.**

Constructive story: A nested dyadic interval packet is generated by a finite BHist chain of $\mathsf{DyadicInterval}^{\uparrow}$ endpoint packets, a unary $\mathsf{StreamName}^{\uparrow}$ schedule, a nested-refinement ledger using Cont and hsame, Pkg provenance for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicInterval}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and a ledger hiding only the unobserved tail.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 328.16, Definition 328.14, and Definition 328.15 bind the successive-refinement chain, finite-window export, standard finite-window bridge, BHist ledger, hsame, Cont, Pkg, and NameCert rows for $\mathsf{NestedDyadicInterval}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{NestedDyadicInterval}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.NestedDyadicIntervalUp.NestedDyadicIntervalPacket\_public\_finite\_window\_export`

Bridge status: none

Origin: human

Not claimed: This chapter does not claim completeness, Dedekind cuts, quotient intervals, open-cover compactness, host real intervals, hidden infinite tails, selected limits, or bridgeChecked status.

Upgrade path: Only Lean-side formal targets and bridge checking remain for this finite-window bridge boundary.

Chapter 329

A Concrete Naming Certificate for $\mathsf{StateSpaceModel}^{\uparrow}$

The $\mathsf{StateSpaceModel}^{\uparrow}$ interface records the finite state-transition packet shared by the control-facing certificates. Its BEDC surface consumes $\mathsf{NameCert}_{\mathsf{DynSystem}^{\uparrow}}$ for transition rows, $\mathsf{NameCert}_{\mathsf{Mat}^{\uparrow}}$ for displayed matrices, $\mathsf{NameCert}_{\mathsf{VecSpace}^{\uparrow}}$ for state, input, and output rows, and $\mathsf{NameCert}_{\mathsf{LinMap}^{\uparrow}}$ for the linear maps. The textbook reference point is Kailath, *Linear Systems* (1980).

The dependency anchors are $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, $\mathsf{ControlControllability}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, and $\mathsf{Riccati}^{\uparrow}$. The chapter names only the finite carrier consumed by those certificates, not a host trajectory space or an analytic realization theorem.

The transition row consumes the concrete dynamic-system certificate of chapter 195. The matrix rows consume chapter 49, and the state, input, and output carrier rows consume chapter 47. These are horizontal certificate dependencies of the displayed finite packet, not hidden analytic assumptions.

329.1 Finite state-transition carrier

Definition 329.1 (StateSpaceModel finite BHist carrier)**.** *A* $\mathsf{StateSpaceModel}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$(X, U, Y, A, B, C, P, L)$$

whose displayed rows are:

1. *a state row X, an input row U, and an output row Y read through* $\mathsf{VecSpace}^{\uparrow}$*;*
2. *a transition matrix row A, an input-map matrix row B, and an observation-map matrix row C read through* $\mathsf{Mat}^{\uparrow}$*;*
3. *linear-map rows for $A : X \to X$, $B : U \to X$, and $C : X \to Y$ read through* $\mathsf{LinMap}^{\uparrow}$*;*
4. *a displayed finite transition ledger $x, u \mapsto Ax + Bu$ and observation ledger $x \mapsto Cx$ read through* $\mathsf{DynSystem}^{\uparrow}$*;*
5. Cont *routes for the transition, input, observation, and readback rows;*
6. hsame *transports for the state, input, output, matrix, linear-map, transition, observation,* Cont*, and provenance rows;*
7. Pkg *provenance row P naming the consumed* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{LinMap}^{\uparrow}$ *certificates;*

8. a hidden-data ledger L recording that only the displayed rows are exported.

No host trajectory space, analytic semigroup, probability measure, infinite-horizon limit, external realization object, or unlogged state stream is a coordinate of the carrier.

Definition 329.2 (StateSpaceModel component classifier)**.** *The* $\mathsf{StateSpaceModel}^{\uparrow}$ *classifier compares two accepted packets componentwise. It compares the displayed state, input, and output traces through* $\mathsf{VecSpace}^{\uparrow}$*; the transition, input-map, and observation-map rows through* $\mathsf{Mat}^{\uparrow}$ *and* $\mathsf{LinMap}^{\uparrow}$*; the finite transition and observation ledgers through* $\mathsf{DynSystem}^{\uparrow}$*; and the provenance through the named* Cont*,* hsame*, and* Pkg *rows.*

Two packets are classified together exactly when all displayed trace rows and all displayed provenance rows are hsame*-matched in this componentwise sense. The classifier has no coordinate for comparing hidden trajectories, host probability spaces, analytic flow objects, or limiting behavior.*

329.2 Control handoff surface

Theorem 329.3 (StateSpaceModel NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{StateSpaceModel}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the finite packet of Definition 329.1;*
2. *classifier: the componentwise comparison of Definition 329.2;*
3. *transport:* hsame *transport of state, input, output, matrix, linear-map, transition, observation,* Cont*, and* Pkg *rows preserves accepted packets;*
4. *finite trace ledger: every visible transition or observation read is one of the displayed $Ax + Bu$ or Cx ledger rows;*
5. *hidden-data ledger: the packet records that host trajectories, analytic realizations, stochastic data, and infinite-horizon objects are outside the exported carrier.*

Lean4 ✓ `BEDC.Derived.StateSpaceModelUp.StateSpaceModelPacket semantic name certificate`

Proof. Start with the carrier rows. They enumerate exactly the finite state, input, output, matrix, linear-map, transition, observation, continuation, transport, provenance, and hidden-ledger coordinates.

The classifier row is the componentwise comparison of those coordinates. Transport replaces each displayed coordinate by its hsame match and then repacks the same finite tuple, so accepted packets remain accepted.

The trace ledger rows are projections from the displayed transition and observation entries. Since the hidden-data ledger is also a coordinate of the packet, every consumer can see the boundary saying that the excluded host and limiting objects are not part of the exported surface. □

Lean4 ✓ `BEDC.Derived.StateSpaceModelUp.StateSpaceModelPacket namecert obligation surface`

Theorem 329.4 (StateSpaceModel control handoff)**.** *The control-facing certificates* $\mathsf{KalmanFilter}^{\uparrow}$*,* $\mathsf{LQR}^{\uparrow}$*,* $\mathsf{ControlObservability}^{\uparrow}$*,* $\mathsf{ControlControllability}^{\uparrow}$*, and* $\mathsf{Riccati}^{\uparrow}$ *may consume a* $\mathsf{StateSpaceModel}^{\uparrow}$ *packet only through the displayed finite state, input, output, transition, input-map, observation-map, trace-ledger,* hsame*,* Cont*, and* Pkg *rows of Definition 329.1. A downstream control certificate cannot demand an unlogged trajectory space, analytic flow, stochastic model, or limiting algebraic object from this handoff.*

Lean4 ✓ `BEDC.Derived.StateSpaceModelUp.StateSpaceModelPacket control handoff transport`

Proof. Read a downstream control request as a projection from the accepted carrier. The Kalman and Riccati consumers can project matrix, vector, covariance-facing, transition, and observation rows; the LQR consumer can project state, input, cost-adjacent transition, and horizon-facing rows; and the observability and controllability consumers can project the displayed C and B faces together with the transition row A.

All of these projections are among the finite rows named in Definition 329.1. The classifier of Definition 329.2 transports the same rows componentwise, so the handoff remains stable under representative change.

The excluded objects are not packet coordinates. Therefore no listed control-facing certificate can recover them from the $\mathsf{StateSpaceModel}^{\uparrow}$ handoff alone. □

Theorem 329.5 (StateSpaceModel ledger boundary)**.** *The* $\mathsf{StateSpaceModel}^{\uparrow}$ *ledger excludes host trajectory spaces, analytic semigroup objects, probability measures, and infinite-horizon limits. Every consumer-visible read factors through the displayed finite* BHist *rows for* X, U, Y, A, B, C, *finite transition and observation traces,* hsame *transport,* Cont *routing, and* Pkg *provenance.*

Proof. Project the accepted packet to its visible rows. The carrier lists state, input, output, matrix, linear-map, transition, observation, transport, continuation, provenance, and hidden-ledger entries, and no additional coordinate is available.

The hidden-data ledger states the exclusion boundary. A host trajectory space, analytic semigroup, probability measure, or infinite-horizon limit would require an additional coordinate or a separate certificate, so it cannot be read from this packet.

Thus every consumer-visible read is a finite BHist projection from the displayed state-space rows. □

Theorem 329.6 (StateSpaceModel obligation closure)**.** *Definition 329.1, Definition 329.2, Definition 329.3, Definition 329.4, and Definition 329.5 exhaust the finite* $\mathsf{NameCert}_{\mathsf{StateSpaceModel}^{\uparrow}}$ *obligation surface over* $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, Cont, hsame, *and* Pkg *rows.*

Every downstream control certificate reads only these finite rows and their displayed handoff boundaries.

Proof. Project the carrier coordinates. The visible tuple contains the state, input, output, matrix, linear-map, transition, observation, continuation, transport, package, and hidden-data ledger rows, and the classifier compares exactly those coordinates componentwise.

The NameCert obligation theorem records the same rows as the local certificate surface. The control handoff theorem then restricts Kalman, LQR, controllability, observability, and Riccati consumers to the displayed finite coordinates and trace ledgers.

The ledger-boundary theorem accounts for the excluded host trajectory, analytic-flow, stochastic, and infinite-horizon objects. Since no downstream control certificate can read outside the listed rows, the finite obligation surface is exhausted. □

Theorem 329.7 (StateSpaceModel public finite-transition export)**.** *Definition 329.1, Definition 329.2, Definition 329.3, Definition 329.4, Definition 329.5, and Definition 329.6 jointly export the public finite* $\mathsf{StateSpaceModel}^{\uparrow}$ *interface over* $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, Cont, hsame, *and* Pkg *rows.*

Kalman, LQR, controllability, observability, and Riccati consumers read only the displayed finite state, input, output, transition, input-map, observation-map, trace-ledger, transport, continuation, provenance, and local name rows.

Proof. Project the carrier rows. They display the state, input, output, matrix, linear-map, transition, observation, trace, continuation, transport, package, hidden-data ledger, and local naming coordinates used by the public $\mathsf{StateSpaceModel}^{\uparrow}$ packet.

Invoke the classifier and the NameCert obligation surface. Together they make the componentwise comparison and the local certificate boundary depend only on the displayed $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, Cont, hsame, and Pkg rows.

Use the control handoff, ledger boundary, and obligation closure to restrict downstream Kalman, LQR, controllability, observability, and Riccati reads to those finite rows. The same boundary excludes host trajectories, analytic semigroups, stochastic data, and infinite-horizon limits from the exported interface. □

Theorem 329.8 (StateSpaceModel public interface boundary)**.** *The public* $\mathsf{StateSpaceModel}^{\uparrow}$ *interface exports exactly the finite state, input, output, transition, input-map, observation-map, trace-ledger, classifier-transport,* hsame*,* Cont*,* Pkg*, and* NameCert *rows isolated by Definition 329.1, Definition 329.2, Definition 329.4, Definition 329.5, and Definition 329.6. No further public coordinate is part of the certificate boundary.*

Proof. Project the carrier and classifier definitions. They expose the finite state, input, output, transition, input-map, observation-map, trace-ledger, classifier-transport, continuation, sameness, package, and naming rows carried by a $\mathsf{StateSpaceModel}^{\uparrow}$ packet.

Compose those projections with Definition 329.4. The handoff routes every control-facing read through the same displayed rows, so no consumer-facing state-space coordinate can be read outside the finite certificate surface.

Apply Definition 329.5 and Definition 329.6 to close the projection under the visible ledger and obligation rows. These two results repack the projected rows as the public interface boundary and show that the exported surface is exhausted by the listed data.

The boundary therefore excludes host trajectory spaces, analytic semigroups, stochastic models, infinite-horizon limits, controllability tests, observability tests, filtering optimality, regulator optimality, and standard bridge data. □

Theorem 329.9 (StateSpaceModel standard finite-transition bridge)**.** *Any standard finite state-transition presentation accepted by this chapter is read into the same finite BEDC packet rows for state, input, output, transition, input map, observation map, trace ledger,* hsame*,* Cont*,* Pkg*, and* NameCert*. Conversely, every accepted* $\mathsf{StateSpaceModel}^{\uparrow}$ *packet exposes exactly that standard finite-transition surface and no further state-space coordinate.*

Proof. Start with an accepted standard finite-transition presentation. Apply Definition 329.7 to read the finite state, input, output, transition, input-map, observation-map, trace-ledger, transport, continuation, provenance, and local name rows.

Next apply Definition 329.8. This identifies the public interface with the same packet rows and prevents a consumer from reading outside the displayed $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, Cont, hsame, and Pkg surface.

For the converse direction, project an accepted packet through Definition 329.5. The ledger boundary says that every state-transition, input-map, observation-map, and trace read is one of the recorded finite rows, so the packet exposes exactly the standard finite transition surface.

The bridge does not assert controllability, observability, filtering optimality, regulator optimality, stochastic models, analytic trajectories, or infinite-horizon semantics; those objects are not coordinates of the accepted packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{StateSpaceModel}^{\uparrow}}$.

Constructive story: A state-space-model packet is seeded by finite BHist rows for state, input, output, transition, input-map, observation-map, transition and observation traces, hsame transports, Cont routes, Pkg provenance, and a hidden-data ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{StateSpaceModel}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public surface of Definition 329.7, Definition 329.8, and Definition 329.9 binds the finite state, input, output, matrix, linear-map, transition, observation, trace-ledger, transport, continuation, provenance, name, standard finite-transition bridge, and downstream control handoff rows to $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, Cont, hsame, and Pkg.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{StateSpaceModel}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.StateSpaceModelUp.StateSpaceModelPacket\_semantic\_name\_certificate`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close host trajectory spaces, analytic semigroups, probability measures, infinite-horizon limits, controllability tests, observability tests, filtering optimality, regulator optimality, or bridge-checked schema verification.

Upgrade path: The paper-axis treatment is mature; bridgeChecked status requires formal bridge-schema acceptance for the displayed state-space-model surface.

Chapter 330

A Concrete Naming Certificate for $\mathsf{FiniteVector}^{\uparrow}$

The $\mathsf{FiniteVector}^{\uparrow}$ interface names fixed-length finite component data over the already displayed $\mathsf{Nat}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, and optional $\mathsf{VecSpace}^{\uparrow}$ certificate surfaces. Pierce, Types and Programming Languages (2002), treats length-indexed finite sequences as typed finite data; the BEDC packet below keeps the same finite-index reading at the BHist level. It records the length row, component spine, index-component pairing rows, componentwise classifier ledger, read continuations, and package provenance, without forming an infinite sequence, quotient vector, basis choice, dimension theorem, or linear-independence principle.

The finite-vector source surface consumes chapter 28, chapter 36, chapter 34, and, when component provenance is present, chapter 47. These sibling rows supply the length, spine, index-component pairing, and optional component-provenance surfaces, so the $\mathsf{FiniteVector}^{\uparrow}$ carrier is not a kernel-only island.

330.1 Finite-vector carrier

Definition 330.1 (FiniteVector carrier)**.** *A* $\mathsf{FiniteVector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$V = (n, L, I, C, R, P, H)$$

with the following visible rows:

1. *n is a* $\mathsf{Nat}^{\uparrow}$ *length row;*
2. *L is a* $\mathsf{List}^{\uparrow}$ *component spine whose displayed length is n;*
3. *I is a finite* $\mathsf{Prod}^{\uparrow}$ *spine of index-component pairing rows, one row for each visible index below n;*
4. *C is the optional component provenance row, read through* $\mathsf{VecSpace}^{\uparrow}$ *exactly when the entries are vector-space rows and omitted otherwise;*
5. *R is the componentwise* hsame *ledger comparing displayed components at matching indices;*
6. *P is the* Pkg *provenance tying the packet to the consumed* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Prod}^{\uparrow}$*, and optional* $\mathsf{VecSpace}^{\uparrow}$ *certificate boundaries;*
7. *H is the ledger that hides only unused positions outside the displayed length and records every public component read through the displayed* Cont *routes.*

The carrier predicate is FiniteVectorPacket(n, L, I, C, R, P, H)*. It contains no infinite stream, no quotient of component rows, no ambient basis selection, and no dimension or linear-independence datum beyond the displayed finite length.*

Definition 330.2 (FiniteVector classifier)**.** *For accepted* FiniteVector$^{\uparrow}$ *carriers* $V = (n, L, I, C, R, P, H)$ *and* $V' = (n', L', I', C', R', P', H')$*, the classifier* FiniteVectorSame(V, V') *holds exactly when the following finite rows are displayed:*

1. *an* hsame *row comparing the* Nat$^{\uparrow}$ *length rows* n *and* n'*;*
2. *a* List$^{\uparrow}$ *classifier row comparing the component spines* L *and* L' *after length transport;*
3. *for each displayed index below the transported length, a* Prod$^{\uparrow}$ *classifier row comparing the corresponding index-component pairing rows in* I *and* I'*;*
4. *when vector-space component provenance is present, a* VecSpace$^{\uparrow}$ *classifier row comparing the corresponding component provenance rows* C *and* C'*;*
5. *the same* Cont *routes and* Pkg *provenance showing that every public read uses the displayed length, spine, pair rows, and componentwise* hsame *ledger.*

No other classifier is exported by the seed packet.

Theorem 330.3 (FiniteVector length-index stability)**.** *Let* $V = (n, L, I, C, R, P, H)$ *be an accepted* FiniteVector$^{\uparrow}$ *carrier. If the* Nat$^{\uparrow}$ *length row,* List$^{\uparrow}$ *component spine,* Prod$^{\uparrow}$ *index-component pair rows, optional* VecSpace$^{\uparrow}$ *component provenance, componentwise* hsame *ledger,* Cont *routes,* Pkg *provenance, and outside-length ledger are transported by displayed* hsame *along the same public routes named by* P*, then the transported packet* $V' = (n', L', I', C', R', P', H')$ *is again an accepted* FiniteVector$^{\uparrow}$ *carrier.*

Moreover, every public component read at a displayed index below n *transports to the matching read below* n'*, and the transported packet hides only positions outside the transported displayed length.*

Lean4 ✓ `BEDC.Derived.FiniteVectorUp.FiniteVectorPacket length index transport`

Proof. Project the seven coordinates of Definition 330.1. The Nat$^{\uparrow}$ row transports first, so the displayed length of the target packet is fixed before any component read is considered.

Transport the List$^{\uparrow}$ spine along that length row and then transport each Prod$^{\uparrow}$ index-component pair. The pair rows keep the index and the component in the same finite slot, so a read below the displayed length remains below the transported displayed length.

If the component provenance row is present, transport it through the stated VecSpace$^{\uparrow}$ classifier; otherwise the packet stays in the component-agnostic branch. The componentwise hsame ledger then repacks over the transported spine.

Finally transport the Cont routes, Pkg provenance, and outside-length ledger. Since H hides only positions outside the displayed length, its transported copy hides only positions outside the transported length, and the result is an accepted FiniteVector$^{\uparrow}$ carrier. □

Theorem 330.4 (FiniteVector componentwise ledger exactness)**.** *For accepted* FiniteVector$^{\uparrow}$ *carriers* V *and* V'*, a proof of* FiniteVectorSame(V, V') *is equivalent, as public BEDC data, to the finite componentwise ledger consisting of the transported length row, the transported list spine, the transported index-component pairing rows, the optional transported* VecSpace$^{\uparrow}$ *component provenance, and the displayed* hsame *comparison at every visible index.*

Consequently, the classifier does not compare hidden positions, does not form a quotient of component spines, and does not add a host vector equality outside the displayed ledger.

Lean4 ✓ `BEDC.Derived.FiniteVectorUp.FiniteVectorComponentLedger transport`

Proof. From a classifier proof, read off the five rows listed in Definition 330.2. They are exactly the length comparison, spine comparison, pair-row comparisons, optional vector-space provenance comparison, and componentwise hsame rows.

Conversely, suppose the finite ledger rows are displayed. Repack them in the order required by Definition 330.2: first the length row, then the list spine, then the pair rows, then the optional component provenance row, and finally the shared route and provenance rows.

The outside-length ledger is not part of the component comparison except for recording which positions are not publicly read. Therefore the equivalence exposes precisely the visible component rows and does not introduce a quotient, an infinite tail, or host vector equality. □

Lean4 ✓ `BEDC.Derived.FiniteVectorUp.FiniteVectorSame componentwise ledger exactness`

Theorem 330.5 (FiniteVector NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteVector}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the* BHist *packet* (n, L, I, C, R, P, H) *of Definition 330.1;*
2. *classifier and stability: the classifier of Definition 330.2 together with length-index transport from Definition 330.3;*
3. *length-index exactness: the visible* $\mathsf{Nat}^{\uparrow}$ *length row and the assertion that the* $\mathsf{List}^{\uparrow}$ *component spine has exactly that displayed length;*
4. *componentwise ledger: the* $\mathsf{Prod}^{\uparrow}$ *index-component pair rows and the* hsame *comparisons of Definition 330.4;*
5. *downstream consumer boundary: the* Pkg *and* Cont *rows exposing finite component reads to later vector, matrix, and finite-dimensional certificate consumers while hiding only positions outside the displayed length.*

These rows are the full public seed surface for the finite-vector name.

Lean4 ✓ `BEDC.Derived.FiniteVectorUp.FiniteVectorPacket semantic name certificate`
Lean4 ✓ `BEDC.Derived.FiniteVectorUp.FiniteVectorPacket namecert obligation surface`

Proof. The carrier row fixes the displayed length, component spine, pair rows, optional component provenance, componentwise ledger, provenance, and outside-length ledger. This gives the source domain of the finite-vector name.

The classifier and stability row is supplied by Definition 330.2 and Definition 330.3. Together they say that every accepted replacement is componentwise hsame transport along the displayed Cont routes.

The length-index and componentwise rows are projections of the same carrier. The length row bounds the public read surface, and the pair rows identify which component belongs to each visible index.

Finally the downstream boundary is exactly the Pkg, Cont, and outside-length ledger. Since no coordinate contains an infinite sequence, quotient vector, basis choice, dimension theorem, or linear-independence witness, the five listed rows exhaust the $\mathsf{NameCert}_{\mathsf{FiniteVector}^{\uparrow}}$ obligation surface. □

Theorem 330.6 (FiniteVector scoped kernel boundary)**.** *The* $\mathsf{FiniteVector}^{\uparrow}$ *carrier, classifier, length-index stability, componentwise ledger exactness, and* $\mathsf{NameCert}_{\mathsf{FiniteVector}^{\uparrow}}$ *obligation surface*

bind the public finite-vector surface exactly to $\mathsf{Nat}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, *optional* $\mathsf{VecSpace}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$.

The boundary exports no infinite stream, quotient vector, basis choice, dimension datum, or linear-independence datum. Later matrix, linear-map, and finite-dimensional consumers can read only the displayed finite length, spine, index-component rows, componentwise comparisons, routes, provenance, and local name certificate.

Proof. Start with the carrier of Definition 330.1. It displays the $\mathsf{Nat}^{\uparrow}$ length row, $\mathsf{List}^{\uparrow}$ component spine, $\mathsf{Prod}^{\uparrow}$ index-component rows, optional $\mathsf{VecSpace}^{\uparrow}$ provenance, componentwise ledger, route provenance, and outside-length ledger as one finite BHist packet.

The classifier of Definition 330.2 and the transport statement of Definition 330.3 identify how accepted replacements move along the displayed hsame and Cont routes. No comparison outside those rows is introduced.

The exactness theorem Definition 330.4 shows that visible component equality is precisely the finite length, spine, pair-row, optional component-provenance, and componentwise hsame ledger. The $\mathsf{NameCert}_{\mathsf{FiniteVector}^{\uparrow}}$ surface of Definition 330.5 then repacks those rows for downstream consumers.

The listed exclusions follow by projection: the carrier has no coordinate for an infinite stream, quotient vector, basis choice, dimension witness, or linear-independence witness. Therefore the public boundary is exactly the displayed kernel surface named above. □

Theorem 330.7 (FiniteVector standard schema bridge boundary)**.** *The public finite-vector surface of Definition 330.6 bridges to the standard bounded finite-sequence reading exactly through the* $\mathsf{Nat}^{\uparrow}$ *length row, the* $\mathsf{List}^{\uparrow}$ *component spine, the* $\mathsf{Prod}^{\uparrow}$ *index-component rows, optional* $\mathsf{VecSpace}^{\uparrow}$ *component provenance, the componentwise* hsame *ledger,* Cont *read routes,* Pkg *provenance, and the outside-length hiding ledger.*

The bridge exports no infinite stream, quotient vector, basis choice, dimension theorem, or linear-independence theorem.

Proof. Project the carrier of Definition 330.1. It exposes the length row, component spine, index-component rows, optional component provenance, componentwise ledger, read routes, package provenance, and outside-length ledger as the finite packet.

Use length-index stability from Definition 330.3. The displayed $\mathsf{Nat}^{\uparrow}$ length bounds every public component read, so accepted replacements preserve which $\mathsf{Prod}^{\uparrow}$ index-component rows are visible and which positions are hidden outside the length.

Apply Definition 330.4. Componentwise equality is exactly the visible hsame ledger on the displayed component spine, transported along the same Cont read routes and Pkg provenance.

Finally use Definition 330.6. The scoped kernel boundary exhausts all public finite-vector reads by the rows just projected. Since the packet has no coordinate for infinite streams, quotient vectors, basis choice, dimension, or linear independence, none of those structures is exported by the standard bridge. □

Theorem 330.8 (FiniteVector zero length has empty component-read surface)**.** *Let* $V = (n, L, I, C, R, P, H)$ *be an accepted* $\mathsf{FiniteVector}^{\uparrow}$ *carrier. If the displayed* $\mathsf{Nat}^{\uparrow}$ *length row* n *is the zero row* e *of Definition 28.1, then the public component-read surface of* V *is empty:*

1. *the* $\mathsf{List}^{\uparrow}$ *component spine* L *is displayed as the empty spine;*
2. *the* $\mathsf{Prod}^{\uparrow}$ *index-component spine* I *has no public index-component pair row;*
3. *the componentwise ledger* R *has no public component-comparison row;*

4. the ledger H records only outside-length hiding data and no public component read.

Moreover, if $V' = (n', L', I', C', R', P', H')$ is another accepted $\mathsf{FiniteVector}^{\uparrow}$ *carrier whose displayed* $\mathsf{Nat}^{\uparrow}$ *length row is also* e*, then a classifier row*

$$\mathsf{FiniteVectorSame}(V, V')$$

contains no indexed $\mathsf{Prod}^{\uparrow}$ *comparison and no componentwise read comparison. Its public comparison data are exactly the zero length comparison, the empty-spine* $\mathsf{List}^{\uparrow}$ *comparison, the displayed provenance rows, the shared* Cont *routes, and the outside-length ledgers.*

Proof. Project the accepted carrier through Definition 330.1. The first coordinate says that n is the displayed $\mathsf{Nat}^{\uparrow}$ length row, and the hypothesis identifies that row with the zero unary history e. The same carrier clause says that L is a $\mathsf{List}^{\uparrow}$ component spine whose displayed length is n. Therefore L has displayed length zero. By the zero endpoint exactness of Definition 36.79, a zero displayed list length is exactly the empty-spine readback. Thus the component spine contributes no component slot.

The third coordinate of Definition 330.1 defines I as a finite $\mathsf{Prod}^{\uparrow}$ spine with one index-component pairing row for each visible index below n. There is no visible index below the zero $\mathsf{Nat}^{\uparrow}$ row: a visible index below e would be a strict predecessor of the zero unary history, while Definition 28.1 generates zero as the empty base and generates larger unary rows only by one-extension. Hence the indexing set for I is empty, so the finite $\mathsf{Prod}^{\uparrow}$ spine has no public pair row.

The componentwise ledger R compares displayed components at matching indices. Since the preceding paragraph leaves no displayed index and the first paragraph leaves no component slot, there is no indexed component comparison for R to expose. The last carrier coordinate says that H hides only unused positions outside the displayed length and records every public component read through displayed Cont routes. A public component read requires a visible index below n together with its index-component row in I; both are absent at length zero. Therefore H records only the outside-length hiding data.

For the classifier statement, unfold Definition 330.2 for the two accepted zero-length carriers. The length row remains present and compares n with n'. The $\mathsf{List}^{\uparrow}$ row compares the two empty component spines obtained above. The indexed $\mathsf{Prod}^{\uparrow}$ clause ranges over displayed indices below the transported length, but that transported length is again zero, so the clause has no row to display. The optional component provenance coordinate can only contribute its displayed provenance declaration; it does not create an indexed component read because no component slot exists. Finally the Cont, Pkg, and outside-length ledger rows are exactly the remaining public rows named by the classifier. The exactness statement of Definition 330.4 confirms that no hidden position, quotient of spines, or host vector equality is added beyond this displayed ledger. □

Theorem 330.9 (FiniteVector successor length exposes terminal component read)**.** *Let $V = (n, L, I, C, R, P, H)$ be an accepted* $\mathsf{FiniteVector}^{\uparrow}$ *carrier. If the displayed* $\mathsf{Nat}^{\uparrow}$ *length row n is a successor row over a predecessor length m, then the public component-read surface of V decomposes into the predecessor finite-vector read surface of length m together with exactly one terminal* $\mathsf{Prod}^{\uparrow}$ *index-component row at the successor boundary.*

Equivalently, the displayed $\mathsf{List}^{\uparrow}$ *spine splits into the predecessor component spine and one terminal component slot, the* $\mathsf{Prod}^{\uparrow}$ *spine I splits into the predecessor index-component rows and the terminal index-component pairing row, the componentwise ledger R splits into the predecessor* hsame *comparison rows and the terminal component comparison, and H hides only positions outside the displayed successor length.*

Proof. Project the seven carrier coordinates from Definition 330.1. The first coordinate identifies n as the displayed $\mathsf{Nat}^{\uparrow}$ length row, and the hypothesis writes that row as the one-step successor of m. The zero endpoint of Definition 330.8 gives the base boundary for the induction over displayed unary length rows.

For the successor step, split the $\mathsf{List}^{\uparrow}$ spine along the successor form of the unary length row. The displayed prefix has length m, and the one remaining displayed slot is the terminal component slot at the successor boundary. No additional slot is available because the carrier requires the displayed length of L to be exactly n.

Now split the finite $\mathsf{Prod}^{\uparrow}$ spine I. By the carrier clause, I has one index-component pairing row for each visible index below n. The visible indices below the successor row are precisely the predecessor visible indices below m together with the terminal boundary index. Hence I is the predecessor pair-row spine plus exactly one terminal $\mathsf{Prod}^{\uparrow}$ index-component row.

Apply Definition 330.4 to identify the classifier rows exposed by this split. The predecessor part contributes the finite hsame rows over the predecessor spine, and the terminal pair row contributes exactly the terminal component comparison. The exactness theorem also rules out hidden-position comparisons, quotient spine equality, and host vector equality.

Finally inspect the last carrier coordinate. The ledger H records every public component read through the displayed Cont routes and hides only unused positions outside the displayed length. Since the displayed length is the successor row over m, the predecessor reads and the terminal read are public, while every position beyond that successor length remains hidden. □

Theorem 330.10 (FiniteVector public component recursion boundary)**.** *Every public component read of an accepted* $\mathsf{FiniteVector}^{\uparrow}$ *packet is generated by induction on the displayed* $\mathsf{Nat}^{\uparrow}$ *length row. The zero row is exactly the empty component-read surface of Definition 330.8; the successor row is exactly the predecessor read surface together with one terminal* $\mathsf{Prod}^{\uparrow}$ *index-component row, as in Definition 330.9.*

Consequently the public recursion boundary exports the displayed $\mathsf{Nat}^{\uparrow}$ *length, the finite* $\mathsf{List}^{\uparrow}$ *component spine, the finite* $\mathsf{Prod}^{\uparrow}$ *index-component rows, componentwise* hsame *ledger rows,* Cont *routes, and* Pkg *provenance. It exports no infinite stream, quotient vector, basis choice, dimension theorem, or linear-independence datum.*

Proof. Induct on the displayed unary $\mathsf{Nat}^{\uparrow}$ length row carried by Definition 330.1. In the zero case, apply Definition 330.8. The component spine, index-component spine, and componentwise ledger then expose no public component row.

In the successor case, apply Definition 330.9. The displayed packet splits into the predecessor read surface and exactly one terminal $\mathsf{Prod}^{\uparrow}$ index-component row at the successor boundary.

Finally use Definition 330.4 to identify the classifier ledger exposed by the induction. The ledger records precisely the displayed componentwise hsame rows and the associated $\mathsf{Cont}/\mathsf{Pkg}$ provenance, so it cannot supply an infinite stream, quotient vector, basis, dimension theorem, or linear-independence witness. □

Theorem 330.11 (FiniteVector standard bridge boundary)**.** *The public component-recursion packet of Definition 330.10 interprets as the standard finite-vector schema exactly through the displayed* $\mathsf{Nat}^{\uparrow}$ *length-index row, terminal component read, componentwise ledger,* $\mathsf{List}^{\uparrow}/\mathsf{Nat}^{\uparrow}/\mathsf{VecSpace}^{\uparrow}$ *provenance, visible* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows.*

The bridge carries no basis choice, quotient vector, infinite sequence, or dimension theorem. In particular, the standard reading is only the finite component packet generated by the displayed length recursion and its terminal read boundary.

Proof. First fix the length-index surface. Apply Definition 330.3 and Definition 330.5. These identify the displayed $\mathsf{Nat}^{\uparrow}$ length row, $\mathsf{List}^{\uparrow}$ component spine, optional $\mathsf{VecSpace}^{\uparrow}$ provenance, visible routes, package data, and local certificate rows used by the finite-vector packet.

Next read the component ledger. Use Definition 330.4 to identify visible component equality with the componentwise hsame rows, and use Definition 330.8 for the empty read at length zero.

For the successor boundary, apply Definition 330.9. It supplies the unique terminal $\mathsf{Prod}^{\uparrow}$ index-component row beyond the predecessor surface, so every displayed finite-vector component read is generated by the length recursion.

Finally apply Definition 330.10. The public recursion boundary repacks the length row, terminal reads, componentwise ledger, provenance, visible transports, and certificate rows as the standard finite-vector bridge. The carrier has no coordinate for basis choice, quotient vectors, infinite sequences, or a dimension theorem, so none is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteVector}\uparrow}$.

Constructive story: A finite-vector packet is generated by a $\mathsf{Nat}^{\uparrow}$ length row, a $\mathsf{List}^{\uparrow}$ component spine, $\mathsf{Prod}^{\uparrow}$ index-component pair rows, optional $\mathsf{VecSpace}^{\uparrow}$ component provenance, componentwise hsame rows, Cont routes for public reads, Pkg provenance, and a ledger hiding only positions outside the displayed length.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteVector}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 330.6, Definition 330.7, Definition 330.8, Definition 330.9, Definition 330.10, and Definition 330.11 bind the finite-vector surface to $\mathsf{Nat}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, optional $\mathsf{VecSpace}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, with zero-length and successor-length component-read surfaces serving as mature finite consumer examples.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteVector}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FiniteVectorUp.FiniteVectorPacket\_semantic\_name\_certificate`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close infinite sequences, quotient vectors, basis choice, a dimension theorem, or linear independence.

Upgrade path: No further paper-side theory grade remains for this finite length-indexed component package; bridge verification remains on the independent verification axis.

Chapter 331

A Concrete Naming Certificate for $\mathsf{Divisibility}^{\uparrow}$

The $\mathsf{Divisibility}^{\uparrow}$ interface names the finite arithmetic surface in which one natural-number row divides another by an explicitly displayed multiplication witness. In the sense of Hardy and Wright, *An Introduction to the Theory of Numbers*, divisibility is the relation that records a multiplier q with $bq = a$. The BEDC surface below keeps the relation constructive: the multiplier, product ledger, bounded search row, visible divisibility ledger, and provenance all remain finite BHist rows. It does not introduce quotient classes, ideal membership, or classical decidability.

The multiplier witness is read through the arithmetic rows supplied by chapter 28 and the $\mathsf{Mul}^{\uparrow}$ product surface, while bounded-search reads use the $\mathsf{Order}^{\uparrow}$ row. Downstream consumers such as chapter 64 and chapter 303 consume the divisibility ledger through the same finite NatUp, product, order, prime, and modular dependency surface.

Definition 331.1 (Divisibility finite-history carrier)**.** *A* $\mathsf{Divisibility}^{\uparrow}$ *source is a finite* BHist *packet*

$$D = (a, b, q, w, o, l, p)$$

with the following visible rows:

1. *a and b are accepted* $\mathsf{Nat}^{\uparrow}$ *rows naming the dividend and divisor;*
2. *q is an accepted* $\mathsf{Nat}^{\uparrow}$ *multiplier row;*
3. *w is the displayed* $\mathsf{Mul}^{\uparrow}$ *witness row whose multiplication ledger records $b \cdot q = a$;*
4. *o is an* $\mathsf{Order}^{\uparrow}$ *boundedness row recording the unary search envelope for q whenever the consumer asks for a bounded witness;*
5. *l is the visible divisibility ledger tying the a, b, q, w, and o rows to the same displayed classifier;*
6. *p is the* Pkg *provenance row naming the* $\mathsf{Nat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, $\mathsf{Mul}^{\uparrow}$, $\mathsf{Order}^{\uparrow}$, $\mathsf{Prime}^{\uparrow}$, *and* $\mathsf{ModularArithmetic}^{\uparrow}$ *certificate boundaries used by the packet.*

The carrier predicate is $\mathsf{DivLedger}(a, b, q, w, o, l, p)$. *Two accepted sources classify together only when all displayed rows transport componentwise by* hsame *and the multiplication and boundedness reads follow the* Cont *routes recorded in l and p.*

Lean4 (definition) `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier`

Theorem 331.2 (Divisibility multiplication-witness closure)**.** *Let $D = (a, b, q, w, o, l, p)$ be an accepted* $\mathsf{Divisibility}^{\uparrow}$ *source. The divisibility assertion exported by D is exactly the displayed* $\mathsf{Mul}^{\uparrow}$ *witness row w for $b \cdot q = a$, together with the* $\mathsf{Nat}^{\uparrow}$ *rows a, b, and q named in Definition 331.1. Every transport of D by the componentwise* hsame *rows in l gives another accepted source with the transported multiplication witness and no additional host divisibility predicate.*

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier mul witness transport closure`
Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityBHistCarrier mul witness closure`

Proof. Project the carrier of Definition 331.1. The rows a, b, and q supply the displayed natural-number data, and w is the only coordinate that reads a multiplication computation.

Transport each of these rows by the hsame data recorded in l. Since the ledger also carries the continuation route used to read multiplication, the transported packet has the same visible product comparison, now over the transported rows.

The remaining coordinates record boundedness and provenance. They contain no coordinate for an external divisibility relation, quotient class, or decidable predicate, so the multiplication witness row exhausts the exported divisibility assertion. □

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityLedger multiplication witness closure`

Theorem 331.3 (Divisibility order-bounded ledger)**.** *For an accepted source $D = (a, b, q, w, o, l, p)$, every bounded search read of the divisibility witness is exactly the* $\mathsf{Order}^{\uparrow}$ *row o together with the unary envelope recorded by l. The row bounds the displayed multiplier q inside the finite search region selected by the dividend row a when such a region is requested, and otherwise exports no order fact beyond the visible boundedness ledger.*

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityBHistCarrier order bounded ledger`

Proof. Read o through the carrier of Definition 331.1. It is typed over the same a, b, and q rows used by the multiplication witness, so its boundedness comparison cannot name a different multiplier.

When a bounded consumer requests a search envelope, the ledger l supplies the finite unary route that compares q with the selected bound. The route is a displayed order row, not a global well-ordering principle.

No coordinate in the source stores least witnesses, unbounded search, or classical existence. Thus the bounded read is exhausted by o and the finite envelope recorded by l. □

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier order bounded ledger`

Theorem 331.4 (Divisibility NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Divisibility}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: the source of Definition 331.1 is inhabited by taking the divisor row b to be the certified natural row for 1, the multiplier row q to be a, and w to be the displayed* $\mathsf{Mul}^{\uparrow}$ *unit multiplication ledger;*
2. *classifier transport: the classifier compares accepted sources by componentwise* hsame *transport of a, b, q, w, o, l, and p;*
3. *multiplication-witness closure: Definition 331.2 is the only exported divisibility assertion;*
4. *order-bounded exactness: Definition 331.3 is the only exported bounded search surface;*

5. *downstream readback:* $\mathsf{Prime}^{\uparrow}$ *and* $\mathsf{ModularArithmetic}^{\uparrow}$ *consumers read only the divisor, multiplier, product, boundedness, ledger, and provenance rows of the same packet.*

These five rows form the full public seed obligation for naming finite divisibility data over certified natural-number histories.

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier namecert obligation surface`

Proof. The habitation row uses the displayed natural-number unit. With $b = 1$ and $q = a$, the $\mathsf{Mul}^{\uparrow}$ unit ledger supplies the witness row w, while the boundedness and divisibility ledgers are the finite rows that record this same calculation.

Classifier transport is componentwise. Transporting a, b, q, w, o, l, and p by their displayed hsame rows gives a packet with the same carrier shape and the same multiplication and boundedness continuation routes.

The multiplication and order theorems identify the only arithmetic reads exported from the carrier. Since the provenance row names exactly the natural, additive, multiplicative, order, prime, and modular certificates, downstream consumers can read no further object from the local $\mathsf{NameCert}_{\mathsf{Divisibility}^{\uparrow}}$ surface. □

Theorem 331.5 (Divisibility to Prime sibling route)**.** *Every* $\mathsf{Prime}^{\uparrow}$ *consumer of an accepted* $\mathsf{Divisibility}^{\uparrow}$ *row reads the displayed divisor, multiplier, multiplication witness, boundedness, ledger, and provenance rows of the carrier in Definition 331.1. The downstream prime certificate of chapter 64 consumes this route as a finite sibling dependency: divisor tests pass through b, q, w, o, l, and p, together with the dividend row a that indexes the same packet.*

Thus $\mathsf{Prime}^{\uparrow}$ *obtains no external divisibility predicate, quotient-like shortcut, gcd routine, least-witness selector, host congruence, or ambient number-theoretic decision principle from* $\mathsf{Divisibility}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier public prime modular consumer boundary`

Proof. Project the accepted row through Definition 331.1. The projection exposes the finite carrier $D = (a, b, q, w, o, l, p)$, with b the displayed divisor, q the displayed multiplier, w the multiplication witness, o the boundedness row, l the ledger, and p the provenance row.

Apply Definition 331.2. The only multiplicative claim available to the downstream prime packet is the displayed witness for $b \cdot q = a$; it is not an external divisibility predicate and it does not name a quotient carrier.

Apply Definition 331.3. The bounded part of the read is exhausted by o and l, so the route supplies a finite envelope rather than a least-witness search or a host decision procedure.

Finally read chapter 64 through the same provenance row p. The prime consumer receives the divisor-facing finite packet and no quotient-like shortcut, because every row used by the consumer is already one of the displayed $\mathsf{Divisibility}^{\uparrow}$ rows. □

Theorem 331.6 (Divisibility prime and modular boundary)**.** *Every* $\mathsf{Prime}^{\uparrow}$ *or* $\mathsf{ModularArithmetic}^{\uparrow}$ *consumer of an accepted* $\mathsf{Divisibility}^{\uparrow}$ *source must factor through the same finite rows $D = (a, b, q, w, o, l, p)$. A prime-oriented consumer may read b, q, and the product ledger w as the visible witness surface for divisor tests. A modular-arithmetic consumer may read the same witness as a zero-remainder certificate only through the displayed* $\mathsf{Mul}^{\uparrow}$ *product,* $\mathsf{Order}^{\uparrow}$ *boundedness row, and provenance carried by p.*

No primality decision, gcd computation, quotient residue class, finite-field structure, or host congruence is exported by the $\mathsf{Divisibility}^{\uparrow}$ *packet.*

Proof. Project the accepted source through Definition 331.1. The prime-facing read obtains only the divisor row, multiplier row, and multiplication witness already present in D.

For a modular consumer, the same witness is read through the product row and the boundedness ledger. The provenance row p names the $\mathsf{ModularArithmetic}^{\uparrow}$ boundary, but it does not add a quotient carrier or external congruence relation.

Thus both downstream reads factor through the finite source itself. Any primality decision, gcd computation, quotient residue class, finite-field law, or host congruence would require a coordinate absent from D. □

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier prime modular boundary`

Theorem 331.7 (DivisibilityUp public certificate)**.** *For every accepted finite* $\mathsf{Divisibility}^{\uparrow}$ *source* $D = (a, b, q, w, o, l, p)$*, Definition 331.1, Definition 331.2, Definition 331.3, Definition 331.4, and Definition 331.6 assemble the public* $\mathsf{NameCert}_{\mathsf{Divisibility}^{\uparrow}}$ *consumer certificate over* BHist*, multiplication witnesses, order-bounded ledgers,* hsame*,* Cont*, and* Pkg*.*

It exports no gcd algorithm, Euclidean division, primality decision, quotient residue class, finite-field law, or host congruence.

Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier public certificate export`
Lean4 ✓ `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier public consumer certificate`

Proof. Project D through Definition 331.1. The projection exposes only the dividend row, divisor row, multiplier row, multiplication witness row, boundedness row, divisibility ledger, and provenance row.

Apply Definition 331.2 to identify the only multiplicative read, and apply Definition 331.3 to identify the only bounded-search read. These two steps leave no coordinate for an external divisibility predicate or quotient object.

Apply Definition 331.4 to package the carrier, classifier transport, multiplication, boundedness, and downstream readback rows as the displayed $\mathsf{NameCert}_{\mathsf{Divisibility}^{\uparrow}}$ surface.

Finally, use Definition 331.6 to expose the same finite packet as the public $\mathsf{NameCert}_{\mathsf{Divisibility}^{\uparrow}}$ consumer certificate for $\mathsf{Prime}^{\uparrow}$ and $\mathsf{ModularArithmetic}^{\uparrow}$. Any gcd algorithm, Euclidean division, primality decision, quotient residue class, finite-field law, or host congruence would require a row absent from the certificate. □

Theorem 331.8 (Divisibility bounded-witness public readback)**.** *Every public consumer of an accepted* $\mathsf{Divisibility}^{\uparrow}$ *packet that asks for a bounded witness reads exactly the multiplier row* q*, the multiplication witness* w *for* $b \cdot q = a$*, the order envelope* o*, the ledger* l*, and the provenance row* p *from Definition 331.1. PrimeUp and ModularArithmeticUp consumers factor through those rows, together with the displayed dividend and divisor entries that index the same carrier packet.*

The public readback exports no gcd algorithm, least witness, quotient residue class, finite-field law, or host decidability predicate. Its complete bounded witness surface is the finite row family already displayed by the $\mathsf{Divisibility}^{\uparrow}$ *carrier, multiplication witness, order-bounded ledger, and prime/modular consumer boundary.*

Proof. Project the accepted packet through Definition 331.1. The only rows available to a bounded-witness consumer are the multiplier q, the multiplication witness w, the order envelope o, the ledger l, and the provenance row p, indexed by the displayed dividend and divisor entries.

Apply Definition 331.2. The product check is read solely as the displayed witness for $b \cdot q = a$, so the consumer receives no separate quotient object or external divisibility predicate.

Next apply Definition 331.3. The bounded part of the readback is exactly the order envelope and ledger row already present in the carrier, not a least-witness search or a host decidability routine.

Finally use Definition 331.6. PrimeUp and ModularArithmeticUp can consume the bounded witness only through the same finite rows, so no gcd algorithm, quotient residue class, finite-field law, or host decidability predicate is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{Divisibility}\uparrow}$.

Constructive story: Divisibility is generated by finite natural-number rows for a, b, and q, a displayed multiplication witness for $b \cdot q = a$, an optional bounded search row, a visible divisibility ledger, and provenance over the arithmetic dependency certificates.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Divisibility}\uparrow}$, maturePackageClosed)

Scope closed: Definition 331.1, Definition 331.2, Definition 331.3, Definition 331.4, Definition 331.5, and Definition 331.6 bind the carrier, multiplication-witness row, order-bounded ledger, NameCert obligation surface, Prime sibling route, and prime/modular consumer boundary for finite divisibility data.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Divisibility}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.DivisibilityUp.DivisibilityFiniteHistoryCarrier\_order\_bounded\_ledger`

Bridge status: none

Origin: human

Not claimed: This chapter does not close gcd algorithms, Euclidean division, primality decisions, unique factorization, quotient residue classes, finite fields, or a standard bridge.

Upgrade path: The paper-side theory axis is complete for the finite divisibility consumer catalogue over the multiplication-witness, bounded-ledger, prime/modular, hsame, Cont, and Pkg rows.

Chapter 332

A Concrete Naming Certificate for $\mathsf{ModulusOfConvergence}^{\uparrow}$

The $\mathsf{ModulusOfConvergence}^{\uparrow}$ interface names the explicit convergence-rate packet used by the Bishop–Bridges constructive-analysis reading of regular rational sequences and real completion. It is a support object for $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$, adjacent to $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{FastCauchy}^{\uparrow}$, and $\mathsf{NestedDyadicInterval}^{\uparrow}$. It records finite precision requests and late observation witnesses; it does not form a quotient completion, choose a limit, or appeal to host real equality. Its concrete dependency route consumes chapter 291 for finite precision rows, chapter 126 for stream observation windows, chapter 301 for regular-readback witnesses, and chapter 38 for the real-seal handoff.

Definition 332.1 (ModulusOfConvergence BHist carrier)**.** *A* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *carrier packet is a finite* BHist *row package*

$$M = (p, u, \mu, s, r, \ell, P)$$

with the following visible coordinates:

1. *p is the precision-request history row, read as a unary or dyadic precision demand through* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. *u is the unary index selector row that chooses the threshold index bound returned for the request p;*
3. *μ is the modulus-function row, read as the displayed assignment from precision rows to threshold rows;*
4. *s is the* $\mathsf{StreamName}^{\uparrow}$ *observation schedule whose entries are tested after the selected bound;*
5. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *late-observation witness row showing that every displayed observation past the chosen bound satisfies the requested precision;*
6. *ℓ is the finite ledger recording the precision request, selected bound, late-observation witness, and the dependency anchors* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*;*
7. *P is the* Pkg *provenance for the same dependency anchors and for the local* $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$ *row.*

The carrier accepts exactly those finite packets whose listed rows are present in one history and are connected by displayed Cont *windows. It contains no infinite choice of thresholds, quotient stream, completed real, or hidden limit selector.*

Theorem 332.2 (ModulusOfConvergence NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$ *obligation surface consists of the carrier packet of Definition 332.1, the classifier identifying two packets when corresponding unary precision rows choose* hsame *index bounds and the same late-observation ledger, the* hsame *transport rows for precision and threshold histories, the* Cont *extension rows for finite observation windows, and the exactness ledger naming* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceBHistCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket namecert obligation surface`

Proof. Project an accepted packet to the seven carrier coordinates. The precision row, unary selector, modulus row, observation schedule, late-observation witness, ledger, and provenance row are all visible in the same finite BHist package.

The classifier compares the precision and threshold coordinates through hsame and then compares the late-observation ledger through the displayed source certificates. The same ledger rows name the dyadic precision source, the stream observation source, the regular-sequence witness, and the real-name consumer boundary.

The stability and exactness fields are therefore just the finite transport and window-extension rows already carried by the packet. No additional completion, choice, or quotient coordinate is available for the local naming certificate. □

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket semantic name certificate`

Theorem 332.3 (ModulusOfConvergence composition stability)**.** *If two accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packets have composable* Cont *windows, then their composed packet preserves the precision request, the selected threshold bound, the modulus-function row, the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *late-observation witness, and the dependency ledger through the same* hsame *classifier. The composition exports only the displayed finite convergence-rate ledger.*

Proof. Restrict each packet to the finite rows named by Definition 332.1. The only data available for composition are the precision request, unary selector, modulus row, observation schedule, late witness, ledger, and package provenance.

Compose the Cont windows along their shared displayed histories. The composite window keeps the same selected threshold bound for the transported precision request and carries forward the same late-observation witness rows.

Finally transport the resulting rows through the componentwise hsame classifier of Definition 332.2. The composed packet has the same carrier shape and no constructor for a chosen limit or quotient completion, so composition is stable inside the finite ledger. □

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket composition stability`
Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceCarrier composition stability`

Theorem 332.4 (ModulusOfConvergence tail restriction stability)**.** *For every accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packet and every tail restriction whose first index is* hsame*-above the selected bound, the restricted packet is again accepted. Its classifier keeps the same precision request, modulus row, late-observation witness, and dependency ledger, while the* Cont *window is restricted to the displayed tail.*

Lean4 ✓ BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceRatePacket tail restriction stability
Lean4 ✓ BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceCarrier tail restriction stability
Lean4 ✓ BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket tail restriction stability

Proof. Start with the selected threshold bound in the unary index selector. A tail whose first index is hsame-above that bound remains inside the late window named by the precision request.

Restrict the observation schedule and late-observation witness rows to that tail. The dyadic endpoint rows and regular-sequence witness rows are inherited from the original packet because the carrier ledger already records them for all displayed observations beyond the bound.

Repack the restricted schedule with the same precision request, modulus row, ledger, and provenance. The Cont route is the restricted route, and the componentwise hsame comparisons are unchanged on the retained rows, so the tail packet is accepted by the same classifier. □

Theorem 332.5 (ModulusOfConvergence paired late-window common refinement)**.** *Let M_0 and M_1 be accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packets with transported precision requests, selected threshold rows, and displayed late-tail restrictions. If both packets are consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *reads over the same displayed dependency boundary, then there is one common displayed late window through which both restricted schedules and both late-observation witnesses factor by* hsame *and* Cont*.*

The common window exposes only the two precision rows, the transported threshold rows, the modulus rows, the observation schedules, the late-observation witnesses, the dependency ledgers, the Pkg *provenance rows, and the local* $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$ *rows. It does not expose quotient completion, a selected real limit, a global threshold choice, or host real equality.*

Proof. Apply Definition 332.4 to M_0 and M_1. Each transported precision request keeps its selected threshold row and restricts its observation schedule and late-observation witness to a displayed late tail.

Next apply Definition 332.3 to the two restricted tails along their displayed Cont windows. The composite window is the common late window, and both restricted schedules factor through it by the componentwise hsame classifier.

Use Definition 332.6 to identify the rows visible to downstream consumers. The only exposed coordinates are the two precision rows, transported thresholds, modulus rows, schedules, witnesses, dependency ledgers, package provenance rows, and local naming-certificate rows.

Finally apply Definition 332.8. The $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads therefore share that finite late-window ledger, and no quotient completion, selected real limit, global threshold choice, or host real equality is introduced. □

Theorem 332.6 (ModulusOfConvergence ledger exactness)**.** *An accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packet exposes exactly the precision request, selected bound, late-observation witness, and dependency anchors* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *recorded in its ledger. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the packet factors through those rows and the displayed* hsame*,* Cont*, and* Pkg *provenance.*

Proof. Read the ledger coordinate ℓ of Definition 332.1. By definition it records the precision request, the bound selected by the unary selector, the late-observation witness, and the four dependency anchors.

Apply the obligation surface of Definition 332.2. It permits downstream reads only through the componentwise classifier, finite window extension, and package provenance already present in the carrier.

Thus a $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer can inspect exactly the displayed convergence-rate ledger and no extra completion object, quotient equality, global modulus choice, or selected real limit. □

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket ledger exactness`

Theorem 332.7 (ModulusOfConvergence scoped dependency packet)**.** *For an accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packet, the carrier, classifier, composition, tail-restriction, and ledger exactness rows form one scoped BEDC dependency packet over* BHist*. Precision and threshold transport are read only through* hsame*, finite observation windows are read only through* Cont*, provenance is read only through* Pkg*, and the public certificate row is read only through* $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$*.*

The packet preserves the displayed $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *anchors. It excludes quotient completion, selected real limits, and global threshold choice.*

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceCarrier scoped dependency packet`

Proof. Project the seven carrier coordinates of Definition 332.1. They are the precision request, unary threshold selector, modulus row, observation schedule, late-observation witness, dependency ledger, and package/name provenance surface.

Apply Definition 332.2 to bind the accepted packet to the displayed classifier, transport rows, carrier obligations, and NameCert registration.

Apply Definition 332.3 and Definition 332.4. They keep the same BHist, hsame, Cont, and Pkg rows stable under composition and tail restriction.

Finally apply Definition 332.6. It says that every $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer read factors through the listed BEDC rows and keeps the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ anchors visible. Hence no completion object, quotient equality, selected limit, or global threshold choice is exposed by the scoped packet. □

Theorem 332.8 (ModulusOfConvergence RegSeqRat and RealUp public export)**.** *An accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packet exports a public consumer package for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*. The package consists exactly of the precision request, unary threshold selector, modulus row,* $\mathsf{StreamName}^{\uparrow}$ *observation schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *late-observation witness,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint ledger,* hsame *transports,* Cont *windows, and* Pkg *provenance displayed in this chapter.*

Every $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the accepted packet factors through this public package. Such a consumer cannot read a completion coordinate, quotient equality, selected limit, or global choice of thresholds.*

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceRatePacket semantic name certificate`

Proof. The seven carrier rows are those of Definition 332.1: the precision request, unary threshold selector, modulus row, observation schedule, late-observation witness, dependency ledger, and provenance/certificate surface.

The carrier, classifier, and stability fields are fixed by Definition 332.2. Late-window stability is supplied by Definition 332.4, so changing the visible observation bound transports only the displayed BHist, hsame, Cont, and Pkg rows.

Consumer factorization is exactly Definition 332.6. The exact BEDC scope is then the scope of Definition 332.7: the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ anchors are retained, and no completion coordinate, quotient equality, selected limit, or global threshold choice is available. □

Theorem 332.9 (ModulusOfConvergence finite-rate bridge packet)**.** *Any standard bridge for the displayed convergence-rate package may read exactly the precision request, unary threshold selector, modulus row,* $\mathsf{StreamName}^{\uparrow}$ *observation schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *late-observation witness,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint ledger,* hsame *transports,* Cont *windows, and* Pkg *provenance isolated by Definition 332.8. It may not read quotient completion, selected real limits, global threshold choice, or host real equality.*

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceFiniteRateBridge rows`

Proof. Project the carrier through Definition 332.1. The visible rows are the finite precision request, unary threshold selector, modulus row, scheduled observations, late-observation witness, endpoint ledger, and package/name provenance.

Apply Definition 332.2 to bind these rows to the accepted $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$ surface. Tail restriction through Definition 332.4 keeps the same BHist, hsame, Cont, and Pkg coordinates when a consumer narrows the visible observation window.

Ledger exactness is supplied by Definition 332.6. The dependency boundary is the packet of Definition 332.7, and the public $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ read is exactly Definition 332.8.

The excluded data are not coordinates of the carrier. A bridge that reads a quotient completion, a selected real limit, a global threshold choice, or host real equality would therefore leave the displayed finite-rate package rather than using the boundary proved here. □

Theorem 332.10 (ModulusOfConvergence standard bridge)**.** *Let* $M = (p, u, \mu, s, r, \ell, P)$ *be an accepted* $\mathsf{ModulusOfConvergence}^{\uparrow}$ BHist *packet. Then* M *determines the standard explicit-modulus-of-convergence schema by reading exactly the precision request* p*, selected threshold* $u(p)$*, modulus row* μ*,* $\mathsf{StreamName}^{\uparrow}$ *observations* s*,* $\mathsf{RegSeqRat}^{\uparrow}$ *late-window witness* r*,* hsame *transports,* Cont *windows,* Pkg *provenance, dependency ledger* ℓ*, and* NameCert *row* P *displayed in this chapter.*

Conversely, any displayed standard explicit-modulus package whose rows are exactly those BEDC rows repacks as the same $\mathsf{ModulusOfConvergence}^{\uparrow}$ *public packet. The bridge exports no quotient completion, no selected real limit, and no global choice of thresholds outside the displayed finite threshold row.*

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceStandardBridge boundary`

Proof. Project the carrier of M using Definition 332.1. The precision request, selected unary threshold, modulus row, observation schedule, late-window witness, ledger, and package/name provenance are already the coordinates of the accepted packet.

The naming and obligation surface is the surface of Definition 332.2. It fixes the classifier, the displayed BHist rows, the hsame transports, the Cont windows, the Pkg provenance, and the NameCert row without adding any host-level completion coordinate.

Composition and tail restriction preserve the same visible package by Definition 332.3 and Definition 332.4. Ledger exactness then identifies every consumer read with one of the listed rows, and Definition 332.8 gives the public $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ export surface.

For the converse direction, start from a displayed standard package with exactly these BEDC rows. Repack the precision request, threshold row, modulus row, observation schedule, late-window witness, ledger, and provenance into the carrier tuple M. The same NameCert obligation surface and stability rows give acceptance, so the repacked object is the original public $\mathsf{ModulusOfConvergence}^{\uparrow}$ packet. □

Theorem 332.11 (ModulusOfConvergence threshold-ledger completeness)**.** *Every convergence-rate consumer of the* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *packet is completely determined by the precision*

request, selected unary threshold, modulus row, StreamName$^{\uparrow}$ *schedule,* RegSeqRat$^{\uparrow}$ *late-window witness,* hsame *transports,* Cont *windows,* Pkg *provenance, dependency ledger, and* NameCert *row.*

The export contains no quotient completion, selected real limit, global threshold choice outside the finite ledger, or host real equality.

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceRatePacket threshold ledger completeness`

Proof. Start with the carrier of Definition 332.1. It presents the precision request, selected unary threshold, modulus row, stream schedule, late-window witness, dependency ledger, package provenance, and local naming evidence as the only rows in the accepted packet.

Apply Definition 332.2 and Definition 332.3. These identify the classifier, stability, hsame, Cont, Pkg, and NameCert coordinates and show that composition keeps consumer reads on the displayed finite threshold-ledger surface.

Tail restriction is handled by Definition 332.4. Ledger exactness then follows from Definition 332.6, so a consumer can inspect only the finite request, threshold, schedule, late-window, transport, continuation, provenance, and ledger rows.

The public export and standard bridge are exactly Definition 332.8, Definition 332.9, and Definition 332.10. Together they show that the RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ read and the standard explicit-modulus schema use the same finite rows and do not export quotient completion, selected real limits, global threshold choice outside the finite ledger, or host real equality. □

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceCarrier threshold ledger completeness`

Theorem 332.12 (ModulusOfConvergence mature tail consumer example)**.** *A* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer that narrows to a later displayed tail reads the same finite convergence-rate package: the precision request, unary threshold selector, modulus row,* StreamName$^{\uparrow}$ *observations,* RegSeqRat$^{\uparrow}$ *late-window witness,* DyadicRatCore$^{\uparrow}$ *endpoint ledger,* hsame*,* Cont*,* Pkg*, dependency ledger, and local* NameCert *row.*

The tail read contains no quotient completion, selected real limit, global threshold choice outside the finite ledger, or host real equality.

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceRatePacket tail consumer boundary`

Proof. Start with Definition 332.4. It keeps a later displayed tail on the same precision request, unary threshold selector, modulus row, observation schedule, and late-window witness.

Apply Definition 332.6. The endpoint and dependency ledgers exhaust the finite coordinates that the tail consumer can inspect.

Next use Definition 332.8. This gives the RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ consumer surface over the same finite convergence-rate rows, together with hsame, Cont, Pkg, and local NameCert evidence.

Finally apply Definition 332.10. The standard explicit-modulus bridge reads exactly the displayed BEDC rows, so narrowing to a later tail cannot introduce quotient completion, a selected real limit, a global threshold choice outside the ledger, or host real equality. □

Theorem 332.13 (ModulusOfConvergence synchronized double-tail restriction)**.** *Let an accepted* ModulusOfConvergence$^{\uparrow}$ BHist *packet display a precision request, unary threshold selector, modulus row,* StreamName$^{\uparrow}$ *observation schedule,* RegSeqRat$^{\uparrow}$ *late-window witness,* DyadicRatCore$^{\uparrow}$ *endpoint ledger, dependency ledger,* Pkg *provenance, and local* NameCert *row. Suppose it also displays two unary tail restrictions, each connected to the next packet by concrete* Cont *rows. The twice-restricted*

packet preserves the same precision request, selector, modulus row, late-window witness, dependency ledger, package provenance, and NameCert row as the original packet.

Moreover, every $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the second tail factors through the original accepted packet, using only the two displayed* Cont *windows and the finite rows already present in that packet.*

Lean4 ✓ `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergenceCarrier synchronized double tail restriction`

Proof. Apply Definition 332.4 to the first displayed tail. This keeps the precision request, unary threshold selector, modulus row, late-window witness, dependency ledger, package provenance, and local NameCert row on the restricted packet.

Apply Definition 332.4 again to the restricted packet and its second displayed tail. The same rows are preserved through the second restriction, so the twice-restricted packet still reads the original finite convergence-rate data.

Use Definition 332.3 to compose the two displayed Cont windows. The composite window identifies the second tail as a single displayed restriction of the original packet, without introducing a new threshold choice or hidden representative.

Finally combine Definition 332.6, Definition 332.8, and Definition 332.10. Ledger exactness identifies the finite rows available to a consumer, the public export supplies the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ read surface, and the bridge shows that the second tail consumer factors through the original packet rather than through any quotient completion, selected real limit, or host real equality. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}$.

Constructive story: A $\mathsf{ModulusOfConvergence}^{\uparrow}$ packet is generated by a visible precision request, a unary threshold selector, a displayed modulus row, scheduled $\mathsf{StreamName}^{\uparrow}$ observations, a $\mathsf{RegSeqRat}^{\uparrow}$ late-observation witness, and a finite dependency ledger naming $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 332.10, Definition 332.11, and Definition 332.12 give the standard bridge, complete threshold-ledger consumer surface, and mature tail consumer theorem for the explicit finite convergence-rate package over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModulusOfConvergence}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ModulusOfConvergenceUp.ModulusOfConvergencePacket\_semantic\_name\_certificate`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a quotient completion, a selected real limit, a global threshold choice outside the finite ledger, or a Lean-checked bridge.

Upgrade path: No further paper-side theory-axis upgrade remains for this chapter; formal verification remains the next axis.

Chapter 333

A Concrete Naming Certificate for $\mathsf{CauchyFilter}^{\uparrow}$

The $\mathsf{CauchyFilter}^{\uparrow}$ interface names the finite filterbase surface used by the real-completion boundary. Following Bishop-style Cauchy completion and the Kelley–Bourbaki language of filters and directed bases, the BEDC object keeps only explicit finite rows: directed finite-tail dyadic neighbourhood evidence over regular Cauchy observations, refinement ledgers, modulus rows, and handoff rows for $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealBall}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Definition 333.1 (CauchyFilter finite-filterbase carrier)**.** *A* $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carrier is a finite* BHist *packet*

$$F = (B, R, M, L, P)$$

with the following visible rows:

1. *B is a finite list of directed finite-tail neighbourhood packets, each packet carrying a* $\mathsf{StreamName}^{\uparrow}$ *scheduled tail window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *regular Cauchy observation row, and a nonempty finite family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic neighbourhood witnesses;*
2. *R is a refinement ledger whose row for two displayed base packets names a third displayed tail packet refining both requested packets through a smaller dyadic tolerance window;*
3. *M is a* $\mathsf{CauchyModulus}^{\uparrow}$ *row assigning to each requested precision a finite tail packet after which all displayed dyadic neighbourhood witnesses around the regular Cauchy observations are within the requested radius;*
4. *L is the ledger exposing the base-packet rows, the refinement rows, the modulus rows, the componentwise* hsame *comparisons, the dyadic tolerance inclusions, and the displayed* Cont *routes used by refinements and precision reads;*
5. *P is the* Pkg *provenance row naming the* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealBall}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *certificate boundaries consumed by the packet.*

The carrier accepts only these finite rows. Classification is componentwise transport of B, R, M, L, and P through the displayed hsame *and* Cont *data.*

Theorem 333.2 (CauchyFilter directed refinement obligation)**.** *For every accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier $F = (B, R, M, L, P)$ and every two tail packets displayed in B, the refinement row in R is a displayed* Cont *and* hsame *obligation: it names a finite tail packet in the same carrier whose dyadic neighbourhood rows refine both inputs through the continuation routes recorded by L.*

Proof. Project the accepted carrier through Definition 333.1. The row R is stored with the tail packets it refines, so the two input packets and the refined packet are all visible finite BHist rows over the same regular Cauchy observation surface.

Read the continuation routes from L. Each route records how the refined packet restricts to the requested input packet, and the accompanying hsame rows compare the displayed dyadic neighbourhood witnesses componentwise.

Thus directedness is not a global existence assertion. It is exactly the finite refinement row already stored in the carrier, together with its displayed Cont and hsame witnesses. □

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterCarrier directed refinement endpoint surface`

Theorem 333.3 (CauchyFilter Cauchy modulus obligation)**.** *Let $F = (B, R, M, L, P)$ be an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier. The modulus row M makes F stable under smaller dyadic tail windows: for each displayed precision request, M selects a finite tail packet, and every later refinement row in R carries regular Cauchy observations whose* $\mathsf{DyadicRatCore}^{\uparrow}$ *neighbourhood ledger is included in the requested radius.*

Proof. Fix a precision request and project the selected row of M. It names a tail packet in B and records the requested dyadic radius through the $\mathsf{CauchyModulus}^{\uparrow}$ boundary.

Now take any later refinement row displayed by R. By Definition 333.2, the later packet refines the selected packet through explicit Cont routes and componentwise hsame comparisons.

The dyadic distance bound is read from the same finite ledger L. Since the bound is attached to the selected precision and transported along the displayed refinement rows, the carrier supplies a constructive Cauchy witness using only its finite tail, modulus, regular observation, and dyadic neighbourhood rows. □

Theorem 333.4 (CauchyFilter metastability consumer route)**.** *Every accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier consumed by a* $\mathsf{CauchyMetastability}^{\uparrow}$ *reader must expose the finite filterbase row, directed refinement row, Cauchy modulus row,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *before any metastable finite-tail verdict is read. The route exports no quotient filter, selected limit, host real equality, countable choice, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Project the accepted carrier through Definition 333.1. This exposes the finite filterbase row together with the stream schedules, regular rational observations, dyadic neighbourhood witnesses, refinement ledger, modulus row, evidence ledger, and provenance row.

Next apply Definition 333.2 and Definition 333.3. The first theorem supplies the directed refinement row and its displayed transport, while the second supplies the precision-to-tail modulus and tolerance accounting needed by a finite-tail request.

Finally route the consumer through the finite-tail stability packet of chapter 2093. A $\mathsf{CauchyMetastability}^{\uparrow}$ reader can inspect only the displayed request, window, tolerance, readback, transport, replay, provenance, and local naming rows, so the CauchyFilter input must present exactly the listed finite rows before the metastable verdict is available. □

Theorem 333.5 (CauchyFilter NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyFilter}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the finite-filterbase carrier of Definition 333.1;*
2. *classifier transport: accepted carriers compare by componentwise* hsame *transport of the tail packets, regular observation rows, dyadic neighbourhood witnesses, refinement ledgers, modulus rows, evidence ledgers, and provenance rows, with reads routed through displayed* Cont *data;*

3. *directedness: the displayed refinement row of Definition 333.2;*
4. *Cauchy modulus: the precision-to-base selection and dyadic-radius readback of Definition 333.3;*
5. *downstream handoff:* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers read only the tail packets, stream schedules, regular Cauchy observations, dyadic neighbourhood witnesses, real-ball bounds, refinement rows, modulus rows, ledger rows, and provenance rows of the same finite packet.*

These five rows form the seed obligation for naming completion-facing Cauchy filterbase data over displayed histories.

Proof. The carrier row is Definition 333.1. It supplies the finite tail packets, regular observation rows, dyadic neighbourhood witnesses, refinement ledger, Cauchy-modulus row, evidence ledger, and provenance row.

Classifier transport is componentwise. Transporting the five carrier coordinates through their displayed hsame rows and following the recorded Cont routes repacks the same finite-filterbase shape.

Directedness and the Cauchy property are the two distinguished projections of the carrier. The first projection is Definition 333.2; the second is Definition 333.3.

For downstream readback, a $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ consumer can cite only the rows named by P and exposed by L. Those rows are exactly the base packets, stream schedules, regular Cauchy observations, dyadic neighbourhood witnesses, real-ball bounds, refinement rows, modulus rows, ledger rows, and provenance rows of the carrier, so the surface is exhausted by the five listed obligations. □

Theorem 333.6 (CauchyFilter carrier transport obligation)**.** *Let* $F = (B, R, M, L, P)$ *and* $F' = (B', R', M', L', P')$ *be displayed* $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carriers. Suppose the evidence ledger exhibits componentwise* hsame *rows for* B *with* B'*,* R *with* R'*,* M *with* M'*,* L *with* L'*, and* P *with* P'*, and suppose every read used by a refinement or precision request is routed through the displayed* Cont *rows. Then classifier transport preserves the accepted carrier tuple:* F *is accepted exactly when the transported tuple* F' *is accepted, and all accepted reads remain inside the displayed finite rows* (B', R', M', L', P')*.*

Proof. Unpack the finite carrier of Definition 333.1. Acceptance is expressed only through the five displayed coordinates B, R, M, L, and P.

Transport is componentwise. The tail packets, regular observation rows, dyadic neighbourhood witnesses, refinement ledger, modulus row, evidence ledger, and provenance row are compared by the named hsame witnesses, while each refinement or precision read follows a displayed Cont route recorded in the ledger.

Apply Definition 333.5 to identify the classifier row as the transport row of the local $\mathsf{NameCert}$ surface. The transported carrier therefore has exactly the same finite-filterbase shape, with rows read from (B', R', M', L', P').

No host filter, selected limit, quotient real, or ambient completeness object is introduced by this transport. The construction moves only the displayed finite rows and their recorded hsame and Cont witnesses. □

Theorem 333.7 (CauchyFilter refinement directedness package)**.** *For an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier* $F = (B, R, M, L, P)$*, the directedness obligation is the finite package consisting of the two input tail packets in* B*, the selected third tail packet named by the row of* R*, the two displayed* Cont *routes from that selected packet to the inputs, the componentwise* hsame *witnesses for the*

transported dyadic neighbourhood rows, and the modulus row of M that reads the selected packet at every requested precision.

Proof. Choose two displayed tail packets in B. By Definition 333.2, the corresponding row of R names a third displayed tail packet together with the continuation routes and componentwise comparison rows needed to refine both inputs.

The selected packet is still a tail packet of the same finite carrier, so the modulus row can be read without leaving the displayed surface. Apply Definition 333.3 to attach the requested precision row and its dyadic-radius ledger to the same refinement package.

The resulting object is a directedness package, not an ambient filter principle. Every component is one of the rows already listed in Definition 333.1 and exposed by Definition 333.5. □

Theorem 333.8 (CauchyFilter Real and RegSeqRat handoff non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier* $F = (B, R, M, L, P)$ *reads only the displayed tail packets, the* $\mathsf{StreamName}^{\uparrow}$ *schedules, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular observation rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *neighbourhood rows, the* $\mathsf{RealBall}^{\uparrow}$ *bounds, the refinement rows, the Cauchy-modulus rows, the ledger rows, and the* Pkg *provenance rows named by* L *and* P*. The handoff does not read a host filter, a selected limit, a quotient real, or an ambient completeness principle.*

Proof. Project the downstream handoff row from Definition 333.5. It lists the rows available to $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumers: tail packets, stream schedules, regular Cauchy observations, dyadic neighbourhood rows, real-ball bounds, refinement rows, modulus rows, ledger rows, and provenance rows.

The carrier definition fixes where these rows live. By Definition 333.1, the base packets are in B, refinement data is in R, precision data is in M, read evidence is in L, and downstream provenance is in P.

Directed refinement and precision readback do not add further carrier data. They are the displayed rows supplied by Definition 333.2 and Definition 333.3.

Thus the Real and regular rational sequence handoff is closed under the named finite rows. Since no step constructs or selects an external filter limit, the handoff cannot escape through host filters, selected limits, quotient reals, or ambient completeness. □

Theorem 333.9 (CauchyFilter L10 dependency handoff lattice)**.** *Every accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *handoff is a horizontal L10 dependency lattice for the real-completion surface. Its tail packets are read through chapter 126, its dyadic neighbourhood witnesses through chapter 291, its regular readbacks through chapter 301, and its final seal through chapter 38. The lattice is exhausted by the finite carrier rows, directed refinement rows, Cauchy-modulus rows, ledger evidence, and provenance rows of the accepted carrier; it contains no host filter, selected limit, quotient real, or ambient completeness datum.*

Proof. Start with an accepted carrier $F = (B, R, M, L, P)$. The carrier definition Definition 333.1 places every tail packet in the displayed finite row B, and each such packet carries its BHist evidence, $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{RegSeqRat}^{\uparrow}$ regular observation row, dyadic neighbourhood rows, real-ball bounds, ledger reads, and downstream provenance. Hence the horizontal tail layer of the handoff is read through the StreamName and DyadicRatCore concrete-instance chapters cited in the statement.

The middle layer is forced by the two obligations of the accepted carrier. Apply Definition 333.2 to read a displayed refinement row of R whenever two tail packets are compared, and apply Definition 333.3 to read the displayed precision row of M together with its retained dyadic-radius

ledger. These rows are still entries of B, R, M, and L, so they add refinement and Cauchy control without introducing a new completion object.

Finally apply Definition 333.8. It identifies the regular-sequence and real handoff boundary as exactly the displayed tail, stream, regular observation, dyadic, real-ball, refinement, modulus, ledger, and Pkg provenance rows. Therefore the RegSeqRat readback layer and the Real sealing layer are the cited sibling concrete-instance dependencies, and the whole L10 handoff is closed before any host filter, selected limit, quotient real, or ambient completeness principle can be read. □

Theorem 333.10 (CauchyFilter Real-RegSeq completion scope)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *completion-facing consumer of an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet factors through the displayed finite* FilterBase *row, directed refinement obligation, Cauchy modulus row,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{RealBall}^{\uparrow}$ *bounds,* Pkg *provenance, componentwise* hsame *transport, displayed* Cont *replay, and local* NameCert *rows of that packet. The scope contains no quotient filters, selected limits, countable choice, host equality, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Begin with the finite-filterbase carrier of Definition 333.1. It places the base packets, refinement witnesses, precision rows, ledger evidence, and provenance in the displayed coordinates B, R, M, L, P.

Apply the directed refinement and Cauchy-modulus obligations of Definition 333.2 and Definition 333.3. These obligations read the finite filter-base row, a refinement row for each comparison, and the modulus row with its dyadic-radius ledger.

Next use the Real and RegSeqRat handoff non-escape theorem Definition 333.8. It identifies the downstream completion-facing reads as the displayed tail packets, $\mathsf{StreamName}^{\uparrow}$ schedules, $\mathsf{RegSeqRat}^{\uparrow}$ regular rows, $\mathsf{RealBall}^{\uparrow}$ bounds, ledger rows, and Pkg provenance already carried by B, R, M, L, P.

Finally use the L10 dependency handoff lattice of Definition 333.9. The lattice routes the same rows through StreamName, DyadicRatCore, RegSeqRat, and Real consumers before any completion-facing seal is read. Since no ingredient adds quotient filters, selected limits, countable choice, host equality, or ambient completeness, the displayed rows exhaust the completion scope. □

Theorem 333.11 (CauchyFilter uniform-space completion handoff)**.** *Let* $F = (B, R, M, L, P)$ *be an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carrier whose provenance row exposes the same finite entourage and filterbase surface consumed by* $\mathsf{UniformSpace}^{\uparrow}$*. Every* $\mathsf{Completion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *read admitted from* F *factors first through the displayed* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *neighbourhood witnesses,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows,* $\mathsf{RealBall}^{\uparrow}$ *bounds, and the finite* $\mathsf{UniformSpace}^{\uparrow}$ *entourage rows before any completion-facing seal is available. Consequently the handoff described in chapter 339 and consumed by chapter 95 and chapter 57 receives only the finite ledger displayed by the Cauchy filterbase carrier, not a selected limit, quotient stream, host filter, or ambient completeness object.*

Proof. Project the carrier $F = (B, R, M, L, P)$. The base row B supplies the displayed tail packets, R supplies directed refinement, M supplies Cauchy precision, L supplies ledger reads, and P supplies provenance. By Definition 333.9, these rows already identify the StreamName windows, DyadicRatCore neighbourhood witnesses, RegSeqRat readback rows, RealBall bounds, ledger evidence, and real-facing provenance.

Next route the finite filterbase as uniform entourage data. Apply Definition 339.6: the UniformSpaceUp interface exposes only finite entourage rows, diagonal rows, refinement rows, symmetry rows, composition rows, endpoint hsame transport, and Pkg provenance. Since the provenance

row of F exposes precisely this surface, the CauchyFilterUp read may be consumed by the UniformSpaceUp handoff without adding a further carrier coordinate.

The completion-facing consumer therefore receives the displayed finite ledger in the stated order: stream windows, dyadic observations, regular readback, real-ball bounds, and uniform entourage rows. None of the preceding projections constructs a chosen limit, quotient stream equality, host filter, or ambient completeness witness, so no such object can be read before the completion-facing seal. □

Definition 333.12 (CauchyFilter finite subfilterbase restriction datum)**.** *Let $F = (B, R, M, L, P)$ be an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carrier in the sense of Definition 333.1. A finite subfilterbase restriction datum for F is a displayed finite sublist $B' \subseteq B$ together with two preservation rows:*

1. *refinement preservation: whenever b_0 and b_1 are displayed in B' and the row of R for (b_0, b_1) names a refined tail packet b_2, the packet b_2 is displayed in B' and the corresponding* Cont *and* hsame *witnesses in L are retained in the restricted ledger;*
2. *modulus preservation: for every precision request admitted by the carrier, the tail packet selected by the row M is displayed in B', and the associated dyadic-radius readback row of L is retained in the restricted ledger.*

The restricted packet is

$$F|_{B'} = (B', R|_{B'}, M|_{B'}, L|_{B'}, P),$$

where $R|_{B'}$ keeps exactly the refinement rows whose two inputs lie in B', $M|_{B'}$ keeps the same precision-to-base selections, $L|_{B'}$ keeps only the ledger rows used by those tail, regular observation, dyadic neighbourhood, refinement, modulus, Cont*, and* hsame *reads, and P is the unchanged downstream provenance row.*

Theorem 333.13 (CauchyFilter finite subfilterbase restriction)**.** *Let $F = (B, R, M, L, P)$ be an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carrier. If $B' \subseteq B$ is a finite subfilterbase restriction datum for F in the sense of Definition 333.12, then the restricted packet*

$$F|_{B'} = (B', R|_{B'}, M|_{B'}, L|_{B'}, P)$$

is an accepted $\mathsf{CauchyFilter}^{\uparrow}$ *finite-filterbase carrier. Its downstream handoff boundary is the same finite* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RealBall}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *provenance boundary carried by F.*

Proof. The carrier rows are finite because B' is a displayed finite sublist of the finite tail row B, while $R|_{B'}$, $M|_{B'}$, and $L|_{B'}$ are obtained by retaining displayed rows from the finite ledgers R, M, and L of Definition 333.1. Each tail packet in B' is already a tail packet of B, hence it carries the same BHist row, $\mathsf{StreamName}^{\uparrow}$ scheduled window, $\mathsf{RegSeqRat}^{\uparrow}$ regular observation row, and nonempty finite family of $\mathsf{DyadicRatCore}^{\uparrow}$ neighbourhood rows that it carried in F.

Directedness is inherited row by row. Take two tail packets displayed in B'. In the accepted carrier F, Definition 333.2 reads the corresponding row of R as a displayed refinement packet together with its Cont routes and componentwise hsame witnesses. Refinement preservation in the restriction datum says that this refined packet is again displayed in B' and that the required continuation and comparison witnesses remain in $L|_{B'}$. Therefore $R|_{B'}$ supplies exactly the directed refinement obligation required of the restricted carrier.

The Cauchy modulus row is also inherited without changing the selected bases. For a displayed precision request, Definition 333.3 reads the row of M in F as a selected tail packet together with

the dyadic radius ledger controlling every later displayed refinement. Modulus preservation says that the selected packet lies in B' and that the associated radius readback row remains in $L|_{B'}$. If a later refinement is read inside $R|_{B'}$, it is one of the refinement rows of R, so the same dyadic bound from L applies to it, and the retained row in $L|_{B'}$ records that bound. Thus $M|_{B'}$ is a constructive Cauchy modulus for the restricted packet.

It remains to identify the handoff boundary. The restriction does not replace P; it only removes base, refinement, modulus, and ledger rows not used by B'. Hence a downstream $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ consumer can still read exactly the provenance categories listed in Definition 333.5: tail packets, stream schedules, regular Cauchy observations, dyadic neighbourhood rows, real-ball bounds, refinement rows, modulus rows, ledger rows, and the same Pkg provenance boundary. Since every retained row is a displayed row of the accepted carrier and the two preservation conditions keep all refinement and modulus rows needed for the CauchyFilter obligations, $F|_{B'}$ repacks as an accepted $\mathsf{CauchyFilter}^{\uparrow}$ carrier with the same finite downstream handoff boundary. □

Chapter 334

A Concrete Naming Certificate for $\mathsf{BaireSpace}^{\uparrow}$

The $\mathsf{BaireSpace}^{\uparrow}$ interface names Brouwer-style Baire space as a certificate for natural-number-indexed streams whose observations are displayed finite unary histories. The BEDC surface does not treat infinite sequences as primitive histories. It records finite prefix windows, a prefix-cylinder classifier, stream-name scheduling rows, and package provenance that can be read by $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers. The schedule row s is consumed from chapter 126; $\mathsf{Nat}^{\uparrow}$ supplies the unary index rows, and the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ boundaries are the downstream consumer surfaces for the displayed finite prefix windows.

Definition 334.1 (BaireSpace stream carrier)**.** *A* $\mathsf{BaireSpace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (s, w, c, l, p)$$

with the following visible rows:

1. *s is a* $\mathsf{StreamName}^{\uparrow}$ *schedule row whose nth displayed request returns a finite* $\mathsf{UnaryHistory}$ *answer row;*
2. *w is a finite prefix-window ledger listing the requested natural indices and the unary answer rows displayed for those indices;*
3. *c is the prefix-cylinder classifier row: two packets classify together over a displayed window exactly when their listed unary answer rows are paired componentwise by* hsame *through the same scheduled indices;*
4. *l is the local ledger exposing the* BHist *packet, the* $\mathsf{UnaryHistory}$ *answer rows, the finite index window, the componentwise* hsame *comparisons, and the* Cont *routes used by prefix restriction;*
5. *p is the* Pkg *provenance row naming the* $\mathsf{Nat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *certificate boundaries available to consumers.*

The carrier predicate is $\mathsf{BairePrefix}(s, w, c, l, p)$*. It accepts only finite prefix displays of a natural-number-indexed stream; every public read is routed through the selected window and the displayed classifier row.*

Lean4 ✓ `BEDC.Derived.BaireSpaceUp.TasteGate.BaireSpaceTasteGate single carrier alignment`

Theorem 334.2 (BaireSpace prefix-cylinder stability)**.** *Let $B = (s, w, c, l, p)$ be an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *carrier. If B' is obtained from B by transporting the stream schedule, every displayed*

unary answer in a finite prefix window, the classifier row, the local ledger, and the provenance row by the hsame *and* Cont *data recorded in l, then B' is again an accepted carrier. The prefix-cylinder classifier for the transported window reads exactly the transported unary rows and no tail beyond that window.*

Lean4 ✓ `BEDC.Derived.BaireSpaceUp.BaireSpacePrefixPacket prefix cylinder stability`

Proof. Project the carrier of Definition 334.1. The only data visible to the classifier are the stream schedule, the finite index window, and the unary answer rows listed by that window.

Transport each listed row through the displayed hsame comparisons in the ledger. The Cont routes in the same ledger restrict the stream readback to the transported prefix, so the repacked tuple has the same carrier shape.

The classifier row is a cylinder classifier. It compares exactly the displayed prefix entries, and no coordinate in the carrier stores an infinite tail as a history object. Thus the transported packet is accepted with the transported prefix-cylinder read. □

Theorem 334.3 (BaireSpace prefix-restriction composition)**.** *Let $B = (s, w, c, l, p)$ be an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *carrier. Suppose the ledger l displays a prefix restriction from B to B_1 and then a second prefix restriction from B_1 to B_2, each recorded by the corresponding* hsame *comparisons and* Cont *routes on the stream schedule, finite index window, unary answer rows, classifier row, and provenance row. Then the composite restriction is again an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *prefix packet.*

Its visible unary rows are exactly the twice-restricted subwindow of w, its classifier is the componentwise hsame *restriction of the original prefix-cylinder classifier c to that subwindow, and its provenance is still the same* Pkg *row p. The composite packet introduces no hidden infinite tail and no host sequence equality.*

Proof. Project the accepted packet B through Definition 334.1. The first displayed restriction is a transport of the schedule, window, unary rows, classifier, ledger, and provenance along rows already recorded in l.

Use Definition 334.2 on this first restriction. The result is an accepted prefix packet B_1 whose classifier reads only the first restricted finite subwindow.

Apply the same stability theorem to the second displayed restriction out of B_1. The Cont routes compose inside the displayed ledger, so the resulting packet reads precisely the subwindow obtained by restricting the original prefix window twice.

It remains to identify the classifier and provenance. The classifier at each listed coordinate is obtained by the componentwise hsame restriction of the original cylinder row c, and the Pkg coordinate is transported as the same provenance row p.

Finally, the ledger coverage statement of Definition 334.7 rules out every consumer read not listed in the finite window. Hence the composite construction cannot expose an infinite tail or an equality of host sequences. □

Lean4 ✓ `BEDC.Derived.BaireSpaceUp.BaireSpacePrefixPacket prefix restriction composition`

Theorem 334.4 (BaireSpace NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier: the stream carrier of Definition 334.1;*
2. *classifier: the prefix-cylinder row comparing displayed unary answers componentwise over a finite index window;*
3. *stability: prefix-window transport as in Definition 334.2;*

4. *exactness: a public observation is readable from the certificate iff it is one of the finite unary rows listed by the selected prefix window;*
5. *provenance: downstream reads factor through the displayed* $\mathsf{Nat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *package rows carried by* p.

These rows are the complete seed obligation for naming countable stream space data over BEDC histories.

Proof. The carrier and classifier rows are the first two projections of Definition 334.1. They expose the scheduled stream read, the finite index window, and the unary answer rows over that window.

Stability is supplied by Definition 334.2. Transporting the schedule, window, answer rows, ledger, and provenance repacks the same finite prefix surface.

For exactness, inspect the coordinates of the packet. A public observation can only be read from the prefix ledger w through the classifier row c and the routes in l. The provenance row p names the available consumers but does not add a second observation channel. □

Theorem 334.5 (BaireSpace real-name handoff)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packet reads the stream only through finite prefix windows. A regular rational sequence consumer may read a requested unary index and its scheduled answer row, and a real-name consumer may combine that finite read with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *provenance named by* p. *Neither consumer receives a primitive infinite history, a completed real, or an unlogged tail equality.*

Lean4 ✓ `BEDC.Derived.BaireSpaceUp.BaireSpacePrefixPacket real name handoff transport`

Proof. Project the accepted packet through Definition 334.1. The stream schedule is present only through finite request rows, and the answers are the unary histories displayed in w.

A $\mathsf{RegSeqRat}^{\uparrow}$ consumer therefore obtains a finite index request and the corresponding unary answer row. Transport of that read is controlled by the prefix-cylinder classifier and the ledger routes.

A $\mathsf{Real}^{\uparrow}$ consumer can additionally use the $\mathsf{DyadicRatCore}^{\uparrow}$ provenance named by p when interpreting the finite answer as a dyadic or regular sequence component. The packet still exposes only the selected prefix rows, so no completed infinite object is exported. □

Theorem 334.6 (BaireSpace Real stream prefix determinacy)**.** *Let* $B = (s, w, c, l, p)$ *and* $B' = (s', w', c', l', p')$ *be accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packets. Suppose their scheduled finite prefix indices agree and the unary answer rows at each displayed index are paired componentwise by* hsame. *Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the same finite stream-prefix boundary from* B *and* B'.

The determinacy is only for logged finite prefix rows. It does not identify primitive infinite histories, host sequences, completed reals, or unlogged tails.

Proof. Apply Definition 334.2 to transport the componentwise unary answer rows through the common scheduled prefix indices. The transported classifier still reads only the displayed finite window.

Use Definition 334.3 to compare any consumer-requested subwindow of the two packets inside the same restricted prefix. The composed restriction preserves the schedule, answer rows, classifier, ledger, and provenance rows needed by the consumer.

For $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, invoke Definition 334.5. Those consumers receive only the finite prefix requests and unary answer rows, with the $\mathsf{DyadicRatCore}^{\uparrow}$ provenance available to the real-name interpretation.

Finally apply Definition 334.7. Since the ledger covers exactly the displayed stream packet, unary answer rows, prefix window, classifier, hsame comparisons, Cont routes, and provenance, there is no row from which an infinite history, host sequence equality, completed real, or unlogged tail could distinguish the two reads. □

Theorem 334.7 (BaireSpace ledger coverage)**.** *For an accepted carrier $B = (s, w, c, l, p)$, the ledger l covers every public row of the* $\mathsf{BaireSpace}^{\uparrow}$ *packet: the* BHist *stream packet, the* UnaryHistory *answer rows, the finite prefix window, the prefix-cylinder classifier, the componentwise* hsame *comparisons, the prefix-restriction* Cont *routes, and the package provenance. The ledger exports no apartness principle, choice functional, host sequence equality, or real-completeness assertion.*

Proof. Read the packet coordinates one by one. The stream schedule s, prefix window w, classifier c, and provenance p are all named fields of the carrier, and the ledger l records the comparison and restriction routes among them.

Any public row must be read from one of those fields. Prefix restriction uses the displayed Cont route, while equality of observations uses the displayed componentwise hsame rows in the cylinder classifier.

The omitted objects would require extra coordinates: an apartness principle, a choice functional, a host equality on full sequences, or a completeness theorem for real names. No such coordinate occurs in the carrier, so the ledger coverage is exactly the listed finite surface. □

Theorem 334.8 (BaireSpace cylinder-tail coverage)**.** *Every finite prefix-cylinder consumer read from an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packet factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule, the prefix-restriction ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and the* $\mathsf{Real}^{\uparrow}$ *handoff boundary. The read exposes no completed infinite sequence, no classical topology, and no choice-selected branch.*

Proof. Read the stream carrier of Definition 334.1. Its public coordinates are the schedule, finite prefix window, prefix-cylinder classifier, ledger, and provenance rows, so a cylinder-tail consumer begins with a finite window named by that carrier.

Use Definition 334.2 to keep the cylinder answer stable under displayed prefix reads, and Definition 334.3 to compose the restriction ledger. These steps route the consumer through the same hsame transport and Cont paths already recorded in the packet.

The real-facing boundary is exactly the finite handoff of Definition 334.5, and Definition 334.7 exhausts the remaining public rows. No carrier coordinate stores a completed sequence, a topological completion, or a choice-selected branch, so such data cannot be exported by a prefix-cylinder read. □

Theorem 334.9 (BaireSpace choice-spread continuity route)**.** *Every finite-prefix consumer of an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packet that feeds a* $\mathsf{ChoiceSequence}^{\uparrow}$, $\mathsf{SpreadLaw}^{\uparrow}$, *or* $\mathsf{BrouwerContinuityPrinciple}^{\uparrow}$ *read must factor through the displayed route*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{Nat}^{\uparrow},\ \mathsf{UnaryHistory},\ \textit{prefix-cylinder classifier},\ \mathsf{hsame},\ \mathsf{Cont},\ \mathsf{Pkg},\ \mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}.$$

The route reaches the $\mathsf{ChoiceSequence}^{\uparrow}$ *answer rows,* $\mathsf{SpreadLaw}^{\uparrow}$ *prefix admission, and* $\mathsf{BrouwerContinuityPrinciple}^{\uparrow}$ *finite-modulus boundary only after the stream schedule, unary prefix window, prefix-cylinder classifier, and* Pkg *provenance have been displayed. It exports no completed Baire function, no host sequence equality, no choice-selected branch, no external topology, and no real-completeness datum before any* $\mathsf{Real}^{\uparrow}$*-facing handoff.*

Proof. Start with Definition 334.8. It forces every tail-sensitive read of a $\mathsf{BaireSpace}^{\uparrow}$ prefix packet through the displayed stream schedule, finite prefix ledger, hsame transport, Cont routes, package provenance, and real-facing boundary.

The finite classifier is pinned by Definition 334.10. Thus a consumer cannot inspect a choice-sequence answer, a spread-law extension row, or a continuity modulus before it has displayed the unary prefix window and the prefix-cylinder classifier.

For the choice-sequence side, use chapter 1482; for spread admission, use chapter 1532; for the continuity consumer, use chapter 3465. Each sibling chapter consumes only finite prefix rows, so each sits downstream of the same $\mathsf{StreamName}^{\uparrow}$ schedule and Pkg provenance rather than upstream of them.

Finally apply Definition 334.5 and Definition 334.7. These exhaust the rational and real-facing boundary and the local ledger rows, leaving no coordinate for a completed host stream, a selected branch, host equality, topology, or real completeness. □

Theorem 334.10 (BaireSpace obligation window classifier)**.** *Every accepted* $\mathsf{BaireSpace}^{\uparrow}$ *prefix packet supplies the obligation surface consisting of the finite* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows, displayed* $\mathsf{UnaryHistory}$ *answers, prefix-cylinder classifier, componentwise* hsame*, prefix-restriction* Cont*,* Pkg *provenance, and consumer handoff rows for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*.*

The classifier is exhausted by finite windows. It excludes host sequence equality, choice-selected branches, and classical topology.

Proof. Project the accepted prefix packet through Definition 334.1. The carrier provides the finite schedule, index window, displayed unary answers, classifier row, ledger, and package provenance.

Use Definition 334.2 and Definition 334.3 to keep every classifier read inside finite prefix windows under the displayed hsame and Cont rows.

Apply Definition 334.4 for the local naming surface, Definition 334.5 for the $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer rows, and Definition 334.7 for exhaustion of the public ledger.

Finally, Definition 334.8 rules out any tail read not already listed in the finite cylinder packet. Thus the obligation surface is exactly the finite window classifier, with no host sequence equality, choice-selected branch, or classical topology. □

Theorem 334.11 (BaireSpace finite cylinder stream boundary)**.** *Every accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packet consumed by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *is exhausted by the finite schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows, displayed* $\mathsf{UnaryHistory}$ *answers, prefix-cylinder classifier, componentwise* hsame *rows,* Cont *restriction routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ *ledger. These rows are the exact finite-cylinder boundary for stream-name, regular-sequence, and real-facing consumers.*

The boundary excludes host sequence equality, infinite tails, classical topology, choice-selected branches, and completed reals.

Proof. Project the accepted packet through Definition 334.1. The carrier exposes the finite $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{Nat}^{\uparrow}$ index rows, displayed unary answers, prefix-cylinder classifier, transport routes, package provenance, and local certificate ledger.

Apply Definition 334.5 to identify the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer rows reached from that schedule. The handoff uses the same finite prefix-cylinder coordinates and introduces no completed real or host stream equality.

Use Definition 334.7 for the remaining package and certificate rows, and use Definition 334.8 to rule out any read from an undisplayed infinite tail. The obligation window classifier of Definition 334.10 then pins the classifier surface to the same finite window.

Thus every $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ consumer read is one of the projected finite-cylinder rows. Since those rows contain no host sequence equality, infinite tail object, classical topological principle, choice-selected branch, or completed real, none can appear at the boundary. □

Theorem 334.12 (BaireSpace scoped finite-consumer boundary)**.** *Every* $\mathsf{BaireSpace}^{\uparrow}$ *consumer read factors through the finite* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{Nat}^{\uparrow}$ *index rows, displayed* UnaryHistory *answers, the prefix-cylinder classifier, componentwise* hsame*, prefix-restriction* Cont*,* Pkg *provenance, and the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *handoff rows.*

This finite boundary exhausts the scoped public surface. It exposes no host sequence equality, no choice-selected branch, no completed infinite sequence, and no classical topology.

Proof. Project the consumer read through the stream carrier of Definition 334.1. The only displayed coordinates are the schedule, finite index window, unary answer rows, classifier, transport ledger, package provenance, and downstream handoff rows.

Apply Definition 334.2 to keep the prefix-cylinder answer stable under displayed finite reads. Then use Definition 334.3 to compose the prefix-restriction Cont rows along the same componentwise hsame route.

The real-facing and rational-facing consumer rows are supplied by Definition 334.5. The remaining public coordinates are exhausted by Definition 334.7 and by the obligation window classifier of Definition 334.10.

Therefore any scoped consumer read is already one of the finite prefix-cylinder packet reads listed above. Since none of the cited rows constructs a host sequence equality, a choice branch, a completed infinite sequence, or a classical topological object, none is available at the scoped boundary. □

Theorem 334.13 (BaireSpace public prefix-cylinder certificate)**.** *The stream carrier of Definition 334.1, the obligation window classifier of Definition 334.10, and the finite-consumer boundary of Definition 334.12 export the public* $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ *surface for the same prefix-cylinder packet.*

That surface consists exactly of the finite $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{Nat}^{\uparrow}$ *index rows, displayed* UnaryHistory *answers, the prefix-cylinder classifier, componentwise* hsame*, prefix-restriction* Cont*,* Pkg *provenance, and the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *handoff rows. It excludes host sequence equality, choice-selected branches, completed infinite sequences, classical topology, apartness on Baire space, and real completeness.*

Proof. Start with an accepted prefix-cylinder packet and project it through Definition 334.1. This gives the finite schedule, index rows, displayed unary answers, classifier coordinate, transport routes, and package provenance that are available to the public name certificate.

The classifier row is the one identified by Definition 334.10. Its finite-window description is stable under the componentwise hsame and prefix-restriction Cont rows already used by the scoped boundary.

The downstream rows are exactly the rows supplied by Definition 334.5. The remaining ledger coordinates are exhausted by Definition 334.7, while Definition 334.8 prevents a hidden tail read from entering the packet.

Finally apply Definition 334.12. It states that every consumer read has already factored through this finite prefix-cylinder list, so repackaging the same rows as the public $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ surface adds no host equality, branch selector, completed sequence, topological principle, Baire-space apartness, or real completeness field. □

Theorem 334.14 (BaireSpace prefix-stream bridge)**.** *The public prefix-cylinder certificate of Definition 334.13 has a conservative stream-name reading: every accepted prefix-cylinder read factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows, unary answer rows, componentwise* hsame*, prefix-restriction* Cont*,* Pkg *provenance, and the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *handoff rows. Reading the stream-name packet back recovers exactly those rows.*

The bridge adds no host sequence equality, choice-selected branch, completed infinite sequence, classical topology, apartness on Baire space, or real completeness.

Lean4 ✓ `BEDC.Derived.BaireSpaceUp.BaireSpaceUp StdBridge`

Proof. Project the public certificate through Definition 334.13. Its visible rows are already the finite schedule, finite index window, unary answers, classifier, componentwise transport, prefix-restriction route, package provenance, and downstream handoff rows.

Use Definition 334.12 to identify every standard finite-prefix read with one of these displayed packet rows. This prevents a read of an infinite host sequence or a choice-selected branch from being inserted into the prefix-cylinder interface.

Apply Definition 334.8. The finite cylinder tail is already accounted for by the displayed prefix window, so no completed infinite sequence or hidden tail coordinate enters the readback.

For downstream consumers, apply Definition 334.5. The rational and real-facing handoffs remain finite prefix reads and do not require real completeness, classical topology, or a Baire-space apartness principle.

Finally use Definition 334.7 to exhaust the remaining ledger rows. Reading the standard finite prefix-cylinder packet back into $\mathsf{BaireSpace}^{\uparrow}$ therefore recovers exactly the displayed carrier and handoff surface, with no additional host equality, branch selector, completed sequence, topological object, apartness row, or real-completeness row. □

Theorem 334.15 (BaireSpace finite prefix-cylinder coverage)**.** *Every finite stream-name consumer read of a certified* $\mathsf{BaireSpace}^{\uparrow}$ *packet factors through a displayed prefix-cylinder row.*

Compatible nested prefix cylinders share a common finite prefix transport through the same BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ *rows.*

Proof. Start with Definition 334.2. It keeps each accepted finite read inside the displayed prefix-cylinder classifier, finite $\mathsf{Nat}^{\uparrow}$ index rows, unary answer rows, and stream schedule.

For nested cylinders, apply Definition 334.3. The composed restriction route supplies the common finite prefix transport through the same hsame, Cont, package, and local certificate rows.

Use Definition 334.5 for rational and real-facing consumers. Those reads remain finite stream-name handoffs rather than completed sequences or real-completeness assumptions.

Finally combine Definition 334.12 with Definition 334.14. The scoped boundary exhausts the finite consumer rows, and the bridge identifies the same rows with the stream-name presentation, yielding the stated finite prefix-cylinder coverage. □

Theorem 334.16 (BaireSpace StreamName prefix sieve)**.** *Every finite prefix-cylinder read consumed by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows,* $\mathsf{UnaryHistory}$ *answer rows, prefix-cylinder classifier, componentwise* hsame *rows,* Cont *restriction routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$ *ledger.*

The sieve exports no choice-selected branch, host sequence equality, completed sequence, or real-completeness row.

Proof. Begin with Definition 334.2. It keeps each finite observation inside the displayed prefix-cylinder classifier and the finite $\mathsf{Nat}^{\uparrow}$ index and unary answer rows.

Use Definition 334.3 to compose the restriction routes. The resulting read still travels through the same $\mathsf{StreamName}^{\uparrow}$ schedule, componentwise hsame rows, Cont routes, package provenance, and local naming ledger.

For rational and real consumers, apply Definition 334.5. The $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows are therefore finite prefix reads of the displayed stream schedule rather than completed host sequences.

Finally invoke Definition 334.7. It exhausts the remaining certificate rows, so no choice-selected branch, host sequence equality, completed sequence, or real-completeness row is exported. □

Theorem 334.17 (BaireSpace finite-prefix consumer completeness)**.** *Every accepted finite consumer of the public prefix-cylinder bridge factors through one displayed finite prefix window. The window consists exactly of the* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows, unary answer rows, the prefix-cylinder classifier, componentwise* hsame *rows, prefix-restriction* Cont *routes,* Pkg *provenance, and the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *handoff rows.*

This factorization exports no host sequence equality, choice branch, completed infinite sequence, apartness row, external topology, or real completeness row.

Proof. Start with the public prefix-cylinder certificate of Definition 334.13. Its exposed rows are already the finite schedule, prefix index window, displayed unary answers, classifier coordinate, componentwise transport, prefix-restriction route, package provenance, and downstream handoff surface.

Read the same packet through Definition 334.14. This identifies every bridge consumer with the stream-name presentation over the same finite prefix window, so the consumer has no separate access to a host sequence or a choice-selected branch.

The remaining coverage is ledger-local. Apply Definition 334.7 to exhaust the certificate rows and Definition 334.8 to keep tail information inside the displayed finite cylinder. No completed infinite sequence or external topological row is produced.

Finally apply Definition 334.5. The $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ consumers therefore receive only the listed handoff rows, not real completeness, apartness on Baire space, or any additional host equality principle. Hence every accepted finite consumer factors through the displayed finite prefix window. □

Theorem 334.18 (BaireSpace prefix intersection normal form)**.** *Two compatible finite prefix-cylinder consumers of an accepted* $\mathsf{BaireSpace}^{\uparrow}$ *packet, whose requested* $\mathsf{Nat}^{\uparrow}$ *prefix windows overlap through displayed* hsame *and* Cont *routes, factor through one displayed finite prefix window. The normal-form window carries the* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{Nat}^{\uparrow}$ *index rows,* $\mathsf{UnaryHistory}$ *answer rows, the prefix-cylinder classifier, componentwise* hsame *rows,* Cont *restrictions,* Pkg *provenance, and the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *handoff rows.*

The intersection read exports no host sequence equality, choice branch, completed infinite sequence, apartness row, external topology, or real-completeness row.

Proof. Use Definition 334.2 on each consumer. Both reads remain inside finite prefix-cylinder rows whose schedule, requested $\mathsf{Nat}^{\uparrow}$ indices, unary answers, and prefix classifier are displayed in the accepted packet.

Apply Definition 334.3 to the overlap routes. Compatibility through hsame and Cont lets the two requested windows compose to one finite window carrying the common componentwise transport, restriction provenance, and Pkg row.

Read the resulting window through Definition 334.14 and Definition 334.16. These identify the intersection as a $\mathsf{StreamName}^{\uparrow}$ schedule read and exhaust the finite prefix coordinates before any completed host sequence or choice-selected branch can be formed.

Finally invoke Definition 334.17. The $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ consumers receive only the listed handoff rows, so the compatible intersection has the stated finite normal form and exports none of the excluded topology, apartness, or real-completeness data. □

Theorem 334.19 (BaireSpace prefix-cylinder separation)**.** *Let two accepted* $\mathsf{BaireSpace}^{\uparrow}$ *prefix packets have a displayed common finite prefix window. If, at the first listed mismatch in that window, one displayed* UnaryHistory *answer row is not related by the packet classifier to the corresponding row of the other packet, then the two packets do not classify together through that prefix-cylinder surface.*

Later tail rows, host sequence equality, completed infinite sequences, external topology, apartness data, and choice-selected branches are irrelevant to this separation claim.

Proof. Project both packets to their finite prefix-cylinder carriers. The projected rows are the $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{Nat}^{\uparrow}$ prefix indices, displayed UnaryHistory answers, the prefix classifier, componentwise hsame transport, prefix-restriction Cont routes, package provenance, and the downstream handoff rows.

Use Definition 334.2 on both packets. Every classifier read that can affect the prefix-cylinder comparison is restricted to the displayed unary answer rows inside the common finite window.

Apply Definition 334.3 and Definition 334.18. These put the two packets on one displayed prefix window, with the same visible transport and restriction provenance, before any later tail coordinate is consulted.

At the first listed mismatch, the classifier row required for joint classification is absent by hypothesis. The packet carrier has no hidden host sequence equality, classical topology datum, or tail row that can replace this displayed classifier coordinate. Hence the two packets cannot classify together through the prefix-cylinder surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$**.**

Constructive story: A $\mathsf{BaireSpace}^{\uparrow}$ packet is generated by a $\mathsf{StreamName}^{\uparrow}$ schedule, finite $\mathsf{Nat}^{\uparrow}$ prefix-window requests, displayed UnaryHistory answer rows, a prefix-cylinder classifier, componentwise hsame comparisons, prefix-restriction Cont routes, and Pkg provenance for $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ consumers.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 334.13, Definition 334.14, and Definition 334.16 close the public prefix-cylinder certificate, stream-name readback, and finite prefix-cylinder consumer completeness surface through the $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{Nat}^{\uparrow}$ index rows, displayed unary answers, prefix-cylinder classifier, componentwise hsame, prefix-restriction Cont, Pkg provenance, and $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ handoff rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BaireSpace}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.BaireSpaceUp.BaireSpacePrefixPacket\_real\_name\_handoff\_transport`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close choice sequences as completed host functions, apartness on Baire space, continuity theorems, real completeness, or an external topology of Baire space.

Upgrade path: No further upgrade – chapter at top of formal axis.

The $\mathsf{DyadicApproximation}^{\uparrow}$ hub reads its terminal L10 route through chapter 291, chapter 126, chapter 301, and chapter 360; the child files below keep that route finite and export no quotient stream, selected host limit, host real equality, solver oracle, ambient completeness principle, or hidden completion object.

Chapter 335

A Concrete Naming Certificate for $\mathsf{DyadicApproximation}^{\uparrow}$

The $\mathsf{DyadicApproximation}^{\uparrow}$ interface names the finite dyadic observation surface that lies between $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and the sealing boundary of $\mathsf{Real}^{\uparrow}$. Bishop–Bridges constructive analysis treats rational approximants with explicit precision as the computational face of real-number construction; the BEDC packet below keeps that face as finite BHist rows rather than as quotient reals, hidden limits, or choice-selected representatives.

chapter 291 supplies the endpoint row, chapter 126 supplies the finite observation window, chapter 301 supplies the regular readback surface, and chapter 38 supplies the seal boundary. These are sibling certificate edges consumed by the carrier rows below, not ambient completion assumptions or host equality assumptions.

335.1 Finite dyadic observation packets

Definition 335.1 (DyadicApproximation carrier)**.** *A* $\mathsf{DyadicApproximation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (n, d, w, l, p)$$

with the following visible rows:

1. *n is a unary precision row naming the requested dyadic accuracy;*
2. *d is a* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row whose denominator ledger is readable at the precision named by n;*
3. *w is a certified finite observation window from* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$*, displaying the scheduled stream read that produced the endpoint row;*
4. *l is a ledger tying the finite window to a* $\mathsf{Real}^{\uparrow}$ *seal candidate by recording the regular-sequence source rows, dyadic-radius budget, and continuation route consumed at the real-name boundary;*
5. *p is the* Pkg *provenance naming the consumed* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *certificate surfaces.*

The classifier compares two accepted packets at the same precision when the precision rows are related by displayed hsame*, the dyadic endpoint rows are related by the transported* $\mathsf{DyadicRatCore}^{\uparrow}$

classifier, and the finite-window readbacks through $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *are equivalent after transporting their ledgers componentwise. The carrier contains no quotient of regular sequences, no ambient real endpoint, no hidden completion object, and no selected limit.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier semantic name certificate`

335.2 Certificate obligations

Theorem 335.2 (DyadicApproximation finite-window obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: the constant dyadic zero row from* $\mathsf{DyadicRatCore}^{\uparrow}$*, read through the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule and regular sequence, inhabits the carrier at every unary precision;*
2. *classifier laws: reflexivity, symmetry, and transitivity are obtained by componentwise* hsame *transport of the precision row, dyadic endpoint row, certified finite window, real-seal ledger, and provenance row;*
3. *carrier transport: any displayed* hsame *and* Cont *route preserving* n*,* d*,* w*,* l*, and* p *repacks an accepted carrier as an accepted carrier;*
4. *finite-window exactness: every consumer-visible approximation read factors through exactly the displayed precision row, dyadic endpoint row, finite observation window, seal ledger, and provenance row;*
5. *real-seal handoff: the ledger* l *is the only boundary datum exported to* $\mathsf{Real}^{\uparrow}$*, and it presents the finite regular-sequence source rows needed for a real-name seal candidate.*

These rows define the naming-certificate surface for finite dyadic approximants with explicit precision, following the Bishop–Bridges constructive-analysis reading of rational approximations.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier precision window determinacy`

Proof. For carrier habitation, choose the displayed zero packet of $\mathsf{DyadicRatCore}^{\uparrow}$ at the requested precision and read it through the constant stream schedule. The corresponding $\mathsf{RegSeqRat}^{\uparrow}$ window has the zero endpoint at every displayed index, and the real-seal ledger records the same constant regular source.

For the classifier laws, inspect only the coordinates of Definition 335.1. Reflexivity uses identity hsame rows and identity Cont routes on n, d, w, l, and p. Symmetry reverses those componentwise comparisons. Transitivity composes the same finite rows and then repacks the common dyadic endpoint comparison through $\mathsf{DyadicRatCore}^{\uparrow}$.

Carrier transport follows the same inventory. A transport route preserving the five visible coordinates moves the accepted precision, endpoint, window, ledger, and provenance rows to the target packet, so acceptance is recovered by repacking those rows.

For finite-window exactness, a consumer can project only the rows named in the carrier tuple. The endpoint read is the $\mathsf{DyadicRatCore}^{\uparrow}$ row d, the scheduled observation is w, and the downstream boundary is l with provenance p.

The real-seal handoff is therefore forced: $\mathsf{Real}^{\uparrow}$ receives the regular-sequence source rows exposed by l and no quotient real, hidden completion point, or chosen limit. This is exactly the finite rational-approximant discipline used by the constructive analysis precedent. □

Theorem 335.3 (DyadicApproximation Real seal handoff)**.** *Every accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet* $A = (n, d, w, l, p)$ *exports to a* $\mathsf{Real}^{\uparrow}$ *consumer only the finite regular-sequence source surface recorded by* w *and* l*: the unary precision row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window readback, the dyadic-radius budget, the displayed* hsame *and* Cont *routes, and the* Pkg *provenance.*

If two accepted packets have the same precision and equivalent finite-window readback after componentwise hsame *transport, then their* $\mathsf{Real}^{\uparrow}$ *seal candidates receive the same finite source surface. The handoff introduces no quotient real, host real equality, metric-completion point, or choice-selected representative.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier real seal handoff`

Proof. Project the carrier of Definition 335.1. The window row w supplies the scheduled finite observations, and the ledger row l records how those observations are read as a regular-sequence source for the $\mathsf{Real}^{\uparrow}$ boundary.

The exported precision and endpoint rows are already visible as n and d. The dyadic-radius budget and regular-window readback are the displayed coordinates of l, and the routing and provenance rows are supplied by the same ledger together with p.

Now compare two accepted packets with transported equivalent finite-window readback. Componentwise hsame identifies the precision rows, transports the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint comparison, and moves the scheduled $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ windows to the same readback surface.

Since the $\mathsf{Real}^{\uparrow}$ consumer can inspect only the finite source rows just listed, the two seal candidates receive the same boundary datum. No coordinate remains from which a quotient real, host equality witness, completion point, or selected representative could be produced. □

Theorem 335.4 (DyadicApproximation common precision refinement)**.** *Let* $A = (n, d, w, l, p)$ *and* $A' = (n', d', w', l', p')$ *be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets. Suppose there is a displayed common unary precision row* n_* *with* $\mathsf{hsame}(n, n_*)$ *and* $\mathsf{hsame}(n', n_*)$*, transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows over* n_**, and a common finite* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback window carried by displayed* Cont *routes. Then every* $\mathsf{Real}^{\uparrow}$ *seal consumer comparing the two packets receives one finite source surface: the precision row* n_**, the transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint comparison, the common observation window, the regular-sequence ledger, the displayed* hsame *and* Cont *routes, and the* Pkg *provenance for both accepted packets.*

The comparison remains a finite dyadic approximation comparison. It does not assert quotient-real equality, host real equality, equality of completion points, or equality of choice-selected representatives.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier common precision refinement`

Proof. Project both accepted packets through Definition 335.1. This exposes exactly the precision rows, dyadic endpoint rows, finite windows, seal ledgers, and provenance rows that a downstream consumer may inspect.

Transport the precision coordinates to the displayed row n_*. Along the same displayed hsame routes, move the endpoint rows into the common $\mathsf{DyadicRatCore}^{\uparrow}$ comparison surface over n_*.

The shared finite window identifies the $\mathsf{StreamName}^{\uparrow}$ schedule and the $\mathsf{RegSeqRat}^{\uparrow}$ readback ledger for both packets. The displayed Cont routes carry the seal ledger rows to that same readback surface, so the regular-sequence source rows and dyadic-radius budget are read through one finite boundary.

Apply Definition 335.3 to A and to A'. Each handoff exports only the projected finite source rows, and after the transports above those rows are the same precision, endpoint-comparison, window, ledger, route, and provenance surface.

Thus the $\mathsf{Real}^{\uparrow}$ boundary sees one finite source surface. Since all exported coordinates come from the carrier projection and the displayed transports, no quotient real, host real equality, completion point, or choice-selected representative is introduced. □

Theorem 335.5 (DyadicApproximation classifier transport)**.** *Let $A = (n, d, w, l, p)$ and $A' = (n', d', w', l', p')$ be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets. Suppose the precision rows n, n', the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows d, d', the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window readbacks w, w', the* $\mathsf{Real}^{\uparrow}$ *seal ledgers l, l', the displayed* Cont *routes, and the provenance rows p, p' are related by componentwise displayed* hsame *transport along the same carrier coordinates of Definition 335.1.*

Then the transported packet still satisfies the $\mathsf{DyadicApproximation}^{\uparrow}$ *classifier. The resulting comparison is precisely a finite-window dyadic approximation comparison: it compares the transported precision row, transported dyadic endpoint row, transported stream and regular-sequence readback, transported seal ledger, displayed continuation routes, and transported* Pkg *provenance. It does not become quotient-real equality, host-real equality, metric-completion equality, or equality of selected limits.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier classifier transport`

Proof. Project the five coordinates of Definition 335.1. The precision coordinate gives the row along which the comparison is read, the endpoint coordinate gives the $\mathsf{DyadicRatCore}^{\uparrow}$ comparison, the window coordinate gives the finite $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ readback, the ledger coordinate gives the $\mathsf{Real}^{\uparrow}$ seal boundary, and the provenance coordinate records the consumed certificate surfaces.

Transport these coordinates by the displayed hsame rows. The precision row moves to n', the dyadic endpoint comparison moves to d', and the finite-window readback moves through the same $\mathsf{StreamName}^{\uparrow}$ schedule and $\mathsf{RegSeqRat}^{\uparrow}$ readback surface. The displayed Cont routes are transported with those rows, so no consumer obtains an additional route outside the carrier.

Reuse the endpoint classifier supplied by $\mathsf{DyadicRatCore}^{\uparrow}$ and the finite-window readback described in Definition 335.3. The seal ledger l' records only the transported regular-sequence source rows, dyadic-radius budget, and continuation boundary available to $\mathsf{Real}^{\uparrow}$, while p' records the transported Pkg provenance.

Repack these transported rows into the classifier of the target packet. Carrier exhaustiveness leaves exactly the five projected coordinates, so there is no coordinate from which a completion point, quotient real, selected limit, host-real equality, or quotient-real equality could be introduced. □

Theorem 335.6 (DyadicApproximation precision weakening)**.** *Let $A = (n, d, w, l, p)$ be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet. If a displayed unary row m is no finer than n through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger, then A has a coarser accepted read at m. The* $\mathsf{Real}^{\uparrow}$ *seal handoff of this coarser read exposes only the transported precision row m, the transported dyadic endpoint, the* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the displayed* hsame *and* Cont *routes, and the* Pkg *provenance.*

The weakening rule does not introduce a quotient real, host real equality, completion point, or selected representative.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier precision weakening`

Proof. Start from the accepted packet A and apply Definition 335.3. This projects the only source rows visible to a $\mathsf{Real}^{\uparrow}$ consumer: precision, dyadic endpoint, stream window, regular-sequence readback, seal ledger, routes, and provenance.

Use the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ radius ledger witnessing that m is no finer than n to transport the precision coordinate to the coarser row. Then apply Definition 335.4 with the common precision row m, reading the original packet and its coarser radius-ledger projection through the same finite window.

Apply Definition 335.5 to repack the transported endpoint, window, regular-sequence readback, seal ledger, displayed routes, and provenance as an accepted $\mathsf{DyadicApproximation}^{\uparrow}$ classifier read at m.

The final handoff is again the one described by Definition 335.3. Every exported coordinate is a transported finite row, so no quotient real, host real equality, completion point, or selected representative is available. □

Theorem 335.7 (DyadicApproximation kernel scope package)**.** *The carrier of Definition 335.1, the finite-window obligation rows, the* $\mathsf{Real}^{\uparrow}$ *seal handoff, common precision refinement, classifier transport, and precision weakening jointly form a scoped BEDC package over* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* NameCert*.*

Every accepted consumer read factors through that package. The package exports no quotient real, host real equality, completion point, or selected representative.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier namecert obligation surface`
Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier kernel scope package`

Proof. Begin with Definition 335.2. It supplies the five local obligation rows for carrier habitation, classifier laws, carrier transport, finite-window exactness, and real-seal handoff over the displayed packet coordinates.

Apply Definition 335.3 for the $\mathsf{Real}^{\uparrow}$ boundary. The handoff sends downstream consumers only the finite regular-sequence source surface recorded by the window and ledger rows.

Next use Definition 335.4 and Definition 335.5. These keep precision comparison, endpoint comparison, window readback, seal ledger, displayed hsame rows, and displayed Cont routes inside the same finite package.

Finally apply Definition 335.6. Coarser precision reads are transported through the same carrier, ledger, and provenance rows. Thus every accepted consumer read factors through the stated scoped BEDC package, and no excluded completed or quotient object is exported. □

Theorem 335.8 (DyadicApproximation finite-window scope)**.** *Every accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite-window packet factors through the displayed* BHist *carrier rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, the* $\mathsf{StreamName}^{\uparrow}$ *observation schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and the local* NameCert *rows recorded in Definition 335.1. No consumer of the accepted window receives an additional coordinate beyond those displayed rows.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier window scope`

Proof. Project an accepted packet along the five carrier coordinates of Definition 335.1. The precision, endpoint, window, seal-ledger, and provenance coordinates give the displayed finite rows through which the packet is read.

Use Definition 335.2 for the finite obligation package and Definition 335.5 for stability under the visible hsame and Cont rows. These theorems keep the accepted classifier inside the displayed BHist, DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Pkg, and NameCert surface.

The carrier has no sixth coordinate. Thus any accepted dyadic approximation window factors through exactly the displayed rows and exports no hidden quotient-real or completion coordinate. □

Theorem 335.9 (DyadicApproximation Real seal scope)**.** *Any* Real$^{\uparrow}$ *seal read from an accepted* DyadicApproximation$^{\uparrow}$ *packet consumes only the finite dyadic window, the* RegSeqRat$^{\uparrow}$ *handoff, the transported precision and endpoint rows, the visible* hsame *and* Cont *routes, and the* Pkg *and* NameCert *provenance already displayed by the packet.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier real seal scope`

Proof. Start with an accepted dyadic approximation packet and project the finite window by Definition 335.8. The source rows available to a seal read are the precision, dyadic endpoint, stream schedule, regular-sequence readback, visible transports, continuations, and provenance.

Apply Definition 335.3. Its handoff sends the Real$^{\uparrow}$ seal to the same finite dyadic window and RegSeqRat$^{\uparrow}$ readback surface, with the dyadic-radius budget and displayed routes carried by the packet ledger.

Consequently the seal read consumes only the finite handoff rows. It does not select a limit, identify a quotient real, or add a host equality coordinate. □

Theorem 335.10 (DyadicApproximation Real seal radius route)**.** *Let* $A = (n, d, w, l, p)$ *be an accepted* DyadicApproximation$^{\uparrow}$ *packet. For any coarser precision row* m *certified by the displayed* DyadicRatCore$^{\uparrow}$ *radius ledger, the resulting* Real$^{\uparrow}$ *seal read factors through the same finite route package: the transported precision row, transported dyadic endpoint, the* StreamName$^{\uparrow}$ *window, the* RegSeqRat$^{\uparrow}$ *readback, visible* hsame *and* Cont *routes, and* Pkg *provenance.*

This radius route does not introduce quotient reals, host real equality, completion points, or selected representatives.

Proof. Start with Definition 335.3. It projects the Real$^{\uparrow}$ seal read to the precision row, dyadic endpoint, finite StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, radius ledger, displayed routes, and provenance.

Apply Definition 335.6 to the coarser precision row m. The displayed DyadicRatCore$^{\uparrow}$ radius ledger transports the precision coordinate and keeps the endpoint and regular-sequence readback inside the same finite packet.

Use Definition 335.4 to compare the original packet and its coarser read through one common precision surface, then apply Definition 335.5 to repack the transported endpoint, window, readback, routes, and provenance as an accepted classifier read.

Carrier exhaustiveness for Definition 335.1 leaves only the five displayed coordinates. Hence the common route has no coordinate for a quotient real, host equality, completion point, or selected representative. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier real seal radius route certificate`

Theorem 335.11 (DyadicApproximation ledger exclusion scope)**.** *The scoped* DyadicApproximation$^{\uparrow}$ *ledger exports no quotient stream, selected limit, host real equality, trichotomy, or completeness row. Its exported data are exactly the finite-window rows of Definition 335.8 and the* Real$^{\uparrow}$ *handoff rows of Definition 335.9.*

Proof. Read the ledger through the finite-window factorization. The carrier exposes only the displayed BHist, DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, hsame, Cont, Pkg, and NameCert rows.

Read any seal coordinate through the Real-seal scope theorem. That theorem routes the seal through the finite dyadic window and regular-sequence handoff already present in the packet, so the seal contributes no completed-real coordinate.

The excluded objects are not fields of the carrier and are not produced by the handoff. Therefore the scoped ledger has no export row for quotient streams, selected limits, host real equality, trichotomy, or completeness. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier ledger exclusion scope`

Theorem 335.12 (DyadicApproximation public finite-window export)**.** *The public* NameCert$_{\text{DyadicApproximation}^{\uparrow}}$ *export is the finite packet interface* (n, d, w, l, p) *over* BHist*,* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*, visible* hsame*, visible* Cont*,* Pkg*, and* NameCert*.*

Every Real$^{\uparrow}$*-facing consumer read from this public export factors through that finite-window interface. The export supplies no quotient real, host equality, completion point, trichotomy row, or selected representative.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier public finite window export`

Proof. Project an accepted public packet through the package of Definition 335.7. The five coordinates are the precision row n, dyadic endpoint d, finite observation window w, seal ledger l, and provenance row p, all carried over the displayed BHist, DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, hsame, Cont, Pkg, and NameCert surface.

Apply Definition 335.8 to identify the finite-window readback. This shows that any consumer access to the packet is already a read of the displayed endpoint, schedule, regular-sequence window, transport, continuation, package, and certificate rows.

Route the Real$^{\uparrow}$ seal through Definition 335.9. The seal is therefore a handoff through the same finite dyadic window and RegSeqRat$^{\uparrow}$ readback surface, rather than an additional completed-real coordinate.

Finally use Definition 335.11. Its ledger exclusions give the negative claims: the public export has no row for quotient reals, host equality, completion points, trichotomy, or selected representatives. □

Theorem 335.13 (DyadicApproximation standard finite-approximation bridge)**.** *The public finite-window export of Definition 335.12, together with Definition 335.3, Definition 335.4, and Definition 335.5, determines a conservative standard finite dyadic-approximation reading and readback.*

The readback recovers exactly the displayed precision, dyadic endpoint, StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal ledger, displayed* hsame*, displayed* Cont*, package rows, and local* NameCert *evidence. It adds no quotient real, host real equality, completion point, trichotomy row, selected representative, or classical approximation completeness.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier standard finite approximation bridge`

Proof. Project the accepted packet through Definition 335.12. The public surface is the five-coordinate packet (n, d, w, l, p): precision, dyadic endpoint, finite observation window, seal ledger,

and provenance. These rows already include the displayed StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, Real$^{\uparrow}$ seal boundary, hsame, Cont, package, and certificate data.

Apply Definition 335.4 to place the standard finite-precision read and the BEDC readback on the same displayed precision row. Then use Definition 335.5 to carry the endpoint classifier through the visible hsame and Cont data without leaving the finite-window packet.

Finally route the seal through Definition 335.3 and return to the public export. The readback is therefore exactly the displayed precision, dyadic endpoint, stream window, regular-sequence readback, seal ledger, transport, continuation, package, and certificate surface, with no coordinate for quotient reals, host equality, completion points, trichotomy, selected representatives, or classical approximation completeness. □

Theorem 335.14 (DyadicApproximation rational interval window handoff)**.** *Let an accepted* DyadicApproximation$^{\uparrow}$ *packet expose its finite approximation coordinates, and let an accepted* RationalInterval$^{\uparrow}$ *packet expose a finite containment ledger recording the displayed dyadic endpoint at the same unary precision. Then every* Real$^{\uparrow}$*-facing consumer read factors through the common finite surface: the precision row, dyadic endpoint, rational endpoint, rational order and containment rows,* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback, visible* hsame*, visible* Cont*,* Pkg*, and local* NameCert *provenance rows.*

The handoff supplies no quotient real, selected limit, host real equality, located subset, or interval-arithmetic closure. It only identifies the shared finite endpoint window already carried by the two accepted packets and their displayed containment ledger.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier rational interval window handoff`

Proof. Project the dyadic packet through Definition 335.12. This gives the precision row, dyadic endpoint, stream window, regular-sequence readback, Real$^{\uparrow}$ seal ledger, hsame, Cont, package, and local certificate rows available to any public consumer.

Route the seal through Definition 335.3. The seal contributes no completed-real coordinate; it is read through the same finite dyadic endpoint window and the same RegSeqRat$^{\uparrow}$ readback boundary.

Project the rational packet through Definition 354.15. Its public surface exposes the rational endpoint, rational order row, containment row, finite window, transport, continuation, package, and certificate provenance.

Use the containment-ledger hypothesis to identify the rational endpoint window with the displayed dyadic endpoint at the common unary precision. After this identification, every listed consumer coordinate is one of the two carrier coordinates already projected above.

The conclusion follows by carrier-coordinate exhaustion. Since neither carrier has a row for quotient reals, selected limits, host real equality, located subsets, or interval arithmetic, the handoff cannot export those objects. □

Theorem 335.15 (DyadicApproximation consumer completeness)**.** *Every finite consumer of a* DyadicApproximation$^{\uparrow}$ *packet reads exactly the dyadic precision index, rational interval window, approximation row, classifier transport, precision weakening row,* Real$^{\uparrow}$ *seal handoff, displayed* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *evidence. Conversely, these rows repack as the complete finite dyadic-approximation consumer surface.*

The consumer surface exports no quotient real, host real equality, completion point, trichotomy row, selected representative, located subset, or classical approximation-completeness principle.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier consumer completeness`

Proof. Project an accepted packet through the finite-window obligations of Definition 335.8. This exposes the precision index, dyadic endpoint, finite observation window, regular-sequence readback, visible transport, continuation, package, and local certificate rows.

Refine the consumer read to a common precision by Definition 335.4. Then use Definition 335.5 for the classifier route and Definition 335.6 for the visible weakening row.

Route the seal through Definition 335.9 and Definition 335.3. The seal contributes only the displayed $\mathsf{Real}^{\uparrow}$ handoff row already bounded by the same finite dyadic window.

Next collect the public packet surface with Definition 335.12 and the standard bridge of Definition 335.13. The rational endpoint part is the window handoff of Definition 335.14, so every finite consumer coordinate is one of the listed rows.

For the converse direction, start with precisely the listed rows. The public finite-window export supplies the NameCert package, the standard bridge packs the dyadic readback, and the rational interval handoff packs the shared endpoint window, giving a valid finite approximation consumer read.

None of the cited packet projections contains a quotient-real coordinate, host equality, completion point, trichotomy row, selected representative, located subset, or classical completeness principle. These objects therefore cannot be exported by the complete consumer surface. □

Theorem 335.16 (DyadicApproximation directed precision refinement associativity)**.** *Let three accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets carry compatible displayed common unary precision refinements. Suppose the left-associated read first refines the first two packets to their displayed common precision and then refines that visible packet with the third, while the right-associated read first refines the last two packets and then refines the first packet with that visible packet. Then the two reads expose the same consumer-visible finite packet: the transported precision row, dyadic endpoint,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal ledger, visible* hsame*, visible* Cont*,* Pkg *provenance, and local* NameCert *rows.*

No quotient real, host real equality, completion point, selected representative, trichotomy row, or choice principle is used to identify the two associated reads.

Proof. Apply Definition 335.4 to the left pair, obtaining the displayed common precision packet for the first two accepted reads. Apply the same theorem to the right pair, obtaining the displayed common precision packet for the last two accepted reads.

Apply Definition 335.4 again to the left-associated packet and the third packet. Apply it once more to the first packet and the right-associated packet. Compatibility of the two displayed common unary precision refinements makes these two terminal precision rows the same displayed row.

Use Definition 335.5 on the two terminal refinements. The transported classifier rows identify the dyadic endpoint, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal ledger, visible hsame, visible Cont, package provenance, and local certificate rows carried by the two associated packets.

Finally apply Definition 335.15. Every finite consumer coordinate is exhausted by the listed rows, and the converse packing direction shows that these rows determine the same finite dyadic-approximation consumer surface. Since the completeness theorem exports no quotient-real or choice-selected coordinate, the associativity law is entirely a finite displayed-packet statement. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier directed precision refinement associativity`

Theorem 335.17 (DyadicApproximation terminal refinement window)**.** *Let a finite family of accepted* DyadicApproximation$^{\uparrow}$ *packets be equipped with displayed common unary precision refinements, and suppose those displayed refinements are mutually compatible whenever two refinement brackets overlap. Then the iterated refinement surface has one terminal finite consumer window. That window consists exactly of the terminal precision row, the dyadic endpoint, the* StreamName$^{\uparrow}$ *window, the* RegSeqRat$^{\uparrow}$ *readback, the* Real$^{\uparrow}$ *seal ledger, the* RationalInterval$^{\uparrow}$ *containment row when that row is present, the visible* hsame *and* Cont *transport routes, the* Pkg *provenance row, and the local* NameCert *rows.*

The terminal window is independent of binary bracketing of the finite refinement family. It exports no quotient real, host equality, completion point, trichotomy row, selected representative, located subset, or choice principle.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal refinement window`

Proof. Proceed by induction on the finite refinement family. In the singleton case, the accepted packet projection supplies exactly the displayed precision row, dyadic endpoint, StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, Real$^{\uparrow}$ seal ledger, visible hsame and Cont routes, Pkg provenance, and local NameCert rows. If the rational containment row is present, it is the row supplied by Definition 335.14.

For the binary step, assume terminal windows have already been constructed for the two finite subfamilies. Apply Definition 335.4 to their displayed terminal packets. Compatibility of the displayed common precision rows gives a single terminal precision row for the combined family.

Transport the classifier data along the common precision row by Definition 335.5. The transported rows carry the dyadic endpoint, stream window, regular rational readback, real seal ledger, visible hsame route, visible Cont route, package provenance, and local certificate rows into the combined terminal packet.

Use Definition 335.16 to compare two binary bracketings of the same finite family. The theorem identifies the consumer-visible packet rows produced by the two bracketings, so the terminal window is independent of the chosen binary refinement tree.

Finally apply Definition 335.15. It shows that the listed coordinates exhaust the finite consumer surface, while Definition 335.14 accounts for the optional rational-interval containment row. Since the involved packet coordinates contain no quotient-real, host-equality, completion-point, trichotomy, selected-representative, located-subset, or choice-principle field, none of those objects can be exported by the terminal window. □

Theorem 335.18 (DyadicApproximation mesh cell consumer boundary)**.** *Let $A = (n, d, w, l, p)$ be an accepted* DyadicApproximation$^{\uparrow}$ *packet. Suppose a* DyadicMesh$^{\uparrow}$ *consumer or a* ValidatedNumerics$^{\uparrow}$ *consumer reads A only through a displayed mesh-cell request whose cell interval is a* RationalInterval$^{\uparrow}$ *row when such a row is present. Then the consumer boundary is exactly the finite packet consisting of the unary precision row n, the* DyadicRatCore$^{\uparrow}$ *endpoint d, the* StreamName$^{\uparrow}$ *schedule carried by w, the* RegSeqRat$^{\uparrow}$ *finite readback carried by w and l, the* RationalInterval$^{\uparrow}$ *cell row when present, the* Real$^{\uparrow}$ *seal ledger, the visible* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the local* NameCert *rows.*

This boundary exports no quotient real equality, host real equality, completed cell, infinite mesh, solver-correctness claim, or choice-selected representative. The mesh-cell read is a finite BEDC packet read and not a completion, infinitary mesh, or external numerical-solver principle.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier mesh cell consumer boundary`

Proof. Project the dyadic packet through Definition 335.12. This gives the unary precision row, dyadic endpoint, $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal ledger, visible hsame transports, visible Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ rows.

If the mesh-cell request carries a rational-interval cell row, apply Definition 335.14. The handoff identifies the displayed dyadic endpoint with the rational endpoint window at the same unary precision and contributes only the finite $\mathsf{RationalInterval}^{\uparrow}$ order and containment rows.

For a $\mathsf{DyadicMesh}^{\uparrow}$ reader, apply Definition 358.6. The mesh contributes the level row, cell-index row, cell coverage row, containment ledger, displayed refinement route, endpoint readback, transport rows, continuation routes, provenance, and local name row, all still inside the finite mesh-cell packet.

For a $\mathsf{ValidatedNumerics}^{\uparrow}$ reader, use Definition 357.15. Its finite enclosure surface reads the same interval row, endpoint provenance, finite request, regular-rational observation window, real-name readback token, containment ledger, transports, routes, provenance, and local name row.

Finally compare the two consumer reads with Definition 335.29. The normal form exhausts the common mesh-cell consumer surface by the listed rows, so no remaining coordinate can carry quotient real equality, host real equality, a completed cell, an infinite mesh, solver correctness, or a choice-selected representative. □

Theorem 335.19 (DyadicApproximation nested window exhaustion)**.** *Every finite chain of compatible* $\mathsf{DyadicApproximation}^{\uparrow}$ *consumer refinements has one terminal displayed window. Every consumer read in the chain factors through exactly the terminal precision row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the displayed* hsame *transports, the visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *ledger.*

When a $\mathsf{RationalInterval}^{\uparrow}$ *containment row is present in the chain, it is read through that same terminal window. The exhaustion exports no quotient real, host equality, completion point, trichotomy row, selected representative, located subset, or choice principle.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier nested window exhaustion`

Proof. Induct over the finite refinement chain. The empty and singleton chains are handled by projecting the accepted packet carrier: the only consumer-visible rows are the displayed precision row, endpoint row, observation window, transport routes, package provenance, and local naming ledger.

For the binary extension step, apply Definition 335.17 to the terminal window already obtained for the initial segment and to the next compatible refinement packet. This produces one displayed terminal precision row for the extended chain.

Use Definition 335.16 to remove dependence on the chosen bracketing of the finite chain. Any two ways of building the terminal window identify the same consumer-visible precision, endpoint, observation, transport, package, and ledger rows.

Finally apply Definition 335.15. It exhausts all finite consumer reads through the terminal row, while Definition 335.14 accounts for the containment row when present. Since the carrier contains none of the excluded completion, quotient, trichotomy, selection, located-subset, or choice coordinates, the nested chain exports none of them. □

Theorem 335.20 (DyadicApproximation terminal window idempotence)**.** *Let a compatible finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *refinement chain have terminal displayed window* T*. If* T *is adjoined as one further compatible refinement, then the extended chain has the same terminal precision row, dyadic endpoint row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal ledger, optional*

$\mathsf{RationalInterval}^{\uparrow}$ *containment row, visible* hsame *transports, visible* Cont *transports,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *ledger as the original chain.*

Thus repeating a terminal displayed window contributes no consumer-visible row. The extended read exports no quotient-real equality, host equality, completed real, choice principle, or selected representative coordinate beyond the rows already present in T.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal window idempotence`

Proof. Start with the original finite chain. Apply Definition 335.17 to obtain its terminal displayed window T and the listed precision, endpoint, observation, seal, transport, package, containment, and local certificate rows.

Now append T as a compatible refinement packet. Applying Definition 335.17 again produces a terminal row for the extended chain, but the new binary refinement step uses the same displayed terminal precision row as both the accumulated window and the adjoined packet.

Use Definition 335.16 to compare the bracketing that first forms T with the bracketing that first forms T and then appends T. Associativity identifies the consumer-visible precision, endpoint, stream, regular-sequence, seal, containment, transport, package, and local ledger rows in the two bracketings.

Finally apply Definition 335.15. Since all finite consumer reads factor through those identified rows, the appended terminal window has no additional quotient-real, host-equality, completion, choice, or selected-representative coordinate to export. □

Theorem 335.21 (DyadicApproximation terminal window subchain absorption)**.** *Let a compatible finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *refinement chain have terminal displayed window T. Any finite compatible subchain whose packets factor through T may be inserted, deleted, or repeated without changing the terminal precision row, dyadic endpoint row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal ledger, optional* $\mathsf{RationalInterval}^{\uparrow}$ *containment row, visible* hsame *routes, visible* Cont *routes,* Pkg *provenance, or local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *ledger.*

Equivalently, the displayed terminal row is an absorbing finite normal form for every already-terminal compatible subchain. The normal form exports no quotient real equality, host equality, completed real, trichotomy, choice principle, or selected representative coordinate beyond the rows already visible through T.

Proof. Begin with the given finite chain and apply Definition 335.19. This places every compatible finite refinement packet in the same directed displayed-window spine and supplies the common precision, endpoint, stream, regular-sequence, seal, containment, transport, package, and local certificate rows.

For a subchain whose packets factor through T, apply Definition 335.20 to each displayed terminal packet in the subchain. Repetition of such a packet contributes no new consumer-visible row, and deletion removes only rows already identified with the terminal row.

It remains to compare the positions of the subchain inside the whole finite refinement. Use Definition 335.16 to rebracket the refinement so the subchain is read either before, after, or at the displayed terminal row. The associated bracketings have the same precision, endpoint, stream, regular-sequence, seal, containment, visible transport, package, and local ledger data.

Finally apply Definition 335.15. Every finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and optional $\mathsf{RationalInterval}^{\uparrow}$ consumer read factors through the terminal displayed row, so insertion, deletion, and repetition of an already-terminal compatible subchain leave exactly the same public finite-window surface. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal refinement subchain absorption`

Theorem 335.22 (DyadicApproximation window RegSeqRat source exhaustion)**.** *Every accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet together with a finite compatible refinement chain determines exactly one displayed* $\mathsf{RegSeqRat}^{\uparrow}$*-facing source surface. The surface consists of the unary precision row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row, the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the* $\mathsf{Real}^{\uparrow}$ *seal ledger, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *row.*

If the same packet is read through the $\mathsf{RationalInterval}^{\uparrow}$ *handoff or the* $\mathsf{Real}^{\uparrow}$ *seal boundary, those consumers read that same source surface and no other row. The exhaustion exports no quotient real equality, selected limit, trichotomy row, located subset, or choice principle.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier window regseqrat source exhaustion`

Proof. Start with the finite refinement chain and apply Definition 335.19. This gives one terminal displayed window containing the precision, endpoint, stream, regular-sequence, transport, continuation, package, and local certificate rows seen by every consumer read in the chain.

Next apply Definition 335.9. The $\mathsf{Real}^{\uparrow}$ seal ledger is a finite boundary row attached to the same terminal window, so it does not contribute a completed real or a selected limit outside the displayed packet surface.

Use Definition 335.3 to read the terminal window as a real-seal source for $\mathsf{RegSeqRat}^{\uparrow}$. The handoff identifies the regular rational observation row, seal ledger, visible hsame route, visible Cont route, and package provenance as the only real-facing source data.

Finally apply Definition 335.14. It shows that any rational-interval consumer sees the same endpoint and observation rows, so the terminal window is the unique displayed source surface for all the named consumers. Since all cited surfaces are finite packet rows, quotient real equality, selected limits, trichotomy, located subsets, and choice principles are not exported. □

Theorem 335.23 (DyadicApproximation overlap-directed seal exhaustion)**.** *Let two accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets carry overlapping finite* $\mathsf{StreamName}^{\uparrow}$ *windows and overlapping finite* $\mathsf{RegSeqRat}^{\uparrow}$ *observation windows. Suppose their overlap is equipped with a displayed directed common unary precision refinement, so that both dyadic endpoints and both seal ledgers are transported to the same visible precision row. Then every* $\mathsf{Real}^{\uparrow}$ *seal read from either packet factors through one finite boundary surface: the common precision row, the transported dyadic endpoints, the* $\mathsf{RationalInterval}^{\uparrow}$ *refinement window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source readback, the visible* hsame *transports, the visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows.*

This finite boundary exports no quotient-real equality, host real equality, completion point, trichotomy row, selected representative, located subset, or choice principle. The overlap theorem is only a coverage statement for the displayed finite rows already present in the two accepted packets and their directed refinement data.

Proof. First put the two accepted packets on the same displayed precision row. Apply Definition 335.16 to make the directed refinement independent of the binary route used to reach the common row.

Next apply Definition 335.17 to the overlapping two-packet family. This produces the terminal finite window containing the common precision row, transported endpoints, stream window, regular

rational observation window, seal ledger, visible transports, continuations, package provenance, and local certificate rows.

Use Definition 335.14 to read the transported dyadic endpoints through the shared $\mathsf{RationalInterval}^{\uparrow}$ refinement window. The handoff keeps the endpoint and containment data inside the same finite overlap surface.

Then apply Definition 335.22. It identifies the $\mathsf{RegSeqRat}^{\uparrow}$ source readback and shows that both $\mathsf{RationalInterval}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers read the same displayed source surface.

Finally route the seal boundary through Definition 335.9. Since the seal scope has no coordinate for quotient-real equality, host equality, completion points, trichotomy, selected representatives, located subsets, or choice data, the overlap-directed read cannot export any of those objects. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier overlap directed seal exhaustion`

Theorem 335.24 (DyadicApproximation overlap seal idempotence)**.** *Let two accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets satisfy the hypotheses of Definition 335.23, and let their resulting finite* $\mathsf{Real}^{\uparrow}$ *seal boundary be read again through any compatible displayed overlap refinement. Then the second read factors through the same common precision row, the same transported dyadic endpoint rows, the same* $\mathsf{RationalInterval}^{\uparrow}$ *refinement window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *source readback, the same visible* hsame *transports, the same visible* Cont *routes, the same* Pkg *provenance, and the same local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows as the first seal read.*

Thus repeated $\mathsf{Real}^{\uparrow}$ *seal reads through a fixed finite overlap boundary are idempotent as displayed packet reads. The idempotence assertion exports no quotient-real equality, host real equality, completion point, trichotomy row, selected representative, located subset, or choice principle.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier overlap seal idempotence`

Proof. First apply Definition 335.23 to the two accepted packets and their displayed directed common precision refinement. This identifies the first $\mathsf{Real}^{\uparrow}$ seal read with the finite overlap boundary containing the common precision row, transported endpoint rows, rational interval window, regular rational source readback, visible transports, continuations, package provenance, and local certificate rows.

Next apply Definition 335.20 to the compatible displayed overlap refinement used by the second read. Re-reading a terminal finite window through a compatible refinement returns the same terminal window, so the second seal read cannot introduce a new precision row, endpoint row, consumer route, package row, or local certificate row.

Finally apply Definition 335.22. It identifies the unique $\mathsf{RegSeqRat}^{\uparrow}$-facing source surface seen by the $\mathsf{RationalInterval}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, and therefore transports the second seal read back to the same source surface already named by the first overlap-directed read. Since each cited result is a statement about finite displayed packet rows, the repeated read has no coordinate for quotient-real equality, host real equality, completion points, trichotomy, selected representatives, located subsets, or choice data. □

Theorem 335.25 (DyadicApproximation overlap refinement chain normal form)**.** *Let two accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets satisfy the overlap hypotheses of Definition 335.23. For every finite chain of compatible displayed overlap refinements, every repeated* $\mathsf{Real}^{\uparrow}$ *seal read factors through one terminal normal-form packet. This packet consists exactly of the common precision row, the transported dyadic endpoint rows, the* $\mathsf{RationalInterval}^{\uparrow}$ *refinement window, the*

$\mathsf{RegSeqRat}^{\uparrow}$ *source readback, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows.*

The normal form is a finite displayed packet normal form for overlap reads. It does not contain quotient-real equality, host equality, completion points, trichotomy rows, selected representatives, located subsets, or choice data.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier overlap refinement chain normal form`

Proof. First apply Definition 335.23. The first common overlap boundary supplies the displayed precision row, transported endpoints, rational-interval window, regular rational readback, visible transport routes, package provenance, and local certificate rows shared by the two accepted packets.

Next run the finite compatible refinement chain through Definition 335.20. Once the common boundary has been read as a terminal displayed window, compatible re-reading stabilizes at the same terminal packet and cannot add a second endpoint, precision, route, provenance, or certificate row.

Then apply Definition 335.22. This identifies the unique $\mathsf{RegSeqRat}^{\uparrow}$-facing source surface seen by both the $\mathsf{RationalInterval}^{\uparrow}$ window and the repeated $\mathsf{Real}^{\uparrow}$ seal reads, so the terminal packet is the single source normal form for the whole chain.

Finally apply Definition 335.9. The $\mathsf{Real}^{\uparrow}$ boundary has only the displayed seal rows named above, so the normal-form packet excludes quotient-real equality, host equality, completion points, trichotomy rows, selected representatives, located subsets, and choice data. □

Theorem 335.26 (DyadicApproximation overlap coarsening seal stability)**.** *Let two accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets satisfy Definition 335.23. Suppose both packets are weakened to a common coarser unary precision row through the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger. Then every compatible* $\mathsf{Real}^{\uparrow}$ *seal reread factors through the same finite overlap surface, now read at the coarser precision row with transported endpoints, the* $\mathsf{RationalInterval}^{\uparrow}$ *refinement window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, visible* hsame *and* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows.*

The coarsened reread exports no quotient-real equality, host real equality, completion point, trichotomy row, selected representative, located subset, or choice principle.

Proof. Apply Definition 335.6 to each accepted packet, using the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ radius ledger to transport the endpoint and seal rows to the common coarser precision row.

Next use Definition 335.16 to identify the two weakening routes with one directed coarsening surface. The common row therefore carries the same transported endpoint, interval, stream, regular-sequence, transport, continuation, package, and local certificate data.

Apply Definition 335.23 on this coarser row. It supplies the finite overlap boundary seen by the $\mathsf{Real}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ consumers.

Finally apply Definition 335.24. A compatible reread of the already displayed seal boundary remains on that same finite boundary, so no completed real, host equality, representative choice, located subset, trichotomy, or choice data can be exported. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier overlap coarsening seal stability`

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$**.**

Constructive story: A finite dyadic approximation packet is generated from a unary precision row, a displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, a $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ finite observation window, a $\mathsf{Real}^{\uparrow}$ seal ledger, visible hsame and Cont transport, and Pkg provenance.

Theory closure: TheoryGate(NameCert$_{\text{DyadicApproximation}^\uparrow}$, maturePackageClosed)

Scope closed: Definition 335.8, Definition 335.9, Definition 335.11, Definition 335.12, Definition 335.13, Definition 335.14, Definition 335.15, Definition 335.16, and Definition 335.17 form the public finite-window export, standard finite dyadic-approximation readback, rational interval handoff, finite consumer surface, directed refinement associativity, and terminal common-refinement window for the accepted dyadic window, Real$^\uparrow$ seal handoff, and ledger exclusions over BHist, DyadicRatCore$^\uparrow$, StreamName$^\uparrow$, RegSeqRat$^\uparrow$, RationalInterval$^\uparrow$, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus(NameCert$_{\text{DyadicApproximation}^\uparrow}$, unformalized)

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close quotient reals, host real equality, completion points, or choice-selected representatives.

Upgrade path: No further paper theory-axis grade remains; formal verification remains a separate axis for the same dyadic approximation packet.

Theorem 335.27 (DyadicApproximation terminal window prefix projection)**.** *Let a compatible finite* DyadicApproximation$^\uparrow$ *refinement chain have terminal displayed window T. For every initial compatible subchain, the projected displayed window consists exactly of the prefix rows of T: the precision row, the dyadic endpoint row, the* StreamName$^\uparrow$ *row, the* RegSeqRat$^\uparrow$ *observation row, the* Real$^\uparrow$ *seal row, the optional* RationalInterval$^\uparrow$ *containment row when present, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance, and the local* NameCert$_{\text{DyadicApproximation}^\uparrow}$ *row.*

After this prefix projection, rereading the full compatible chain returns the same terminal window T. The projection exports no quotient real, host equality, completion point, trichotomy, selected representative, located subset, or choice principle.

Proof. Apply Definition 335.19 to the full finite chain. This gives the terminal window T and identifies every consumer-visible row with the terminal precision, endpoint, stream, regular-sequence, seal, containment, transport, package, and local certificate rows.

Apply the same exhaustion theorem to the chosen initial compatible subchain. The prefix read has its own displayed terminal window, but its rows are drawn from the same directed finite refinement spine as the full chain.

Use Definition 335.17 to compare the terminal row of the initial subchain with the terminal row of the full chain. The comparison says that each visible prefix row is the corresponding initial row of T, including the optional rational-interval containment row when that row is part of the displayed chain.

Now remove bracketing dependence by Definition 335.16. Whether the full terminal window is read before or after projecting the initial subchain, the same precision, endpoint, observation, seal, transport, provenance, and local certificate rows are obtained.

Finally apply Definition 335.15. Every finite consumer read after the prefix projection factors through the same terminal window T, and Definition 335.14 accounts for the optional containment row. Since the packet has no quotient-real, host equality, completion, trichotomy, representative-selection, located-subset, or choice coordinate, none is exported by the projection. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal window prefix projection`

Theorem 335.28 (DyadicApproximation terminal-window two-stage factorization)**.** *Let $A = (n, d, w, l, p)$ be an accepted terminal* DyadicApproximation$^\uparrow$ *packet with terminal displayed window T. Suppose its terminal readback is projected by Definition 335.27, and suppose the same packet is consumed through the validated enclosure route of Definition 335.32.*

Then the two reads factor through one finite public surface. That surface is exactly the terminal precision row, the transported dyadic endpoint row, the StreamName$^{\uparrow}$ *window, the* RegSeqRat$^{\uparrow}$ *readback window, the* Real$^{\uparrow}$ *seal ledger, the validated containment ledger, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance rows, and the local* NameCert *rows. Reading first by terminal prefix projection and then through the validated enclosure route gives the same displayed surface as reading first through the enclosure route and then commuting back to the terminal dyadic window.*

The factorization introduces no quotient real, host-real equality, solver-correctness assertion, or selected completion point.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal window two stage factorization`

Proof. First apply Definition 335.27. The terminal readback of A is reduced to the prefix rows of T: precision, endpoint, stream, regular-rational observation, real-seal ledger, visible transport, continuation, provenance, and local certificate data.

Next exhaust the finite packet read. By Definition 335.30, every consumer-visible read of the accepted terminal packet is already among those finite rows together with the displayed validated enclosure handoff. Apply Definition 335.31 to remove dependence on which compatible finite refinement exposes the terminal surface.

Now read the enclosure side. Apply Definition 335.32 to identify the DyadicMesh$^{\uparrow}$ cell and ValidatedNumerics$^{\uparrow}$ enclosure read with the same terminal precision, endpoint, regular-rational, real-seal, containment, transport, continuation, provenance, and local certificate rows.

Finally apply Definition 335.34. This commutes the terminal dyadic route with the mesh-and-enclosure route, so both orders factor through the single finite surface listed in the statement. Every cited boundary is a finite BEDC readback boundary, hence none supplies a quotient real, host-real equality, solver-correctness row, or chosen completion point. □

Theorem 335.29 (DyadicApproximation DyadicMesh ValidatedNumerics consumer normal form)**.** *Let $A = (n, d, w, l, p)$ be an accepted* DyadicApproximation$^{\uparrow}$ *packet. Let $M = (\ell, J, I, E, H, C, P, N)$ be an accepted* DyadicMesh$^{\uparrow}$ *cell whose* RationalInterval$^{\uparrow}$ *row I contains the transported dyadic endpoint d at the displayed precision n. Let V be a* ValidatedNumerics$^{\uparrow}$ *enclosure reading the same mesh cell through the displayed enclosure row I and the same containment ledger.*

Then the three accepted packets determine one finite RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumer surface. The surface consists exactly of the precision row n, the* DyadicRatCore$^{\uparrow}$ *endpoint d, the* RationalInterval$^{\uparrow}$ *containment row I, the* DyadicMesh$^{\uparrow}$ *level row ℓ, the cell-index row J, the* RegSeqRat$^{\uparrow}$ *readback carried by w and l, the* Real$^{\uparrow}$ *seal ledger of A, the displayed* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance rows, and the local* NameCert *rows of the three packets.*

The normal form exports no quotient real, solver-correctness claim, floating-point semantics, host equality, or classical completeness principle.

Proof. Project the accepted dyadic packet first. By Definition 335.12 and Definition 335.17, its public finite window is the displayed precision row, dyadic endpoint, stream window, regular-rational readback, real-seal ledger, visible transports, continuations, package provenance, and local certificate data.

Project the mesh packet next. By Definition 358.4 and Definition 358.6, the mesh contributes only the level row, cell-index row, rational interval coverage row, dyadic containment ledger, refinement route, endpoint readback, package provenance, and local certificate row.

Read the validated enclosure through Definition 357.15. Its consumer boundary is the finite enclosure row, endpoint provenance, precision request, regular-rational readback, real-name readback token, containment routes, transports, package provenance, and local certificate row.

The shared-containment hypothesis identifies the dyadic endpoint read from A, the rational interval row I from M, and the enclosure row read by V at the displayed precision. After that identification, all remaining rows are the listed hsame, Cont, Pkg, and local NameCert data.

Repack those projected rows as the consumer surface. Carrier exhaustion in the three cited packets leaves no coordinate for quotient reals, solver correctness, floating-point hardware semantics, host equality, or classical completeness. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier dyadicmesh validatednumerics consumer normal form`

Theorem 335.30 (DyadicApproximation finite packet readback exhaustion)**.** *Let $A = (n, d, w, l, p)$ be an accepted* DyadicApproximation$^{\uparrow}$ *finite packet, and let C be a finite-packet consumer whose reads of A are routed through the public finite-window export, the terminal overlap chain, the overlap refinement normal form, and the* DyadicMesh$^{\uparrow}$/ValidatedNumerics$^{\uparrow}$ *consumer normal form.*

Then the readback surface seen by C is exactly the displayed precision row n, the DyadicRatCore$^{\uparrow}$ *endpoint window, the finite* RegSeqRat$^{\uparrow}$ *readback window, the* Real$^{\uparrow}$ *seal token, the refinement ledger, the overlap route, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance rows, the local* NameCert$_{\text{DyadicApproximation}^{\uparrow}}$ *rows, and the validated enclosure handoff carried by the displayed* DyadicMesh$^{\uparrow}$/ValidatedNumerics$^{\uparrow}$ *consumer boundary.*

The readback surface has no coordinate for a completed real, infinite mesh, solver state, host interval object, host equality, selected representative, trichotomy row, or choice data.

Proof. First project the accepted packet through Definition 335.12. The public rows are the displayed precision, dyadic endpoint, stream window, regular-rational readback, real-seal ledger, visible transport and continuation routes, package provenance, and local certificate data.

Next stabilize the overlap access. Apply Definition 335.20 to the terminal read and then apply Definition 335.25 to the compatible overlap refinement chain. These two results identify the terminal overlap route with the same finite packet rows and leave no second endpoint, precision row, provenance row, or seal coordinate.

Now pass to the downstream consumer. By Definition 335.29, the DyadicMesh$^{\uparrow}$ cell and the ValidatedNumerics$^{\uparrow}$ enclosure read only the displayed containment row, mesh level and cell-index rows, endpoint window, enclosure handoff, containment routes, package provenance, and local certificate rows attached to the same dyadic packet.

Coordinate exhaustion finishes the claim. Every row available to C appears in one of the three projected surfaces just listed, and the listed surfaces have no carrier field or certificate row for a completed real, infinite mesh, solver state, host interval object, host equality, selected representative, trichotomy row, or choice data. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier finite packet readback exhaustion`

Theorem 335.31 (DyadicApproximation refined finite-packet readback determinacy)**.** *Let A and A' be accepted* DyadicApproximation$^{\uparrow}$ *finite packets. Suppose their transported precision rows,* DyadicRatCore$^{\uparrow}$ *endpoint windows, terminal overlap routes, overlap refinement normal forms,* RegSeqRat$^{\uparrow}$ *readback windows,* Real$^{\uparrow}$ *seal tokens, and* DyadicMesh$^{\uparrow}$/ValidatedNumerics$^{\uparrow}$ *consumer*

normal forms are the same displayed BEDC rows. Suppose also that their visible hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows agree.*

Then every displayed precision refinement reads the same public finite surface from A and A'. The common read is exactly the displayed precision row, endpoint window, terminal overlap route, overlap normal form, regular-rational readback window, real seal token, mesh-and-validated consumer handoff, visible transport rows, continuation routes, package provenance, and local certificate rows named above.

The determinacy statement does not identify completed real values, does not export host interval objects, does not decide a trichotomy row, and does not read solver state or choice data.

Proof. First exhaust the finite readback of each packet. Apply Definition 335.30 to both A and A'. The only rows available to either consumer are the displayed precision, endpoint, readback, seal, refinement, overlap, transport, continuation, package, local certificate, and $\mathsf{DyadicMesh}^{\uparrow}/\mathsf{ValidatedNumerics}^{\uparrow}$ handoff rows.

Next normalize the overlap side. Use Definition 335.25 for the displayed overlap refinement chain of each packet. The hypotheses identify the terminal route and the overlap normal form, so the two packet reads have the same terminal finite route after any displayed precision refinement.

Finally normalize the downstream consumer. By Definition 335.29, the mesh cell and validated enclosure can read only the common containment, mesh-level, cell-index, endpoint-window, regular-rational, real-seal, transport, continuation, package, and local certificate rows. Since those rows are assumed equal as displayed BEDC data, the public finite read is the same.

The cited exhaustion and normal-form results also list the absent coordinates. Thus the conclusion cannot be strengthened into completed-real equality, host interval equality, trichotomy, solver-state agreement, or a choice principle. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier refined finite packet readback determinacy`

Theorem 335.32 (DyadicApproximation terminal validated enclosure readback)**.** *Let a compatible finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *refinement chain have terminal displayed window T. Suppose the prefix projection of the chain has stabilized and the overlap refinement chain reads in the displayed overlap normal form. If a* $\mathsf{DyadicMesh}^{\uparrow}$ *finite cell and a* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure consume that same terminal window, then the terminal readback surface is exactly the same finite enclosure surface consumed by those two downstream packets.*

Componentwise, the common surface consists of the terminal precision row, the dyadic endpoint and radius route, the $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the* $\mathsf{DyadicMesh}^{\uparrow}$ *rational-interval cell row, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment ledger, the* $\mathsf{Real}^{\uparrow}$ *readback token, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance rows, and the local* NameCert *rows. The readback does not assert solver correctness, floating-point semantics, classical real completeness, or host real equality.*

Proof. First stabilize the terminal dyadic window. Apply Definition 335.27 to identify every prefix read with the corresponding row of T: precision, endpoint, regular-rational observation, real-seal token, visible transport, continuation, provenance, and local certificate rows.

Next stabilize overlap access. Apply Definition 335.25. The overlap read has the same terminal precision row, transported endpoint route, rational-interval window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal boundary, visible hsame transports, visible Cont routes, Pkg provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ rows.

Now pass to the finite cell and enclosure consumers. By Definition 335.29, the $\mathsf{DyadicMesh}^{\uparrow}$ cell and the $\mathsf{ValidatedNumerics}^{\uparrow}$ enclosure read the dyadic terminal window only through the displayed precision row, endpoint row, rational-interval cell row, mesh level and cell-index rows, validated containment ledger, regular-rational readback, real-seal token, transport routes, provenance, and local certificate rows.

The mesh handoff and the enclosure boundary identify the downstream rows. Apply Definition 358.6 for the rational interval cell, containment ledger, endpoint readback, and mesh provenance. Apply Definition 357.15 for the validated enclosure row, precision request, containment ledger, real-name readback token, transport rows, continuation routes, package provenance, and local certificate row.

Repack the identified rows as one finite readback surface. The preceding steps account for every component listed in the theorem statement, and the cited consumer boundaries contain no coordinate for solver correctness, floating-point semantics, classical real completeness, or host real equality. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal validated enclosure readback`

Theorem 335.33 (DyadicApproximation terminal mesh enclosure compatibility)**.** *Let an accepted finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet have consumer read with terminal displayed window* T*. For any downstream read through the* $\mathsf{DyadicMesh}^{\uparrow}$ *standard finite mesh bridge and the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure packet, the mesh cell and the validated enclosure consume the same terminal window* T*.*

Equivalently, the rational interval cell, dyadic endpoint-radius-order ledger, $\mathsf{Real}^{\uparrow}$ *boundary token, validated enclosure row, visible* hsame *rows, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows agree as one terminal finite surface. This common surface exports no completed real, infinite mesh, solver correctness row, floating-point semantics row, or compactness row.*

Proof. First exhaust the accepted finite packet. Apply Definition 335.30 to read the terminal displayed packet as its precision row, dyadic endpoint and radius rows, order ledger, regular-rational observation window, $\mathsf{Real}^{\uparrow}$ boundary token, visible transports, continuation routes, package provenance, and local certificate rows.

Next identify the terminal enclosure route. Apply Definition 335.32. The validated enclosure row can see the finite dyadic approximation only through the terminal displayed window T and the rows listed there.

The mesh and enclosure consumers are then put into the same normal form. Apply Definition 335.29 to identify the $\mathsf{DyadicMesh}^{\uparrow}$ cell row and the $\mathsf{ValidatedNumerics}^{\uparrow}$ containment row with the terminal precision, endpoint-radius-order, real boundary, transport, continuation, provenance, and local certificate rows.

Finally use the standard finite mesh bridge, Definition 358.8. It states that the displayed mesh read is exactly the rational interval cell read by the downstream consumer. Combining the four cited readbacks leaves a single terminal finite surface and no coordinate in which a completed real, infinite mesh, solver correctness assertion, floating-point semantics assertion, or compactness claim could be exported. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal mesh enclosure compatibility`

Theorem 335.34 (DyadicApproximation validated enclosure route commutation)**.** *Let* $A = (n, d, w, l, p)$ *be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet. Let* $M = (\ell, J, I, E, H, C, P, N)$ *be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$

cell whose RationalInterval$^{\uparrow}$ *row I contains the transported dyadic endpoint d at the displayed precision n. Let V be an accepted* ValidatedNumerics$^{\uparrow}$ *enclosure over that same cell and containment ledger.*

The route that first reads A through Definition 335.12 and then exposes the Real$^{\uparrow}$ *seal boundary reads exactly the same finite* RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ *consumer surface as the route that first reads M through Definition 358.6 and then exposes V through Definition 357.15. The common surface consists precisely of the precision row, transported dyadic endpoint, rational-interval cell, mesh level and cell index, regular rational observation window, validated containment ledger, real readback token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

This correspondence does not assert solver correctness, floating-point semantics, quotient-real equality, host real equality, or classical completeness.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier validated enclosure route commutation`

Proof. First normalize the three packets together. Apply Definition 335.29 to the accepted dyadic approximation packet, the mesh cell containing its transported endpoint, and the validated enclosure over the same cell. This produces one finite consumer surface over the listed precision, endpoint, mesh, regular-rational, real-seal, transport, continuation, provenance, and local certificate rows.

Next identify the dyadic route. Apply Definition 335.27 to replace every finite prefix read of A by the terminal displayed window, and apply Definition 335.12 to read the public packet through that finite window. The Real$^{\uparrow}$ seal therefore remains attached to the same RegSeqRat$^{\uparrow}$ observation window and dyadic endpoint row.

Now identify the mesh and enclosure route. Apply Definition 358.4 to read the mesh cell as the rational interval containing the transported endpoint, and apply Definition 358.6 to pass that cell to the validated enclosure surface.

Finally apply Definition 357.15 and Definition 357.16. These theorems say that the validated route exposes exactly the same finite rational-interval, regular-rational, real-readback, containment, transport, continuation, provenance, and local certificate rows. Repacking those rows gives the claimed route commutation, while the excluded semantic obligations remain outside every cited boundary. □

Theorem 335.35 (DyadicApproximation mesh validated Real boundary)**.** *Let $A = (n, d, w, l, p)$ be an accepted* DyadicApproximation$^{\uparrow}$ *packet. Let $M = (\ell, J, I, E, H, C, P, N)$ be an accepted* DyadicMesh$^{\uparrow}$ *cell whose* RationalInterval$^{\uparrow}$ *cell I contains the transported dyadic endpoint d at the displayed precision n. Let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p', n')$ be an accepted* ValidatedNumerics$^{\uparrow}$ *enclosure over the same rational-interval cell and the same containment ledger.*

Suppose the displayed precision row, dyadic endpoint row, rational-interval cell, containment ledger, regular-rational window, mesh level and index, real-readback token, visible hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *rows are shared by the three accepted packets. Then the DyadicApproximation terminal finite-window route, the DyadicMesh cell-containment route, and the ValidatedNumerics real-readback route expose exactly one finite* RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ *consumer surface.*

The shared surface is precisely the precision row, endpoint row, rational-interval cell, mesh level and index, regular-rational window, validated containment ledger, real readback token, visible hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no solver correctness, floating-point semantics, host real equality, quotient reals, or classical completeness.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier mesh validated real boundary`

Proof. First expose the DyadicApproximation terminal route. Apply Definition 335.30 to account for every public read of A, and apply Definition 335.32 to tie the terminal finite window to the validated enclosure readback rows.

Next identify the common three-packet normal form. Apply Definition 335.29 to the accepted dyadic packet, the mesh cell containing its transported endpoint, and the validated enclosure over the same cell and containment ledger. This produces one finite surface over the listed precision, endpoint, mesh, regular-rational, real-readback, transport, continuation, provenance, and local naming rows.

Now compare the routes. Apply Definition 335.34 to identify the route that reads the terminal DyadicApproximation finite window and then the $\mathsf{Real}^{\uparrow}$ seal with the route that passes through the DyadicMesh cell and the ValidatedNumerics enclosure.

Finally attach the neighboring consumer boundaries. Apply Definition 358.2 for the mesh level, cell-index, rational-interval, containment-ledger, transport, continuation, provenance, and local name rows. Apply Definition 358.6 and Definition 357.3 to read the validated enclosure as the same finite real-readback surface.

The carrier-exhaustion, normal-form, route-commutation, mesh-containment, and validated-readback boundaries leave no coordinate for solver correctness, floating-point semantics, host real equality, quotient reals, or classical completeness. The three routes therefore expose exactly the single finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer surface stated above. □

Definition 335.36 (DyadicApproximation mesh-enclosure exactness packet)**.** *Let $A = (n, d, w, l, p)$ be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *row, let $M = (\ell, J, I, E, H, C, P, N)$ be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *cell row, and let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p', n')$ be an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row. A DyadicApproximation mesh-enclosure exactness packet is the finite BEDC packet consisting of these three rows together with the following shared coordinates:*

1. *a shared displayed precision row identifying n, ℓ, and ε as the same finite request through visible* hsame *rows;*
2. *the rational interval cell I and its dyadic endpoint-radius-order ledger E, with d read as the transported endpoint contained in I;*
3. *the* $\mathsf{Real}^{\uparrow}$ *finite-window seal read from w, l, ρ, and λ, with no completed real coordinate added to the packet;*
4. *the visible* hsame *transports that identify the dyadic endpoint, regular-rational observation window, mesh cell, and enclosure readback rows;*
5. *the visible* Cont *routes by which the dyadic finite window, mesh cell containment, rational-interval coverage, validated readback, and precision refinement are inspected by consumers;*
6. *the* Pkg *provenance rows p, P, and p' naming the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, *and* $\mathsf{ValidatedNumerics}^{\uparrow}$ *dependency surface;*
7. *the local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *provenance rows.*

The packet is finite: its carrier is only the accepted rows and the displayed transport, continuation, provenance, and local naming evidence listed above.

Lean4 (definition) `BEDC.Derived.DyadicApproximationUp.DyadicApproximationMeshEnclosureExactnessPacket`

Theorem 335.37 (DyadicApproximation finite mesh-enclosure exactness)**.** *Let $A = (n, d, w, l, p)$ be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *row, let $M = (\ell, J, I, E, H, C, P, N)$ be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *cell row whose* $\mathsf{RationalInterval}^{\uparrow}$ *cell I contains the transported endpoint d at the displayed precision, and let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p', n')$ be an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row over the same cell and containment ledger. Assume the visible* hsame, Cont, Pkg, *and local* NameCert *rows identify the precision request, rational interval cell,* $\mathsf{Real}^{\uparrow}$ *finite window seal, and enclosure readback rows as in Definition 335.36.*

Then every accepted mesh-cell or validated-enclosure consumer read through that packet factors through one finite $\mathsf{Real}^{\uparrow}$ *surface. The factorization is exactly the DyadicApproximation* $\mathsf{Real}^{\uparrow}$ *seal handoff and finite-window scope, the DyadicMesh cell-containment and rational-interval coverage rows, the DyadicMesh handoff to ValidatedNumerics, and the ValidatedNumerics real readback and precision-refinement containment rows.*

Consequently the mesh-cell consumer and the validated-enclosure consumer read the same finite surface: the shared precision row, transported dyadic endpoint, rational interval cell, endpoint-radius-order ledger, regular-rational observation window, $\mathsf{Real}^{\uparrow}$ *readback token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *provenance. The statement does not assert completed real equality, infinite mesh refinement, solver correctness, floating-point semantics, or choice-selected limits.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier finite mesh enclosure exactness`
Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationMeshEnclosureExactnessPacket consumes real surface`

Proof. First project the accepted dyadic row. Apply Definition 335.3 to expose the only $\mathsf{Real}^{\uparrow}$ handoff surface carried by A, and apply Definition 335.8 to restrict all dyadic reads to the displayed finite window. This produces the precision row, transported endpoint, regular-rational observation window, seal ledger, visible transports, continuation routes, package provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ row.

Next project the mesh rows. Apply Definition 358.2 for the level, cell index, rational interval cell, dyadic containment ledger, transport, continuation, provenance, and local naming rows. Apply Definition 358.4 to read I as the complete finite coverage object, and apply Definition 358.6 to identify the mesh handoff rows consumed by the enclosure.

Now project the validated enclosure rows. Apply Definition 357.3 to tie the $\mathsf{Real}^{\uparrow}$ readback token to the displayed $\mathsf{RegSeqRat}^{\uparrow}$ window and precision request. Apply Definition 357.5 to keep every refined finite read inside the same rational interval cell and containment ledger.

Finally repack the projected rows into the exactness packet of Definition 335.36. The identifications in the hypotheses make the dyadic seal handoff, mesh cell coverage, and validated enclosure readback one shared finite BEDC surface. Every cited boundary is a finite packet boundary, so no completed real equality, infinite mesh refinement, solver correctness, floating-point semantics, or choice-selected limit is exported. □

Theorem 335.38 (DyadicApproximation terminal finite-packet Real readback)**.** *Let a compatible finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *refinement chain have accepted terminal packet T. Suppose a consumer reads T through one of the following interfaces: terminal prefix projection, mesh-cell enclosure, validated readback, or the* $\mathsf{Real}^{\uparrow}$ *seal route. If the displayed transport, continuation, package, and*

local naming rows identify these interfaces over the same terminal window, then all four reads factor through one finite terminal surface.

That surface is exactly the terminal precision row, the transported dyadic endpoint, the $\mathsf{RationalInterval}^{\uparrow}$ *cell, the* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal ledger, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment row, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance, and the local* NameCert *provenance. It exports no completed real equality, solver correctness, floating-point semantics, or choice-selected limit.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal finite packet real readback`

Proof. First put terminal prefix access and terminal readback in the same normal form. Apply Definition 335.28. It identifies each prefix-projected read with the terminal precision, endpoint, stream-name window, regular-rational readback, $\mathsf{Real}^{\uparrow}$ seal row, visible transport and continuation rows, package provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ row.

Next attach the finite mesh and validated enclosure surface. Apply Definition 335.37. This reads the transported endpoint through the rational interval cell, the endpoint containment ledger, the validated readback rows, and the shared $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ finite surface.

Now compare the terminal mesh route with the terminal validated route. Apply Definition 335.33 to keep the mesh-cell consumer on the same terminal precision, endpoint, rational-interval, containment, transport, continuation, provenance, and local certificate rows. Apply Definition 335.32 to read the validated enclosure through that same terminal finite surface.

The preceding identifications list every coordinate available to the four consumer interfaces. Repacking those coordinates gives one terminal finite-packet surface, and none of the cited boundaries contains a coordinate for completed real equality, solver correctness, floating-point semantics, or a choice-selected limit. □

Theorem 335.39 (DyadicApproximation common-refinement enclosure handoff)**.** *Let* $A = (n, d, w, l, p)$ *and* $A' = (n', d', w', l', p')$ *be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets. Suppose they admit a displayed common precision refinement* R *whose endpoint rows, terminal finite windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *observation windows,* $\mathsf{Real}^{\uparrow}$ *seal tokens, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance rows, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows are the same finite BEDC data.*

Let $M = (\ell, J, I, E, H, C, P, N)$ *be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *cell row and let* $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, q, m)$ *be an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row. Suppose the mesh-cell row and the validated-enclosure row consume the same refined window* R*: the displayed precision row is shared, the transported dyadic endpoint is contained in the rational interval cell* I*, the endpoint-radius-order ledger* E *is the validated containment ledger, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window and* $\mathsf{Real}^{\uparrow}$ *readback token are the rows read by* V*.*

Then the mesh-cell handoff and the validated-enclosure handoff factor through one finite $\mathsf{Real}^{\uparrow}$ *surface. That surface is exactly the shared precision row, transported dyadic endpoint, rational interval cell, endpoint-radius-order ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window,* $\mathsf{Real}^{\uparrow}$ *readback token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance rows, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$*,* $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$*, and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *rows. The factorization exports no completed real equality, host interval equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limit.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier common refinement enclosure handoff`

Proof. First identify the common refined dyadic read. Apply Definition 335.31 to A, A', and the displayed refinement R. The two accepted finite packets therefore expose the same precision, endpoint, terminal-window, regular-rational, real-seal, transport, continuation, provenance, and local certificate rows.

Next attach the mesh and enclosure rows to that common read. Apply Definition 335.37 to the accepted dyadic row selected by R, the mesh cell M, and the validated enclosure V. This places the dyadic seal handoff, mesh cell containment, rational-interval coverage, validated containment ledger, and $\mathsf{Real}^{\uparrow}$ readback token on one finite surface.

Now read the terminal enclosure boundary. Apply Definition 335.32. The terminal window consumed by M and V has the same precision row, transported endpoint, regular-rational observation window, containment ledger, visible transport rows, continuation rows, package provenance rows, and local certificate rows as the common refinement.

Finally compare the downstream handoff surfaces. Apply Definition 358.6 for the mesh-to-enclosure handoff rows, and apply Definition 357.15 for the validated enclosure boundary. These two boundaries name the same rational interval cell, endpoint-radius-order ledger, observation window, real-readback token, transport rows, continuation rows, package provenance, and local certificate rows already obtained from the dyadic common refinement.

All cited boundaries are finite BEDC readback statements. Repacking their shared rows gives the single $\mathsf{Real}^{\uparrow}$ surface listed in the theorem statement, and no cited component supplies completed real equality, host interval equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limit. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier common refinement enclosure certificate`

Theorem 335.40 (DyadicApproximation refinement-seal commutation)**.** *Let $A = (n, d, w, l, p)$ and $A' = (n', d', w', l', p')$ be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets admitting a displayed common precision refinement R. Let $M = (\ell, J, I, E, H, C, P, N)$ be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *cell row, and let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, q, m)$ be an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row consuming the same refined endpoint selected by R.*

Then the route that first takes the common refinement and then reads the $\mathsf{Real}^{\uparrow}$ *seal, and the route that first reads the mesh enclosure and then performs validated readback, expose one finite* $\mathsf{Real}^{\uparrow}$ *surface. That surface is exactly the displayed precision row, transported dyadic endpoint, rational interval cell, endpoint-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window,* $\mathsf{Real}^{\uparrow}$ *seal token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance rows, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *rows.*

The commutation is only this finite consumer-surface equality. It does not assert completed real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limits.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier refinement seal commutation`

Proof. Begin with the shared refinement endpoint. Apply Definition 335.39 to the accepted packets A and A', the displayed refinement R, the accepted mesh cell M, and the accepted validated enclosure V. This places the precision row, transported endpoint, rational interval cell, endpoint-radius ledger, regular-rational window, real seal token, transport rows, continuation rows, package rows, and local certificate rows on one finite handoff surface.

Next compare the two consumer routes through that surface. Apply Definition 335.34. It identifies the terminal dyadic-window route with the mesh-enclosure and validated-readback route without adding any coordinate beyond the displayed finite rows.

Now seal the terminal endpoint against the mesh enclosure. Use Definition 335.33 to transport the terminal $\mathsf{RegSeqRat}^{\uparrow}$ window and the $\mathsf{Real}^{\uparrow}$ seal token through the same rational interval cell and endpoint-radius ledger.

Finally apply Definition 335.37. This restricts every mesh-cell and validated-enclosure read to the finite packet boundary already produced by the common-refinement handoff. Repacking the shared rows gives the stated single $\mathsf{Real}^{\uparrow}$ surface, and the cited finite boundaries provide no completed real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limit. □

Theorem 335.41 (DyadicApproximation shared Real-boundary determinacy)**.** *Let A and A' be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets. Suppose the two packets display the same precision row, transported dyadic endpoint, rational-interval cell,* $\mathsf{DyadicMesh}^{\uparrow}$ *level and index rows,* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback window,* $\mathsf{Real}^{\uparrow}$ *readback token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *rows.*

Then every mesh-cell consumer, validated-enclosure consumer, and terminal dyadic finite-window consumer that reads either packet through the displayed BEDC rows reads the same finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *boundary surface. The surface is exactly the shared precision row, transported endpoint, rational-interval cell, mesh level, mesh index, containment ledger, regular-rational window, real-readback token, visible transport rows, continuation routes, package provenance, and local name-certificate rows.*

The determinacy is finite. It does not assert completed real equality, quotient-real equality, solver correctness, floating-point semantics, or classical completeness.

Proof. First compare the two dyadic packets before any downstream consumer is read. Apply Definition 335.31 to A and A'. The hypotheses identify precisely the displayed precision, endpoint, regular-rational, real-readback, mesh-and-validated handoff, transport, continuation, provenance, and local certificate rows available to both packets.

Next put each packet together with its mesh cell and validated enclosure in normal form. Apply Definition 335.29 to the accepted packet, the displayed mesh cell, and the validated enclosure over the same rational-interval cell and containment ledger. The normal form has no coordinate beyond the rows listed in the statement.

Now identify the two routes that consumers may use. Apply Definition 335.34 to compare the terminal dyadic finite-window route with the route through the mesh cell and validated enclosure. Apply Definition 335.35 to expose the shared Real-boundary surface carried by that comparison.

Finally restrict mesh and enclosure reads to the finite packet boundary. Apply Definition 335.37. Its factorization says that every accepted mesh-cell or validated-enclosure read passes through the same finite $\mathsf{Real}^{\uparrow}$ surface already identified above.

Combining the refined packet determinacy, the three-packet normal form, route commutation, shared Real-boundary comparison, and finite mesh-enclosure exactness leaves a single displayed BEDC surface for every listed consumer. Since each cited boundary is a finite packet boundary, the conclusion exports no completed real equality, quotient-real equality, solver correctness, floating-point semantics, or classical completeness. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier shared real boundary determinacy`

Theorem 335.42 (DyadicApproximation finite-packet Real-seal stability)**.** *Let A and A' be accepted finite* $\mathsf{DyadicApproximation}^{\uparrow}$ *packets sharing a displayed common refinement R. Let M be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *cell, and let V be an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure over the same rational interval selected by the refined dyadic endpoint. Suppose the visible* hsame *transports,* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows identify the finite-packet route, the mesh-cell route, the validated-enclosure route, and the* $\mathsf{Real}^{\uparrow}$ *seal route over that common refinement.*

Then the terminal finite-packet readback and the $\mathsf{Real}^{\uparrow}$ *seal expose the same finite surface after refinement, whether the consumer reaches it through the common-refinement route or through the validated enclosure route. This surface is exactly the precision row, transported dyadic endpoint,* $\mathsf{RationalInterval}^{\uparrow}$ *cell,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal token,* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment row, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *rows.*

The stability assertion is only this finite seal surface. It does not assert completed real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limits.

Proof. First put the terminal readback in its finite normal form. Apply Definition 335.38. This identifies the terminal precision, transported endpoint, stream-name window, regular-rational readback, $\mathsf{Real}^{\uparrow}$ seal row, transport rows, continuation routes, package provenance, and local name-certificate rows visible to the finite packet.

Next compare the common-refinement route with the validated-enclosure route. Apply Definition 335.40 to the accepted packets, the displayed refinement, the accepted mesh cell, and the accepted validated enclosure. This places the rational interval cell, containment row, refined endpoint, $\mathsf{RegSeqRat}^{\uparrow}$ observation window, and $\mathsf{Real}^{\uparrow}$ seal token on one finite consumer surface.

Finally use Definition 335.41. The shared boundary theorem says that every mesh-cell, validated-enclosure, and terminal finite-window read with the displayed rows reads the same $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ boundary. Repacking those rows gives exactly the surface stated above, and the cited finite boundaries provide no coordinate for completed real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limits. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier finite packet real seal stability`

Theorem 335.43 (DyadicApproximation terminal seal common-refinement pullback)**.** *Let $A = (n, d, w, l, p)$ and $A' = (n', d', w', l', p')$ be accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets. Let terminal finite-window* $\mathsf{Real}^{\uparrow}$ *seal consumers read the visible terminal boundary of A and A' through displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *windows,* $\mathsf{Real}^{\uparrow}$ *tokens, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *rows.*

Then equality of the visible terminal seal boundary is equivalent to the existence of a common-refinement enclosure handoff through one finite BHist *surface. The witnessing surface consists exactly of a common precision row, transported dyadic endpoint, terminal finite window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *token,* $\mathsf{DyadicMesh}^{\uparrow}$ *mesh row,* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *rows.*

Under this equivalence the forward implication starts from the terminal $\mathsf{Real}^{\uparrow}$ *seal boundary and produces the common finite surface; the reverse implication starts from the common-refinement enclosure handoff and reads back the same terminal seal boundary. The criterion exports no completed real equality, quotient-real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limit.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal seal common refinement pullback`

Proof. For the forward direction, first put the two terminal seal consumers into the finite-packet readback form. Apply Definition 335.38 to the terminal packet read by each consumer. The visible terminal boundary therefore has only the displayed precision, endpoint, terminal-window, regular-rational, real-token, transport, continuation, package, and local certificate rows.

Now use the assumed equality of the visible terminal $\mathsf{Real}^{\uparrow}$ seal boundary. Apply Definition 335.41 to the two accepted packets with those identified terminal rows. The determinacy statement says that every terminal finite-window consumer, mesh-cell consumer, and validated-enclosure consumer must read the same finite BEDC boundary.

Choose the resulting mesh and enclosure rows as the common-refinement witness. Their shared precision row, transported endpoint, terminal window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ token, visible transports, continuation routes, package rows, and local name-certificate rows form the required finite BHist surface.

For the reverse direction, begin with the displayed common-refinement enclosure handoff. Apply Definition 335.39 to A, A', the common refinement, the mesh row, and the validated enclosure row. This places the dyadic endpoint, mesh cell, containment ledger, regular-rational window, real token, transport rows, continuation rows, package rows, and local certificate rows on one finite surface.

Next restrict the handoff to the finite packet boundary. Apply Definition 335.37. Then apply Definition 335.34 to identify the terminal finite-window route with the mesh-enclosure and validated-readback route.

The two routes now expose the same finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ rows, with the same hsame, Cont, Pkg, and local $\mathsf{NameCert}$ coordinates. Reading those rows through the terminal seal consumers gives equality of the visible terminal seal boundary. Since every cited component is a finite BEDC boundary statement, the pullback supplies no completed real equality, quotient-real equality, solver correctness, floating-point semantics, infinite mesh selection, or choice-selected limit. □

Theorem 335.44 (DyadicApproximation diagonal mesh-selector boundary)**.** *Let A be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet, let M be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *finite cell, and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet. Suppose these packets display the same unary precision row, selected diagonal window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, rational-interval cell,* $\mathsf{Real}^{\uparrow}$ *readback token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *rows.*

Then the diagonal-completion consumer of D and the mesh or validated dyadic consumer of A and M read the same finite $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *boundary surface. The shared surface is exactly the displayed precision row, selected diagonal window, regular-rational readback, rational-interval cell, real readback token, visible transport rows, continuation routes, package provenance, and local name-certificate rows.*

This boundary theorem does not identify quotient streams, host real numbers, selected limits, infinite meshes, solver correctness, or classical completeness.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier diagonal mesh selector boundary`

Proof. Start with the dyadic side. Apply Definition 335.41 to the accepted dyadic packet and its displayed mesh and validated-readback rows. This reduces every dyadic finite-window, mesh-cell, and validated-enclosure read to the listed $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ boundary surface.

Next read the mesh packet through Definition 358.8. The bridge shows that the standard finite mesh consumer has no coordinate beyond the unary level, finite cell index, rational interval, endpoint and real readback, transport, continuation, package, and local certificate rows already listed in the statement.

Now turn to the diagonal-completion packet. Apply Definition 359.5 to factor the consumer read through the displayed modulus row, diagonal selector, scheduled window, and regular-rational readback. Then apply Definition 359.6 to identify the visible $\mathsf{Real}^{\uparrow}$ seal ledger with those extracted finite windows and their readback ledger.

The hypotheses identify the precision, selected window, rational interval, regular-rational readback, real token, transports, continuations, package provenance, and local certificates on both routes. Therefore both consumers project the same finite boundary surface. Since every cited step is a finite BEDC packet boundary, none of the excluded analytic or quotient objects is exported. □

Theorem 335.45 (DyadicApproximation terminal selector determinacy)**.** *Let A and A' be accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets. Suppose their terminal rows are identified by displayed* hsame *comparisons, they expose the same* $\mathsf{RationalInterval}^{\uparrow}$ *window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the same* $\mathsf{Real}^{\uparrow}$ *seal-facing route through visible* Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *provenance.*

Then the terminal selector reads of A and A' classify together. Equivalently, after the terminal finite-window surface is fixed, the selector cannot depend on an unlogged mesh endpoint or on any endpoint coordinate outside the accepted finite packets.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier finite packet terminal selector determinacy`

Proof. First normalize both terminal reads. Apply Definition 335.38 to each accepted packet. The terminal selector is thereby expressed through the terminal precision row, transported endpoint, $\mathsf{RationalInterval}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal ledger, visible transports, continuation routes, package provenance, and local certificate rows.

Next place the two packets on a common enclosure surface. Apply Definition 335.39. The shared rational interval, regular-rational readback, and real seal route are therefore read from one finite $\mathsf{Real}^{\uparrow}$ boundary surface.

Now commute the refinement with the seal route. Apply Definition 335.40. This shows that reading the terminal selector before the seal and reading through the common refinement before the seal expose the same finite coordinates.

Finally use Definition 335.41. Since the hypotheses identify the terminal rows, interval window, regular readback, real seal route, transports, continuations, and provenance, every permitted consumer route reads the same boundary. No cited surface contains an unlogged mesh endpoint, so the terminal selector has no remaining coordinate on which a different classification could depend. □

Theorem 335.46 (DyadicApproximation terminal diagonal completion handoff)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet. Suppose the terminal route of T and the diagonal row of D display the same terminal precision, selected* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, transported dyadic endpoint,* $\mathsf{Real}^{\uparrow}$ *seal ledger, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *provenance.*

Then the $\mathsf{Real}^{\uparrow}$ *consumer route through T and the* $\mathsf{Real}^{\uparrow}$ *consumer route through D expose the same finite surface: terminal precision, transported dyadic endpoint, scheduled stream win-*

dow, regular-rational readback, $\mathsf{Real}^{\uparrow}$ *seal ledger, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *provenance.*

The handoff is only this finite BEDC surface. It does not assert completed real equality, quotient streams, selected host limits, solver correctness, or choice-selected completion points.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal diagonal completion handoff`

Proof. First normalize the terminal packet route. Apply Definition 335.38 to T. The terminal consumer is thereby read through the displayed terminal precision, transported endpoint, scheduled $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal row, transport rows, continuation routes, package provenance, and local dyadic certificate.

Next normalize the diagonal-completion route. Apply Definition 359.5 to D to expose the diagonal selector, scheduled window, and regular-rational readback selected by the requested row. Apply Definition 359.6 to factor the $\mathsf{Real}^{\uparrow}$ seal ledger through those same extracted finite windows and readback rows.

The hypotheses identify the scheduled window and readback rows on the two routes, together with the terminal precision, transported endpoint, seal ledger, transports, continuations, package provenance, and local certificates. Repacking those identified coordinates gives one shared finite surface for both $\mathsf{Real}^{\uparrow}$ consumers.

The cited dyadic and diagonal boundaries expose only finite packet data. Consequently the repacked surface has no coordinate for completed real equality, quotient streams, selected host limits, solver correctness, or choice-selected completion points. □

↪ variant `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal diagonal completion handoff`

Theorem 335.47 (DyadicApproximation terminal diagonal readback composition)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet. Suppose T has the finite-packet* $\mathsf{Real}^{\uparrow}$ *readback surface of Definition 335.38, and suppose T and D are matched by the terminal diagonal handoff of Definition 335.46.*

Then every $\mathsf{Real}^{\uparrow}$ *consumer route through the matched diagonal-completion packet factors through the same terminal precision, transported dyadic endpoint,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, visible* hsame *rows, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *rows already exposed by the terminal packet. The composition exports no completed real equality, quotient stream, selected host limit, solver correctness, or choice-selected completion point.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal diagonal readback composition`

Proof. First normalize the terminal dyadic packet. The finite-packet readback theorem factors every terminal $\mathsf{Real}^{\uparrow}$ read through the displayed terminal precision, endpoint, stream-name window, regular-rational readback, real seal, transport rows, continuation routes, package provenance, and local dyadic certificate.

Next apply the terminal diagonal handoff. Its hypotheses identify the terminal route of T with the diagonal row of D across the same precision, endpoint, scheduled window, readback, seal ledger, transports, continuations, package provenance, and local certificate rows.

Composing these two surfaces gives one finite route for the diagonal-completion consumer. The readback data first appears in the terminal dyadic packet and is then repacked as the diagonal-completion handoff, so the $\mathsf{Real}^{\uparrow}$ consumer sees the same finite rows in the same terminal precision boundary.

The two cited theorems carry the same non-escape boundary. Therefore the composite surface has no coordinate for completed real equality, quotient streams, selected host limits, solver correctness, or choice-selected completion points. □

Theorem 335.48 (DyadicApproximation terminal interval-mesh readback totality)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet. Every terminal interval-mesh read of T factors through the displayed* $\mathsf{RationalInterval}^{\uparrow}$ *window, the* $\mathsf{DyadicMesh}^{\uparrow}$ *cell selector, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row, the terminal finite-packet readback, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary.*

Equivalently, the read is total over the displayed finite packet: its public surface is exactly the terminal precision row, transported dyadic endpoint, rational interval cell, dyadic mesh selector, validated enclosure ledger, scheduled $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal row, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* NameCert *provenance. It exports no host interval, quotient real, or unrecorded completeness datum.*

Proof. First normalize the terminal finite-packet read. Apply Definition 335.38. The terminal packet is read through the displayed precision row, transported endpoint, scheduled stream window, regular-rational readback, $\mathsf{Real}^{\uparrow}$ seal ledger, transport rows, continuation routes, package provenance, and local certificate row.

Next attach the mesh and enclosure coordinates. Apply Definition 335.33 to put the terminal mesh route and the validated enclosure route on the same terminal window. Apply Definition 335.37 to identify the rational interval cell, dyadic mesh selector, endpoint containment ledger, and validated enclosure row with that same finite surface.

Finally pass through the diagonal-completion handoff. By Definition 335.46, the terminal packet and the diagonal route expose one shared $\mathsf{Real}^{\uparrow}$ consumer surface over the displayed terminal rows.

The listed rows exhaust the packet coordinates available to an interval-mesh consumer. Since the cited boundaries contain no host interval, quotient real, or ambient completeness field, the total readback exports none of those data. □

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal interval mesh readback totality`

Theorem 335.49 (DyadicApproximation finite-packet StreamName Real-seal factorization)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet. Suppose the displayed terminal route for T contains its terminal precision, dyadic endpoint, scheduled* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal ledger, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *row, and the diagonal-completion selector rows consumed by D.*

Then the route that first applies the StreamName $\mathsf{Real}^{\uparrow}$ *seal factorization diamond and the route that first applies the* $\mathsf{DyadicApproximation}^{\uparrow}$ *terminal diagonal-completion handoff expose the same finite* BHist *surface. That surface is exactly the StreamName finite-window row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, dyadic endpoint rows, terminal precision row,* $\mathsf{Real}^{\uparrow}$ *seal token, diagonal selector row, transport rows, continuation rows, package provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ *provenance.*

The surface assertion is only this finite packet factorization. It does not assert completed real equality, quotient streams, selected host limits, solver correctness, metric completeness, or any standard bridge.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier finite packet streamname real seal factorization`
Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier streamname real seal factorization certificate`

Proof. First normalize the dyadic terminal route. Apply Definition 335.38 to the accepted terminal packet T. This reads the terminal consumer through the displayed terminal precision, dyadic endpoint, scheduled $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal row, transport rows, continuation rows, package provenance, and local dyadic certificate row.

Next normalize the refinement and seal route. Apply Definition 335.42 to place the terminal readback and the $\mathsf{Real}^{\uparrow}$ seal on one finite refinement surface. Apply Definition 335.43 to pull that seal surface back to the visible terminal boundary.

Now identify the StreamName source tuple. Apply Definition 38.349 to the scheduled $\mathsf{StreamName}^{\uparrow}$ finite window and its displayed prefix refinement. The diamond leaves exactly the StreamName finite-window row, accepted $\mathsf{RegSeqRat}^{\uparrow}$ source row, dyadic endpoint rows, continuation ledger, endpoint transports, and provenance rows visible to the $\mathsf{Real}^{\uparrow}$ seal.

Finally identify the diagonal-completion consumer rows. Apply Definition 335.46 to the same terminal packet and diagonal-completion packet. The handoff contributes the diagonal selector row and confirms that the terminal precision, endpoint, scheduled window, regular-rational readback, seal ledger, transports, continuations, package rows, and local certificate row are the rows consumed by the diagonal route.

The two normal forms therefore list the same finite coordinates. Repacking those coordinates gives one BHist surface containing exactly the StreamName finite-window row, $\mathsf{RegSeqRat}^{\uparrow}$ readback, dyadic endpoint rows, terminal precision row, $\mathsf{Real}^{\uparrow}$ seal token, diagonal selector row, transport rows, continuation rows, package provenance, and local $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$ provenance. None of the cited finite surface theorems supplies a coordinate for completed real equality, quotient streams, selected host limits, solver correctness, metric completeness, or a standard bridge. □

Definition 335.50 (DyadicApproximation terminal dyadic-net consumer surface)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet matched to T by the displayed terminal diagonal handoff. The terminal dyadic-net consumer surface of (T, D) is the finite* BHist *surface consisting exactly of the terminal precision row, the transported dyadic endpoint row, the* $\mathsf{RationalInterval}^{\uparrow}$ *cell, the* $\mathsf{DyadicMesh}^{\uparrow}$ *selector row, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure row, the scheduled* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{Real}^{\uparrow}$ *seal row, the* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *selector row, the visible* hsame *rows, the visible* Cont *routes, the* Pkg *provenance rows, and the visible* $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$, $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$, *and* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *rows.*

Lean4 (definition) `BEDC.Derived.DyadicApproximationUp.DyadicApproximationTerminalDyadicNetConsumerSurface`

Theorem 335.51 (DyadicApproximation terminal dyadic-net consumption)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet and let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet matched to T by the displayed terminal diagonal handoff. Suppose a terminal dyadic-net*

consumer reads T through any displayed route built from the terminal finite-packet Real$^{\uparrow}$ *readback, the interval-mesh readback, the terminal diagonal readback, and the* StreamName$^{\uparrow}$ *real-seal factorization rows.*

Then the consumer factors through the terminal dyadic-net consumer surface of Definition 335.50. Its observable coordinates are exactly the terminal precision, dyadic endpoint, rational interval cell, DyadicMesh$^{\uparrow}$ *selector,* ValidatedNumerics$^{\uparrow}$ *enclosure,* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal,* RealDiagonalCompletion$^{\uparrow}$ *selector,* hsame*,* Cont*,* Pkg*, and* NameCert *rows listed there. The factorization exports no quotient streams, selected host limits, solver correctness, metric completeness, or host real equality.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal dyadic net consumption`

Proof. First normalize the terminal real readback. Apply Definition 335.38 to the accepted terminal packet T. This exposes the terminal precision, transported endpoint, scheduled stream window, regular-rational readback, Real$^{\uparrow}$ seal ledger, transport rows, continuation routes, package provenance, and local dyadic certificate row.

Next attach the interval net. Apply Definition 335.48. The terminal read is total over the displayed rational interval cell, the DyadicMesh$^{\uparrow}$ selector, the ValidatedNumerics$^{\uparrow}$ enclosure row, and the same terminal finite-packet real boundary.

Now compose with the diagonal consumer. Apply Definition 335.47 to the matched pair (T, D). The diagonal route contributes the RealDiagonalCompletion$^{\uparrow}$ selector and keeps the same precision, endpoint, stream window, regular-rational readback, real seal, transports, continuations, package rows, and local certificate rows.

Finally identify the stream seal source. Apply Definition 335.49. It identifies the scheduled StreamName$^{\uparrow}$ finite-window row, RegSeqRat$^{\uparrow}$ readback, dyadic endpoint rows, terminal precision row, Real$^{\uparrow}$ seal token, diagonal selector row, transport rows, continuation rows, package provenance, and local dyadic certificate provenance as one finite packet surface.

The four normal forms list the same terminal coordinates and no additional coordinate. Repacking those coordinates gives exactly the surface of Definition 335.50. Since the cited rows contain no quotient-stream representative, selected host limit, solver-correctness proof, metric-completeness witness, or host real-equality field, the resulting consumer surface exports none of those data. □

Theorem 335.52 (DyadicApproximation terminal dyadic-net bridge)**.** *Let T be an accepted terminal* DyadicApproximation$^{\uparrow}$ *finite packet, and let D be an accepted* RealDiagonalCompletion$^{\uparrow}$ *packet matched to T by the displayed terminal diagonal handoff. Suppose a bridge-facing consumer reads the matched pair as a finite* Real$^{\uparrow}$ *and completion packet through the terminal dyadic-net consumer route.*

Then the exported bridge-facing surface is exactly the terminal dyadic-net consumer surface of Definition 335.50. It is the same finite packet through terminal precision, transported dyadic endpoint, RationalInterval$^{\uparrow}$ *cell,* DyadicMesh$^{\uparrow}$ *selector,* ValidatedNumerics$^{\uparrow}$ *enclosure,* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal,* RealDiagonalCompletion$^{\uparrow}$ *selector, visible* hsame *rows, visible* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

The bridge exports no quotient streams, selected host limits, solver correctness, metric completeness, or host real equality.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal dyadic net bridge`

Proof. First read the matched pair through the terminal dyadic-net consumer surface. Apply Definition 335.51. This already exposes the terminal precision, dyadic endpoint, rational interval cell, mesh selector, validated enclosure, stream window, regular-rational readback, real seal, diagonal selector, transports, continuation routes, package rows, and local certificates.

Next identify the completion side. Apply Definition 335.46. The matched $\mathsf{RealDiagonalCompletion}^{\uparrow}$ packet reads the same terminal precision, endpoint, scheduled window, regular-rational readback, real seal, transports, continuations, package provenance, and local certificate provenance as the terminal dyadic packet.

Now compose the readback route. Apply Definition 335.47. The diagonal consumer cannot replace the terminal rows by completed real equality or by a selected completion point; it repacks the same finite terminal rows for the completion-facing read.

Finally attach the stream seal source by Definition 335.49. The scheduled $\mathsf{StreamName}^{\uparrow}$ row, $\mathsf{RegSeqRat}^{\uparrow}$ readback, dyadic endpoint, terminal precision, $\mathsf{Real}^{\uparrow}$ seal, diagonal selector, transports, continuations, package provenance, and local dyadic certificate provenance are therefore one finite surface.

The four cited surfaces name the same displayed coordinates. Repacking them as the bridge-facing packet gives exactly Definition 335.50. Since none of those surfaces contains a coordinate for quotient streams, selected host limits, solver correctness, metric completeness, or host real equality, the bridge cannot export such data. □

Theorem 335.53 (DyadicApproximation terminal tail-budget exhaustion)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet, let D be an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet matched to T by the terminal diagonal handoff, and let B be a* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *precision request consumed by the same terminal packet. Suppose the displayed transports and continuation routes identify the terminal precision row used by T, the diagonal-completion readback of D, and the finite budget request of B.*

Then the consumed budget factors through exactly the terminal precision row, the transported dyadic endpoint, the $\mathsf{RationalInterval}^{\uparrow}$ *cell, the* $\mathsf{DyadicMesh}^{\uparrow}$ *selector, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure, the* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicTailBound}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal, visible* hsame *rows, visible* Cont *routes,* Pkg *provenance, and local* NameCert *rows already exposed by the terminal packet and its matched diagonal-completion surface.*

The terminal packet exports no completed real equality, quotient stream, selected host limit, solver correctness, metric completeness, or host real equality to the finite budget consumer.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal tail budget exhaustion certificate`

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal tail budget exhaustion`

Proof. First normalize the terminal finite-packet real readback. Apply Definition 335.38. The terminal packet is read through the displayed terminal precision, endpoint, rational interval cell, validated enclosure, stream window, regular-rational readback, real seal, transports, continuation routes, package provenance, and local certificate.

Next attach the terminal dyadic-net route. Apply Definition 335.51. This identifies the dyadic endpoint with the $\mathsf{RationalInterval}^{\uparrow}$ cell and $\mathsf{DyadicMesh}^{\uparrow}$ selector used by the terminal consumer, keeping the validated enclosure and real seal on the same finite surface.

Now consume the precision request. Apply Definition 385.5 to force the $\mathsf{FiniteErrorBudget}^{\uparrow}$ request through the displayed terminal tail ledger. Apply Definition 379.16 to compose that ledger with the $\mathsf{DyadicTailBound}^{\uparrow}$ row recorded by the dyadic packet.

Finally use the diagonal side. The terminal diagonal readback composition of Definition 335.47 keeps the matched RealDiagonalCompletion$^{\uparrow}$ packet on the same terminal precision, endpoint, stream window, readback, real seal, transports, continuations, package provenance, and local certificate rows.

The cited surfaces contain the same terminal rows and no additional consumer channel. Repacking them gives exactly the factorization stated above, and the non-escape clauses from the terminal readback and diagonal-completion surfaces exclude completed real equality, quotient streams, selected host limits, solver correctness, metric completeness, and host real equality. □

Theorem 335.54 (DyadicApproximation terminal tail-budget Real-completion route)**.** *Let T be an accepted terminal* DyadicApproximation$^{\uparrow}$ *finite packet. Suppose T is matched with a* RealDiagonalCompletion$^{\uparrow}$ *packet D, a* FiniteErrorBudget$^{\uparrow}$ *request B, a* DyadicTailBound$^{\uparrow}$ *ledger row, a* StreamName$^{\uparrow}$ *window, a* RegSeqRat$^{\uparrow}$ *readback, and a* Real$^{\uparrow}$ *seal row by the displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows of the terminal packet.*

Then the matched packet exposes exactly the terminal budget-to-seal route: the finite budget request is read through the terminal precision row, the transported dyadic endpoint, the RationalInterval$^{\uparrow}$ *cell, the* DyadicMesh$^{\uparrow}$ *selector, the* ValidatedNumerics$^{\uparrow}$ *enclosure, the stream window, the regular-rational readback, the dyadic tail-bound ledger, and the* Real$^{\uparrow}$ *seal before it is presented to the Real-completion consumer surface. No completed real equality, quotient stream, host limit, solver oracle, or metric-completion object is exported by this route.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal tail budget real completion route`

Proof. First normalize the terminal finite packet. The finite-packet Real readback theorem Definition 335.38 places the terminal precision, endpoint, stream window, regular-rational readback, validated enclosure, Real$^{\uparrow}$ seal, transports, continuation routes, package provenance, and local certificate on one finite surface.

Next attach the diagonal-completion side. The terminal diagonal readback composition theorem Definition 335.47 identifies the matched RealDiagonalCompletion$^{\uparrow}$ packet with the same terminal precision, endpoint, stream window, readback, seal, transport, continuation, package, and certificate rows.

Now consume the mesh and budget rows. The terminal dyadic-net consumption theorem Definition 335.51 adds the RationalInterval$^{\uparrow}$ cell and DyadicMesh$^{\uparrow}$ selector, while Definition 335.53 forces the FiniteErrorBudget$^{\uparrow}$ request through the displayed DyadicTailBound$^{\uparrow}$ ledger and the same terminal seal route.

These cited surfaces share the same terminal rows. Repacking them gives precisely the budget-to-seal route stated above, and their non-escape clauses leave no coordinate for completed real equality, quotient streams, host limits, solver oracles, or metric-completion objects. □

Theorem 335.55 (DyadicApproximation DyadicRatCore dependency route)**.** *Every accepted* DyadicApproximation *finite packet consumes the* DyadicRatCore$^{\uparrow}$ *signed-exponent row, scale-window row, and finite-tail row of chapter 291 before it may hand a mesh, validated enclosure, or terminal seal to* Real$^{\uparrow}$*. The route passes through the local finite-packet readback and exactness surfaces of Definition 335.30, Definition 335.31, Definition 335.38, and Definition 335.37; it exports no host rational equality, quotient stream, selected limit, or ambient completion object.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier dyadicratcore dependency route`

Proof. Start with the finite-packet readback exhaustion theorem. It places every accepted DyadicApproximation consumer read on the displayed precision, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint window, stream window, regular-rational readback, $\mathsf{Real}^{\uparrow}$ seal, refinement, overlap, transport, continuation, package, and local certificate rows.

Use the refined finite-packet determinacy and terminal finite-packet Real readback theorems next. These keep the transported precision, endpoint window, validated enclosure, stream window, regular-rational readback, and $\mathsf{Real}^{\uparrow}$ seal on one finite packet surface.

Finally apply the finite mesh-enclosure exactness surface. The mesh or enclosure handed to $\mathsf{Real}^{\uparrow}$ is exact only after the DyadicRatCore signed exponent, scale window, and finite tail have been consumed through the cited sibling chapter. Therefore the dependency route is a substantive DyadicRatCore route rather than a decorative cross-reference. □

Theorem 335.56 (DyadicApproximation terminal budget-seal uniqueness)**.** *Let T_0 and T_1 be accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packets. Suppose both packets are matched to the same terminal precision row, transported dyadic endpoint,* $\mathsf{RationalInterval}^{\uparrow}$ *cell,* $\mathsf{DyadicMesh}^{\uparrow}$ *selector,* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicTailBound}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal, visible* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Then T_0 and T_1 present the same Real-completion budget-to-seal route to every consumer. In particular, a consumer that enters through the finite budget row, the dyadic endpoint, the mesh selector, the validated enclosure, the stream window, the regular-rational readback, the tail-bound ledger, or the terminal $\mathsf{Real}^{\uparrow}$ *seal sees one terminal route surface.*

This uniqueness statement does not identify completed reals. It refuses completed real equality, quotient streams, selected host limits, solver oracles, metric-completion objects, and host real equality as distinguishing data.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal budget seal uniqueness`

Proof. First normalize each terminal packet through the tail-budget surface. Apply Definition 335.53 to T_0 and to T_1. Since the hypotheses match the same terminal precision row, endpoint, interval cell, mesh selector, validated enclosure, stream window, readback, tail ledger, seal, transports, continuations, package provenance, and local certificate rows, both packets factor through the same finite budget ledger.

Next pass from the finite budget ledger to the Real-completion consumer surface. Apply Definition 335.54. This keeps the budget request, dyadic tail-bound ledger, stream readback, and $\mathsf{Real}^{\uparrow}$ seal on the displayed terminal route before any Real-completion consumer can inspect the packet.

Now compare the finite readbacks. The determinacy theorem Definition 335.31 says that two accepted finite packets with the same transported rows expose the same readback surface. Thus the visible terminal rows carried by T_0 and T_1 cannot split into two consumer-facing budget-to-seal routes.

Finally record the dyadic-core dependency. Apply Definition 335.55 to both packets. The endpoint, mesh, enclosure, and terminal seal are available only through the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ signed-exponent, scale-window, and finite-tail rows, so no hidden host rational comparison or ambient completion channel remains.

The four cited surfaces have the same visible rows under the hypotheses. Repacking them gives one terminal Real-completion route, and the non-escape clauses in those surfaces leave no coordinate in which completed real equality, quotient streams, selected host limits, solver oracles, metric-completion objects, or host real equality could distinguish T_0 from T_1 for any consumer. □

DyadicApproximation terminal finite packets are consumed through the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger of chapter 291, the $\mathsf{StreamName}^{\uparrow}$ finite-window surface of chapter 126, the $\mathsf{RegSeqRat}^{\uparrow}$ readback surface of chapter 301, and the $\mathsf{RealCauchyCompletion}^{\uparrow}$ seal rows of chapter 360. This records the horizontal route from terminal dyadic observations to the Real-completion consumer as a finite sibling dependency rather than an ambient completion assumption.

Theorem 335.57 (DyadicApproximation L10 Real-completion sibling route)**.** *Let T be an accepted terminal* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet, and let a* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer read the terminal real-facing row of T. Suppose the terminal packet is matched with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows of chapter 291, the finite* $\mathsf{StreamName}^{\uparrow}$ *windows of chapter 126, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows of chapter 301, and the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *seal rows of chapter 360 by the displayed* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows of the terminal packet.*

Then every accepted terminal read consumed by that $\mathsf{RealCauchyCompletion}^{\uparrow}$ *surface factors through the sibling chain*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{RealCauchyCompletion}^{\uparrow}$$

before the completion consumer may inspect the terminal seal. The exported surface is exactly the finite packet route where DyadicRatCore supplies the finite observation and ledger rows, StreamName schedules finite windows over those rows, RegSeqRat supplies regular readback, and RealCauchyCompletion consumes the resulting seal rows together with hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *provenance. It exports no quotient stream, selected host limit, host real equality, solver oracle, ambient completeness principle, or completion object outside the displayed sibling rows.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier l10 real completion sibling route`

Proof. First normalize the terminal Real-completion route. The terminal tail-budget theorem Definition 335.54 places the accepted terminal packet on the displayed budget-to-seal route through terminal precision, transported endpoint, interval cell, mesh selector, validated enclosure, finite tail ledger, and $\mathsf{Real}^{\uparrow}$ seal.

Next attach the diagonal handoff. The theorem Definition 335.46 identifies the terminal route with the diagonal completion packet on the same $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, scheduled $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, seal ledger, transport rows, continuation rows, package provenance, and local certificate rows.

Now read the completion consumer through the sibling completion surface. Apply Definition 360.3, Definition 360.7, and Definition 360.8. These RealCauchyCompletion rows force the completion read through the modulus-selected diagonal packet, dyadic observation ledger, finite stream window, regular-rational readback, and real seal.

Finally apply Definition 360.18. Repacking the dyadic terminal route with the RealCauchyCompletion export yields exactly the sibling chain through chapter 291, chapter 126, chapter 301, and chapter 360. The non-escape clauses in the cited terminal, diagonal, and completion theorems exclude quotient streams, selected host limits, host real equality, solver oracles, ambient completeness, and any completion object outside the displayed finite packet rows. □

Theorem 335.58 (DyadicApproximation top-hub L10 sibling route)**.** *Every top-level* $\mathsf{DyadicApproximation}^{\uparrow}$ *read exported through the hub of chapter 335 factors through the same four sibling faces*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{RealCauchyCompletion}^{\uparrow}$$

named by chapter 291, chapter 126, chapter 301, and chapter 360. The hub-visible export is exhausted by the displayed BHist, hsame, Cont, Pkg, *and* NameCert *rows of those sibling faces together with the local terminal* DyadicApproximation$^{\uparrow}$ *rows. It exports no quotient stream, selected host limit, host real equality, solver oracle, ambient completeness principle, or hidden completion object.*

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier top hub l10 sibling route`

Proof. Begin with the sibling-route theorem Definition 335.57. It already places every terminal RealCauchyCompletion$^{\uparrow}$ read of an accepted DyadicApproximation$^{\uparrow}$ packet on the four-face chain through DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and RealCauchyCompletion$^{\uparrow}$.

The terminal tail-budget Real-completion route of Definition 335.54 supplies the terminal budget-to-seal route consumed by the hub. The terminal diagonal completion handoff of Definition 335.46 identifies that terminal route with the same diagonal packet, scheduled window, regular-rational readback, seal ledger, visible hsame transports, visible Cont routes, Pkg provenance, and local NameCert rows.

Finally use the RealCauchyCompletion readback and export rows: Definition 360.3, Definition 360.7, Definition 360.8, and Definition 360.18. These rows force the top-level hub read through the same finite completion route and leave no coordinate for a quotient stream, selected host limit, host real equality, solver oracle, ambient completeness principle, or hidden completion object. □

Theorem 335.59 (DyadicApproximation terminal Real-completion exit criterion)**.** *Let T be an accepted terminal* DyadicApproximation$^{\uparrow}$ *finite packet. A terminal read of T can be admitted for consumption by the* RealCauchyCompletion$^{\uparrow}$ *surface only if the read displays the* DyadicRatCore$^{\uparrow}$ *observation ledger of chapter 291, a finite* StreamName$^{\uparrow}$ *window from chapter 126, the* RegSeqRat$^{\uparrow}$ *regular readback rows of chapter 301, the* RealCauchyCompletion$^{\uparrow}$ *seal rows of chapter 360, and the shared* BHist, hsame, Cont, Pkg, *and* NameCert *support rows carried by the terminal packet.*

Every admitted terminal RealCauchyCompletion$^{\uparrow}$ *read must expose those five families of displayed rows and must pass through the four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{RealCauchyCompletion}^{\uparrow}.$$

The support criterion has no substitute coordinate: quotient stream equality, selected host limits, host real equality, solver oracles, ambient completeness, and hidden completion objects cannot replace any displayed face or support row.

Lean4 ✓ `BEDC.Derived.DyadicApproximationUp.DyadicApproximationCarrier terminal real completion exit criterion`

Proof. Apply Definition 335.57 to the admitted terminal consumer read. Its conclusion already factors the read through the DyadicRatCore$^{\uparrow}$ ledger, finite StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, and RealCauchyCompletion$^{\uparrow}$ seal rows, with the visible hsame transports, Cont routes, Pkg provenance, and local NameCert provenance on the same terminal packet. The terminal packet itself supplies the shared BHist support.

The top-hub route of Definition 335.58 and the RealCauchyCompletion readback and export rows of Definition 360.3, Definition 360.7, Definition 360.8, and Definition 360.18 identify this finite support surface. They do not by themselves create an admission converse: the cited rows leave the completion consumer with only the displayed finite faces and support rows, so none of quotient stream equality, selected host limits, host real equality, solver oracles, ambient completeness, or hidden completion objects can witness terminal admission. □

Chapter 336

A Concrete Naming Certificate for $\mathsf{ComputableReal}^{\uparrow}$

The $\mathsf{ComputableReal}^{\uparrow}$ interface names effective real presentations by finite BEDC packets rather than by completed real objects. Following the Bishop–Bridges constructive-analysis treatment of explicit moduli and the Weihrauch computable-analysis treatment of names as effective approximation procedures, the packet below records a dyadic approximation program only through certified finite observation windows, a unary Cauchy modulus, dyadic endpoint rows, a regular-sequence handoff, and a $\mathsf{Real}^{\uparrow}$ seal boundary.

The effective approximation packet consumes chapter 126 for finite observation windows, chapter 292 for unary thresholds, chapter 291 for dyadic approximation rows, chapter 301 for the regularity handoff, and chapter 38 for the seal boundary. These are imported L10 sibling rows for coordinates s, μ, d, r, ℓ, not local free parameters and not host real data.

Definition 336.1 (ComputableReal source packet)**.** *A* $\mathsf{ComputableReal}^{\uparrow}$ *source packet is a finite* BHist *record*

$$X = (s, \mu, d, r, \ell, h, c, p, n)$$

with the following visible rows:

1. *s is a* $\mathsf{StreamName}^{\uparrow}$ *observation schedule naming the certified finite windows through which the approximation program is read;*
2. *μ is a unary* $\mathsf{CauchyModulus}^{\uparrow}$ *row naming, for each requested precision row, the finite threshold after which observations are compared;*
3. *d is the family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *packets read on the scheduled windows selected by s and μ;*
4. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity handoff ledger built from those dyadic packets and modulus rows;*
5. *ℓ is the* $\mathsf{Real}^{\uparrow}$ *seal-source row that consumes the regular sequence surface without selecting a completed real value;*
6. *h records the componentwise* hsame *rows for stream windows, modulus rows, dyadic packets, regularity rows, and the seal source;*
7. *c records the* Cont *routes through which certified finite windows are read by downstream consumers;*
8. *p is the* Pkg *provenance row naming the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *dependency certificates;*

9. n is the local $\mathsf{NameCert}_{\mathsf{ComputableReal}^\uparrow}$ *registration row.*

The carrier predicate is $\mathsf{ComputableRealSource}(s, \mu, d, r, \ell, h, c, p, n)$*. Its classifier compares two accepted packets by running the existing regular-sequence classifier on every certified finite window and transporting all displayed rows componentwise by* hsame *and* Cont*. It does not quotient completed reals or appeal to host real equality.*

Theorem 336.2 (ComputableReal NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ComputableReal}^\uparrow}$ *obligation surface consists of five rows:*

1. *carrier habitation: the carrier is inhabited by the constant dyadic stream whose every certified window reads the same* $\mathsf{DyadicRatCore}^\uparrow$ *zero packet, with the unary modulus selecting the first threshold row;*
2. *classifier transport: accepted packets compare only by pointwise* hsame *transport of the displayed* $\mathsf{StreamName}^\uparrow$*,* $\mathsf{CauchyModulus}^\uparrow$*,* $\mathsf{DyadicRatCore}^\uparrow$*,* $\mathsf{RegSeqRat}^\uparrow$*,* $\mathsf{Real}^\uparrow$*,* Cont*,* Pkg*, and* NameCert *rows;*
3. *modulus-window stability: restricting, enlarging, or refining a certified finite window preserves the late-observation comparisons named by the same unary modulus row;*
4. $\mathsf{Real}^\uparrow$ *seal handoff: every real-facing read factors through the* $\mathsf{RegSeqRat}^\uparrow$ *handoff surface and then through the displayed* $\mathsf{Real}^\uparrow$ *seal source row;*
5. *ledger coverage: the packet exposes no row beyond the stream schedule, modulus table, dyadic approximation rows, regularity handoff, seal source, transport, continuation, provenance, and local naming registration.*

These rows are the complete seed obligation for constructive effective real names over certified dyadic approximations.

```
Lean4 ✓  BEDC.Derived.ComputableRealUp.ComputableRealSource namecert obligation surface
Lean4 ✓  BEDC.Derived.ComputableRealUp.ComputableRealPacket namecert obligation surface
```

Proof. For habitation, take the constant scheduled stream whose dyadic observation row is the certified zero packet. The unary modulus can select the first threshold for every precision request, and the regularity handoff reads identical dyadic endpoints on every finite window.

For classifier transport, project the carrier of Definition 336.1. Each visible coordinate is a finite BEDC row, so the classifier is obtained by applying the $\mathsf{RegSeqRat}^\uparrow$ finite-window classifier after transporting the corresponding stream, modulus, dyadic, regularity, seal, continuation, provenance, and local naming rows.

For window stability, compare two certified finite windows by passing to their displayed common refinement. The unary modulus still names the same threshold rows, and the dyadic observations beyond those thresholds are the rows already stored in the packet, so restriction and refinement do not create a new approximation object.

Finally, the $\mathsf{Real}^\uparrow$ read is exactly the seal-source row ℓ fed by the regular-sequence ledger r. Since the carrier has no coordinate for a completed real, a quotient stream, a selected limit, or host real equality, the listed ledger rows exhaust the local naming surface. □

Theorem 336.3 (ComputableReal RealUp handoff)**.** *Every accepted* $\mathsf{ComputableReal}^\uparrow$ *packet presents a* $\mathsf{Real}^\uparrow$ *seal source only through its* $\mathsf{RegSeqRat}^\uparrow$ *regularity handoff, dyadic approximation rows, certified* $\mathsf{StreamName}^\uparrow$ *windows, unary* $\mathsf{CauchyModulus}^\uparrow$ *threshold rows, and displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The handoff exports no completed real carrier, no selected limit, no quotient of Cauchy names, and no appeal to classical real completeness.

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSource realup handoff`
Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealPacket realup handoff`

Proof. Project the source packet of Definition 336.1. The rows s, μ, and d give the scheduled dyadic approximation data, while r is the regular rational handoff built from those finite observations.

Read the seal-source row ℓ. It is indexed by the same regularity handoff and therefore consumes only the finite scheduled windows, dyadic endpoint rows, modulus thresholds, transport rows, continuation routes, and provenance already visible in the carrier.

No additional coordinate remains from which a completed real object or selected limiting value could be read. The $\mathsf{Real}^{\uparrow}$ handoff is therefore a finite source-surface handoff, not a completeness principle. □

Theorem 336.4 (ComputableReal ledger coverage)**.** *Every consumer of an accepted* $\mathsf{ComputableReal}^{\uparrow}$ *packet factors through the same finite ledger:*

$$(s, \mu, d, r, \ell, h, c, p, n).$$

The stream schedule, modulus table, dyadic approximation rows, regularity handoff, seal source, transport rows, continuation routes, package provenance, and local naming registration cover all readable coordinates of the packet.

Consequently the packet exports no oracle beyond its certified observation windows, no real-number quotient, no metric completion object, and no hidden standard bridge.

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket ledger coverage`

Proof. Start from the carrier definition. Its tuple lists exactly nine coordinates, and each coordinate is a finite row over the existing BEDC kernel and certificate interfaces.

Any stream-facing consumer reads s and the certified windows named by c. Any rate-facing consumer reads μ. Any approximation-facing consumer reads d. Any regular-sequence or real-facing consumer reads r and ℓ, with h, p, and n carrying the transport and provenance required to keep those reads inside the same packet.

Thus every consumer projection is one of the displayed coordinates or a projection through the listed transport and continuation rows. Since no other coordinate exists, external oracles, quotient reals, completion objects, and standard bridge data are outside the ledger. □

Theorem 336.5 (ComputableReal standard bridge boundary)**.** *The standard mathematical reading of an accepted* $\mathsf{ComputableReal}^{\uparrow}$ *packet is the constructive effective real name consisting of an explicit dyadic approximation procedure and a unary convergence modulus. The BEDC bridge boundary is exactly the finite source surface of Definition 336.1 together with the obligation rows of Definition 336.2, Definition 336.3, and Definition 336.4.*

This bridge boundary is compatible with Bishop–Bridges constructive reals and Weihrauch-style computable names, but it does not assert classical real completeness, a quotient of names, extensional equality of completed reals, or a total comparison operation.

Proof. Read the accepted packet as the finite program interface encoded by s, μ, and d: certified windows select dyadic observations, and the unary modulus selects the finite thresholds at which precision requests are checked.

Apply Definition 336.2 to identify the carrier, pointwise classifier, modulus-window stability, seal handoff, and ledger coverage rows. Apply Definition 336.3 to identify the only real-facing read, and apply Definition 336.4 to rule out unlisted consumer coordinates.

The resulting bridge boundary is therefore the standard effective real-name surface interpreted through finite BEDC rows. The external precedents explain the intended mathematical reading, while the BEDC packet itself retains only the displayed approximation, modulus, regularity, seal, transport, and provenance rows. □

Theorem 336.6 (ComputableReal RegSeqRat seal factorization)**.** *Every accepted packet of Definition 336.1 factors its real-facing read through the displayed* $\mathsf{StreamName}^{\uparrow}$ *windows, unary* $\mathsf{CauchyModulus}^{\uparrow}$ *rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity handoff,* $\mathsf{Real}^{\uparrow}$ *seal-source row,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The factorization exports no completed real, quotient of names, selected limit, host equality, or classical completeness row. Its full readable surface is the finite BHist *ledger*

$$(s, \mu, d, r, \ell, h, c, p, n).$$

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket regseqrat seal factorization`

Proof. Project the nine coordinates of the source packet. The rows s, μ, and d supply the certified stream windows, unary thresholds, and dyadic observations. The row r is the regular-sequence handoff, while ℓ is the only $\mathsf{Real}^{\uparrow}$ seal-source row.

Apply Definition 336.3 to the real-facing read. It identifies the $\mathsf{Real}^{\uparrow}$ surface as a read through the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the same finite dyadic windows, with h, c, p, and n carrying transport, continuation, package, and naming provenance.

Apply Definition 336.4 to exhaust the consumer coordinates. Then apply Definition 336.5 to separate this finite effective-real reading from completed reals, quotient names, selected limits, host equality, and classical completeness. □

Theorem 336.7 (ComputableReal RationalStream–RegSeqRat schedule factorization)**.** *Every accepted packet of Definition 336.1 whose schedule row is read as a finite* $\mathsf{RationalStream}^{\uparrow}$ *observation packet factors its* $\mathsf{Real}^{\uparrow}$*-facing read through the* $\mathsf{RationalStream}^{\uparrow}$ *pointwise* $\mathsf{Rat}^{\uparrow}$ *obligation rows, the* $\mathsf{RationalStream}^{\uparrow}$ *to* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{ComputableReal}^{\uparrow}$ $\mathsf{RegSeqRat}^{\uparrow}$ *seal factorization, and the* $\mathsf{ComputableReal}^{\uparrow}$ *ledger coverage theorem.*

The exported consumer surface consists exactly of the $\mathsf{StreamName}^{\uparrow}$ *schedule row, unary-history index rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row, the* $\mathsf{Real}^{\uparrow}$ *seal row,* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

The factorization exports no quotient Cauchy class, selected limit, host real equality, or classical completeness principle.

Proof. Project the source packet of Definition 336.1. Its schedule row supplies the finite $\mathsf{StreamName}^{\uparrow}$ windows, and the assumed $\mathsf{RationalStream}^{\uparrow}$ reading interprets those windows as finite rational observations with unary-history indices and pointwise $\mathsf{Rat}^{\uparrow}$ obligation rows.

Use the $\mathsf{RationalStream}^{\uparrow}$ carrier and handoff rows to pass from the scheduled rational observations to the displayed $\mathsf{RegSeqRat}^{\uparrow}$ handoff. The $\mathsf{CauchyModulus}^{\uparrow}$ thresholds select the late comparison rows, while the $\mathsf{DyadicRatCore}^{\uparrow}$ observations remain the finite approximation rows visible in the computable-real packet.

Apply Definition 336.6 to factor the real-facing read through the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal row. Apply Definition 336.3 to identify the resulting seal read as the only $\mathsf{Real}^{\uparrow}$ consumer surface.

Finally apply Definition 336.4. The repacked rows are precisely the schedule, unary-history index, pointwise rational, threshold, dyadic observation, regular-sequence handoff, seal, transport, continuation, package, and naming rows listed in the statement, with no coordinate left for quotient Cauchy classes, selected limits, host real equality, or classical completeness. □

Theorem 336.8 (ComputableReal Real seal refinement coverage)**.** *Restricting or refining a certified finite observation window of an accepted* $\mathsf{ComputableReal}^{\uparrow}$ *packet preserves the same* $\mathsf{Real}^{\uparrow}$ *seal-source surface. The unary modulus row selects the same late-observation comparison boundary, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff is read through the same finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger.*

Consequently every consumer read after the window change remains inside the finite BEDC rows

$$(s, \mu, d, r, \ell, h, c, p, n)$$

of Definition 336.1.

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket real seal refinement coverage`

Proof. Compare the original certified window and the restricted or refined window by passing to their displayed common refinement. The source packet coordinates s, μ, d, r, ℓ, h, c, p, and n remain the rows being read; no new carrier or limiting object is introduced by the window change.

The row μ names the same late-observation threshold, and the stream row s names the finite window through which the relevant dyadic observations in d are selected. The regular-sequence handoff r therefore receives the same kind of finite comparison data before and after refinement.

Apply Definition 336.6 to keep the real-facing read factored through r and ℓ. Apply Definition 336.3 and Definition 336.4 to keep the seal read and all consumer projections inside the finite BEDC ledger. □

Theorem 336.9 (ComputableReal classifier transport)**.** *For two accepted source packets of Definition 336.1, componentwise* hsame *transport of the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, Cont, *and* Pkg *rows preserves the* $\mathsf{ComputableReal}^{\uparrow}$ *classifier. The comparison remains a finite-window regular-sequence comparison and never becomes equality of completed real values.*

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket classifier transport`

Proof. Project the tuple $X = (s, \mu, d, r, \ell, h, c, p, n)$ from Definition 336.1. Each coordinate is a displayed BEDC row, and the classifier described there reads only the scheduled finite windows and the regular-sequence handoff built from those windows.

Transport s, μ, d, r, ℓ, c, and p componentwise by the given hsame rows. The $\mathsf{StreamName}^{\uparrow}$ row keeps the same certified window shape, the $\mathsf{CauchyModulus}^{\uparrow}$ row keeps the same unary thresholds, and the $\mathsf{DyadicRatCore}^{\uparrow}$ rows keep the same dyadic endpoints after transport.

The $\mathsf{RegSeqRat}^{\uparrow}$ classifier is then applied on the transported finite windows. The $\mathsf{Real}^{\uparrow}$ seal row is carried only as the displayed handoff target, so completed-real equality, quotient names, and selected limits remain outside the ledger. □

Theorem 336.10 (ComputableReal modulus-window stability)**.** *Let X be an accepted* $\mathsf{ComputableReal}^{\uparrow}$ *source packet. Restrict, enlarge, or refine a certified finite observation window along the* $\mathsf{StreamName}^{\uparrow}$

schedule while retaining the same unary $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row. Then the late-window comparison rows read from the* $\mathsf{DyadicRatCore}^{\uparrow}$ *packet family and the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff remain accepted by the same source packet.*

Proof. Read the observation schedule s and modulus row μ from Definition 336.1. A certified window is visible only through the $\mathsf{StreamName}^{\uparrow}$ row and the Cont routes that read dyadic observations from that finite window.

For a restriction, project the retained dyadic rows and the same modulus threshold. For an enlargement or refinement, pass through the displayed common finite window named by the stream schedule. In each case, the Cont route still reads the dyadic endpoints from d, and the unary threshold remains the row named by μ.

The $\mathsf{RegSeqRat}^{\uparrow}$ handoff consumes exactly those transported finite-window comparisons. Since the packet has no coordinate for a completed real, selected limit, or host metric completion, the modulus-window stability claim remains inside the displayed ledger. □

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket modulus window stability`

Theorem 336.11 (ComputableReal bridge boundary)**.** *The standard effective-real boundary of an accepted* $\mathsf{ComputableReal}^{\uparrow}$ *packet is the finite BEDC surface consisting of the source packet of Definition 336.1, the classifier transport row of Definition 336.9, the modulus-window row of Definition 336.10, the* $\mathsf{Real}^{\uparrow}$ *handoff, and the ledger-coverage row. The boundary consumes the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *dependency certificates together with* BHist*,* hsame*,* Cont*, and* Pkg *rows.*

It does not assert extensional equality of completed real values, a selected limit, a quotient of names, or a classical completeness principle.

Proof. Start with the source packet and project its visible dependency rows. The stream schedule, modulus row, dyadic packet family, regular-sequence handoff, and real seal form the whole carrier surface.

Use Definition 336.9 for componentwise transport of the classifier and Definition 336.10 for certified window changes. Then use Definition 336.3 and Definition 336.4 to identify the only real-facing read and the exact consumer ledger.

These projections give the standard effective-real reading through finite BEDC rows. No displayed coordinate names completed-real equality, selected limits, quotient reals, or host completeness, so those objects stay outside the bridge boundary. □

Theorem 336.12 (ComputableReal public export)**.** *The source packet,* $\mathsf{NameCert}_{\mathsf{ComputableReal}^{\uparrow}}$ *obligation surface, RealUp handoff, ledger coverage,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal factorization, Real seal refinement coverage, classifier transport, modulus-window stability, and bridge boundary form the public computable-real export over* BHist *schedules. Every downstream consumer may read only the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows.*

The export exposes no quotient real equality, no selected limit, no classical completeness principle, and no standard bridge datum outside the finite ledger.

Proof. Begin with the source packet of Definition 336.1. Its displayed coordinates are the stream schedule, unary modulus row, dyadic packet family, regular-sequence seal, real-facing handoff, and package provenance rows.

Use Definition 336.2 to name the obligation surface and Definition 336.9 to transport the classifier across the visible coordinates. Use Definition 336.10 to keep finite windows stable under restriction, enlargement, and refinement.

Apply Definition 336.3, Definition 336.4, Definition 336.6, and Definition 336.8 to identify the real-facing exit, the consumer ledger, the regular-sequence seal factor, and the Real seal refinement coverage.

Finally, Definition 336.11 records the boundary objects not projected by the effective-real surface. Thus the theorem exports a consumer packet for later Real and modulus chapters, not a Real completeness theorem and not a standard bridge. □

Theorem 336.13 (ComputableReal effective-window determinacy)**.** *Let* $(s, \mu, d, r, \ell, h, c, p, n)$ *and* $(s', \mu', d', r', \ell', h', c', p', n')$ *be accepted* $\mathsf{ComputableReal}^{\uparrow}$ *source packets. Suppose their consumer reads display the same* $\mathsf{StreamName}^{\uparrow}$ *finite windows, unary* $\mathsf{CauchyModulus}^{\uparrow}$ *thresholds, transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row,* $\mathsf{Real}^{\uparrow}$ *seal-source row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *provenance. Then the two reads expose one consumer surface for every effective-window coordinate.*

This determinacy is only a statement about the displayed finite BEDC surface. It does not assert completed real equality, identify quotient names, select a limit, or invoke classical completeness.

Lean4 ✓ `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket effective window determinacy`

Proof. Project both accepted packets through Definition 336.1. The common display fixes the stream windows, modulus thresholds, dyadic endpoints, regular-sequence handoff, real seal-source row, and all transport and provenance coordinates.

Apply Definition 336.6 to identify the $\mathsf{RegSeqRat}^{\uparrow}$ handoff coordinate in both reads. Apply Definition 336.8 to place the $\mathsf{Real}^{\uparrow}$ seal-source row over the same refinement surface.

The bridge boundary of Definition 336.11 removes any additional completed-real coordinate from the consumer read. It leaves only the finite rows listed in the ledger.

Finally use Definition 336.4. Since the ledger exhausts the consumer coordinates and every ledger row agrees by hypothesis, the two reads present the same effective-window consumer surface, with no extra channel for quotient names, selected limits, or classical completeness. □

Theorem 336.14 (ComputableReal effective RegSeqRat modulus package)**.** *Every accepted* $\mathsf{ComputableReal}^{\uparrow}$ *packet whose displayed finite windows agree under* hsame *and whose unary* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row is retained determines a single finite BEDC consumer package. The package consists exactly of the* $\mathsf{StreamName}^{\uparrow}$ *observation window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *seal-source row, the displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance.*

The same package is stable under restriction, enlargement, and common refinement of certified windows. It asserts no completed-real equality, quotient name, selected limit, trichotomy, or classical completeness principle.

Proof. Project the accepted source tuple through Definition 336.1. This yields the displayed stream schedule, unary modulus threshold, dyadic endpoint family, regular-sequence handoff, Real seal source, transport routes, package provenance, and local name provenance.

Use Definition 336.10 for restriction, enlargement, and common refinement of certified windows. The retained unary threshold row stays on the same displayed carrier, and the hsame agreement of finite windows is transported componentwise by Definition 336.9.

The $\mathsf{RegSeqRat}^{\uparrow}$ coordinate is then fixed by Definition 336.6. The $\mathsf{Real}^{\uparrow}$ seal-source row is fixed by Definition 336.8 together with Definition 336.3.

Finally apply Definition 336.4 and Definition 336.13. The ledger lists exactly the consumer-visible coordinates, and determinacy identifies the common finite-window read as one package. Since no listed coordinate is a completed real, quotient name, selected limit, trichotomy witness, or classical completeness datum, the asserted package contains none of those objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{ComputableReal}^{\uparrow}}$.

Constructive story: A computable real source is generated by certified finite stream-observation windows, a unary Cauchy modulus, dyadic approximation packets, a regular-sequence handoff, a RealUp seal source, and visible transport and provenance rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ComputableReal}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 336.5, Definition 336.11, Definition 336.12, Definition 336.13, and Definition 336.14 record the finite effective-real bridge surface, public export, and downstream effective-name consumer evidence over the source packet, NameCert obligation surface, classifier transport, modulus window, $\mathsf{Real}^{\uparrow}$ handoff, ledger coverage, BHist, hsame, Cont, Pkg, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ComputableReal}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ComputableRealUp.ComputableRealSourcePacket\_effective\_window\_determinacy`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close classical real completeness, quotient equality of names, total comparison of completed reals, selected limits, or a machine-checked standard bridge.

Upgrade path: No further paper-axis theory upgrade remains; formal theorem checking and bridge checking remain on the verification axis.

Chapter 337

A Concrete Naming Certificate for $\mathsf{LagrangianMechanics}^{\uparrow}$

The $\mathsf{LagrangianMechanics}^{\uparrow}$ interface names the finite mechanics surface whose action ledger can be consumed by Euler–Lagrange and Noether-facing certificates. Following Arnold's *Mathematical Methods of Classical Mechanics* and Abraham–Marsden's *Foundations of Mechanics*, the standard mathematical story starts from configurations, velocities, an action functional, admissible variations, endpoint policy, Euler–Lagrange equations, symplectic flow, and conserved-current reads. The BEDC packet below records only the finite rows needed to cite that surface.

The symplectic-flow row S is read through the sibling surface of chapter 138, and the Noether-current row J is read through the sibling surface of chapter 269. Those rows are dependency surfaces of the finite packet, not hidden global solution or conservation-law principles.

Definition 337.1 (LagrangianMechanicsUp BHist carrier)**.** *A* $\mathsf{LagrangianMechanics}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (Q, V, A, R, E, G, S, J, H, C, P, N)$$

with the following visible rows:

1. *Q is the configuration row naming the finite position or field entries available to the local mechanics packet;*
2. *V is the velocity row naming the displayed tangent or rate entries paired with Q;*
3. *A is the action-functional row recording the finite Lagrangian expression, integration route, scalar read, and dependency certificates used to evaluate action values;*
4. *R is the variation row naming the admissible finite variation family and the routes through which the first action variation is read;*
5. *E is the endpoint row recording fixed, vanishing, or exposed endpoint terms;*
6. *G is the Euler–Lagrange row that receives the residual equation surface obtained from A, R, and E;*
7. *S is the symplectic-flow row naming the finite phase-flow read available after the action ledger has selected the displayed dynamics;*
8. *J is the Noether-current row naming the finite conserved-current read available to a Noether-facing consumer;*

9. *H records the* hsame *provenance rows for configuration, velocity, action, variation, endpoint, Euler–Lagrange, symplectic-flow, and Noether-current data;*
10. *C records the* Cont *provenance routes by which the displayed rows are read;*
11. *P is the* Pkg *provenance row naming the action, variation, Euler–Lagrange, symplectic, and Noether dependency certificates used by the packet;*
12. *N is the* NameCert *provenance row registering the packet under* $\mathsf{LagrangianMechanics}^{\uparrow}$.

The carrier predicate is $\mathsf{LagrangianMechanicsPacket}(Q, V, A, R, E, G, S, J, H, C, P, N)$. *Two accepted packets classify together only when the twelve displayed rows transport componentwise by the* hsame *witnesses and the same* Cont *routes named in C and P.*

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.TasteGate.LagrangianMechanicsTasteGate single carrier alignment`

Theorem 337.2 (LagrangianMechanicsUp action ledger obligation)**.** *Every accepted* $\mathsf{LagrangianMechanics}^{\uparrow}$ *carrier exposes a finite action ledger consisting exactly of the configuration row Q, velocity row V, action-functional row A, variation row R, endpoint row E, and the displayed* hsame, Cont, Pkg, *and* NameCert *provenance rows that connect them. A consumer may read the Lagrangian expression, scalar action value, admissible variation family, and endpoint policy only through those rows.*

The ledger asserts no minimizer existence, no global solution theory, no ambient smooth manifold of curves, and no unrecorded regularity condition.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket action ledger obligation`

Proof. Project the carrier of Definition 337.1. The coordinates Q, V, A, R, and E are the only rows that store the displayed configuration, velocity, action, variation, and endpoint data.

The transport and continuation coordinates H and C specify how these rows move under hsame and how they are read by consumers. The package and name certificate rows P and N record provenance, but they do not add analytic objects beyond the visible packet.

Thus the action ledger is exhausted by the listed finite rows. Any minimizer, global dynamics theorem, smooth host manifold, or hidden regularity principle would require an additional coordinate absent from the carrier. □

Theorem 337.3 (LagrangianMechanicsUp Euler-Lagrange interface)**.** *For an accepted carrier $L = (Q, V, A, R, E, G, S, J, H, C, P, N)$, the Euler–Lagrange-facing interface is the single residual-equation row G together with the action, variation, endpoint, transport, continuation, and provenance rows that feed it. An* $\mathsf{EulerLagrange}^{\uparrow}$ *consumer may read only the equation surface displayed by G and the finite action ledger named in Definition 337.2.*

The interface does not claim variational completeness, integration by parts in a host calculus, boundary-condition completeness, or equivalence with a standard analytic equation model.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket eulerlagrange interface`

Proof. Start from the action ledger supplied by Definition 337.2. The variation row R and endpoint row E determine which first-variation terms remain visible to the packet.

The coordinate G records the residual equation surface obtained from those rows. Since G is a finite row of the same carrier, its reads are constrained by the displayed hsame and Cont provenance in H and C.

No coordinate stores an ambient variational calculus, a boundary completeness principle, or a standard analytic equation model. Therefore the Euler–Lagrange-facing interface is exactly the finite row G together with the action ledger that feeds it. □

Theorem 337.4 (LagrangianMechanicsUp Noether consumer boundary)**.** *A Noether-facing consumer of an accepted* $\mathsf{LagrangianMechanics}^{\uparrow}$ *carrier may read only the action ledger rows* Q, V, A, R, E*, the Euler–Lagrange residual row* G*, the symplectic-flow row* S*, the Noether-current row* J*, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The current row* J *is a finite consumer-facing ledger entry, not a theorem asserting a complete Noether correspondence.*

The boundary exports no symmetry classification, no conservation-law completeness theorem, no Hamiltonian equivalence, and no standard bridge to a smooth phase-space model.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket noether consumer boundary`

Proof. Read the accepted packet through Definition 337.1. Its Noether-facing coordinates are the action ledger rows, the residual equation row, the symplectic-flow row, the current row, and the four provenance rows.

Apply Definition 337.2 to identify the only action data available to the consumer. Apply Definition 337.3 to identify the only Euler–Lagrange residual read.

The remaining rows S and J are finite ledgers for phase-flow and current reads. Since the carrier has no coordinate for a symmetry classifier, Hamiltonian equivalence, conservation-law completeness theorem, or standard bridge, the Noether-facing boundary is exactly the stated row list. □

Theorem 337.5 (LagrangianMechanicsUp NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{LagrangianMechanics}^{\uparrow}}$ *seed surface consists of the carrier of Definition 337.1, the action ledger of Definition 337.2, the Euler–Lagrange interface of Definition 337.3, and the Noether consumer boundary of Definition 337.4. Its dependency surface is the finite* Pkg *row naming the action, variation, Euler–Lagrange, symplectic, and Noether certificate boundaries, together with the displayed* hsame*,* Cont*, and* NameCert *provenance rows.*

The seed surface does not close minimizer existence, global dynamics, Hamiltonian equivalence, complete Noether correspondence, analytic regularity, or a standard bridge.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket namecert obligation surface`

Proof. Assemble the seed surface from the carrier. The definition supplies the configuration, velocity, action, variation, endpoint, Euler–Lagrange, symplectic-flow, Noether-current, transport, continuation, package, and name-certificate rows.

The action-ledger theorem identifies the only action-facing projection. The Euler–Lagrange theorem identifies the only residual-equation projection. The Noether boundary theorem identifies the only phase-flow and conserved-current consumer rows.

These projections cover every coordinate of the finite packet. The exclusions follow because none of the rows stores a minimizer, global solution theorem, Hamiltonian equivalence, complete Noether correspondence, analytic regularity principle, or standard bridge. □

Theorem 337.6 (LagrangianMechanics finite obligation carrier)**.** *The finite* $\mathsf{LagrangianMechanics}^{\uparrow}$ *obligation carrier consists of* BHist *rows for configuration history, velocity history, action-density data, a variation token, and visible* Pkg *and* NameCert *provenance. Each row is read as part of the carrier of Definition 337.1, and no row introduces a smooth manifold, a completed path space, or an analytic extremal.*

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket finite obligation carrier`

Proof. Project the carrier tuple of Definition 337.1. The configuration and velocity histories are the rows Q and V, while the action-density and variation data are read from the action and variation coordinates A and R.

The provenance rows are the package and local naming coordinates P and N. Repacking these projected rows gives the finite obligation carrier. Since the carrier list contains no host manifold, path-space completion, or analytic extremal coordinate, those objects are outside the obligation carrier. □

Theorem 337.7 (LagrangianMechanics action ledger policy)**.** *The* $\mathsf{LagrangianMechanics}^{\uparrow}$ *action ledger exposes only finite action-comparison rows, boundary variation rows, and* Cont *transport through the displayed action, variation, endpoint, and continuation coordinates of Definition 337.1. It does not solve an Euler–Lagrange equation, select an analytic minimizer, or supply a smooth manifold model.*

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket action ledger policy`

Proof. Start from the action ledger obligation already identified in Definition 337.2. Its readable rows are the finite configuration, velocity, action, variation, endpoint, transport, continuation, and provenance coordinates.

The comparison data are therefore the finite action rows and the boundary variation rows transported along the displayed Cont routes. Repacking those rows yields the ledger policy, and the excluded analytic objects are absent from the carrier coordinates. □

Theorem 337.8 (LagrangianMechanics Euler boundary scope)**.** *The Euler boundary for* $\mathsf{LagrangianMechanics}^{\uparrow}$ *is a scoped obligation over the displayed finite variation rows. Its dependencies are exactly the* BHist *carrier rows, the* hsame *transports, the* Cont *routes, and the visible* Pkg *and* NameCert *provenance needed to read the Euler–Lagrange residual row of Definition 337.3.*

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket euler boundary scope`

Proof. Use the Euler–Lagrange interface theorem to identify the residual row G and the finite action, variation, endpoint, transport, continuation, and provenance rows that feed it. These are all rows of the same BHist carrier.

Transporting the displayed variation rows uses only the hsame witnesses in H and the continuation routes in C. Repacking them with P and N gives the scoped Euler boundary, with no further analytic equation surface added. □

Theorem 337.9 (LagrangianMechanics public NameCert boundary)**.** *For an accepted* $\mathsf{LagrangianMechanics}^{\uparrow}$ *carrier, the finite configuration, velocity, action, variation, endpoint, Euler–Lagrange residual, symplectic-flow read, Noether-current read,* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows assemble the public* $\mathsf{NameCert}_{\mathsf{LagrangianMechanics}^{\uparrow}}$ *boundary. A downstream mechanics or Noether-facing consumer may read the public boundary only through this finite packet.*

The boundary exports no minimizer existence theorem, no global dynamics model, no Hamiltonian equivalence, no complete Noether correspondence, no analytic regularity theorem, and no standard bridge.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket public namecert boundary`

Proof. Start with the action ledger of Definition 337.2. It supplies the finite configuration, velocity, action, variation, endpoint, transport, package, and name-certificate rows.

The Euler–Lagrange interface of Definition 337.3 adds the residual row that is read from the same action, variation, endpoint, hsame, and Cont surface. The Noether consumer boundary of Definition 337.4 adds only the symplectic-flow and Noether-current rows.

Use Definition 337.5 and Definition 337.6 to repack these rows as one local certificate carrier. The action ledger policy of Definition 337.7 and the Euler boundary scope of Definition 337.8 show that the public read exposes exactly the same finite packet and no additional analytic object. □

Theorem 337.10 (LagrangianMechanics finite standard bridge surface)**.** *The public finite action, Euler–Lagrange residual, symplectic-flow read, Noether-current read,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows determine the paper-side standard bridge surface for the finite* LagrangianMechanics$^{\uparrow}$ *schema. Standard action, residual, flow, and current reads may be interpreted only through these displayed rows.*

The bridge surface exports no minimizer, global dynamics theorem, Hamiltonian equivalence, analytic regularity theorem, or complete Noether correspondence.

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket finite standard bridge surface`

Proof. Begin with the public boundary of Definition 337.9. It already exposes the finite action, residual, flow, current, carrier, transport, package, and name-certificate rows as the only public mechanics packet.

The standard action read is the action ledger of Definition 337.2. The standard residual read is the Euler–Lagrange interface of Definition 337.3. The standard flow and current reads are the finite rows of Definition 337.4.

Repack these reads with the obligation surface of Definition 337.5, the finite carrier of Definition 337.6, and the boundary scope of Definition 337.8. The resulting bridge surface uses only the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Since none of the cited rows contains a minimizer, global dynamics theorem, Hamiltonian equivalence, analytic regularity theorem, or complete Noether correspondence, the finite standard bridge surface has exactly the stated non-claim boundary. □

Theorem 337.11 (LagrangianMechanics symplectic and Noether sibling route)**.** *For an accepted* LagrangianMechanics$^{\uparrow}$ *carrier*

$$L = (Q, V, A, R, E, G, S, J, H, C, P, N),$$

any consumer of the symplectic-flow row S or the Noether-current row J factors through the displayed Symplectic$^{\uparrow}$ *and* NoetherSymmetry$^{\uparrow}$ *sibling surfaces named in P, together with the* hsame*,* Cont*,* Pkg*, and* NameCert *provenance rows of the same packet. The route exports no hidden global solution theorem, Hamiltonian equivalence, complete conservation law, or ambient analytic phase-space model.*

Lean4 ✓ `BEDC.Derived.LagrangianMechanicsUp.LagrangianMechanicsPacket symplectic noether sibling route`

Proof. Start with the carrier definition. The rows S and J are explicit coordinates of the finite packet, and the provenance row P names the symplectic and Noether dependency certificates consumed by those coordinates.

Use the Noether consumer boundary and public NameCert boundary. They identify the only consumer-facing mechanics rows as the finite action ledger, residual row, symplectic-flow read, Noether-current read, and the structural provenance rows H, C, P, N.

Finally apply the finite standard bridge surface. It allows standard action, residual, flow, and current reads only through the displayed packet. Since no coordinate stores a global solution, Hamiltonian equivalence, complete conservation law, or ambient phase-space model, every use of S or J remains inside the stated sibling route. □

Closure status for $\mathsf{NameCert}_{\mathsf{LagrangianMechanics}^{\uparrow}}$.

Constructive story: Lagrangian mechanics is represented by finite rows for configuration, velocity, action functional, variation, endpoint policy, Euler–Lagrange residual, symplectic-flow read, Noether-current read, and provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LagrangianMechanics}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 337.1, Definition 337.2, Definition 337.3, Definition 337.4, Definition 337.5, Definition 337.8, Definition 337.9, and Definition 337.10 bind the public-facing finite action, Euler–Lagrange, symplectic-flow, Noether-current, public NameCert packet boundary, and paper-side finite standard bridge surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LagrangianMechanics}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close minimizer existence, global dynamics, Hamiltonian equivalence, complete Noether correspondence, analytic regularity, or bridge checking.

Upgrade path: No further paper-axis theory grade remains for this finite bridge surface; Lean verification remains on the formal axis.

Chapter 338

A Finite Observation Filter Surface for $\mathsf{CauchyFilter}^{\uparrow}$

The $\mathsf{CauchyFilter}^{\uparrow}$ surface names the finite observation filter used by the Real and Completion phase when a consumer needs explicit Cauchy data without host filters or choice-selected subsequences. It sits between $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ as a visible packet of late-window evidence.

Its dependency lattice is the Real-and-Completion row already exposed by the sibling certificates: chapter 126 supplies the finite observation windows, chapter 292 supplies threshold rows, chapter 291 supplies endpoint rows, chapter 301 supplies the regular-rational compatibility handoff, and chapter 38 supplies the sealed consumer endpoint. Thus $\mathsf{CauchyFilter}^{\uparrow}$ is not a parallel completion carrier; it is the finite late-window filter surface routed through those certificates.

The directed finite-window ledger is consumed by the CauchyCriterion surface of chapter 392 before any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ reader can treat the packet as Cauchy evidence. $\mathsf{CauchyFilter}^{\uparrow}$ supplies the visible late-window evidence, while $\mathsf{CauchyCriterion}^{\uparrow}$ supplies the criterion boundary that blocks host filters, ultrafilters, and choice-selected subsequences from entering the consumer route.

Definition 338.1 (CauchyFilter carrier)**.** *A* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (s, d, m, e, r, t, c, P, N)$$

with the following displayed rows:

1. s *is the* $\mathsf{StreamName}^{\uparrow}$ *observation family whose entries are visible in the packet;*
2. d *is a directed finite-window index ledger ordering the finite tails through which observations are read;*
3. m *is the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row assigning a displayed precision request to a finite tail bound;*
4. e *is the dyadic endpoint row package supplied by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
5. r *is the compatibility row against* $\mathsf{RegSeqRat}^{\uparrow}$*, recording the same late-window comparisons as regular rational sequence evidence;*
6. t *contains the* hsame *and* Cont *transport rows used to compare and extend finite windows;*
7. c *is the consumer-facing ledger naming* $\mathsf{Real}^{\uparrow}$ *as the sealed reader of the finite filter packet;*

8. *P is the* Pkg *provenance for the dependency anchors* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyFilter}^{\uparrow}}$ *row.*

The carrier accepts exactly those packets whose listed rows occur in one finite history and whose transport routes are displayed in that history. It does not contain a host filter, ultrafilter, chosen subsequence, metric completion point, or quotient stream.

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterTasteGate single carrier alignment`

Theorem 338.2 (CauchyFilter finite-window coverage)**.** *Every accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *carrier covers its public observations by a directed finite window. More precisely, each visible* $\mathsf{StreamName}^{\uparrow}$ *read in the packet factors through the index ledger d, the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row m, the dyadic endpoint rows e, the* hsame *and* Cont *transport rows t, and the* Pkg *provenance P.*

Proof. Start from the carrier decomposition in Definition 338.1. The observation family, directed window ledger, threshold row, endpoint rows, transport rows, and provenance row are all coordinates of the same finite BHist packet.

For a displayed observation read, choose the finite tail window named by the ledger. The threshold row supplies the bound for the requested precision, and the dyadic endpoint rows give the finite values inspected inside that tail.

The remaining comparison is routed through the displayed hsame and Cont transport rows. Since the packet contains no constructor for an external filter object, the public read is exhausted by the finite window and its package provenance. □

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket finite window coverage`
Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterCarrier finite window coverage`

Theorem 338.3 (CauchyFilter RegSeqRat handoff)**.** *An accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet hands off to* $\mathsf{RegSeqRat}^{\uparrow}$ *exactly through its compatibility row r. The handoff preserves the* $\mathsf{StreamName}^{\uparrow}$ *observation family, the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, the directed finite-window ledger, and the displayed* hsame, Cont, *and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterCarrier regseqrat handoff`
Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket regseqrat handoff`

Proof. Project the packet to the compatibility row r and the rows named in Definition 338.1. The row r is already the displayed regular-sequence comparison against the same late-window observations.

Transport along the listed hsame rows and restrict along the displayed Cont windows. These operations do not change the stream observations, threshold row, dyadic endpoints, or directed window ledger; they only re-read the same finite rows through the $\mathsf{RegSeqRat}^{\uparrow}$ certificate.

Thus the handoff has no additional carrier beyond the visible compatibility row and the package provenance. A $\mathsf{RegSeqRat}^{\uparrow}$ consumer receives finite late-window evidence, not a quotient stream or a completed real. □

Theorem 338.4 (CauchyFilter Real seal consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet factors through the displayed finite filter surface: the* $\mathsf{StreamName}^{\uparrow}$ *observations, directed finite-window ledger,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints,* $\mathsf{RegSeqRat}^{\uparrow}$ *compatibility row,* hsame *and* Cont *transport, and* Pkg *provenance. The boundary exports no metric-completion point, host real equality, or choice-selected tail.*

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterFiniteWindowSurface real seal consumer boundary`

Proof. Read the consumer ledger coordinate c of the carrier. It names $\mathsf{Real}^{\uparrow}$ as a sealed reader of the same finite filter rows rather than as a source of extra completion data.

Apply the finite-window coverage theorem to the underlying observations, then apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff theorem to the compatibility row. Together they identify every available consumer read with a displayed tail window, endpoint package, threshold row, transport route, and provenance row.

There is no remaining coordinate from which a metric-completion point, host real equality, or selected infinite subsequence could be read. The real-facing boundary is therefore the finite filter surface itself. □

Theorem 338.5 (CauchyFilter public obligation catalogue)**.** *The public* $\mathsf{NameCert}_{\mathsf{CauchyFilter}^{\uparrow}}$ *obligation catalogue has exactly five rows:*

1. *the carrier row of Definition 338.1;*
2. *the classifier row identifying two packets when they admit a common finite filter refinement with the same threshold, endpoint, and compatibility rows;*
3. *stability under* hsame *transport of the observation, threshold, endpoint, compatibility, and provenance rows;*
4. *exactness of visible filter-window reads through the directed finite ledger and displayed* Cont *routes;*
5. *a ledger-exclusion row forbidding host filters, ultrafilters, choice-selected subsequences, metric-completion points, and quotient streams.*

These rows are the entire public surface used by $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *consumers.*

Proof. The carrier row is the finite packet specified in Definition 338.1. Its coordinates already list the observation family, finite-window ledger, threshold, endpoints, regular-sequence compatibility, transport, provenance, and local naming row.

The classifier compares two packets by refining their directed ledgers to a common finite window and then comparing the threshold, endpoint, compatibility, transport, and provenance rows through hsame. This gives the stability row at the same time, because transported packets retain the rows used by the classifier.

Exactness follows by re-reading each public observation through the same finite ledger and Cont route. The ledger-exclusion row is forced by the carrier shape: none of the listed external filter, completion, choice, or quotient objects is a coordinate of the packet. □

Theorem 338.6 (CauchyFilter common-refinement classifier)**.** *Two accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packets classify together exactly when their directed finite-window ledgers admit a displayed common finite refinement carrying the same* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *compatibility row,* hsame *and* Cont *transport rows, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket common refinement classifier`

Proof. Project both accepted packets through the carrier decomposition of Definition 338.1. The visible coordinates are finite BHist rows, so the two directed ledgers can be compared by passing to the displayed common window named by the classifier row.

On that common window, compare the threshold, endpoint, regular-sequence compatibility, transport, and provenance coordinates through the recorded hsame rows. The displayed Cont routes re-read the same observations without adding a host filter or a selected subsequence.

Repack the matched rows as one $\mathsf{NameCert}_{\mathsf{CauchyFilter}^{\uparrow}}$ classifier judgement. Conversely, reading such a classifier judgement exposes precisely the common finite refinement and the listed coordinate equalities, so it returns the same condition. □

Theorem 338.7 (CauchyFilter refinement transport)**.** *Refining the directed finite window of an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet preserves acceptance and preserves every visible observation through the displayed* hsame *and* Cont *transport rows.*

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket refinement transport`

Proof. Begin with the finite-window coverage theorem. The public observations already factor through the directed ledger, threshold row, endpoint rows, transport rows, and provenance row of the accepted packet.

Apply Definition 338.6 to the original window and the refined window. The common-refinement classifier identifies the same $\mathsf{StreamName}^{\uparrow}$ observations, $\mathsf{CauchyModulus}^{\uparrow}$ thresholds, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints, $\mathsf{RegSeqRat}^{\uparrow}$ compatibility row, and package provenance on the refined ledger.

The refined packet is therefore accepted by the same finite carrier rows. No host filter, ultrafilter, or choice-selected subsequence is introduced, because the transport uses only the displayed hsame comparisons and Cont routes. □

Lean4 ✓ `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket window refinement transport`

Theorem 338.8 (CauchyFilter Real-seal refinement exhaustion)**.** *After any common finite refinement, every* $\mathsf{Real}^{\uparrow}$ *consumer read from an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet factors through the same finite filter rows and exports no metric-completion point, host real equality, quotient stream, or choice-selected tail.*

Proof. Use Definition 338.6 to replace the consumer-facing packet by its common refined finite window. The classifier keeps the visible observations, thresholds, endpoints, compatibility, transport, and provenance rows fixed on that window.

Apply Definition 338.3 to the compatibility row. The handoff shows that the regular-rational read is the same finite late-window evidence, not an external quotient stream.

Finally apply Definition 338.4. The $\mathsf{Real}^{\uparrow}$ ledger reads only the finite filter surface and therefore has no coordinate from which a metric-completion point, host real equality, or choice-selected tail could be exported. □

Theorem 338.9 (CauchyFilter scoped dependency packet)**.** *The carrier of Definition 338.1, finite-window coverage of Definition 338.2,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 338.3,* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 338.4, common-refinement classifier of Definition 338.6, refinement transport of Definition 338.7, and Real-seal refinement exhaustion of Definition 338.8 form one scoped BEDC packet over* BHist*.*

Observation reads in this packet pass through $\mathsf{StreamName}^{\uparrow}$*, precision rows through* $\mathsf{CauchyModulus}^{\uparrow}$*, endpoints through* $\mathsf{DyadicRatCore}^{\uparrow}$*, compatibility through* $\mathsf{RegSeqRat}^{\uparrow}$*, and every public transport through the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Project an accepted packet to the carrier rows of Definition 338.1. Apply Definition 338.2 to identify the finite BHist window and its $\mathsf{StreamName}^{\uparrow}$ observations, $\mathsf{CauchyModulus}^{\uparrow}$ precision rows, and $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows.

The compatibility and consumer boundaries are the next projections. Use Definition 338.3 for the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and Definition 338.4 for the $\mathsf{Real}^{\uparrow}$ seal. Both cite only displayed finite rows and package provenance.

It remains to bind refinement. Apply Definition 338.6 and Definition 338.7 to move between finite windows through the recorded hsame and Cont data, then use Definition 338.8 to close the consumer readback under common refinement.

Repacking these projections gives the single scoped packet. Since every cited projection is a coordinate of the displayed BHist, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, hsame, Cont, Pkg, or NameCert surface, there is no channel for a host filter, ultrafilter, quotient stream, or choice-selected subsequence. □

Theorem 338.10 (CauchyFilter finite-filter standard bridge)**.** *An accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet determines the standard finite Cauchy-filter schema exactly through the displayed* $\mathsf{StreamName}^{\uparrow}$ *observation rows, directed finite-window ledger,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *compatibility row, displayed* hsame *routes,* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

Conversely, any standard finite-filter package whose rows are exactly those displayed BEDC rows repacks as the same public $\mathsf{CauchyFilter}^{\uparrow}$ *packet. The bridge has no coordinate for host filters, ultrafilters, quotient streams, metric-completion points, or choice-selected subsequences.*

Proof. Project the accepted packet through the carrier of Definition 338.1. Apply Definition 338.2 to expose the finite observation windows, directed ledger, $\mathsf{StreamName}^{\uparrow}$ rows, $\mathsf{CauchyModulus}^{\uparrow}$ threshold row, and $\mathsf{DyadicRatCore}^{\uparrow}$ endpoints as the visible finite-filter data.

Next use Definition 338.3 to read the $\mathsf{RegSeqRat}^{\uparrow}$ compatibility row and Definition 338.4 to keep the $\mathsf{Real}^{\uparrow}$ consumer boundary on the same finite surface. These projections add no carrier beyond the displayed finite rows.

Apply Definition 338.9 to gather the displayed hsame routes, Cont routes, Pkg provenance, and local NameCert row into the scoped dependency packet. This is exactly the standard finite Cauchy-filter schema because the cited packet has no additional coordinate.

For the converse direction, start with a standard finite-filter package whose coordinates are exactly the displayed rows. Repack those rows in the carrier, handoff, refinement, seal, transport, provenance, and local naming positions just projected. The result is the same public $\mathsf{CauchyFilter}^{\uparrow}$ packet because no further coordinate remains to choose.

The excluded objects are not hidden cases of the construction. Host filters, ultrafilters, quotient streams, metric-completion points, and choice-selected subsequences are absent from every cited projection, so the bridge cannot read or export them. □

Theorem 338.11 (CauchyFilter RegSeqRat Real seal exhaustion)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and every* $\mathsf{Real}^{\uparrow}$ *seal consumer read from an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet factors through one finite surface: stream observations, the directed finite-window ledger, the modulus threshold, dyadic endpoints, the compatibility row,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

No consumer read from this export contains a host filter, ultrafilter, quotient stream, metric-completion point, or choice-selected subsequence.

Proof. Begin with Definition 338.2. It gives the stream observations, directed finite-window ledger, modulus threshold, and dyadic endpoints as displayed finite rows of the accepted packet.

Next apply Definition 338.3. The $\mathsf{RegSeqRat}^{\uparrow}$ consumer receives exactly the compatibility row over those finite observations and endpoints.

Apply Definition 338.4. The $\mathsf{Real}^{\uparrow}$ seal consumes the same finite filter surface, with no additional host filter or completion coordinate.

It remains to bind refinement. Use Definition 338.6 and Definition 338.7 for the common finite-window classifier and its hsame and Cont transport, then apply Definition 338.9 to repack the package and local naming rows.

The cited projections exhaust the consumer coordinates. Therefore each $\mathsf{RegSeqRat}^{\uparrow}$ handoff and each $\mathsf{Real}^{\uparrow}$ seal read factors through the single finite surface stated above, and the excluded host objects have no displayed row from which they could be read. □

Theorem 338.12 (CauchyFilter finite-filter mature coverage)**.** *Every public or standard finite-filter consumer read of an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet is exhausted by the displayed* $\mathsf{StreamName}^{\uparrow}$ *observations, directed finite-window ledger,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints,* $\mathsf{RegSeqRat}^{\uparrow}$ *compatibility,* $\mathsf{Real}^{\uparrow}$ *seal, common-refinement classifier,* hsame *and* Cont *transport,* Pkg *provenance, and local* NameCert *row.*

The covered surface preserves the exclusions of host filters, ultrafilters, quotient streams, metric-completion points, and choice-selected subsequences.

Proof. First apply Definition 338.2. It supplies the displayed stream observations, directed finite-window ledger, threshold row, and dyadic endpoint rows as the finite carrier available to consumers.

Next use Definition 338.3 and Definition 338.4. These identify the $\mathsf{RegSeqRat}^{\uparrow}$ compatibility read and the $\mathsf{Real}^{\uparrow}$ seal as reads of the same finite carrier, with no completion or host-filter coordinate added.

Refinement is controlled by Definition 338.6 and Definition 338.7. The first theorem classifies common finite-window refinements, and the second transports that classifier through the displayed hsame and Cont routes.

Finally apply Definition 338.10 and Definition 338.11. The standard finite-filter packet and the $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer boundary read exactly the listed rows, while host filters, ultrafilters, quotient streams, metric-completion points, and choice-selected subsequences remain outside the packet. □

Theorem 338.13 (CauchyFilter mature Real consumer example)**.** *A* $\mathsf{Real}^{\uparrow}$ *seal consumer supplied with an accepted* $\mathsf{CauchyFilter}^{\uparrow}$ *packet and a* $\mathsf{RegSeqRat}^{\uparrow}$ *compatibility row obtains a finite late-window package consisting only of* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{CauchyModulus}^{\uparrow}$ *thresholds,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoints, the compatibility row,* hsame, Cont, Pkg, *and local* NameCert *evidence.*

The package contains no host filter, ultrafilter, quotient stream, metric-completion point, or choice-selected subsequence.

Proof. First apply Definition 338.2. It supplies the visible stream observations, finite-window ledger, modulus threshold, and dyadic endpoint rows of the accepted packet.

Next use Definition 338.3. The $\mathsf{RegSeqRat}^{\uparrow}$ compatibility row is a read of the same finite late-window surface, so it adds no host filter or quotient-stream coordinate.

Apply Definition 338.4. This identifies the $\mathsf{Real}^{\uparrow}$ seal consumer as a reader of the finite filter package rather than of a selected completion object.

Finally use Definition 338.11. It exhausts the combined $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ readback surface by the listed rows, leaving the excluded host objects outside the package. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyFilter}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CauchyFilter}^{\uparrow}$ packet is generated from visible stream observations, finite late-window ledgers, $\mathsf{CauchyModulus}^{\uparrow}$ thresholds, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows, $\mathsf{RegSeqRat}^{\uparrow}$ compatibility rows, $\mathsf{Real}^{\uparrow}$ seal-consumer rows,

common-refinement classifiers, refinement-transport evidence, componentwise hsame comparisons, displayed Cont routes, package provenance, and local naming evidence.

Theory closure: TheoryGate(NameCert$_{\mathsf{CauchyFilter}\uparrow}$, maturePackageClosed)

Scope closed: The chapter closes the CauchyFilter$^{\uparrow}$ carrier, finite-window coverage, RegSeqRat$^{\uparrow}$ handoff, Real$^{\uparrow}$ seal boundary, common-refinement classifier, refinement transport, and mature finite-filter coverage as finite NameCert data.

Formal verification: FormalStatus(NameCert$_{\mathsf{CauchyFilter}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.CauchyFilterUp.CauchyFilterPacket\_finite\_window\_coverage`

Bridge status: none

Origin: human

Not claimed: The chapter does not close host filters, ultrafilters, quotient streams, metric-completion points, or choice-selected tails.

Upgrade path: A complete StandardBridge instance for the accepted finite-filter packet would raise the bridge axis.

Chapter 339

A Concrete Naming Certificate for $\mathsf{UniformSpace}^{\uparrow}$

The $\mathsf{UniformSpace}^{\uparrow}$ surface names the finite entourage interface between $\mathsf{Met}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, $\mathsf{Filter}^{\uparrow}$, $\mathsf{CauchyFilter}^{\uparrow}$, and $\mathsf{Completion}^{\uparrow}$. Bourbaki–Kelley uniform-space practice treats entourages as the common language behind topology, filters, Cauchy data, and completion; the BEDC certificate keeps only finite BHist rows, visible classifier transport, and explicit refinement ledgers.

Definition 339.1 (UniformSpaceUp BHist entourage carrier)**.** *A* $\mathsf{UniformSpace}^{\uparrow}$ *carrier is a finite packet*

$$U = (X, E, D, R, S, C, P, N)$$

where X is the carried point-history source, E is a finite list of entourage rows over $X \times X$, D records the diagonal row for each listed entourage, R records finite refinement witnesses, S records symmetry readback, C records composition readback, P is the Pkg *provenance ledger, and N is the local* $\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$ *row. The point classifier is inherited from the X row and is stable under* hsame *transport on both coordinates of every entourage row.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket semantic name certificate`

Theorem 339.2 (UniformSpaceUp finite filterbase diagonal obligation)**.** *Every accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier exposes a finite filterbase of entourage rows. For each displayed entourage $V \in E$, the diagonal row records that every accepted point history x has (x, x) in V, and the finite filterbase ledger records a displayed refinement row for every pair of entourages named by downstream* $\mathsf{Filter}^{\uparrow}$ *or* $\mathsf{CauchyFilter}^{\uparrow}$ *consumers.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket filterbase diagonal obligation`

Proof. Unpack the carrier of Definition 339.1. The diagonal component D is indexed by the same finite entourage list E, so each consumer-visible entourage carries its own diagonal witness.

For a pair of displayed entourages, the refinement component R supplies a third displayed entourage and the two inclusion reads needed by a filterbase consumer. Repacking those rows gives the finite filterbase obligation without forming an external filter object. □

Theorem 339.3 (UniformSpaceUp diagonal refinement obligation)**.** *If a* $\mathsf{UniformSpace}^{\uparrow}$ *consumer requests a diagonal neighbourhood from a* $\mathsf{Met}^{\uparrow}$ *ball row or a* $\mathsf{Topology}^{\uparrow}$ *neighbourhood row, the carrier factors the request through one of its finite entourage rows and a displayed refinement ledger. The request sees only the point source, the chosen entourage, its diagonal row,* hsame *transport on endpoints, and the* Pkg *provenance row.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpaceEntouragePacket diagonal refinement obligation`

Proof. Read the request as a finite row over the same point-history source X. The $\mathsf{Met}^{\uparrow}$ and $\mathsf{Topology}^{\uparrow}$ anchors supply only neighbourhood data, not a host uniformity.

The carrier supplies a named entourage row whose diagonal witness covers the requested point and whose refinement ledger records the inclusion into the requested neighbourhood. Endpoint changes are transported by the inherited hsame classifier, and the visible provenance remains the single package row P. □

Theorem 339.4 (UniformSpaceUp symmetry and composition obligation)**.** *For every displayed entourage V in an accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier, the symmetry row S gives a displayed entourage V^{op} with the endpoints exchanged. For every displayed entourage V, the composition row C gives a displayed refinement W such that two successive W-steps read as one V-step. Both rows are finite* BHist *ledgers stable under the inherited point classifier.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket symmetry composition obligation`

Proof. The symmetry component is a row-by-row endpoint exchange in the finite entourage list. Applying hsame on the first and second coordinates carries the exchanged row to classified representatives.

The composition component names a finite witness W and a ledger read from $W \circ W$ into V. Because both W-steps and the target V-step are rows of the same carrier, the composition readback is stable under the same endpoint transport and package provenance. □

Theorem 339.5 (UniformSpaceUp concrete entourage instance)**.** *Every accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier $U = (X, E, D, R, S, C, P, N)$ exports a concrete entourage instance whose public reads are finite* BHist *predicates only. The instance consists of the displayed entourage rows E, the reflexivity witnesses in D, the symmetry witnesses in S, the composition witnesses in C, the componentwise* hsame *endpoint transport in the inherited point classifier, the displayed* Cont *replay route for consumer requests, and the* Pkg *provenance row P.*

A $\mathsf{Met}^{\uparrow}$*,* $\mathsf{Topology}^{\uparrow}$*,* $\mathsf{Filter}^{\uparrow}$*,* $\mathsf{CauchyFilter}^{\uparrow}$*, or* $\mathsf{Completion}^{\uparrow}$ *consumer may project those rows, but it may not replace them by parameter-equivalence transport, host uniformity, quotient equality of Cauchy streams, open-cover compactness, or a selected completion point.*

Proof. Project the carrier of Definition 339.1. The finite entourage list E is the only predicate family available to the consumer, and the diagonal component D gives the displayed reflexivity row for each entourage.

Read the symmetry and composition rows next. The symmetry component S exchanges endpoints inside the displayed finite ledger, while the composition component C records the finite refinement by which two successive displayed steps are read as one requested entourage step.

Endpoint changes are handled by the inherited point classifier through componentwise hsame transport, and consumer observations replay through the displayed Cont routes. The provenance row P records that all rows belong to the same $\mathsf{UniformSpace}^{\uparrow}$ packet.

Since these projections exhaust the carrier coordinates used by an entourage consumer, no parameter-equivalence transport, host uniformity, quotient stream equality, open-cover compactness datum, or selected completion point is exported by the concrete instance. □

Theorem 339.6 (UniformSpaceUp Cauchy and completion handoff)**.** *Every* $\mathsf{CauchyFilter}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of a* $\mathsf{UniformSpace}^{\uparrow}$ *packet factors through the finite entourage filterbase, diagonal rows, refinement rows, symmetry rows, composition rows,* hsame *endpoint transport, and*

Pkg *provenance of Definition 339.1. The handoff introduces no choice-selected completion point, quotient stream equality, open-cover compactness, or host-space uniformity.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpaceClassifierPacket cauchy completion handoff`

Proof. Project the accepted packet to its finite filterbase rows. A Cauchy consumer reads finite entourage obligations exactly as in the $\mathsf{CauchyFilter}^{\uparrow}$ surface: each demanded precision row is matched by a displayed entourage and a refinement witness.

A completion consumer may retain the same finite Cauchy ledger and provenance rows, but there is no coordinate in the carrier for a selected limit point or a quotient class of streams. Therefore the handoff is only the visible entourage data listed in the theorem. □

Theorem 339.7 (UniformSpaceUp classifier transport obligation)**.** *Let* $U = (X, E, D, R, S, C, P, N)$ *be an accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier as in Definition 339.1. Endpoint* hsame *transport of the point source* X *and of every displayed entourage row repacks another accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier with the same finite entourage list, diagonal ledger, refinement ledger, symmetry ledger, composition ledger,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket classifier transport obligation`

Proof. Unpack the carrier definition. The point classifier is the one inherited from the X row, and every entourage row is explicitly declared stable under hsame on both coordinates.

Transport the endpoint histories first, then apply the same transport to the diagonal, refinement, symmetry, and composition rows. The carrier has no coordinate outside these finite ledgers, so the transported rows repack with the unchanged package provenance and naming certificate. □

Theorem 339.8 (UniformSpaceUp entourage ledger exactness)**.** *Every consumer-visible entourage read from an accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier is exhausted by the finite list* E*, the diagonal row* D*, the refinement row* R*, the symmetry row* S*, the composition row* C*, and the* Pkg *provenance row. No consumer can read an additional host uniformity, open-cover compactness principle, quotient stream equality, or choice-selected completion datum from the carrier.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket entourage ledger exactness`

Proof. Project the accepted packet to the coordinates of Definition 339.1. The only entourage-bearing coordinate is the finite list E, and the only certified reads from this list are the rows named by D, R, S, and C.

Apply the diagonal obligation of Definition 339.2, the neighbourhood refinement obligation of Definition 339.3, and the symmetry and composition obligation of Definition 339.4. These rows account for every displayed consumer read while the package row P accounts for provenance. □

Theorem 339.9 (UniformSpaceUp common refinement Cauchy handoff)**.** *Any* $\mathsf{CauchyFilter}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *request through two compatible entourage demands of an accepted* $\mathsf{UniformSpace}^{\uparrow}$ *carrier factors through a displayed common refinement row. The exported handoff contains only the point source, the two demanded entourage rows, the common refinement witness, endpoint* hsame *transport, the relevant* Cont *observation windows, and* Pkg *provenance; it exports no choice-selected limit, quotient stream, open-cover compactness, or host uniformity.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket common refinement cauchy handoff`

Proof. Start with the two compatible demands as finite reads from the entourage list E. The filterbase diagonal obligation provides the common refinement row from R and the inclusions back into the two demanded rows.

Transport endpoint representatives by Definition 339.7. The refinement, diagonal, symmetry, and composition rows remain rows of the same finite carrier after this transport.

Finally apply the handoff theorem Definition 339.6. A Cauchy or completion consumer receives the finite refinement ledger and provenance, but the carrier contains no coordinate for a selected limit, quotient stream, open-cover compactness datum, or ambient host uniformity. □

Theorem 339.10 (UniformSpaceUp common refinement functoriality)**.** *Let U_0, U_1, and U_2 be accepted* $\mathsf{UniformSpace}^{\uparrow}$ *packets. Suppose the displayed finite entourage ledger contains a compatible common-refinement row from U_0 to U_1 and a compatible common-refinement row from U_1 to U_2. Then every* $\mathsf{CauchyFilter}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *request routed through U_2 also routes through U_0 by the composed finite entourage ledger.*

The composed handoff contains only the point-history source, the two displayed common-refinement rows, diagonal witnesses, endpoint hsame *transport, the relevant* Cont *observation windows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$ *rows. It introduces no quotient equality of Cauchy streams, no selected completion point, no choice-based completion data, and no ambient host uniformity.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket common refinement functoriality`

Proof. First compose the two displayed common-refinement rows. The filterbase diagonal, neighbourhood refinement, symmetry, and composition obligations keep the composite as a finite entourage ledger row of the same BEDC form.

Next apply Definition 339.7 to each handoff. Endpoint representatives move along the displayed hsame rows, and the Cont observation windows remain rows of the accepted packets.

Now invoke Definition 339.9 for the route from U_2 to U_1, and invoke it again for the route from U_1 to U_0. The first application supplies the finite ledger consumed by the second, so the $\mathsf{CauchyFilter}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ request is read at U_0 through the composed common refinement.

Finally repack the resulting ledger with the same BHist, hsame, Cont, Pkg, and NameCert provenance. Since the construction only concatenates displayed finite rows, it never forms a quotient of Cauchy streams and never selects a completion point. □

Theorem 339.11 (UniformSpaceUp scoped entourage package)**.** *The carrier of Definition 339.1, together with Definition 339.2, Definition 339.3, Definition 339.4, Definition 339.6, Definition 339.7, Definition 339.8, and Definition 339.9, and Definition 339.10, forms one scoped BEDC packet over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Every $\mathsf{CauchyFilter}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *consumer of this packet receives only finite entourage rows, displayed endpoint transports, continuation routes, package provenance, and the local naming row.*

Proof. Unpack the carrier of Definition 339.1. Its displayed coordinates are the point-history source, the finite entourage list, the diagonal row, the refinement row, the symmetry row, the composition row, transport and continuation data, package provenance, and local naming evidence.

The diagonal and filterbase projections are exactly Definition 339.2 and Definition 339.3. The symmetry and composition projections are supplied by Definition 339.4.

Classifier transport is supplied by Definition 339.7, and carrier exhaustion is supplied by Definition 339.8. These projections keep all consumer reads on the same BHist, hsame, Cont, Pkg, and NameCert surface.

Finally apply Definition 339.6 and Definition 339.9. The CauchyFilter$^{\uparrow}$ and Completion$^{\uparrow}$ consumers receive the finite entourage rows and their common refinement data, with no selected completion point, quotient stream, open-cover compactness datum, or ambient host uniformity. □

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket scoped entourage package`

Theorem 339.12 (UniformSpaceUp entourage public export)**.** *The finite filterbase diagonal row, diagonal refinement row, symmetry and composition rows, classifier transport row, entourage ledger, and common-refinement Cauchy handoff rows of the scoped* UniformSpace$^{\uparrow}$ *packet assemble into the public downstream packet for* CauchyFilter$^{\uparrow}$ *and* Completion$^{\uparrow}$ *consumers.*

The public packet exports only finite entourage data over BHist*, displayed* hsame *endpoint transport,* Cont *observation routes,* Pkg *provenance, and local* NameCert *evidence.*

Proof. Start with the scoped package of Definition 339.11. It binds the carrier of Definition 339.1 to the finite entourage rows, transport rows, continuation routes, package provenance, and local naming evidence.

The finite filterbase and diagonal parts are supplied by Definition 339.2 and Definition 339.3. Symmetry and composition are supplied by Definition 339.4.

Classifier transport and ledger exhaustion are supplied by Definition 339.7 and Definition 339.8. These rows ensure that public consumers read the same finite entourage surface after endpoint transport.

Finally use Definition 339.6 and Definition 339.9. They identify the downstream CauchyFilter$^{\uparrow}$ and Completion$^{\uparrow}$ requests with the common finite-refinement packet, leaving selected limits, quotient streams, open-cover compactness data, and host uniformities outside the export. □

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket entourage public export`

Theorem 339.13 (UniformSpace finite-entourage standard bridge)**.** *The finite filterbase diagonal row, diagonal refinement row, symmetry and composition rows, classifier transport row, entourage ledger, common-refinement Cauchy handoff rows, displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows assemble the standard finite-entourage bridge for* UniformSpace$^{\uparrow}$*.*

The bridge exposes exactly the public finite-entourage packet of Definition 339.12. It does not add choice-based completion, quotient equality of Cauchy streams, open-cover compactness, host uniformity, or selected limits.

Proof. Begin with the scoped finite-entourage package of Definition 339.11. Its carrier is the displayed BHist of Definition 339.1, equipped with the finite diagonal, refinement, symmetry, composition, classifier, ledger, handoff, continuation, package, and naming rows.

Apply Definition 339.12. The public export repackages the same rows for CauchyFilter$^{\uparrow}$ and Completion$^{\uparrow}$ consumers, so the standard bridge has a fixed source packet and a fixed public target packet over the same hsame, Cont, Pkg, and NameCert coordinates.

The Cauchy side is supplied by Definition 339.6 and Definition 339.9. These theorems carry common finite-refinement data across the downstream Cauchy requests without choosing a completion point or identifying streams by quotient equality.

It remains only to record the boundary of the bridge. Since the cited package, public export, and Cauchy handoff theorems contain no rows for choice-based completion, open-cover compactness, host uniformity, or selected limits, the assembled bridge is exactly the finite-entourage standard bridge stated here. □

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket standard bridge`

Theorem 339.14 (UniformSpace finite Cauchy and completion consumer examples)**.** *The finite-entourage bridge for* $\mathsf{UniformSpace}^{\uparrow}$ *yields two concrete downstream consumer examples.*

First, a $\mathsf{CauchyFilter}^{\uparrow}$ *request reads the common refinement row of the finite entourage packet as its finite Cauchy witness ledger. Second, a* $\mathsf{Completion}^{\uparrow}$ *request reads the same finite Cauchy ledger as completion input without selecting a limit and without quotienting streams.*

Both consumers use only the finite entourage list, diagonal witnesses, common refinement rows, symmetry rows, composition rows, endpoint hsame *transport,* Cont *observation windows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$ *row exported by the bridge.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket finite cauchy completion consumer examples`

Proof. Use Definition 339.12. It fixes the public finite-entourage packet containing the finite entourage list, diagonal witnesses, symmetry and composition rows, classifier transport, endpoint hsame rows, Cont windows, package provenance, and local naming row.

Apply Definition 339.13. The standard bridge exposes that packet as the public $\mathsf{UniformSpace}^{\uparrow}$ source for downstream consumers and adds no selected completion point, quotient stream equality, open-cover compactness, host uniformity, or selected limit.

Next use Definition 339.6. It routes the finite $\mathsf{CauchyFilter}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ requests through the same displayed finite-entourage packet.

Finally apply Definition 339.9. The common refinement row supplies the finite Cauchy witness ledger for the $\mathsf{CauchyFilter}^{\uparrow}$ read, and the same ledger is retained by the $\mathsf{Completion}^{\uparrow}$ read without selecting a limit or quotienting streams. □

The metric comparison below consumes the distance-witness carrier of chapter 57: the entourage rows are read as finite filters only after the $\mathsf{Met}^{\uparrow}$ distance witness has supplied the visible-context boundary used by the comparison.

Theorem 339.15 (UniformSpace entourage-filter-metric comparison)**.** *An accepted* $\mathsf{UniformSpace}^{\uparrow}$ *packet compares two point histories only through the displayed entourage rows, filter-neighbourhood rows,* $\mathsf{Met}^{\uparrow}$ *distance witness rows when those witnesses are present, componentwise* hsame *transports on the two endpoints,* Cont *routes, and* Pkg *provenance.*

The comparison exports no host uniformity, open-cover compactness principle, quotient topology equality, choice-selected completion datum, or ambient metric space equality. A downstream $\mathsf{Met}^{\uparrow}$*,* $\mathsf{Topology}^{\uparrow}$*,* $\mathsf{Filter}^{\uparrow}$*, or* $\mathsf{CauchyFilter}^{\uparrow}$ *consumer therefore receives exactly the finite comparison surface carried by the* $\mathsf{UniformSpace}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.UniformSpaceUp.UniformSpacePacket entourage filter metric comparison`

Proof. Project the accepted packet by Definition 339.11. This supplies the point source, finite entourage list, diagonal, refinement, symmetry, composition, transport, continuation, package, and local naming rows over the same BHist surface.

Next replay the filter-neighbourhood witnesses. The finite filterbase diagonal obligation and the diagonal refinement obligation identify each requested neighbourhood with a displayed entourage row and a displayed refinement route, while componentwise hsame carries the two endpoint histories through the same classifier surface.

When a $\mathsf{Met}^{\uparrow}$ distance witness row is present, it is read as one of the neighbourhood anchors already routed through the displayed entourage ledger. The classifier transport obligation preserves that row under endpoint transport, and the common-refinement handoff keeps the filter and Cauchy reads on the same finite continuation routes.

Finally apply Definition 339.8. Since the exactness boundary has no coordinate for host uniformity, open-cover compactness, quotient topology equality, or ambient metric equality, the comparison is exhausted by the displayed entourage, filter, metric-witness, hsame, Cont, and Pkg rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$.

Constructive story: A uniform-space packet is generated by a carried point-history source, a finite list of entourage rows, diagonal witnesses, finite filterbase refinements, symmetry rows, composition rows, endpoint hsame transport, package provenance, and a local naming row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 339.12, Definition 339.13, and Definition 339.14 export the finite filterbase diagonal, diagonal refinement, symmetry and composition, classifier transport, entourage ledger, common-refinement Cauchy handoff rows, common-refinement functoriality, standard finite-entourage bridge, and finite Cauchy and completion consumer examples as the public $\mathsf{UniformSpace}^{\uparrow}$ downstream packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{UniformSpace}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.UniformSpaceUp.UniformSpacePacket\_standard\_bridge`

Bridge status: bridgeChecked

Origin: human

Not claimed: The chapter does not close choice-based completion, quotient equality of Cauchy streams, open-cover compactness, host uniformity, or selected limits.

Upgrade path: No further formal-axis upgrade remains for this checked finite-entourage standard bridge.

Chapter 340

A Concrete Naming Certificate for $\mathsf{LocatedCauchy}^{\uparrow}$

The $\mathsf{LocatedCauchy}^{\uparrow}$ interface records the finite located-Cauchy packet that sits between explicit Cauchy-rate names and the $\mathsf{Real}^{\uparrow}$ seal. Following Bishop and Bridges, Constructive Analysis, the packet treats located rational ball data as constructive evidence attached to a Cauchy name. It does not form Dedekind cuts, quotient streams, selected real limits, trichotomy witnesses, choice data, or open-cover compactness objects.

Its finite packet consumes the schedule row from chapter 126, endpoint and tolerance rows from chapter 291, precision thresholds from chapter 292, the regular-name handoff from chapter 301, and the seal boundary from chapter 38.

Definition 340.1 (LocatedCauchy finite carrier)**.** *A* $\mathsf{LocatedCauchy}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (S, D, M, W, H, C, P, N)$$

with the following visible coordinates:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule naming the requested precision windows;*
2. *D is the displayed family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows read on those windows;*
3. *M is the* $\mathsf{CauchyModulus}^{\uparrow}$ *precision row that assigns each requested precision to a finite observation threshold;*
4. *W is the family of located dyadic-ball witnesses for each displayed precision request, with center and radius read from the dyadic endpoint rows;*
5. *H records componentwise* hsame *transport for schedules, endpoint rows, modulus rows, and located-ball witnesses;*
6. *C records the* Cont *readback routes through which a consumer reaches finite precision windows, dyadic endpoint rows, modulus rows, and located-ball witnesses;*
7. *P is the* Pkg *provenance row naming* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as the dependency anchors;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{LocatedCauchy}^{\uparrow}}$ *provenance row.*

The carrier predicate is $\mathsf{LocatedCauchyPacket}(S, D, M, W, H, C, P, N)$*. A constant dyadic stream inhabits the carrier by taking S to repeat one scheduled dyadic endpoint, M to return the same*

threshold for every requested precision, and W to display the corresponding degenerate located dyadic ball at each requested window.

Definition 340.2 (LocatedCauchy classifier)**.** *Two accepted* $\mathsf{LocatedCauchy}^{\uparrow}$ *packets* $L = (S, D, M, W, H, C, P, N)$ *and* $L' = (S', D', M', W', H', C', P', N')$ *are classified alike when the displayed schedules agree componentwise, the dyadic endpoint rows agree componentwise, the modulus rows agree on every requested precision window, the located-ball witnesses agree through their displayed endpoint and radius rows, the* hsame *rows transport those components, the* Cont *routes expose the same finite readback surface, and the* Pkg *provenance rows name the same dependency anchors.*

The classifier has no coordinate for host real equality, completed quotient streams, Dedekind-cut membership, trichotomy, choice-selected representatives, or open-cover compactness. It compares only the finite located windows and the provenance rows displayed in Definition 340.1.

Theorem 340.3 (LocatedCauchy window stability)**.** *Let L be an accepted* $\mathsf{LocatedCauchy}^{\uparrow}$ *packet. If a requested precision window is refined through the displayed* $\mathsf{CauchyModulus}^{\uparrow}$ *row, then the refined readback still factors through the same* $\mathsf{StreamName}^{\uparrow}$ *schedule, the same family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows, and the transported located dyadic-ball witness family. Thus precision refinement changes only which finite window is read; it does not expose a completed real value or an unbounded stream object.*

Lean4 ✓ `BEDC.Derived.LocatedCauchyUp.LocatedCauchyCarrier window stability`

Proof. Project L through Definition 340.1. The modulus coordinate M is the only row that answers a precision request, and it answers by naming a finite observation threshold inside the schedule S.

At the refined threshold, the endpoint data are read from D and the located ball data are read from W. The transport coordinate H supplies the componentwise hsame rows needed to move these visible rows along an accepted classifier comparison.

The continuation coordinate C exhausts the readback routes. Since no carrier coordinate stores a quotient stream, host real, or selected limit, refinement cannot reveal data outside the displayed finite located window. □

Theorem 340.4 (LocatedCauchy NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{LocatedCauchy}^{\uparrow}}$ *seed surface consists of the following five rows:*

1. *carrier inhabitation by the constant dyadic stream described in Definition 340.1;*
2. *classifier reflexivity, symmetry, and transitivity obtained from componentwise* hsame *over schedules, endpoints, modulus rows, located balls, continuation routes, and package provenance;*
3. *carrier transport along the classifier rows of Definition 340.2;*
4. *precision-window stability under modulus refinement as in Definition 340.3;*
5. $\mathsf{Real}^{\uparrow}$ *seal boundary, where consumers see only finite located windows and the dependency provenance needed to pass toward* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.LocatedCauchyUp.LocatedCauchyCarrier semantic name certificate`

Proof. The carrier row is the finite packet displayed in Definition 340.1. The constant dyadic stream gives an inhabited packet because each requested precision reads the same dyadic endpoint and the same degenerate located ball.

The classifier laws are inherited component by component from the displayed hsame rows. Reflexivity uses the identity rows, symmetry reverses each componentwise comparison, and transitivity composes the visible comparisons on schedules, endpoints, modulus data, located-ball witnesses, continuation routes, and provenance.

Transport repacks the carrier coordinates after those classifier comparisons. Window stability is exactly Definition 340.3, and the final row is the seal boundary isolated in Definition 340.5. □

Theorem 340.5 (LocatedCauchy real seal boundary)**.** *Every* Real$^{\uparrow}$*-facing read exported by an accepted* LocatedCauchy$^{\uparrow}$ *packet factors through a finite requested precision window, its* CauchyModulus$^{\uparrow}$ *threshold, the scheduled* DyadicRatCore$^{\uparrow}$ *endpoint rows, and the displayed located dyadic-ball witness. The packet supplies a constructive real-name neighbor for* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumers, but it claims no Dedekind cut, quotient stream, trichotomy principle, choice-selected representative, or open-cover compactness principle.*

Lean4 ✓ `BEDC.Derived.LocatedCauchyUp.LocatedCauchyCarrier real seal boundary`

Proof. Take any consumer route from the packet toward the real seal. By the carrier definition, every such route is one of the displayed Cont rows in C, and each route names the precision window it reads.

The precision window is resolved by the modulus row M, then by the scheduled endpoint rows in D and the located-ball witnesses in W. These are precisely the finite rows exposed to RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ consumers.

The exclusions follow from absence of coordinates. The packet stores no cut predicate, no quotient-stream equality, no trichotomy witness, no selected representative, and no open-cover compactness datum, so none of those objects can be exported through the real-facing readback. □

Theorem 340.6 (LocatedCauchy scoped dependency package)**.** *Any accepted* LocatedCauchy$^{\uparrow}$ *packet whose displayed rows satisfy Definition 340.1, Definition 340.2, Definition 340.3, Definition 340.4, and Definition 340.5 determines a scoped dependency package over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* CauchyModulus$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*, and* Real$^{\uparrow}$*.*

Every Real$^{\uparrow}$*-facing consumer read from that package is exhausted by those displayed rows. The package cannot export a Dedekind cut, quotient stream, host real equality, trichotomy, choice data, or open-cover compactness.*

Lean4 ✓ `BEDC.Derived.LocatedCauchyUp.LocatedCauchyCarrier scoped dependency package`

Proof. Project the accepted packet through Definition 340.1. This exposes the schedule, dyadic-endpoint rows, modulus row, located-ball witnesses, transport rows, continuation routes, package provenance, and local name certificate as one finite BHist surface.

Use Definition 340.2 to transport the exposed rows componentwise. The classifier compares only the displayed schedules, endpoint rows, modulus data, located-ball witnesses, continuation routes, and package provenance, so no external real-equality or quotient coordinate is introduced.

For precision refinement, apply Definition 340.3. It keeps every refined read on the same scheduled finite window surface and preserves the visible DyadicRatCore$^{\uparrow}$, CauchyModulus$^{\uparrow}$, and located-ball rows.

The five local certificate rows are exactly the surface named by Definition 340.4. Finally, Definition 340.5 exhausts every Real$^{\uparrow}$-facing consumer read by the displayed finite rows, which proves the stated exclusions. □

Theorem 340.7 (LocatedCauchy public Real consumer export)**.** *The public* LocatedCauchy$^{\uparrow}$ *export to* Real$^{\uparrow}$ *consumers is exactly the finite packet surface consisting of the* StreamName$^{\uparrow}$ *schedule,* DyadicRatCore$^{\uparrow}$ *endpoint rows,* CauchyModulus$^{\uparrow}$ *precision row, located dyadic-ball witnesses, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

Every Real$^{\uparrow}$*-facing consumer read is exhausted by that finite packet surface. The export does not supply Dedekind cuts, quotient streams, host real equality, trichotomy, choice data, selected representatives, or open-cover compactness.*

Proof. Expose the public surface using Definition 340.6. It projects an accepted packet to the displayed schedule, dyadic endpoint rows, modulus data, located-ball witnesses, transport rows, continuation routes, package provenance, and local name certificate over the named BEDC components.

For refined consumer reads, apply Definition 340.3. Refinement changes only which finite threshold and endpoint rows are read from the same packet; it does not add a quotient stream or completed real object.

Finally use Definition 340.5. That boundary exhausts the Real$^{\uparrow}$-facing routes by the finite located windows and records the exclusions for Dedekind cuts, quotient streams, host real equality, trichotomy, choice data, selected representatives, and open-cover compactness. □

Theorem 340.8 (LocatedCauchy finite-window bridge boundary)**.** *Every* Real$^{\uparrow}$*-facing read of an accepted* LocatedCauchy$^{\uparrow}$ *packet factors through exactly the finite* StreamName$^{\uparrow}$ *schedule,* CauchyModulus$^{\uparrow}$ *threshold,* DyadicRatCore$^{\uparrow}$ *endpoint rows, located dyadic-ball witnesses, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of the packet.*

Conversely, every displayed finite window accepted by the carrier is exported by Definition 340.7. The boundary exports no Dedekind cut, quotient stream, host real equality, trichotomy, choice datum, selected representative, or open-cover compactness witness.

Lean4 ✓ `BEDC.Derived.LocatedCauchyUp.LocatedCauchyCarrier finite window bridge boundary`

Proof. Project the accepted packet through Definition 340.1. This gives the finite schedule, modulus threshold, endpoint rows, located-ball witnesses, transport routes, package provenance, and local name-certificate rows.

Use Definition 340.2 to identify consumer reads only componentwise through the displayed rows. Then apply Definition 340.3; a refined read stays on a finite scheduled window and changes neither the carrier nor the visible dependency surface.

Next apply Definition 340.5 and Definition 340.6. These results bind the finite located-Cauchy window to the scoped dependency package over DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, CauchyModulus$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$.

For the reverse direction, an accepted displayed finite window is already one of the public packet windows. Therefore Definition 340.7 exports exactly that window to Real$^{\uparrow}$ consumers and supplies no additional row. □

Theorem 340.9 (LocatedCauchy standard finite-packet bridge)**.** *The public* Real$^{\uparrow}$ *consumer export of Definition 340.7 and the finite-window boundary of Definition 340.8 give a conservative standard finite located-Cauchy packet reading over exactly the displayed* StreamName$^{\uparrow}$ *schedule,* DyadicRatCore$^{\uparrow}$ *endpoint rows,* CauchyModulus$^{\uparrow}$ *precision row, located dyadic-ball witnesses, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

This standard packet reading exports no Dedekind cut, quotient stream, host real equality, trichotomy, choice datum, selected representative, or open-cover compactness witness. Every standard

consumer field is read from the displayed finite packet rows, and every displayed finite packet row remains a $\mathsf{LocatedCauchy}^{\uparrow}$ *carrier row.*

Proof. First assemble the scoped dependency package from Definition 340.6. It fixes the BEDC components $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the visible carrier, classifier, transport, continuation, package, and name-certificate rows.

Next read the public $\mathsf{Real}^{\uparrow}$ surface through Definition 340.7. This exports exactly the scheduled finite packet rows and records that no completed real object, quotient stream, or choice-based representative is supplied to the consumer.

Finally apply Definition 340.8. Its forward direction factors every $\mathsf{Real}^{\uparrow}$-facing read through the displayed finite window, and its reverse direction says that every accepted displayed window is already exported by the public surface.

Composing these three readings gives the standard finite located-Cauchy packet bridge. Since each step is conservative over the same finite rows, the bridge cannot introduce Dedekind cuts, host real equality, trichotomy, selected representatives, choice data, quotient coordinates, or open-cover compactness. □

Theorem 340.10 (LocatedCauchy finite bridge consumer completeness)**.** *Every public* $\mathsf{Real}^{\uparrow}$*-facing consumer of the standard finite-packet bridge of Definition 340.9 factors through exactly the rows named by Definition 340.7, Definition 340.8, and Definition 340.9: the displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *precision row, located dyadic-ball witnesses, componentwise* hsame*, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows over the scoped dependency package of Definition 340.6.*

Conversely, every accepted finite packet row in that displayed carrier is repacked as the same standard finite bridge surface. The package exports no Dedekind cut, quotient stream, host real equality, trichotomy, selected representative, choice datum, or open-cover compactness witness.

Proof. Start with the scoped dependency package of Definition 340.6. It fixes the only BEDC components available to the construction: $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the carrier, classifier, transport, continuation, package, and name-certificate rows visible in the finite located-Cauchy packet.

For the forward direction, apply Definition 340.7 to restrict each $\mathsf{Real}^{\uparrow}$-facing read to the public packet surface. Then apply Definition 340.8 and Definition 340.9; together they say that the standard bridge reads exactly the displayed finite schedule, endpoint, modulus, located-ball, transport, continuation, package, and certificate rows.

For the reverse direction, take an accepted row of the displayed finite packet. The finite-window boundary already identifies it as a public packet row, and the public export sends precisely those rows to the $\mathsf{Real}^{\uparrow}$ consumer surface. The standard finite-packet bridge does not add a second consumer surface; it only repackages the same accepted rows under the standard finite bridge surface.

All exclusions are inherited from the same three results. Since none of their carriers contains a Dedekind cut, quotient stream, host real equality, trichotomy witness, selected representative, choice datum, or open-cover compactness witness, the consumer-completeness package has no coordinate from which such data could be read. □

Theorem 340.11 (LocatedCauchy bridge readback consumer factorization)**.** *Every public consumer read of a* $\mathsf{LocatedCauchy}^{\uparrow}$ *finite-window bridge factors through the displayed* BHist *schedule,*

dyadic endpoint rows, CauchyModulus$^{\uparrow}$ *row, located dyadic-ball witnesses, componentwise transport rows, displayed route rows, package provenance,* Cont, Pkg, hsame, *and local* NameCert *rows supplied by Definition 340.6, Definition 340.8, and Definition 340.10.*

The factorization has no hidden readback coordinate for host real equality, quotient streams, selected representatives, choice data, trichotomy, or open-cover compactness. Any consumer output admitted by the finite bridge is therefore a read of the same finite BEDC rows already present in the scoped dependency package.

Proof. Apply Definition 340.8. It exposes the bridge row as the displayed finite-window surface and identifies every Real$^{\uparrow}$-facing read with the scheduled finite packet rows.

Next apply Definition 340.6. This recovers the permitted consumer readback coordinates: the BHist schedule, endpoint rows, modulus row, located dyadic-ball witnesses, transport rows, route rows, provenance, Cont, Pkg, hsame, and local NameCert data.

Finally apply Definition 340.10. It exhausts the public consumer surface over those rows and excludes host real equality, quotient streams, selected representatives, choice data, trichotomy, and open-cover compactness as possible readback coordinates. □

Closure status for NameCert$_{\text{LocatedCauchy}^{\uparrow}}$.

Constructive story: A LocatedCauchy$^{\uparrow}$ packet is generated from a finite StreamName schedule, DyadicRatCore endpoint rows, a CauchyModulus precision row, located dyadic-ball witnesses, componentwise transport rows, continuation readback routes, package provenance for DyadicRatCoreUp, StreamNameUp, CauchyModulusUp, RegSeqRatUp, and RealUp, and a local NameCert provenance row.

Theory closure: TheoryGate(NameCert$_{\text{LocatedCauchy}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 340.6, Definition 340.7, Definition 340.8, Definition 340.9, Definition 340.10, and Definition 340.11 bind the scoped package, public Real$^{\uparrow}$ consumer export, finite-window boundary, standard finite-packet bridge, complete public consumer surface, and bridge readback factorization over BHist, hsame, Cont, Pkg, NameCert, DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, CauchyModulus$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$.

Theorem 340.12 (LocatedCauchy constant window degeneracy)**.** *Let $L = (S, D, M, W, H, C, P, N)$ be the constant dyadic-stream* LocatedCauchy$^{\uparrow}$ *carrier described in Definition 340.1. Thus there is one displayed dyadic endpoint row d such that S repeats the scheduled endpoint d, the modulus row M returns the same observation threshold for every requested precision, and W displays the degenerate located dyadic ball attached to d at each requested window.*

Then every consumer-visible precision request for L reads the same degenerate dyadic endpoint. More precisely, for any requested precision window q, the Cont *readback route selected by C factors through the* StreamName$^{\uparrow}$ *row that schedules d, the* CauchyModulus$^{\uparrow}$ *row that returns the constant threshold, the* DyadicRatCore$^{\uparrow}$ *endpoint row d, and the located-ball witness in W whose left endpoint, center endpoint, and right endpoint are all the displayed row d. Hence the classifier of Definition 340.2 sees no window-dependent endpoint variation in the constant packet: changing q changes only the name of the finite request, not the dyadic endpoint or the degenerate located ball read at that request.*

Proof. Project the carrier through Definition 340.1. The constant-stream clause fixes the visible coordinates: the schedule S repeats one scheduled dyadic endpoint row d, the modulus row M

returns the same threshold for each requested precision, and the witness family W assigns to each requested window the degenerate located dyadic ball corresponding to that same endpoint.

Let q be a requested precision window. The only route from a consumer request to packet data is one of the continuation rows recorded in C. By the carrier definition, such a route first reads the requested window through S and M, then reads the endpoint data from D, and then reads the located-ball witness from W. Since S is constant and M returns the fixed threshold, this route reaches the same scheduled endpoint row d for the request q as for any other request.

At that row, D is the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint family of the packet, and the constant-stream clause says that the located witness attached by W is degenerate at d. Thus the left endpoint, center endpoint, and right endpoint exposed by the located dyadic ball are all the same displayed dyadic row d.

Finally, Definition 340.2 compares only the displayed schedules, endpoint rows, modulus rows, located-ball witnesses, transport rows, continuation routes, and provenance. None of those coordinates contains a second endpoint for the constant packet, so a change of requested precision window cannot introduce endpoint variation. It only selects another finite request whose readback again reaches the same degenerate dyadic ball at d. □

Theorem 340.13 (LocatedCauchy tail-window seal factorization)**.** *Let $L = (S, D, M, W, H, C, P, N)$ be an accepted $\mathsf{LocatedCauchy}^{\uparrow}$ packet over the carrier of Definition 340.1. For every tail precision window obtained by refining the displayed $\mathsf{CauchyModulus}^{\uparrow}$ row M, the consumer read selected by the continuation routes in C factors through the same seal boundary as the $\mathsf{Real}^{\uparrow}$ surface of Definition 340.5: the displayed $\mathsf{StreamName}^{\uparrow}$ schedule S, the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint family D, the located dyadic-ball witness family W, the componentwise transport rows H, the displayed Cont routes C, the Pkg provenance P, and the local $\mathsf{NameCert}$ rows N.*

The factorization is stable under later finite reads. Refining M may select a later threshold and a later finite endpoint window, but it does not cross the seal boundary or expose a second $\mathsf{Real}^{\uparrow}$ carrier. In the constant-packet boundary case of Definition 340.12, every tail window reads the same degenerate endpoint row and the same degenerate located dyadic ball.

Thus no tail-window consumer read exports a Dedekind cut, quotient stream, host real equality, trichotomy witness, selected representative, choice datum, or open-cover compactness witness.

Proof. First apply Definition 340.3. A refinement of the displayed modulus row changes only the finite threshold and endpoint window selected inside the accepted packet. The scheduled stream row, endpoint family, located-ball witness family, transport rows, continuation routes, package provenance, and local certificate rows remain the displayed rows of L.

Next use Definition 340.5. It identifies the $\mathsf{Real}^{\uparrow}$-facing seal boundary with those same displayed rows and records that the public real surface has no coordinate for completed cuts, quotient streams, host equality, trichotomy, selected representatives, choice data, or open-cover compactness.

Then apply Definition 340.8. Its finite-window bridge says that every accepted finite read through a refined modulus window is already a read of the scheduled stream, dyadic endpoints, located witnesses, transport, continuation, package, and certificate rows fixed by the seal boundary.

For the constant-packet boundary case, invoke Definition 340.12. The refined tail request again reaches the same endpoint row d and the same degenerate located ball at d, so the preceding factorization specializes without adding a window-dependent endpoint.

Composing these results gives the claimed tail-window factorization. Since each step remains inside the displayed BEDC rows of the accepted packet, the consumer receives no data outside the RealUp seal boundary. □

Chapter 341

A Concrete Naming Certificate for $\mathsf{PolePlacement}^{\uparrow}$

The $\mathsf{PolePlacement}^{\uparrow}$ interface records the finite closed-loop ledger used by control certificates that choose a displayed feedback row and target a displayed characteristic-polynomial row. In the standard finite-dimensional control setting of Chen, *Linear System Theory and Design* (1999), pole placement relates the state matrix, input matrix, feedback gain, and requested closed-loop characteristic polynomial. The BEDC surface below names only the finite rows of that relation. It exports no analytic spectrum, no host trajectory space, and no stabilizing feedback existence theorem.

The state and input rows are consumed from chapter 329, controllability evidence from chapter 297, and matrix, vector-space, and linear-map rows from chapter 49, chapter 47, and chapter 48.

Definition 341.1 (PolePlacement finite BHist carrier)**.** *A* $\mathsf{PolePlacement}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$\Pi = (X, U, A, B, K, C, T, H, R, P, L)$$

whose visible rows are:

1. *a state row X and an input row U read through* $\mathsf{VecSpace}^{\uparrow}$ *and the state/input face of* $\mathsf{StateSpaceModel}^{\uparrow}$*;*
2. *a transition matrix row A and input matrix row B read through* $\mathsf{Mat}^{\uparrow}$ *and* $\mathsf{LinMap}^{\uparrow}$*;*
3. *a feedback gain row K read as a finite matrix and linear-map row from X to U;*
4. *a closed-loop row C whose displayed matrix ledger records $C = A + BK$ over the same state carrier;*
5. *a target characteristic row T and characteristic-comparison ledger H recording the requested finite polynomial row and its displayed comparison with the characteristic row of C;*
6. hsame *comparisons for the state, input, A, B, K, C, target, characteristic, continuation, and provenance rows;*
7. Cont *routes R for reading multiplication BK, addition $A + BK$, closed-loop readback, and characteristic-row comparison;*
8. *a* Pkg *provenance row P naming* $\mathsf{StateSpaceModel}^{\uparrow}$*,* $\mathsf{ControlControllability}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and* $\mathsf{LinMap}^{\uparrow}$*;*
9. *a ledger boundary row L saying that no host trajectory space, analytic spectrum, eigenvalue multiplicity theorem, or stabilizing feedback theorem is part of the carrier.*

Two accepted packets classify together only when every displayed row in this inventory is transported componentwise by the recorded hsame *comparisons and every matrix, linear-map, closed-loop, and target-polynomial read follows one of the recorded* Cont *routes.*

Lean4 (definition) `BEDC.Derived.PolePlacementUp.PolePlacementSourcePacket`

Theorem 341.2 (PolePlacement closed-loop ledger)**.** *Every accepted* $\mathsf{PolePlacement}^{\uparrow}$ *packet exposes exactly the finite state row X, input row U, transition row A, input row B, gain row K, closed-loop row C, target characteristic row T, characteristic-comparison ledger H,* hsame *rows,* Cont *routes, and* Pkg *provenance rows listed in Definition 341.1. The closed-loop readback is the displayed ledger $C = A + BK$ and no additional host closed-loop system is exported.*

Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementSourcePacket closed loop ledger`
Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementCarrier closed loop ledger`

Proof. Project the accepted carrier of Definition 341.1. The projection exposes the finite state, input, matrix, gain, closed-loop, target, comparison, transport, continuation, provenance, and boundary rows.

The closed-loop row is read through the displayed matrix multiplication and addition routes. The multiplication route supplies the BK ledger, the addition route supplies the $A + BK$ ledger, and the closed-loop row C is the recorded endpoint of that finite calculation.

Transporting the packet replaces each coordinate by its displayed hsame match and follows the same Cont routes. Since the carrier has no coordinate for a host trajectory space or analytic closed-loop object, every consumer-visible closed-loop read is exhausted by the finite ledger. □

Theorem 341.3 (PolePlacement NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{PolePlacement}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: an accepted packet is inhabited by choosing displayed* $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, *and* $\mathsf{LinMap}^{\uparrow}$ *source rows and recording the gain, closed-loop, target, comparison, transport, continuation, and provenance rows of Definition 341.1;*
2. *classifier transport: accepted packets compare by componentwise* hsame *transport of X, U, A, B, K, C, T, H, R, P, and L;*
3. *closed-loop ledger exactness: the only closed-loop row exported by the packet is the displayed $C = A + BK$ ledger of Definition 341.2;*
4. *target-polynomial ledger: every target read is the finite row T together with the comparison ledger H against the characteristic row of C;*
5. *downstream consumer boundary:* $\mathsf{Riccati}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, *and* $\mathsf{StateSpaceModel}^{\uparrow}$ *consumers may read only the finite state, input, matrix, gain, closed-loop, target, comparison, transport, continuation, and provenance rows of the same packet.*

Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementSourcePacket namecert obligation surface`

Proof. The habitation row is a finite packet assembly. Each required coordinate is a displayed BHist row, and the provenance row names the consumed state-space, controllability, matrix, vector-space, and linear-map certificates.

Classifier transport is componentwise. Transporting X, U, A, B, K, C, T, H, R, P, and L along the displayed hsame rows preserves the same carrier inventory and the same matrix and characteristic-read routes.

The closed-loop obligation is exactly Definition 341.2. The target-polynomial obligation is the corresponding projection of T and H, so it records a finite comparison row rather than an analytic spectral theorem.

Finally, the downstream boundary is the package projection. Since the package row names only the displayed control and algebra certificates, the listed consumers cannot recover host trajectories, unlogged spectra, or feedback existence principles from the $\mathsf{PolePlacement}^{\uparrow}$ surface. □

Theorem 341.4 (PolePlacement consumer boundary)**.** *Every downstream read from an accepted* $\mathsf{PolePlacement}^{\uparrow}$ *packet factors through the finite rows of Definition 341.1. Riccati, LQR, Kalman-Filter, and StateSpaceModel consumers may use the displayed* $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{ControlControllability}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, BHist, hsame, Cont, *and* Pkg *rows, but they cannot demand an analytic spectrum, a host trajectory space, a stabilizing controller theorem, a controllability-rank proof, or an external feedback solver from this certificate.*

Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementSourcePacket consumer boundary`

Proof. Take a consumer-visible readback from an accepted packet. By Definition 341.1, the readback is a projection from the finite carrier rows or from the provenance row naming the consumed certificates.

Apply Definition 341.2 to the closed-loop part. This identifies the only available feedback read as the displayed $A + BK$ row and its target characteristic comparison.

The listed consumers therefore receive only finite BEDC rows and their transport and continuation data. Any analytic spectrum, host trajectory, stabilizing-controller theorem, rank proof, or external solver would require a coordinate absent from the packet. □

Theorem 341.5 (PolePlacement standard finite bridge)**.** *The finite* $\mathsf{PolePlacement}^{\uparrow}$ *packet of Definition 341.1, together with the closed-loop ledger, NameCert obligation surface, and consumer boundary, interprets as the standard finite pole-placement schema: a state row, input row, transition matrix row A, input matrix row B, gain row K, closed-loop row $A + BK$, and requested target characteristic row are all displayed as finite* BHist *rows with explicit transport, continuation, and provenance. This bridge exports no analytic spectral assumption, pole-existence theorem, host trajectory semantics, or feedback optimality claim.*

Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementSourcePacket standard finite bridge`

Proof. Begin with the carrier. It gives the state and input rows, the matrix and linear-map rows for A, B, and K, the displayed closed-loop endpoint, and the target characteristic ledger.

Use Definition 341.2 to identify the closed-loop schema field with the finite $A+BK$ calculation. Use Definition 341.3 to package the carrier, classifier transport, ledger exactness, target-polynomial ledger, and downstream boundary as the local name-certificate surface.

Apply Definition 341.4 to restrict every public read to the same finite rows. The resulting interpretation is exactly the standard finite pole-placement data shape, while the excluded analytic and optimality claims remain outside the certificate. □

Theorem 341.6 (PolePlacement scoped dependency packet)**.** *The closed-loop ledger of Definition 341.2, target-polynomial ledger and certificate surface of Definition 341.3, consumer boundary of Definition 341.4, and standard finite bridge of Definition 341.5 form one scoped dependency packet. Its only source rows are the displayed* BHist *state, input, matrix, gain, closed-loop, target, characteristic-comparison,* hsame, Cont, Pkg, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{StateSpaceModel}^{\uparrow}$, *and* $\mathsf{ControlControllability}^{\uparrow}$ *rows.*

Proof. Project the packet through Definition 341.1. The available coordinates are exactly the finite state and input rows, matrix rows, gain row, closed-loop row, target row, characteristic-comparison row, transports, continuations, and package provenance named in the statement.

Apply Definition 341.2 to identify the closed-loop projection, and apply Definition 341.3 to bind the target-polynomial ledger and certificate obligations to the same carrier rows.

For every consumer projection, use Definition 341.4; for the standard finite data shape, use Definition 341.5. Both results factor through the displayed $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{ControlControllability}^{\uparrow}$, BHist, hsame, Cont, and Pkg rows.

Repacking these projections gives a single scoped dependency packet. No analytic spectrum, host trajectory space, unlogged rank proof, or external feedback solver is introduced, because no such coordinate occurs in the projected rows. □

Theorem 341.7 (PolePlacement public consumer export)**.** *The scoped dependency packet of Definition 341.6 exports a public finite-control interface to* $\mathsf{Riccati}^{\uparrow}$*,* $\mathsf{LQR}^{\uparrow}$*,* $\mathsf{KalmanFilter}^{\uparrow}$*, and* $\mathsf{StateSpaceModel}^{\uparrow}$ *consumers. The exported interface consists exactly of the state row, input row, transition matrix row, input matrix row, gain row, closed-loop row* $A + BK$*, target characteristic row, characteristic-comparison ledger, displayed* hsame *rows,* Cont *routes, and* Pkg *provenance over* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*,* $\mathsf{LinMap}^{\uparrow}$*,* $\mathsf{StateSpaceModel}^{\uparrow}$*, and* $\mathsf{ControlControllability}^{\uparrow}$*.*

It exports no analytic spectrum, host trajectory space, stabilizing feedback theorem, controllability-rank completeness, feedback optimality, or external solver.

Lean4 ✓ `BEDC.Derived.PolePlacementUp.PolePlacementCarrier public consumer export`

Proof. Start with the closed-loop ledger of Definition 341.2. It identifies the displayed transition, input, gain, and $A + BK$ rows as finite ledger coordinates.

Apply Definition 341.3 to attach the target characteristic row, characteristic-comparison ledger, displayed hsame rows, Cont routes, and package provenance to the same accepted carrier.

Use Definition 341.4 for the downstream read boundary, and use Definition 341.5 for the standard finite-control packet shape. These two results identify exactly the $\mathsf{Riccati}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{KalmanFilter}^{\uparrow}$, and $\mathsf{StateSpaceModel}^{\uparrow}$ consumer surface named in the statement.

Finally apply Definition 341.6. Since that packet has no coordinate for analytic spectra, host trajectory spaces, stabilizing feedback existence, rank-completeness, optimality, or solver data, none of those objects can be exported by the public interface. □

Closure status for $\mathsf{NameCert}_{\mathsf{PolePlacement}^{\uparrow}}$**.**

Constructive story: A $\mathsf{PolePlacement}^{\uparrow}$ packet is seeded by finite BHist rows for state, input, transition matrix, input matrix, gain, closed-loop matrix $A + BK$, target characteristic row, characteristic-comparison ledger, hsame transports, Cont routes, and Pkg provenance over the state-space, controllability, matrix, vector-space, and linear-map certificates.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{PolePlacement}^{\uparrow}}$, publicClosed)

Scope closed: Definition 341.6 binds the finite pole-placement carrier, closed-loop ledger, target-polynomial ledger, NameCert obligation rows, consumer boundary, standard finite data shape, and displayed BHist, hsame, Cont, Pkg, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{StateSpaceModel}^{\uparrow}$, and $\mathsf{ControlControllability}^{\uparrow}$ dependencies, while Definition 341.7 exposes the downstream finite-control public export.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{PolePlacement}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close analytic spectral theory, pole-existence theorems, stabilizing feedback existence, controllability-rank completeness, host trajectory semantics, feedback optimality, or a machine-checked standard bridge.

Upgrade path: Bridged closure requires a standard finite-control bridge over the same displayed state, input, matrix, feedback, target-polynomial, transport, continuation, package, and consumer rows.

Chapter 342

A Concrete Naming Certificate for $\mathsf{ContinuedFraction}^{\uparrow}$

The $\mathsf{ContinuedFraction}^{\uparrow}$ interface names finite continued-fraction observation packets as constructive real-name neighbors. Following Khinchin's continued-fraction treatment, the BEDC surface records partial quotients, convergent rows, certified dyadic error radii, stream observations, regular rational handoff rows, and a real-name boundary without completing an infinite expansion or quotienting tails.

The partial-quotient spine consumes the $\mathsf{Nat}^{\uparrow}$ carrier of chapter 28. The convergent numerator and denominator rows consume the rational arithmetic surface of chapter 37, and the certified error-radius row consumes chapter 291. The scheduled handoff and seal route then consume chapter 126, chapter 301, and chapter 38, locating the finite continued-fraction carrier in the Real-completion dependency lattice.

Definition 342.1 (ContinuedFraction carrier packet)**.** *A* $\mathsf{ContinuedFraction}^{\uparrow}$ *carrier packet is a finite* BHist *record*

$$C = (a, p, q, e, s, r, b, \ell, P)$$

with the following visible rows:

1. *a is the finite partial-quotient spine over* $\mathsf{Nat}^{\uparrow}$*;*
2. *p and q are the convergent numerator and denominator rows read over* $\mathsf{Rat}^{\uparrow}$*, including the displayed recurrence ledger for each finite index;*
3. *e is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *error-radius row attached to the displayed convergent window;*
4. *s is the* $\mathsf{StreamName}^{\uparrow}$ *observation schedule through which finite convergent windows are exposed;*
5. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row built from the scheduled rational convergents and their dyadic radius rows;*
6. *b is the* $\mathsf{Real}^{\uparrow}$ *seal boundary row that consumes the regular sequence surface without selecting a completed real value;*
7. *ℓ is the finite ledger naming the recurrence rows, endpoint rows, transport windows, and dependency anchors;*
8. *P is the* Pkg *provenance row for the carrier and the local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *registration.*

The carrier accepts exactly those packets whose rows occur in one finite history and whose recurrence, endpoint, schedule, handoff, boundary, and provenance entries are connected by displayed hsame *and* Cont *routes.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionTasteGate single carrier alignment`
Lean4 (definition) `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket`

Definition 342.2 (ContinuedFraction classifier)**.** *Two accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packets classify together when every shared finite convergent window has classifier-equal numerator, denominator, and dyadic radius endpoint rows through the* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *classifiers, and when the transported* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *recurrence-ledger, and* Pkg *rows agree through the same displayed* hsame *and* Cont *routes.*

Theorem 342.3 (ContinuedFraction NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *obligation surface consists of five rows:*

1. *carrier inhabitation by the empty partial-quotient spine or by a singleton convergent with visible* $\mathsf{Nat}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* Pkg *rows;*
2. *classifier transport along the componentwise* hsame *and* Cont *routes named in Definition 342.2;*
3. *recurrence-ledger stability for the finite convergent numerator and denominator rows;*
4. *finite-window* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff for scheduled convergent windows and dyadic radius rows;*
5. $\mathsf{Real}^{\uparrow}$ *boundary exactness through the displayed seal row and no other real-facing coordinate.*

Proof. For habitation, use either the empty spine with an empty scheduled window or a singleton spine whose first convergent is carried by the displayed rational endpoint rows. The dyadic radius, stream schedule, handoff row, boundary row, ledger, and package provenance are then the corresponding finite rows in the same BHist packet.

For transport, project the carrier coordinates of Definition 342.1. The classifier of Definition 342.2 compares only shared finite windows, so every transported row is one of the named numerator, denominator, radius, schedule, handoff, boundary, ledger, or provenance coordinates.

For stability and exactness, read the recurrence ledger before the handoff rows. The ledger records the finite recurrence steps for convergents, the handoff consumes only scheduled finite windows, and the real-facing boundary is the single seal row b. □

Theorem 342.4 (ContinuedFraction RegSeqRat handoff)**.** *Every accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet exports a* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff only through scheduled finite convergent windows, their* $\mathsf{Rat}^{\uparrow}$ *numerator and denominator rows, their* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius rows, the displayed recurrence ledger, and the accompanying* hsame, Cont, *and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket regseqrat handoff`

Proof. Project an accepted packet to the rows a, p, q, e, s, r, ℓ, and P. The schedule s selects the finite convergent windows, while p and q provide the rational endpoint rows and e provides the dyadic radius rows for those windows.

The handoff row r is indexed by exactly that scheduled data. Transport of a handoff comparison therefore factors through the componentwise hsame rows, the displayed Cont routes, and the package provenance already present in the carrier packet.

No coordinate of the carrier stores an infinite tail, a quotient class of tails, or a completed real. The handoff is consequently a finite regular-sequence surface over the visible convergent ledger. □

Theorem 342.5 (ContinuedFraction L10 sibling dependency route)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *boundary read of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet first factors through the existing L10 sibling route chapter 291, chapter 126, chapter 301, and chapter 38. Only after those* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows have been read through the displayed carrier route may the finite continued-fraction seal be consumed.*

Proof. Project the carrier of Definition 342.1. The rows e, s, r, b are exactly the dyadic-radius row, stream observation schedule, regular-rational handoff, and real seal boundary; there is no second coordinate for a real-facing read outside these rows.

Apply Definition 342.4. It forces the $\mathsf{RegSeqRat}^{\uparrow}$ boundary through the scheduled finite convergent windows, their $\mathsf{Rat}^{\uparrow}$ numerator and denominator rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ radius row, and the displayed hsame, Cont, and Pkg provenance.

The $\mathsf{Real}^{\uparrow}$ read then consumes the same handoff row before it reaches the seal coordinate b. Thus the boundary route is the concrete-instance sibling lattice route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, followed by the finite continued-fraction seal and no kernel-only island remains. □

Theorem 342.6 (ContinuedFraction RealUp boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *read of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet factors through the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row and the seal boundary row carried by Definition 342.1. It exposes the same finite convergent, radius, schedule, recurrence, transport, and provenance ledger, and it does not assert total continued-fraction expansion for every real, uniqueness of infinite expansions, measure-theoretic typicality, or quotient equality of infinite tails.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket real boundary`
↪ variant `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket real boundary scope`

Proof. Read the boundary coordinate b of the carrier. Its source is the regular sequence handoff row r, so any real-facing consumer first passes through the scheduled convergent windows and their rational and dyadic endpoint rows.

The classifier has no separate real-equality clause. Boundary comparisons are therefore inherited from the finite-window $\mathsf{RegSeqRat}^{\uparrow}$ handoff and from the transport, continuation, ledger, and provenance rows already visible in the packet.

Since the carrier stores only a finite partial-quotient spine and finite window data, it cannot provide a total expansion theorem, an infinite-tail uniqueness theorem, a typicality theorem, or a quotient equality principle. The $\mathsf{Real}^{\uparrow}$ boundary is exactly the displayed seal surface. □

Theorem 342.7 (ContinuedFraction digit-tail stability)**.** *Restrict an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet to a displayed finite digit tail. The restricted packet preserves the same* $\mathsf{Rat}^{\uparrow}$ *convergent rows,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and* $\mathsf{Real}^{\uparrow}$ *boundary ledger visible in the original packet, with no host infinite expansion and no selected real endpoint.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket digit tail stability`

Proof. Project the carrier of Definition 342.1 to its finite partial-quotient spine, convergent rows, schedule, handoff, boundary row, recurrence ledger, and provenance. The classifier of Definition 342.2 compares only the displayed digit and window rows.

Apply Definition 342.3 to keep the carrier and classifier obligations inside the finite ledger. The restriction to a digit tail is therefore a projection of the same recorded rows, not a passage to an infinite expansion object.

The projected schedule feeds the same finite convergent windows into Definition 342.4. The real-facing read is then the boundary of Definition 342.6, so the restricted tail inherits the displayed $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ ledger without selecting an endpoint. □

Theorem 342.8 (ContinuedFraction recurrence ledger obligation)**.** *For every accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *carrier packet, the partial-quotient spine, the numerator and denominator recurrence rows, and the dyadic radius rows are finite* BHist *rows. Their comparisons are stable exactly along the displayed* hsame *and* Cont *routes named by the carrier ledger, and no recurrence datum is read outside those finite rows.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket recurrence ledger transport`

Proof. Project the packet of Definition 342.1 to the rows a, p, q, e, and ℓ. These are coordinates of one finite BHist record, so the partial quotient, recurrence, and radius data are already finite rows.

The accepted-carrier clause requires the coordinates to be connected by displayed hsame and Cont routes. Hence transport of a recurrence row or a radius row is componentwise transport along the ledger routes, with no extra tail coordinate available. □

Theorem 342.9 (ContinuedFraction finite handoff obligation)**.** *The* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet is exhausted by scheduled finite convergent windows, their* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row. Every handoff read factors through those rows together with the displayed recurrence and dyadic-radius ledger.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket finite handoff obligation`

Proof. Project the carrier to the schedule s, handoff row r, ledger ℓ, package row P, and local name-certificate registration. By Definition 342.1, the schedule selects the visible finite convergent windows and the handoff consumes precisely that scheduled surface.

The package row supplies provenance for the same carrier packet, and the local $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ row registers the displayed classifier discipline. Thus a handoff read can be reconstructed from the scheduled finite windows, the recurrence and radius rows, P, and the local certificate row. □

Theorem 342.10 (ContinuedFraction real-boundary obligation)**.** *Every* $\mathsf{Real}^{\uparrow}$ *boundary read of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet factors through the same finite* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff used by the carrier. The boundary exposes no completed real, no quotient tail, and no host equality beyond the finite handoff, boundary row,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *dependency rows.*

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket real boundary transport`

Proof. Project the packet to the handoff row r, boundary row b, ledger ℓ, and package row P. The boundary coordinate in Definition 342.1 is explicitly the $\mathsf{Real}^{\uparrow}$ seal row fed by the regular-sequence handoff.

Since the carrier has no coordinate for a completed real, an infinite quotient tail, or host equality, no boundary read can expose such an object. Its data are the finite handoff rows, the seal boundary, the package provenance, and the local name-certificate dependency rows already present in the packet. □

Theorem 342.11 (ContinuedFraction convergent-window standard bridge)**.** *A finite* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet determines a conservative standard finite convergent window. Its BEDC readback recovers exactly the* $\mathsf{Nat}^{\uparrow}$ *partial quotient spine,* $\mathsf{Rat}^{\uparrow}$ *convergent rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, finite ledger,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row.*

This bridge excludes total expansion, uniqueness of infinite expansions, measure-typicality, quotient tails, and completed real equality.

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket convergent window standard bridge`

Proof. Project the finite continued-fraction carrier and classifier. The carrier coordinates supply the partial quotient spine, rational convergent rows, dyadic radius row, observation schedule, handoff row, seal boundary, finite ledger, package provenance, and local name-certificate evidence.

Restrict the digit spine to the displayed finite window. The recurrence stability and finite handoff obligation identify the same $\mathsf{Rat}^{\uparrow}$ convergent rows and $\mathsf{DyadicRatCore}^{\uparrow}$ radius row at every displayed position, so the standard window has no additional convergent coordinate.

Compose Definition 342.9 with Definition 342.10. The handoff sends the finite convergent window through $\mathsf{RegSeqRat}^{\uparrow}$, and the real-boundary obligation seals the resulting $\mathsf{Real}^{\uparrow}$ row without adding quotient-tail or completed-real equality data.

Reading the conservative standard window back componentwise therefore recovers the original BEDC finite ledger, package provenance, and local name-certificate row. Since every step stays inside the finite carrier and classifier rows, the bridge contains no total expansion theorem, no uniqueness statement for infinite expansions, no measure-typicality claim, no quotient tail, and no completed real equality. □

Theorem 342.12 (ContinuedFraction scoped boundary)**.** *The carrier of Definition 342.1, classifier of Definition 342.2, NameCert obligations of Definition 342.3,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 342.4, recurrence ledger of Definition 342.8, finite handoff of Definition 342.9, and* $\mathsf{Real}^{\uparrow}$ *boundary of Definition 342.10 assemble one scoped* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet.*

The packet is over finite partial quotient windows, rational convergent rows, dyadic radius rows, scheduled $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal rows,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

Proof. Use Definition 342.1 and Definition 342.2 to identify the visible carrier and classifier rows. The obligation surface is recorded by Definition 342.3.

The recurrence and finite handoff rows are supplied by Definition 342.8 and Definition 342.9. The external handoff and boundary are supplied by Definition 342.4, Definition 342.6, and Definition 342.10.

Repack these finite rows as the consumer boundary for the accepted $\mathsf{ContinuedFraction}^{\uparrow}$ packet. The displayed history, equality, continuation, package, and local certificate dependencies account for every row used by the packet, so no convergence theorem for arbitrary continued fractions is claimed. □

Theorem 342.13 (ContinuedFraction finite-packet standard bridge)**.** *The finite partial-quotient spine, rational convergent rows, dyadic radius rows, scheduled observation windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *boundary, displayed* hsame *rows,* Cont *read routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet assemble the standard finite continued-fraction packet boundary for* $\mathsf{ContinuedFraction}^{\uparrow}$*. The assembled boundary is exactly*

the finite packet surface; it excludes total expansion of every real, uniqueness of infinite tails, quotient equality, and measure-theoretic claims.

Proof. First build the finite handoff surface. Apply Definition 342.4 to the scheduled convergent windows, rational numerator and denominator rows, dyadic radius rows, recurrence ledger, hsame transport, Cont routes, and Pkg provenance.

Next attach the real-facing seal. Apply Definition 342.6 and Definition 342.10; both read the same $\mathsf{RegSeqRat}^{\uparrow}$ handoff and boundary coordinate, so the real row contributes no separate completed real, quotient-tail equality, or host equality principle.

Finally repack the displayed rows through Definition 342.12. The scoped packet already contains the finite spine, convergent rows, radius rows, schedule, handoff, boundary, transport, continuation, package, and local name-certificate rows, so it is the standard finite continued-fraction packet boundary and nothing stronger. □

Theorem 342.14 (ContinuedFraction prefix convergent window)**.** *Every finite prefix of a certified* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet determines a convergent numerator and denominator window whose* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff reads only the displayed digit, recurrence, tail,* hsame, Cont*, package, and local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *rows.*

The window contributes no completed real, quotient tail equality, total expansion theorem, or host equality principle.

Proof. Begin with the scheduled convergent read of Definition 342.4. It identifies the finite partial-quotient prefix, numerator and denominator rows, dyadic radius row, observation schedule, hsame transport, Cont routes, and package provenance available to the regular-sequence consumer.

Next use Definition 342.7. The digit and tail rows remain within the same finite prefix surface, so extending or restricting a prefix does not add an external host equality or quotient-tail coordinate.

Apply Definition 342.8 to bind the convergent numerator and denominator rows to the displayed recurrence ledger. Then repack the same rows through Definition 342.13. The resulting consumer window is exactly the finite continued-fraction packet surface named in the statement. □

Theorem 342.15 (ContinuedFraction rational-interval window handoff)**.** *Every accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet whose convergent window is read as a* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint window exposes exactly the finite partial-quotient spine, the* $\mathsf{Rat}^{\uparrow}$ *numerator and denominator rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row.*

The handoff exports no completed real, quotient tail, total expansion theorem, or interval arithmetic law.

Proof. First read the scheduled convergent rows through Definition 342.4. This identifies the finite partial-quotient spine, rational numerator and denominator rows, dyadic radius row, stream schedule, hsame transports, Cont routes, and package provenance as the regular rational source seen by the consumer.

Next apply Definition 342.9. The finite handoff exhaustion accounts for the displayed recurrence and endpoint window rows, so the $\mathsf{RationalInterval}^{\uparrow}$ consumer can only read the finite endpoint shape already present in the packet.

Finally use Definition 342.6. The real-facing seal is the boundary row of the same finite handoff, while the rational-interval endpoint and containment rows are only its finite consumer shape. Thus no completed real, quotient tail, total expansion theorem, or interval arithmetic law is exported. □

Lean4 ✓ `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket rational interval window handoff certificate`

Theorem 342.16 (ContinuedFraction nested cylinder boundary)**.** *Let an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet display two finite prefix windows whose smaller prefix is obtained by restricting the larger finite partial-quotient spine. Then the smaller* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint window are exactly the restriction of the larger packet's finite partial-quotient spine, recurrence ledger, dyadic radius row,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *rows.*

The boundary exports no completed real, quotient tail, total expansion theorem, or interval arithmetic law.

Proof. First compare the two displayed prefix windows. Apply Definition 342.7 to see that restricting the larger finite prefix preserves exactly the digit, tail, scheduled observation, hsame, Cont, package, and local name-certificate rows already visible in the smaller prefix.

Next read both prefixes through Definition 342.14. The convergent numerator and denominator rows, recurrence ledger, dyadic radius row, and $\mathsf{RegSeqRat}^{\uparrow}$ handoff for the smaller window are therefore the restricted rows of the larger packet, with no extra host equality or quotient-tail coordinate.

Finally apply Definition 342.15 and Definition 342.10. These identify the rational-interval endpoint window and real-facing boundary as consumer views of the same finite handoff, so the nested cylinder boundary is precisely the finite restriction stated above and exports nothing beyond that surface. □

Theorem 342.17 (ContinuedFraction common-refinement cylinder exhaustion)**.** *Let P and Q be accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packets whose finite prefix cylinders overlap, and let a finite consumer compare the two packets only through that overlap. Then the comparison refines to a displayed common prefix cylinder, and the common consumer surface is exactly the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{Real}^{\uparrow}$ *boundary row, the displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row.*

The common prefix cylinder exports no completed real equality, quotient tail, total expansion, or interval arithmetic law.

Proof. First apply Definition 342.16 to the overlapping finite prefix cylinders. It restricts both accepted packets to the same displayed prefix rows: finite partial quotients, recurrence ledger, scheduled observations, dyadic radius row, transports, routes, provenance, and local name-certificate data.

Next apply Definition 342.15. The restricted prefix is read as the rational-interval endpoint window together with the regular rational handoff, so the consumer sees the interval endpoint surface only through the displayed finite rows.

Now use Definition 342.9. The finite handoff repacks the convergent and recurrence rows into the packet obligation surface without adding a completed real, quotient tail, or total expansion coordinate.

Finally apply Definition 342.10. The real-facing boundary row is the boundary of the same finite cylinder handoff, and the cited handoff theorems provide exactly the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows named in the statement. □

Theorem 342.18 (ContinuedFraction convergent prefix window normal form)**.** *Every finite* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read of an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet restricted to a certified prefix factors through one displayed prefix normal form. The normal form consists exactly of the finite partial-quotient spine, numerator and denominator convergent rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *boundary row, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$ *row.*

The factorization is unchanged by restricting to a smaller certified prefix or by passing to a common overlapping prefix cylinder. It exports no completed real equality, quotient tail, total expansion theorem, interval arithmetic law, or host equality principle.

Proof. First apply Definition 342.14. It reads the certified prefix through the finite partial-quotient spine, numerator and denominator convergent rows, dyadic radius row, schedule, regular rational handoff, visible transports, continuation routes, package provenance, and local name-certificate row.

Next apply Definition 342.15. The rational-interval view is only the endpoint boundary of the same finite convergent window, so it does not add an interval arithmetic law or a host equality principle.

Use Definition 342.16 for prefix restriction. The smaller certified prefix inherits exactly the restricted spine, recurrence, radius, schedule, handoff, boundary, transport, continuation, package, and local certificate rows from the larger packet.

Finally apply Definition 342.17. Any consumer comparison over overlapping certified prefixes refines to the same common prefix cylinder, and that cylinder contains precisely the rows listed in the normal form. Completed real equality, quotient tail, total expansion, interval arithmetic, and host equality are absent from those finite rows. □

Theorem 342.19 (ContinuedFraction dyadic approximation extraction)**.** *Let P be an accepted* $\mathsf{ContinuedFraction}^{\uparrow}$ *packet whose displayed rows include a finite convergent window, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, a* $\mathsf{StreamName}^{\uparrow}$ *schedule, a* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and a* $\mathsf{Real}^{\uparrow}$ *boundary row. Then the same visible rows determine an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet.*

The precision row of the $\mathsf{DyadicApproximation}^{\uparrow}$ *packet is the displayed window precision of P, its endpoint row is the transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *convergent/radius endpoint, its window is the scheduled regular-rational readback, and its ledger is the existing real-boundary handoff. The extraction introduces no quotient real, infinite-tail equality, selected endpoint, or completeness principle.*

Proof. Start with Definition 342.4. It reads the accepted continued-fraction prefix as the displayed regular-rational source window, with the schedule, recurrence ledger, transport rows, continuation routes, package provenance, and local name-certificate row still visible.

Next apply Definition 342.15. The same prefix window supplies the finite rational endpoint row, and the $\mathsf{DyadicRatCore}^{\uparrow}$ radius row transports that endpoint into the dyadic endpoint coordinate required by the approximation packet.

Use Definition 342.17 to identify the finite consumer surface when the packet is restricted or compared inside a common prefix cylinder. The precision, endpoint, scheduled readback, ledger, transport, route, provenance, and local certificate rows remain exactly the displayed rows named in the statement.

Finally apply Definition 335.2 and Definition 335.3. These repack the transported precision, endpoint, window, and ledger rows as an accepted $\mathsf{DyadicApproximation}^{\uparrow}$ packet and seal its $\mathsf{Real}^{\uparrow}$ boundary through the existing handoff. Since every coordinate came from a displayed finite row, no quotient real, infinite-tail equality, selected endpoint, or completeness principle is added. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}$.

Constructive story: A $\mathsf{ContinuedFraction}^{\uparrow}$ packet is generated by a finite partial-quotient spine, rational convergent rows, dyadic radius rows, scheduled observation windows, a regular-sequence handoff, a real-name seal boundary, and a finite provenance ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 342.4, Definition 342.6, Definition 342.12, and Definition 342.13 form the bridged public export surface by binding the finite carrier, classifier, recurrence-ledger obligation, regular-sequence handoff obligation, real-boundary obligation, standard finite-packet boundary, and displayed hsame, Cont, Pkg, and NameCert dependencies for continued-fraction packets over existing BEDC kernels.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContinuedFraction}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ContinuedFractionUp.ContinuedFractionPacket\_convergent\_window\_standard\_bridge`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close total expansion for every real, uniqueness of infinite expansions, measure-theoretic typicality, quotient equality of infinite tails, or machine-checked standard bridges.

Upgrade path: No further paper-side theory grade remains for the finite continued-fraction packet; formal verification and bridge checking remain separate.

Chapter 343

A Concrete Naming Certificate for $\mathsf{BishopReal}^{\uparrow}$

The $\mathsf{BishopReal}^{\uparrow}$ interface records the Bishop–Bridges 1985 constructive-analysis reading of real names inside the BEDC certificate layer. Its carrier is not a Dedekind cut, a quotient real, or a completed host number. It is a finite certificate surface over regular rational names, locatedness evidence, apartness evidence, explicit modulus rows, and the visible $\mathsf{Real}^{\uparrow}$ seal.

This chapter consumes finite observation schedules from chapter 126, dyadic endpoint and tolerance rows from chapter 291, the regular-Cauchy naming route from chapter 371, and the visible seal boundary of chapter 38. These are substantive carrier and ledger dependencies rather than adjacent topics: the packet coordinates $S, Q, D, M, L, A, E, H, C, P, N$ route every public constructive-real read through those surfaces.

Definition 343.1 (BishopReal regular located carrier)**.** *A* $\mathsf{BishopReal}^{\uparrow}$ *packet is a finite* BHist *row*

$$B = (S, Q, D, M, L, A, E, H, C, P, N)$$

with the following visible coordinates:

1. *S is a* $\mathsf{StreamName}^{\uparrow}$ *schedule naming the finite windows through which the rational approximation stream is inspected;*
2. *Q is a certified* $\mathsf{RegSeqRat}^{\uparrow}$ *name read on those scheduled windows;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint packet used for finite tolerance and interval observations;*
4. *M is the explicit* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row controlling the regular sequence windows;*
5. *L is the displayed* $\mathsf{LocatedReal}^{\uparrow}$ *evidence row;*
6. *A is the displayed* $\mathsf{ApartnessReal}^{\uparrow}$ *evidence row;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal consumed by downstream real-facing interfaces;*
8. *H records componentwise* hsame *transport for $S, Q, D, M, L, A,$ and E;*
9. *C records the visible* Cont *routes through which a consumer reaches the finite stream windows, dyadic endpoint packets, modulus rows, locatedness rows, apartness rows, and seal row;*
10. *P is the* Pkg *provenance row naming* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedReal}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as the dependency anchors;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{BishopReal}^\uparrow}$ *ledger row.*

The carrier predicate is $\mathsf{BishopRealPacket}(S, Q, D, M, L, A, E, H, C, P, N)$*. Its classifier compares two accepted packets only by passing through common finite stream windows, the same dyadic endpoint packet family, the displayed modulus rows, the locatedness and apartness evidence rows, and the visible* $\mathsf{Real}^\uparrow$ *seal. No coordinate stores a Dedekind cut, quotient real, trichotomy principle, selected limit, or classical completeness witness.*

Lean4 (definition) `BEDC.Derived.BishopRealUp.BishopRealPacket`

Theorem 343.2 (BishopReal located-apartness transport)**.** *For any two accepted* $\mathsf{BishopReal}^\uparrow$ *packets* $B = (S, Q, D, M, L, A, E, H, C, P, N)$ *and* $B' = (S', Q', D', M', L', A', E', H', C', P', N')$*, a componentwise* hsame *comparison of their stream schedules, regular rational names, dyadic endpoint packets, modulus rows, locatedness rows, apartness rows, and* $\mathsf{Real}^\uparrow$ *seals transports the local classifier from* B *to* B'*. Downstream reads of locatedness or apartness therefore factor through the same finite stream-window and dyadic-endpoint surface, never through trichotomy or host real equality.*

Proof. Project the two carrier rows through Definition 343.1. The schedule coordinates give the only stream windows a consumer may inspect, and the dyadic endpoint coordinates give the only finite tolerance packets available at those windows.

Transport the regular rational, modulus, locatedness, apartness, and seal rows componentwise along the displayed hsame witnesses. Each read is reached through one of the visible Cont routes in the carrier, so the transported packet has the same finite observation shape as the source packet.

The forbidden host data are absent from the carrier. Since no coordinate stores trichotomy, quotient equality, a cut, or a selected limit, the classifier cannot export any such principle after transport. □

Lean4 ✓ `BEDC.Derived.BishopRealUp.BishopRealPacket located apartness transport`

Theorem 343.3 (BishopReal RegSeqRat readback)**.** *Every* $\mathsf{Real}^\uparrow$ *seal read exported by an accepted* $\mathsf{BishopReal}^\uparrow$ *packet factors through the certified* $\mathsf{RegSeqRat}^\uparrow$ *name* Q*, the scheduled finite windows* S*, the* $\mathsf{DyadicRatCore}^\uparrow$ *endpoint packets* D*, and the explicit* $\mathsf{ModulusOfConvergence}^\uparrow$ *row* M*. The readback exposes only the regular rational name, its dyadic finite observations, and the displayed real seal.*

Lean4 ✓ `BEDC.Derived.BishopRealUp.BishopRealPacket regseqrat readback`

Proof. Let a downstream consumer read the seal coordinate E of a packet B. By the carrier definition, E is stored together with the schedule S, regular name Q, dyadic packet family D, and modulus row M.

The continuation coordinate C gives the finite routes by which E is reached. Each such route also names the stream window, dyadic endpoint packet, and modulus row used for the observation. Thus the seal read has the advertised regular-sequence handoff as part of its visible packet.

Nothing else remains to read. The packet has no coordinate for a quotient class, cut membership predicate, choice-selected endpoint, or classical completeness argument, so the readback is exhausted by S, Q, D, M, and E. □

Theorem 343.4 (BishopReal ledger obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{BishopReal}^\uparrow}$ *ledger surface consists exactly of the carrier, classifier, stability, readback, and dependency rows displayed by Definition 343.1, Definition 343.2, and Definition 343.3. Its dependency anchors are* $\mathsf{DyadicRatCore}^\uparrow$*,* $\mathsf{StreamName}^\uparrow$*,* $\mathsf{RegSeqRat}^\uparrow$*,* $\mathsf{LocatedReal}^\uparrow$*,* $\mathsf{ApartnessReal}^\uparrow$*,* $\mathsf{ModulusOfConvergence}^\uparrow$*, and* $\mathsf{Real}^\uparrow$*.*

Proof. The carrier row is the packet of Definition 343.1. It lists the stream schedule, regular rational name, dyadic endpoint packet, modulus, locatedness, apartness, seal, transport, continuation, provenance, and local ledger coordinates.

The classifier and stability rows are supplied by Definition 343.2. They compare packets only through common finite stream windows and componentwise transport of the visible rows.

The exactness and readback row is Definition 343.3. The provenance coordinate P and ledger coordinate N list precisely the seven dependency anchors named in the statement, so the ledger surface has no further exported row. □

Theorem 343.5 (BishopReal carrier construction obligation)**.** *The carrier obligation for* $\mathsf{BishopReal}^{\uparrow}$ *is to construct the finite packet of Definition 343.1 from a certified* $\mathsf{RegSeqRat}^{\uparrow}$ *name, scheduled* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint packets, a displayed* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row, displayed* $\mathsf{LocatedReal}^{\uparrow}$ *and* $\mathsf{ApartnessReal}^{\uparrow}$ *evidence rows, the visible* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transport, finite* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ *ledger.*

Proof. Read the coordinates of Definition 343.1. They list exactly the regular rational name, finite observation windows, dyadic endpoint packets, convergence modulus, locatedness and apartness rows, real seal, transport, continuation, provenance, and local ledger.

The construction obligation is therefore finite: provide those displayed rows and repack them as the carrier predicate. No Dedekind cut, quotient real, trichotomy principle, selected limit, or classical completeness coordinate is available to the constructor. □

Theorem 343.6 (BishopReal classifier stability obligation)**.** *The classifier stability obligation for* $\mathsf{BishopReal}^{\uparrow}$ *is componentwise transport under* hsame *for the* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedReal}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows along the finite* Cont *routes displayed in the carrier. Accepted packets may classify together only through those finite routes and their shared BEDC dependency surface.*

Proof. Apply Definition 343.2. It transports the stream schedule, regular rational name, dyadic endpoint packet, modulus row, locatedness row, apartness row, and $\mathsf{Real}^{\uparrow}$ seal componentwise along the displayed hsame witnesses.

The same theorem records that every transported read is reached through one of the finite Cont routes in the carrier. Thus the classifier is stable exactly on the displayed packet surface and does not acquire host real equality, trichotomy, or a quotient comparison. □

Theorem 343.7 (BishopReal readback ledger exhaustion obligation)**.** *The readback-ledger exhaustion obligation for* $\mathsf{BishopReal}^{\uparrow}$ *is that every exported* $\mathsf{Real}^{\uparrow}$ *seal read factors through the certified* $\mathsf{RegSeqRat}^{\uparrow}$ *name, the scheduled finite windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint packets, the displayed* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row, and the dependency anchors* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedReal}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *The exhausted ledger excludes Dedekind cuts, quotient reals, trichotomy, selected limits, and classical completeness.*

Proof. First apply Definition 343.3. It says each $\mathsf{Real}^{\uparrow}$ seal read passes through the regular rational name, scheduled windows, dyadic endpoint packets, and explicit convergence modulus.

Then apply Definition 343.4. Its provenance and local ledger rows list exactly the seven dependency anchors in the statement, so the readback has no further exported row.

The non-constructive real principles are absent twice: they are not carrier coordinates, and they are not ledger anchors. The readback surface is therefore exhausted by the finite BEDC rows already displayed. □

Theorem 343.8 (BishopReal public NameCert export)**.** *The carrier construction, classifier stability,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, located-apartness transport, readback-ledger exhaustion, explicit modulus rows, and* $\mathsf{Real}^{\uparrow}$ *seal assemble the public* $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ *export over regular rational names. Every public read factors through exactly the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows.*

The public export contains no Dedekind cut, quotient real, trichotomy, selected limit, or classical completeness row.

Proof. First read the carrier from Definition 343.1. It lists the regular rational name, finite stream windows, dyadic endpoint packets, convergence modulus, locatedness and apartness rows, visible real seal, transport, continuation, provenance, and local naming ledger.

Next apply Definition 343.2 and Definition 343.3. These identify the componentwise transport rows and the $\mathsf{Real}^{\uparrow}$ seal readback as finite reads of the same constructive-real packet.

Then use Definition 343.4, Definition 343.5, Definition 343.6, and Definition 343.7. Together they exhaust the carrier, classifier, ledger, construction, and readback rows named in the statement.

Project the visible BHist, hsame, Cont, Pkg, NameCert, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows from that surface. Repacking those rows gives the public $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ export.

Dedekind cuts, quotient reals, trichotomy, selected limits, and classical completeness remain outside the export because none is present in the carrier or ledger surface. □

Theorem 343.9 (BishopReal standard finite-packet bridge)**.** *Definition 343.8, Definition 343.3, and Definition 343.7 determine the standard Bishop-style finite packet bridge for* $\mathsf{BishopReal}^{\uparrow}$ *over* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{LocatedReal}^{\uparrow}$*,* $\mathsf{ApartnessReal}^{\uparrow}$*,* $\mathsf{ModulusOfConvergence}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. The bridge packet consists only of the regular rational name, locatedness row, apartness row, modulus row,* $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transports,* Cont *routes,* Pkg *provenance, and* NameCert *ledger rows displayed by the BEDC carrier.*

Consequently the standard constructive-real packet exported by $\mathsf{BishopReal}^{\uparrow}$ *has no Dedekind cut, quotient real, trichotomy, selected limit, or classical completeness coordinate.*

Lean4 ✓ `BEDC.Derived.BishopRealUp.BishopRealPacket standard finite packet bridge`

Proof. First project the public export from Definition 343.8. It supplies the finite BHist, hsame, Cont, Pkg, NameCert, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows of the accepted constructive-real packet.

Next identify the regular rational name and the visible $\mathsf{Real}^{\uparrow}$ seal through Definition 343.3. The readback passes only through the certified $\mathsf{RegSeqRat}^{\uparrow}$ name, scheduled finite windows, dyadic endpoint packets, and explicit modulus row.

Finally apply Definition 343.7. It says every standard field of the readback is one of the displayed finite BEDC rows over $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedReal}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The excluded real principles are not present in the public export, not present in the readback, and not present in the exhausted ledger. The resulting packet is therefore exactly the standard finite-packet bridge claimed in the statement. □

Theorem 343.10 (BishopReal regular-Cauchy located Real seal)**.** *Let* $B = (S, Q, D, M, L, A, E, H, C, P, N)$ *be an accepted* $\mathsf{BishopReal}^{\uparrow}$ *packet. Suppose its* $\mathsf{RegSeqRat}^{\uparrow}$ *name, locatedness row, apartness row, modulus row, and* $\mathsf{Real}^{\uparrow}$ *seal are transported along the displayed* hsame *witnesses and read only through the displayed* Cont *routes of Definition 343.1. Then* B *exports one finite constructive-real seal surface.*

The surface consists exactly of the regular rational name Q, the scheduled finite windows S, the dyadic endpoint packets D, the locatedness row L, the apartness row A, the modulus row M, the $\mathsf{Real}^{\uparrow}$ *seal E, the visible* hsame *transports, the visible* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ *ledger. Every public read of the accepted packet factors through those rows and through no Dedekind cut, quotient real, trichotomy principle, selected limit, or classical completeness witness.*

Lean4 ✓ `BEDC.Derived.BishopRealUp.BishopRealPacket regular cauchy located real seal`

Proof. First read the regular rational and seal coordinates. Apply Definition 343.3 to identify every $\mathsf{Real}^{\uparrow}$ seal read with the certified $\mathsf{RegSeqRat}^{\uparrow}$ name, scheduled finite windows, dyadic endpoint packets, explicit modulus row, and displayed seal.

Next transport the constructive-real evidence rows. Apply Definition 343.2 to carry the regular rational name, locatedness row, apartness row, modulus row, and seal row along the displayed hsame witnesses and through the same finite Cont routes.

Now exhaust the public ledger. Apply Definition 343.7 to show that every exported read is accounted for by the listed dependency anchors and finite BEDC rows.

Finally apply Definition 343.9. It repackages those rows as the standard Bishop-style finite packet over $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedReal}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Since the bridge has no coordinate for cuts, quotient reals, trichotomy, selected limits, or classical completeness, the same exclusions hold for the seal surface. □

Theorem 343.11 (BishopReal finite constructive-real consumer completeness)**.** *Every finite consumer read of an accepted* $\mathsf{BishopReal}^{\uparrow}$ *packet factors through exactly the regular rational name, scheduled finite windows, dyadic endpoint packets, locatedness row, apartness row, modulus row, visible* $\mathsf{Real}^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ *rows of Definition 343.10. Conversely those rows repack as the finite constructive-real consumer surface of the accepted packet.*

Thus the mature consumer surface for $\mathsf{BishopReal}^{\uparrow}$ *is precisely the displayed regular-Cauchy located real packet. It contains no Dedekind cut, quotient real, trichotomy principle, selected limit, or classical completeness witness.*

Proof. Project the accepted carrier through Definition 343.1. The carrier lists the regular rational name, scheduled finite windows, dyadic endpoint packets, locatedness row, apartness row, modulus row, visible seal, transport routes, package row, and local certificate ledger as the available public coordinates.

Next transport the real evidence through Definition 343.2 and read back the regular name through Definition 343.3. These two results identify every constructive-real read with the displayed regular rational name, its finite windows, its dyadic endpoint packets, and its explicit modulus and locatedness-apartness rows.

Now exhaust the ledger. Apply Definition 343.7 and Definition 343.8. The first theorem says that no finite read leaves the displayed ledger, while the second exports that ledger as the public NameCert surface of the accepted packet.

Finally apply Definition 343.9 and Definition 343.10. They repack the same rows as the standard finite constructive-real packet and the regular-Cauchy located $\mathsf{Real}^{\uparrow}$ seal. Since the carrier and both repackings have no coordinate for cuts, quotient reals, trichotomy, selected limits, or classical completeness, those structures cannot be consumed from the finite packet. □

Theorem 343.12 (BishopReal located-apartness seal factorization)**.** *Every locatedness or apartness read exported by an accepted* $\mathsf{BishopReal}^{\uparrow}$ *packet factors through the same finite scheduled*

$\mathsf{RegSeqRat}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint packets,* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row, and* $\mathsf{Real}^{\uparrow}$ *seal row. Equivalently, the public constructive-real evidence read is one packet surface containing the regular rational name, scheduled finite windows, dyadic endpoints, explicit convergence modulus, locatedness row, apartness row, visible* hsame *transports, displayed* Cont *routes,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$ *evidence, and the visible* $\mathsf{Real}^{\uparrow}$ *seal.*

The factorization exports no trichotomy principle, quotient real, Dedekind cut, host real equality, selected representative, or classical completeness witness.

Proof. First transport the constructive-real evidence. Apply Definition 343.2; locatedness and apartness travel along the displayed hsame witnesses and remain on the same finite Cont routes as the regular rational name, modulus row, and seal row.

Next read back the regular name. By Definition 343.3, every seal-facing read of the regular rational coordinate is represented by scheduled finite windows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint packets, the explicit modulus row, and the visible $\mathsf{Real}^{\uparrow}$ seal.

Now exhaust the certificate ledger. Apply Definition 343.7; no locatedness or apartness read can leave the displayed dependency anchors, transport rows, continuation routes, package provenance, and local name evidence.

Finally apply Definition 343.11. It repackages exactly the transported locatedness, apartness, modulus, regular name, endpoint, and seal rows as the finite constructive-real consumer surface. Since the surface has no coordinate for trichotomy, quotient reals, cuts, host real equality, selected representatives, or classical completeness, the same exclusions hold for every exported locatedness or apartness read. □

Closure status for $\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$.

Constructive story: A $\mathsf{BishopReal}^{\uparrow}$ packet is generated from a certified $\mathsf{RegSeqRat}^{\uparrow}$ name, finite stream windows, dyadic endpoint packets, an explicit convergence modulus, locatedness evidence, apartness evidence, componentwise transport rows, continuation routes, package provenance, and the visible $\mathsf{Real}^{\uparrow}$ seal.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 343.1, Definition 343.2, Definition 343.3, Definition 343.4, Definition 343.5, Definition 343.6, Definition 343.7, Definition 343.8, Definition 343.9, Definition 343.10, Definition 343.11, and Definition 343.12 name the finite constructive real-neighbor certificate surface, standard bridge, regular-Cauchy located $\mathsf{Real}^{\uparrow}$ seal, finite constructive-real consumer surface, and located-apartness seal factorization over regular rational names, locatedness, apartness, explicit modulus rows, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BishopReal}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.BishopRealUp.BishopRealPacket\_standard\_finite\_packet\_bridge`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Dedekind-cut reals, quotient reals, trichotomy, selected limits, classical completeness, or formal verification of the finite consumer theorem.

Upgrade path: No further paper-axis theory grade remains; Lean verification remains on the formal axis.

Chapter 344

A Concrete Naming Certificate for $\mathsf{StoppingTime}^{\uparrow}$

Classically, a stopping time is a random time whose event $\{\tau \leq n\}$ is visible from the information available by time n, as in Williams, *Probability with Martingales* (1991), or Durrett, *Probability: Theory and Examples* (2019). The $\mathsf{StoppingTime}^{\uparrow}$ surface below keeps only the finite-prefix version of that object: a BEDC ledger over probability and process rows, with no host filtration, no optional sampling theorem, and no choice of an infinite stopping rule.

The finite prefix ledger is a carrier and classifier input from chapter 184 for probability rows, chapter 93 for visible information prefixes, and chapter 190 when the process row is read through a martingale dependency. These dependencies are the rows consumed by the packet surface below, not ambient background structure.

Definition 344.1 (StoppingTime source packet)**.** *A* $\mathsf{StoppingTime}^{\uparrow}$ *source packet is a finite* BHist *record*

$$S = (\Omega, X, F, n, w, h, c, p)$$

with the following visible rows:

1. Ω *is the consumed* $\mathsf{ProbSpace}^{\uparrow}$ *probability-source row;*
2. X *is a finite family of* $\mathsf{RandomVar}^{\uparrow}$ *process-observation rows, read either directly or through a consumed* $\mathsf{Martingale}^{\uparrow}$ *or* $\mathsf{MarkovChain}^{\uparrow}$ *dependency row;*
3. F *is a finite filtration-prefix ledger whose* k*th row lists the observable event names available up to the displayed unary time* $k \leq n$*;*
4. n *is the unary time row naming the finite prefix horizon;*
5. w *is the stopping-rule witness row: for each displayed* $k \leq n$*, the event row saying that the rule has stopped by* k *is read from the* F_k *ledger and the process rows* $X_0, \ldots, X_k$*;*
6. h *records componentwise* hsame *transport for the probability source, process rows, unary time row, filtration-prefix rows, and stopping witness;*
7. c *records the* Cont *read routes from prefix observations to the event row* $\{w \leq k\}$ *and from dependency certificates to the visible process rows;*
8. p *is the* Pkg *provenance row naming the consumed* $\mathsf{ProbSpace}^{\uparrow}$*,* $\mathsf{RandomVar}^{\uparrow}$*,* $\mathsf{Martingale}^{\uparrow}$*, or* $\mathsf{MarkovChain}^{\uparrow}$ *dependency certificates.*

The carrier predicate StoppingTimeSource$(\Omega, X, F, n, w, h, c, p)$ *accepts exactly such finite packets. Its classifier transports the displayed rows componentwise and compares the stopping witness only through the same finite filtration prefix; it does not compare host stochastic processes or infinite sigma-algebra towers.*

Lean4 (definition) `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket`

Theorem 344.2 (StoppingTime NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$ *obligation surface consists of the source packet of Definition 344.1, carrier habitation by the rule that stops at the displayed horizon n, classifier transport by componentwise* hsame*, filtration-prefix stability under certified prefix restriction, ledger coverage for all stopping-event reads, and the standard finite stopping-time boundary. These rows consume only* $\mathsf{ProbSpace}^{\uparrow}$*,* $\mathsf{RandomVar}^{\uparrow}$*,* $\mathsf{Martingale}^{\uparrow}$ *or* $\mathsf{MarkovChain}^{\uparrow}$ *dependency packets,* BHist *histories,* hsame *rows,* Cont *routes, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket namecert obligation surface`

Proof. For habitation, take the displayed rule that stops at the horizon row n. Every event $\{w \le k\}$ is then either absent before the horizon or the terminal event at the horizon, both read through the finite probability ledger of Ω and the displayed prefix rows.

Classifier transport is obtained by projecting the tuple $S = (\Omega, X, F, n, w, h, c, p)$. Each coordinate has a corresponding hsame comparison, and the Cont routes transport the read of each event $\{w \le k\}$ along the matched process and filtration-prefix rows.

The remaining obligations are exactness statements about the same finite ledger. Prefix restriction keeps only rows whose time coordinate lies in the certified prefix, and ledger coverage says that no stopping-event read has a source outside Ω, X, F, n, w, h, c, and p. □

Theorem 344.3 (StoppingTime filtration-prefix stability)**.** *Let $S = (\Omega, X, F, n, w, h, c, p)$ be an accepted* $\mathsf{StoppingTime}^{\uparrow}$ *source packet. Restrict the unary time horizon to a certified prefix $m \le n$ and retain only the rows $X_0, \ldots, X_m$, $F_0, \ldots, F_m$, the witness events $\{w \le k\}$ for $k \le m$, and the corresponding* hsame*,* Cont*, and* Pkg *rows. The resulting finite packet is again an accepted* $\mathsf{StoppingTime}^{\uparrow}$ *source packet over the prefix horizon m.*

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket prefix transport`
Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket filtration prefix stability`

Proof. Unfold Definition 344.1. Acceptance is stated row by row over the displayed unary prefix, so each retained time $k \le m$ was already one of the accepted time rows of the original packet.

Project the retained process rows, filtration-prefix rows, and stopping witness events. The read route for $\{w \le k\}$ still factors through F_k and $X_0, \ldots, X_k$, because those rows all lie inside the retained prefix.

The inherited hsame comparisons and Cont routes have the same endpoints after prefix restriction, and the Pkg provenance row still names the same dependency certificates. Repacking these rows gives the accepted prefix packet. □

Theorem 344.4 (StoppingTime ledger coverage)**.** *Every consumer-visible read from an accepted* $\mathsf{StoppingTime}^{\uparrow}$ *packet factors through one of the displayed rows of Definition 344.1: the* $\mathsf{ProbSpace}^{\uparrow}$ *source, the* $\mathsf{RandomVar}^{\uparrow}$ *process rows, the optional* $\mathsf{Martingale}^{\uparrow}$ *or* $\mathsf{MarkovChain}^{\uparrow}$ *dependency row, the unary time row, the finite filtration-prefix ledger, the stopping witness events, the* hsame *comparisons, the* Cont *read routes, and the* Pkg *provenance. No host filtration, infinite stopping time, optional sampling statement, or selected limit is exported.*

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket ledger coverage`

Proof. Inspect the carrier tuple. It has exactly the eight coordinates $(\Omega, X, F, n, w, h, c, p)$, and each coordinate is a finite BEDC row or a finite family indexed by the displayed unary prefix.

A probability read factors through Ω. A process read factors through X and its dependency certificate. A stopping-event read factors through the finite filtration-prefix row F_k, the process prefix ending at k, and the continuation route recorded in c.

There is no carrier coordinate for a host filtration tower, an infinite random time, a theorem about stopped processes, or a limiting construction. Thus the listed finite rows cover all readable packet content. □

Theorem 344.5 (StoppingTime standard boundary)**.** *The standard mathematical boundary represented by* $\mathsf{StoppingTime}^{\uparrow}$ *is the finite-prefix stopping rule: for every displayed time $k \leq n$, the event that the rule has stopped by k is read from the finite information ledger F_k and the process observations through time k. The BEDC packet agrees with the classical stopping-time intuition from finite probability-process prefixes, but it does not assert a host filtration, completed sigma-algebra sequence, optional stopping theorem, stopped martingale construction, or standard stochastic-process bridge.*

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket standard boundary`

Proof. Read the stopping witness row w through the source packet. For each displayed $k \leq n$, the witness event $\{w \leq k\}$ is attached by a Cont route to the finite ledger F_k and the process prefix $X_0, \ldots, X_k$.

The $\mathsf{ProbSpace}^{\uparrow}$ row supplies the probability-source boundary, while the $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Martingale}^{\uparrow}$, or $\mathsf{MarkovChain}^{\uparrow}$ dependency row supplies the process rows consumed by the packet. The provenance row p records that these are the only dependency certificates read by the stopping rule.

Therefore the standard interpretation is exactly the finite-prefix adaptedness condition for stopping rules. Any theorem requiring an infinite filtration, stopped process, optional sampling, or a host stochastic-process object lies outside this seed certificate. □

Theorem 344.6 (StoppingTime scoped dependency envelope)**.** *The source packet of Definition 344.1, the* $\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$ *obligation surface, filtration-prefix stability, ledger coverage, and standard boundary bind every accepted stopping-rule row to finite* BHist *prefixes, displayed* hsame *transport,* Cont *read routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$ *row. No host filtration, infinite stopping time, optional stopping theorem, or selected stochastic-process limit is introduced.*

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket scoped dependency envelope`

Proof. Project the source tuple $S = (\Omega, X, F, n, w, h, c, p)$ from Definition 344.1. Its probability source, process rows, unary horizon, filtration-prefix ledger, stopping witness, transport, read routes, and provenance are all finite rows of one displayed packet.

Apply Definition 344.2 and Definition 344.3 to keep habitation, classifier transport, and prefix restriction inside the same finite BHist ledger. The accepted stopping-event row $\{w \leq k\}$ is therefore read only through the displayed prefix F_k, the process prefix up to k, and the corresponding hsame and Cont rows.

Apply Definition 344.4 and Definition 344.5 to close the consumer boundary. Those rows already name the Pkg provenance and local $\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$ registration, and they explicitly leave host filtrations, infinite stopping times, optional stopping, and stochastic-process limits outside the packet. □

Theorem 344.7 (StoppingTime public consumer export)**.** *The scoped packet of Definition 344.6 exports a public finite-prefix stopping-rule certificate to* $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Martingale}^{\uparrow}$, *and* $\mathsf{MarkovChain}^{\uparrow}$ *consumers. The exported certificate consists exactly of the probability source row, process rows, unary horizon, finite filtration-prefix ledger, stopping-event witness rows,* hsame *transport,* Cont *read routes, and* Pkg *provenance.*

It exports no host filtration, infinite stopping time, optional stopping theorem, stopped martingale construction, or selected stochastic-process limit.

Lean4 ✓ `BEDC.Derived.StoppingTimeUp.StoppingTimeSourcePacket public consumer export`

Proof. Begin with Definition 344.2. It binds the probability source, process rows, unary horizon, stopping-event witness rows, transport, read routes, and package provenance to the local accepted packet.

Apply Definition 344.3 to keep the filtration read finite at every displayed horizon. Then use Definition 344.4 to identify the stopping-event witness rows as ledger entries over the same prefix.

Next apply Definition 344.5; it is the public probability-process boundary through which $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Martingale}^{\uparrow}$, and $\mathsf{MarkovChain}^{\uparrow}$ consumers read the packet.

Finally compose these rows with Definition 344.6. The envelope contains no host filtration, infinite stopping time, optional stopping theorem, stopped martingale construction, or selected limit, so the public certificate exports none of them. □

Closure status for $\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$.

Constructive story: A stopping-time packet is generated from a displayed $\mathsf{ProbSpace}^{\uparrow}$ source, finite $\mathsf{RandomVar}^{\uparrow}$ process rows optionally supplied through $\mathsf{Martingale}^{\uparrow}$ or $\mathsf{MarkovChain}^{\uparrow}$, a unary time horizon, a finite filtration-prefix ledger, stopping-event witness rows, componentwise hsame transport, finite Cont read routes, and Pkg provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 344.1, Definition 344.2, Definition 344.3, Definition 344.4, Definition 344.5, Definition 344.6, and Definition 344.7 bind the obligation surface, filtration-prefix stability, ledger coverage, finite standard-boundary bridge, exported finite-prefix stopping-rule certificate, public finite-prefix stopping-rule examples, cross-consumer completeness for $\mathsf{ProbSpace}^{\uparrow}$, $\mathsf{RandomVar}^{\uparrow}$, $\mathsf{Martingale}^{\uparrow}$, and $\mathsf{MarkovChain}^{\uparrow}$ finite-prefix consumers, BHist prefixes, hsame transport, Cont routes, Pkg provenance, and local NameCert row as the full mature public finite-prefix stopping-rule scope.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StoppingTime}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close host filtrations, infinite stopping times, optional stopping, stopped martingales, selected limits, or a standard stochastic-process bridge.

Upgrade path: The paper-axis treatment is mature; further progress is formal verification and bridge checking.

Chapter 345

A Concrete Naming Certificate for $\mathsf{FreeMonoid}^{\uparrow}$

The $\mathsf{FreeMonoid}^{\uparrow}$ interface names finite BEDC word histories over a displayed payload row. In the standard algebraic account, as in Mac Lane's treatment of free algebraic constructions and the usual formal-language presentation, a free monoid is generated by finite words with empty word and concatenation. The BEDC certificate below records that surface without importing a host free-monoid primitive.

Definition 345.1 (FreeMonoid word carrier)**.** *Fix a payload history source row* $A : \mathsf{BHist} \to \mathsf{Prop}$ *and a payload classifier* $\sim_A$*. A* $\mathsf{FreeMonoid}^{\uparrow}$ *word is a finite* BHist *spine*

$$W = (s, \ell, p, h, c, q)$$

whose positions are licensed by $\mathsf{List}^{\uparrow}$*, whose length row* ℓ *is licensed by* $\mathsf{Nat}^{\uparrow}$*, whose payload entries* p *are carried by* A*, whose endpoint history* h *is represented by the displayed list spine, whose route row* c *records the* Cont *reads for empty word, singleton insertion, and concatenation, and whose provenance row* q *records the* Pkg *dependencies on* A*,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*, and* $\mathsf{Monoid}^{\uparrow}$*.*

Two accepted words classify together exactly when their length rows agree and their corresponding payload positions compare by hsame *over the payload rows, transported along the displayed* Cont *routes. The classifier does not identify words by an external quotient or by a host list type.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidTasteGate single carrier alignment`

Theorem 345.2 (FreeMonoid empty word unit)**.** *The empty* BHist *spine is an accepted* $\mathsf{FreeMonoid}^{\uparrow}$ *word, its length row is the* $\mathsf{Nat}^{\uparrow}$ *zero row, and concatenating it on either side of an accepted word returns a word classified with the original endpoint. The unit rows are read only through the empty-word constructor, the* $\mathsf{List}^{\uparrow}$ *empty-spine license, the* $\mathsf{Nat}^{\uparrow}$ *zero-length row, the* $\mathsf{Monoid}^{\uparrow}$ *append unit surface, and the same* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier empty word unit`

Proof. Use the empty constructor of the finite list spine for the position row and the zero row of $\mathsf{Nat}^{\uparrow}$ for the length row. This gives a carried word with no payload entry and no hidden endpoint.

For the two unit laws, read concatenation through the $\mathsf{Monoid}^{\uparrow}$ append surface. The left and right empty-history continuation laws identify the resulting endpoint with the original word endpoint under hsame, while the length ledger reads zero plus the displayed length and the displayed length plus zero as the same $\mathsf{Nat}^{\uparrow}$ row. □

Theorem 345.3 (FreeMonoid concatenation associativity)**.** *For accepted* $\mathsf{FreeMonoid}^{\uparrow}$ *words* u*,* v*, and* w*, both concatenation parenthesizations*

$$(u \cdot v) \cdot w \quad \textit{and} \quad u \cdot (v \cdot w)$$

are accepted and classify together. The witness is the finite BHist *append-associativity route together with the* $\mathsf{List}^{\uparrow}$ *append-spine associativity row, the* $\mathsf{Nat}^{\uparrow}$ *length-addition associativity row, and componentwise* hsame *transport of the payload positions.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier concat associativity`

Proof. First concatenate the displayed list spines. The $\mathsf{List}^{\uparrow}$ append readback keeps the positions finite and records the same ordered payload rows in both parenthesizations.

Next apply the $\mathsf{Monoid}^{\uparrow}$ append associativity surface to the endpoint histories. The resulting hsame route transports the endpoint row without changing any payload entry.

Finally compare the length rows. Both paths read the same finite addition ledger for the three displayed lengths, so the $\mathsf{Nat}^{\uparrow}$ row agrees with the positionwise payload transport. These rows repack as the classifier witness for the two accepted concatenation endpoints. □

Theorem 345.4 (FreeMonoid NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$ *obligation surface consists of exactly five finite rows:*

1. *carrier habitation by the empty word of Definition 345.2;*
2. *classifier reflexivity, symmetry, and transitivity from the* $\mathsf{List}^{\uparrow}$ *position classifier, the* $\mathsf{Nat}^{\uparrow}$ *length row, and the payload* hsame *rows;*
3. *carrier transport under the classifier by componentwise payload transport and length agreement;*
4. *concatenation closure by the* $\mathsf{Monoid}^{\uparrow}$ *append surface and the* $\mathsf{List}^{\uparrow}$ *represented-spine append route;*
5. *ledger exactness for empty-word, singleton, and concatenation reads.*

No host free-monoid carrier, external quotient, infinite word, or language recognizer is part of the obligation.

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier namecert obligation surface`

Proof. The habitation row is the empty finite spine with the zero length row. This is the carried endpoint fixed by Definition 345.2.

The classifier laws are inherited componentwise. $\mathsf{List}^{\uparrow}$ supplies the finite position comparison, $\mathsf{Nat}^{\uparrow}$ supplies length agreement, and the payload classifier supplies the hsame rows on each displayed position.

For transport and closure, move each payload position along the classifier route and then use the displayed append readback. Concatenation remains a finite spine, and the endpoint route is the $\mathsf{Monoid}^{\uparrow}$ append continuation.

The ledger has only three read forms: empty word, singleton insertion, and concatenation. Each read is stored with its source provenance and length row, so every accepted consumer read projects back to one of those displayed rows. □

Theorem 345.5 (FreeMonoid ledger normal form)**.** *Every accepted* $\mathsf{FreeMonoid}^{\uparrow}$ *consumer read has a unique displayed ledger shape: empty word, singleton insertion of one payload row, or concatenation of two previously accepted word rows. The normal form records the source provenance,*

the $\mathsf{List}^{\uparrow}$ *position spine, the* $\mathsf{Nat}^{\uparrow}$ *length row, the* $\mathsf{Monoid}^{\uparrow}$ *append route when present, and the componentwise payload* hsame *rows. It exports no separate evaluator for words.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier ledger normal form`

Proof. Inspect the carrier row of Definition 345.1. The only constructors recorded in the route row are empty word, singleton insertion, and concatenation.

In the empty case, the position spine is empty and the length row is the $\mathsf{Nat}^{\uparrow}$ zero row. In the singleton case, the spine has one displayed payload entry and one source provenance read. In the concatenation case, the two input word rows and the append route determine the displayed output spine and the length-addition row.

These cases exhaust the route row, so a consumer cannot read a hidden word evaluation, host list operation, or language-level recognizer from the packet. □

Theorem 345.6 (FreeMonoid public seal)**.** *The public* $\mathsf{FreeMonoid}^{\uparrow}$ *seal is the finite packet consisting of the word carrier of Definition 345.1, the empty-unit and associativity rows of Definition 345.2 and Definition 345.3, the* $\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$ *obligation surface of Definition 345.4, and the ledger normal form of Definition 345.5. This packet is the consumer-facing certificate for finite word histories over the displayed payload source.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier public seal`

Proof. Package the carrier, classifier, unit, concatenation, and ledger rows named in the preceding blocks. Each row is a finite BHist, hsame, Cont, or Pkg dependency over the payload source, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Monoid}^{\uparrow}$.

The public seal exposes exactly those rows. Since the carrier has no coordinate for a host free-monoid object, external quotient, infinite stream, automaton, or language semantics, downstream chapters can consume only the displayed finite word-history certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$.

Constructive story: A free-monoid word is generated as a finite BHist spine whose positions are licensed by $\mathsf{List}^{\uparrow}$, whose length row is licensed by $\mathsf{Nat}^{\uparrow}$, whose concatenation route is the $\mathsf{Monoid}^{\uparrow}$ append surface, and whose payload positions compare componentwise by hsame under the displayed Pkg provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 345.6 binds the finite word-history packet with empty word, singleton insertion, concatenation, length addition, componentwise payload transport, source provenance, empty concatenation inversion from Definition 345.7, singleton concatenation inversion from Definition 345.8, and the concrete $\mathsf{List}^{\uparrow}$ continuation monoid instance of Definition 345.9.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$, unformalized)

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close host free-monoid quotients, infinite words, formal-language recognizers, automata semantics, or a standard bridge.

Upgrade path: Remaining work is formal verification of the displayed finite word-history consumer package and standard-bridge checking.

Theorem 345.7 (FreeMonoid empty concatenation inversion)**.** *Fix one payload source row* $A : \mathsf{BHist} \to \mathsf{Prop}$ *and one payload classifier* $\sim_A$*. Let* u *and* v *be accepted* $\mathsf{FreeMonoid}^{\uparrow}$ *words for this same payload,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*, and* $\mathsf{Monoid}^{\uparrow}$ *setup, and let* $u \cdot v$ *be their displayed concatenation word. If* $u \cdot v$ *is classified with the empty* $\mathsf{FreeMonoid}^{\uparrow}$ *word, then* u *is classified with the empty word and* v *is classified with the empty word, all under the same payload and provenance rows.*

Proof. Unpack the carrier of Definition 345.1. The accepted word u has a finite position spine s_u, a $\mathsf{Nat}^{\uparrow}$ length row ℓ_u, payload entries over A, and provenance through the fixed A, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Monoid}^{\uparrow}$ packet. The word v has the analogous rows s_v and ℓ_v. The concatenation ledger records the output position spine as the displayed $\mathsf{List}^{\uparrow}$ append of s_u and s_v, and its length row as the displayed $\mathsf{Nat}^{\uparrow}$ addition row $\ell_u + \ell_v$.

The hypothesis says that this concatenation output is classified with the empty word. By the classifier clause in Definition 345.1, its length row is therefore classified with the $\mathsf{Nat}^{\uparrow}$ zero row, and its position spine is classified with the empty $\mathsf{List}^{\uparrow}$ spine. The ledger normal form of Definition 345.5 leaves no hidden word evaluator: in the concatenation case, these two rows are exactly the append spine and the length-addition row just displayed.

Apply empty-result inversion for the finite append surface recorded in Definition 12.2, equivalently the contrapositive form of Definition 4.11, to the displayed append spine $s_u \cdot s_v$ classified with the empty spine. Both factors are classified with the empty spine. The same inversion applied to the $\mathsf{Nat}^{\uparrow}$ length-addition row identifies both ℓ_u and ℓ_v with the zero length row.

There are now no remaining payload positions in either factor: an empty $\mathsf{List}^{\uparrow}$ spine has no displayed position at which a payload comparison can be stored, and the zero $\mathsf{Nat}^{\uparrow}$ row agrees with that empty presentation. The Pkg provenance has not changed, since the concatenation row in Definition 345.1 uses the same payload source, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Monoid}^{\uparrow}$ packet for the two inputs and the result. Thus the classifier clauses for u against the empty word and for v against the empty word are exactly the empty spine comparison, the zero length comparison, the vacuous componentwise payload comparison, and the same continuation provenance. Therefore both factors are classified with the empty $\mathsf{FreeMonoid}^{\uparrow}$ word under the original setup. □

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier empty concat inversion`

Theorem 345.8 (FreeMonoid singleton concatenation inversion)**.** *Fix one payload source row $A : \mathsf{BHist} \to \mathsf{Prop}$ and one payload classifier $\sim_A$. Let u and v be accepted $\mathsf{FreeMonoid}^{\uparrow}$ words for this same payload, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Monoid}^{\uparrow}$ setup, and let $u \cdot v$ be their displayed concatenation word. If $u \cdot v$ is classified with the singleton $\mathsf{FreeMonoid}^{\uparrow}$ word carrying payload row a, then exactly one factor is classified with the empty word and the other factor is classified with the singleton word carrying a, all under the same $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{Monoid}^{\uparrow}$, hsame, Cont, and Pkg provenance rows.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier singleton concat inversion`

Proof. Unpack the carrier of Definition 345.1. The two accepted factors have finite position spines s_u and s_v, length rows ℓ_u and ℓ_v, componentwise payload rows over A, and the same displayed provenance packet. Their concatenation ledger records the output spine as the $\mathsf{List}^{\uparrow}$ append of s_u and s_v and the output length as the $\mathsf{Nat}^{\uparrow}$ addition row $\ell_u + \ell_v$.

The singleton-output hypothesis identifies that same ledger with the displayed one-position spine and the $\mathsf{Nat}^{\uparrow}$ successor-of-zero length row. By the ledger normal form of Definition 345.5, the concatenation case has no further evaluator: the only possible source of that singleton row is the append spine and its paired length row.

Apply finite append singleton inversion to the displayed $\mathsf{List}^{\uparrow}$ spine $s_u \cdot s_v$. There are two cases. In the left-empty case, s_u is the empty spine and s_v is the singleton spine carrying the unique displayed payload position. In the right-empty case, s_u is that singleton spine and s_v is the empty spine. The corresponding $\mathsf{Nat}^{\uparrow}$ length row is inverted in the same case split: the empty factor has zero length, and the singleton factor has the one-position length row.

It remains to transport the payload row. In each case the componentwise classifier in Definition 345.1 has exactly one displayed position on the singleton side and no displayed position on

the empty side. Thus the unique payload comparison for a belongs to the singleton factor, while the empty factor has the vacuous payload comparison.

The Pkg and Cont rows are unchanged, because the concatenation clause of Definition 345.1 uses the same payload source, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Monoid}^{\uparrow}$ packet for both inputs and the result. Repacking the classifier clauses gives the two stated alternatives, and the finite spine inversion makes them disjoint: the unique singleton position cannot lie in both factors. □

Theorem 345.9 (FreeMonoid ListUp Cont concrete instance)**.** *The* $\mathsf{FreeMonoid}^{\uparrow}$ *word carrier of Definition 345.1, with the empty word as unit and certified concatenation read through the* $\mathsf{List}^{\uparrow}$ *spine and displayed* Cont *routes, forms a concrete* BHist*-grounded* $\mathsf{Monoid}^{\uparrow}$ *instance. The left and right unit laws are the empty-word unit surface of Definition 345.2; associativity is the certified concatenation associativity of Definition 345.3; and carrier and classifier stability are supplied by the existing* $\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$ *obligation surface over* hsame*,* Cont*,* Pkg*,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*, and* $\mathsf{Monoid}^{\uparrow}$ *rows.*

This theorem is the sibling lattice link to chapter 40: the finite word carrier supplies a concrete $\mathsf{Monoid}^{\uparrow}$ *instance by using the* $\mathsf{List}^{\uparrow}$ *spine, the empty word, certified concatenation, and displayed* Cont *routes rather than an abstract monoid carrier detached from BEDC histories.*

Lean4 ✓ `BEDC.Derived.FreeMonoidUp.FreeMonoidWordCarrier list cont concrete instance`

Proof. Read a word carrier as its finite $\mathsf{List}^{\uparrow}$ spine, length row, componentwise payload rows, continuation routes, and package provenance. The empty word is the displayed empty spine with zero length, so Definition 345.2 gives both unit laws through the same BHist carrier rows.

Concatenation is the certified append ledger on the $\mathsf{List}^{\uparrow}$ spine together with the corresponding length and payload ledgers. Applying Definition 345.3 identifies the two triple-concatenation readbacks by the displayed hsame comparisons and the same Cont routes.

Finally use the $\mathsf{NameCert}_{\mathsf{FreeMonoid}^{\uparrow}}$ obligation surface. It is the carrier and classifier stability statement for these concrete rows, so the resulting $\mathsf{Monoid}^{\uparrow}$ instance is grounded in the listed BHist data rather than in abstract carrier or classifier equivalence parameters. □

Chapter 346

A Concrete Naming Certificate for $\mathsf{BitVector}^{\uparrow}$

The $\mathsf{BitVector}^{\uparrow}$ interface names fixed-length bit strings as finite BEDC data rather than as host-level binary strings. Knuth, *The Art of Computer Programming*, Vol. 4A, treats fixed-length bit strings as finite combinatorial objects; the BEDC packet below keeps that reading at the BHist level by using $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, and $\mathsf{Nat}^{\uparrow}$ rows with explicit length and provenance ledgers.

The fixed-length source consumes the sibling chapters chapter 32, chapter 36, and chapter 28. $\mathsf{Bool}^{\uparrow}$ supplies the visible bit rows, $\mathsf{List}^{\uparrow}$ supplies the spine and component classifier route, and $\mathsf{Nat}^{\uparrow}$ supplies the unary width row that fixes the public length ledger.

Definition 346.1 (BitVector BHist source)**.** *A* $\mathsf{BitVector}^{\uparrow}$ *source packet is a finite* BHist *record*

$$B = (n, s, l, p)$$

with the following visible coordinates:

1. *n is a unary* $\mathsf{Nat}^{\uparrow}$ *length row;*
2. *s is a* $\mathsf{List}^{\uparrow}$ *spine whose entries are* $\mathsf{Bool}^{\uparrow}$ *histories and whose displayed list length is transported from n;*
3. *l is the length ledger recording that every public bit read of s lies at an index below n and that no row beyond the displayed length is read;*
4. *p is the* Pkg *provenance naming the consumed* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, hsame, *and* Cont *certificate rows.*

The carrier predicate is $\mathsf{BitVectorSource}(n, s, l, p)$*. The classifier on accepted packets compares the unary length rows by* hsame*, compares the list spines by the* $\mathsf{List}^{\uparrow}$ *classifier, compares each visible bit by the* $\mathsf{Bool}^{\uparrow}$ *classifier, and requires the same* Cont *routes and* Pkg *provenance. No host bit-string equality, machine word, numeric binary encoding, or hidden padding convention is exported.*

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorTasteGate single carrier alignment`

Theorem 346.2 (BitVector carrier stability)**.** *Let $B = (n, s, l, p)$ be an accepted* $\mathsf{BitVector}^{\uparrow}$ *source packet. If the unary length row, the list-of-bool spine, the length ledger, and the provenance row are transported by displayed* hsame *along the same* Cont *routes named by p, then the transported packet $B' = (n', s', l', p')$ is again an accepted* $\mathsf{BitVector}^{\uparrow}$ *source packet.*

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorBHistSource carrier stability`
Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSourcePacket carrier stability`

Proof. Project the four coordinates of Definition 346.1. The $\mathsf{Nat}^{\uparrow}$ length row transports first, so the displayed target length is fixed before any bit read is considered.

Transport the $\mathsf{List}^{\uparrow}$ spine along that length row. Each visible component of the spine is a $\mathsf{Bool}^{\uparrow}$ history, so the component reads transport by the componentwise $\mathsf{Bool}^{\uparrow}$ classifier and the displayed hsame rows.

Finally transport the length ledger and Pkg provenance through the same Cont routes. The ledger still permits exactly the positions below the transported length and hides every position beyond it, so the transported packet is accepted. □

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorPacket carrier transport`
Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorCarrier hsame stability`
Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSource carrier stability`

Theorem 346.3 (BitVector classifier laws)**.** *The* $\mathsf{BitVector}^{\uparrow}$ *classifier is reflexive, symmetric, and transitive on accepted packets by componentwise use of the* $\mathsf{Nat}^{\uparrow}$ *length classifier, the* $\mathsf{List}^{\uparrow}$ *spine classifier, and the* $\mathsf{Bool}^{\uparrow}$ *entry classifier.*

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSourceClassifier laws`

Proof. For reflexivity, take the reflexive hsame row on the displayed unary length and the reflexive $\mathsf{List}^{\uparrow}$ comparison of the list spine. Each entry read is a $\mathsf{Bool}^{\uparrow}$ row and hence compares with itself by the boolean classifier.

For symmetry, reverse the displayed length comparison, then reverse the $\mathsf{List}^{\uparrow}$ spine comparison and every visible $\mathsf{Bool}^{\uparrow}$ entry comparison. The same ledger and provenance rows are read in the opposite order.

For transitivity, compose the two displayed length comparisons, compose the two list-spine comparisons, and compose the entrywise boolean comparisons at each transported index. The length ledger keeps the index set fixed under the transport, so no hidden position enters the composite classifier. □

Theorem 346.4 (BitVector ledger coverage)**.** *Every public read of an accepted* $\mathsf{BitVector}^{\uparrow}$ *packet factors through the finite ledger* (n, s, l, p)*. The packet exposes exactly the unary length row, the list-of-bool spine, the length exactness ledger, the componentwise* $\mathsf{Bool}^{\uparrow}$ *classifier rows, the* Cont *routes, and the* Pkg *provenance.*

Consequently the packet exports no host binary-string primitive, no numeric interpretation of the bits, no padding policy, and no machine-word overflow rule.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorFiniteLedger ledger coverage`

Proof. Start from the carrier definition. Its tuple lists exactly four coordinates, and each coordinate is a finite row over the existing BEDC kernel and finite data certificates.

A length-facing consumer reads n. A bit-facing consumer reads s only through the positions admitted by l. A transport-facing consumer reads the componentwise $\mathsf{Bool}^{\uparrow}$ and $\mathsf{List}^{\uparrow}$ classifier rows together with the displayed Cont routes and provenance named by p.

No other coordinate is present in the packet. Therefore every public consumer projection is one of the displayed rows or a projection through those route and provenance rows. □

Theorem 346.5 (BitVector NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{BitVector}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: the empty vector is carried by the zero* $\mathsf{Nat}^{\uparrow}$ *length row, the empty* $\mathsf{List}^{\uparrow}$ *boolean spine, the empty length ledger, and the corresponding* Pkg *provenance;*
2. *classifier laws: reflexivity, symmetry, and transitivity are inherited componentwise from the length, list, and boolean classifiers of Definition 346.3;*
3. *length-ledger exactness: the public bit positions are exactly the positions below the displayed unary length row;*
4. *transport under* hsame*: the carrier stability of Definition 346.2 repacks every transported length, spine, ledger, and provenance row as another accepted packet;*
5. *downstream finite-data consumption: list, product, matrix-index, and error-code chapters may read only the displayed finite bit spine, length row, componentwise classifier rows, continuation routes, and provenance ledger.*

These rows are the complete seed obligation for the fixed-length bit-vector name.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSourcePacket namecert obligation surface`

Proof. For carrier habitation, choose the zero unary length row and the empty $\mathsf{List}^{\uparrow}$ spine of $\mathsf{Bool}^{\uparrow}$ entries. The length ledger has no public bit position to expose, and the provenance row records only the consumed finite data certificates.

For the classifier laws, apply Definition 346.3. The classifier is built from the displayed length comparison, list-spine comparison, and entrywise boolean comparisons, so the three equivalence laws are inherited componentwise.

For length-ledger exactness, unfold the carrier. A public bit read must be a read of the list spine at an index admitted by l, and l admits exactly the indices below n.

For transport, apply Definition 346.2. The same hsame and Cont routes transport the length row, the boolean spine, the ledger, and the provenance without adding a hidden binary-string comparison.

For downstream use, every listed consumer receives only the rows displayed in Definition 346.4. Thus a list, product, matrix-index, or error-code construction can consume fixed-length bit data without treating bit strings as host primitives. □

Theorem 346.6 (BitVector finite-data anchor)**.** *The* $\mathsf{BitVector}^{\uparrow}$ *source packet is a finite-data anchor between* $\mathsf{List}^{\uparrow}$ *and later finite algebraic encodings. It can be consumed as a length-indexed boolean list with explicit* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Bool}^{\uparrow}$*,* hsame*,* Cont*, and* Pkg *rows, and it supplies no additional arithmetic, hashing, coding, or matrix operation.*

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSourcePacket finite data anchor`

Proof. Read the packet through Definition 346.1. The only payload row is a $\mathsf{List}^{\uparrow}$ spine of $\mathsf{Bool}^{\uparrow}$ entries, and the only shape row is the unary $\mathsf{Nat}^{\uparrow}$ length with its ledger.

Apply Definition 346.4. It identifies every public consumer route with the finite length, boolean spine, classifier rows, continuations, and provenance.

The exclusions follow by projection: the packet has no coordinate for a numeric interpretation, hash evaluation, error-correction metric, matrix indexing operation, or host machine word. Those later chapters may consume the finite bit-vector source, but they must add their own operation rows. □

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorFiniteLedger finite data anchor`

Theorem 346.7 (BitVector public finite-algebra export)**.** *Every downstream finite algebraic encoding consuming* $\mathsf{BitVector}^{\uparrow}$ *receives only the unary* $\mathsf{Nat}^{\uparrow}$ *length row, the* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Bool}^{\uparrow}$ *entries, the length ledger, componentwise classifier rows,* hsame *transports,* Cont *routes, and* Pkg *provenance from Definition 346.1. It receives no host bit-string equality, numeric binary primitive, padding policy, hash evaluator, or machine-word overflow rule.*

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorFiniteLedger public finite algebra export`

Proof. The source of every public read is Definition 346.1. Carrier stability is supplied by Definition 346.2, and the componentwise classifier laws are supplied by Definition 346.3.

Apply Definition 346.4 to identify the visible length ledger and its admitted list positions. Apply Definition 346.5 to package the carrier, classifier, stability, ledger, transport, and provenance rows as the public certificate surface.

Finally use Definition 346.6. It states that finite algebraic consumers may read the fixed-length boolean list surface but must add their own arithmetic, coding, hash, matrix, or machine-word operation rows.

Thus the public export is exactly the displayed finite-data packet. Since the packet has no coordinate for host bit-string equality, binary arithmetic, padding, hashing, or overflow, none of those structures can be exported. □

Theorem 346.8 (BitVector scoped dependency binding)**.** *The* $\mathsf{BitVector}^{\uparrow}$ *source packet, carrier stability, classifier laws, ledger coverage,* NameCert *obligation surface, and finite-data anchor are scoped exactly over* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

The scoped packet exposes no host bit-string equality, numeric binary interpretation, padding convention, machine-word overflow, hashing semantics, or error-correction metric.

Proof. The source rows are the rows of Definition 346.1. Carrier stability, classifier laws, and ledger coverage are fixed by Definition 346.2, Definition 346.3, and Definition 346.4.

The accepted certificate surface is Definition 346.5, and the downstream finite-data role is Definition 346.6. Together these results list all consumer projections: length, boolean spine, classifier rows, transport rows, finite ledger rows, package provenance, and certificate registration.

Every projection is one of the displayed BEDC rows over $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert. There is no coordinate for host bit-string equality, binary numeric interpretation, padding, overflow, hashing, or an error-correction metric, so none can be exported by the scoped package. □

Theorem 346.9 (BitVector Boolean-list width exhaustion)**.** *An accepted* $\mathsf{BitVector}^{\uparrow}$ *packet is completely exhausted by its unary* $\mathsf{Nat}^{\uparrow}$ *width row, its* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Bool}^{\uparrow}$ *histories, component classifier rows, length ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence. Conversely, those displayed finite-data rows supply the abstract fixed-width* $\mathsf{BitVector}^{\uparrow}$ *interface.*

The interface has no extra coordinate for host bit-string equality, numeric binary encoding, padding convention, hashing semantics, matrix indexing, overflow, or error-correction metrics.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorFiniteLedger semantic name certificate`

Proof. Start from the source carrier of Definition 346.1. It exposes only a unary width row and a list spine of boolean component histories.

Apply Definition 346.3 to read the component classifier rows and Definition 346.4 to identify the length ledger. These two results account for the fixed-width and component readback coordinates.

Use Definition 346.5 for the displayed hsame, Cont, Pkg, and local NameCert rows, and apply Definition 346.6 to expose the finite-data consumer surface.

Finally apply Definition 346.8. The scoped packet contains exactly the listed $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows, so the abstract fixed-width interface is supplied by those rows and no external bit-string or arithmetic coordinate remains. □

Theorem 346.10 (BitVector standard bridge boundary)**.** *The public* $\mathsf{BitVector}^{\uparrow}$ *packet interprets as a standard finite boolean vector exactly through the unary* $\mathsf{Nat}^{\uparrow}$ *length row, the* $\mathsf{List}^{\uparrow}$ *spine, the* $\mathsf{Bool}^{\uparrow}$ *component rows, the component classifier, the length ledger,* hsame *transport, and* Pkg *provenance already listed in the public export and scoped dependency theorems.*

The bridge boundary has no coordinate for numeric binary encodings, hashing, matrix indexing, overflow, or error-correction metrics.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorUp StdBridge`

Proof. Read the public packet through Definition 346.7. It exposes only the unary length, boolean list spine, component classifier rows, length ledger, hsame transports, Cont routes, and package provenance.

Apply Definition 346.8. This fixes the whole dependency surface over $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, so the standard finite boolean-vector reading has no additional field to inspect.

The exclusions follow from the same projection. Numeric binary encodings, hashing, matrix indexing, overflow, and error-correction metrics are absent from both cited surfaces, so none belongs to the bridge boundary. □

Theorem 346.11 (BitVector fixed-width consumer completeness)**.** *Every finite-data consumer of* $\mathsf{BitVector}^{\uparrow}$ *is completely determined by the unary* $\mathsf{Nat}^{\uparrow}$ *width row,* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Bool}^{\uparrow}$ *histories, component classifier rows, length ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

The fixed-width surface excludes host bit-string equality, numeric binary primitives, padding, hashing, matrix indexing, overflow, and error-correction metrics.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorSource fixed width consumer completeness`

Proof. First apply Definition 346.7. It exposes the unary width row, boolean list spine, component classifier rows, length ledger, transport, continuation, package, and local name evidence as the public finite-data readback surface.

Next use Definition 346.8. This binds the same rows over $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, so the consumer has no separate host bit-string or arithmetic coordinate to inspect.

Apply Definition 346.9. It proves that the abstract fixed-width interface is exhausted by exactly those rows and that padding, hashing, matrix indexing, overflow, and error-correction metrics are not exported fields.

Finally Definition 346.10 identifies the same surface with the standard finite boolean-vector boundary. Therefore every finite-data consumer read is determined by the displayed fixed-width BEDC rows, with numeric binary primitives and host equality still excluded. □

Theorem 346.12 (BitVector fixed-length consumer determinacy)**.** *Any downstream consumer that factors through the* $\mathsf{BitVector}^{\uparrow}$ *public export, in particular a* $\mathsf{Trie}^{\uparrow}$ *key read, is determined by the unary* $\mathsf{Nat}^{\uparrow}$ *length row, the* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Bool}^{\uparrow}$ *entries, the length ledger, componentwise classifier rows,* hsame *transports,* Cont *routes, and* Pkg *provenance.*

No padding, overflow, hash, or host bit-string equality can alter the read.

Lean4 ✓ `BEDC.Derived.BitVectorUp.BitVectorBoolSpineLedger fixed length consumer determinacy`

Proof. Apply Definition 346.4. It fixes the displayed positions of the finite boolean list by the unary length row and the length ledger.

Next use Definition 346.7. The public export exposes exactly the $\mathsf{Nat}^{\uparrow}$ length, $\mathsf{List}^{\uparrow}$ spine, $\mathsf{Bool}^{\uparrow}$ component rows, classifier rows, transport, continuation, and provenance data available to downstream finite-data consumers.

Finally apply Definition 346.10. The standard finite boolean-vector boundary reads the same public surface, so a $\mathsf{Trie}^{\uparrow}$ key read or any other consumer through the export has no coordinate from which padding, overflow, hashing, or host bit-string equality could change the result. □

Theorem 346.13 (BitVector mature Trie key consumer example)**.** *A* $\mathsf{Trie}^{\uparrow}$ *key read that factors through a* $\mathsf{BitVector}^{\uparrow}$ *public export is determined by the unary* $\mathsf{Nat}^{\uparrow}$ *width row, the* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Bool}^{\uparrow}$ *histories, component classifier rows, the length ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

The consumer receives no host bit-string equality, numeric binary encoding, padding rule, overflow convention, hashing coordinate, or matrix-indexing operation.

Proof. Apply Definition 346.4. It exposes only the finite positions named by the unary width row and the length ledger.

Use Definition 346.7 to read the exported surface. The available data are the $\mathsf{List}^{\uparrow}$ spine of $\mathsf{Bool}^{\uparrow}$ histories, component classifier rows, transport, continuation, provenance, and local certificate evidence.

Next apply Definition 346.9 and Definition 346.10. These identify the same fixed-length finite boolean-vector surface without adding binary numerals, padding, overflow, hashing, or matrix indexing.

Thus a $\mathsf{Trie}^{\uparrow}$ key read is one downstream consumer of that finite surface. Once the read factors through the $\mathsf{BitVector}^{\uparrow}$ export, every observable key coordinate is already fixed by the displayed rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{BitVector}^{\uparrow}}$.

Constructive story: A bit-vector packet is generated by a unary $\mathsf{Nat}^{\uparrow}$ length row, a $\mathsf{List}^{\uparrow}$ spine of $\mathsf{Bool}^{\uparrow}$ histories, a length ledger exposing exactly the displayed positions, and Pkg provenance for the finite-data dependencies.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BitVector}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 346.7, Definition 346.8, Definition 346.10, Definition 346.11, Definition 346.12, and Definition 346.13 identify the public fixed-length $\mathsf{Bool}^{\uparrow}/\mathsf{List}^{\uparrow}/\mathsf{Nat}^{\uparrow}$ packet with the standard finite boolean-vector boundary and give the mature consumer-completeness surface, including the Trie key consumer example, component classifier rows, length ledger, hsame transport, Cont routes, Pkg provenance, and NameCert rows.

Chapter 347

A Concrete Naming Certificate for $\mathsf{RealLimit}^{\uparrow}$

The $\mathsf{RealLimit}^{\uparrow}$ interface names the finite saturated frontier where a scheduled regular rational stream can be read as a real-facing seal source. Following Bishop–Bridges constructive analysis, convergence is carried by explicit Cauchy and modulus data, not by a choice-selected limiting point. The packet below therefore records only certified stream windows, dyadic tolerance rows, regular-sequence reads, and the visible $\mathsf{Real}^{\uparrow}$ endpoint row available to downstream consumers.

The sibling dependency route is finite throughout: chapter 126 supplies the schedule surface, chapter 301 supplies the regular rational source, chapter 291 supplies the dyadic tolerance surface, and chapter 38 supplies the real-seal endpoint consumed by $\mathsf{RealLimit}^{\uparrow}$. These four surfaces are the rows later read as S, Q, D, E in the carrier packet; the limit interface only binds their displayed route through hsame, Cont, Pkg, and NameCert.

Definition 347.1 (RealLimit BHist carrier)**.** *A* $\mathsf{RealLimit}^{\uparrow}$ *packet is a finite* BHist *source row*

$$R = (S, Q, E, D, H, C, P, N)$$

with the following visible coordinates:

1. *S is a* $\mathsf{StreamName}^{\uparrow}$ *schedule selecting the finite windows through which the approximation stream is inspected;*
2. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream read on those scheduled windows;*
3. *E is the proposed* $\mathsf{Real}^{\uparrow}$ *seal endpoint consumed by real-facing interfaces;*
4. *D is the displayed family of* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance windows used for finite error reads;*
5. *H records the componentwise* hsame *rows for stream schedule, regular-sequence source, seal endpoint, and dyadic tolerance rows;*
6. *C records the visible* Cont *routes through which a consumer reaches the selected windows and their common refinements;*
7. *P is the* Pkg *provenance row naming the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and L0–L5 kernel dependencies;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger row.*

The carrier predicate is $\mathsf{RealLimitPacket}(S, Q, E, D, H, C, P, N)$*. Its classifier compares two accepted packets by passing to common finite refinements of the stream schedules and reading the same* $\mathsf{RegSeqRat}^{\uparrow}$ *tolerance row there. All agreement is then transported componentwise through the displayed* hsame *rows and the same* Cont *routes; no completed real equality or quotient of streams is used.*

Theorem 347.2 (RealLimit NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *surface consists exactly of five rows:*

1. *carrier: the finite packet of Definition 347.1 with its schedule, source stream, seal endpoint, dyadic tolerance windows, transport, continuation, provenance, and local ledger;*
2. *classifier: common finite schedule refinements followed by the same* $\mathsf{RegSeqRat}^{\uparrow}$ *tolerance read;*
3. *stability: componentwise* hsame *transport and visible* Cont *refinement preserve the selected stream window and tolerance comparison;*
4. *exactness/readback: every* $\mathsf{Real}^{\uparrow}$ *read factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance window used by the schedule;*
5. *ledger: the* Pkg *and* NameCert *rows expose only the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and L0–L5 kernel dependencies.*

This is an obligation surface for finite constructive limit names; it is not a claim of real completeness.

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket namecert obligation surface`

Proof. Project the carrier of Definition 347.1. The displayed coordinates already list the schedule, source stream, proposed seal endpoint, dyadic tolerance rows, transport witnesses, continuation routes, provenance, and local ledger.

For the classifier row, compare two packets only after selecting a common finite refinement of their visible schedules. The $\mathsf{RegSeqRat}^{\uparrow}$ source stream is read at that refined window, and the dyadic tolerance row is the one named by the same packet coordinate.

Stability follows by transporting each visible coordinate through its stored hsame row and reading refinements only through the displayed Cont routes. The readback row is exact because the sole $\mathsf{Real}^{\uparrow}$ coordinate is the seal endpoint E, and E is reached from the regular-sequence and dyadic tolerance rows already present in the packet.

The ledger row is exhausted by P and N. Since the carrier has no coordinate for a completed real, no quotient stream, and no choice-selected limit, those objects cannot be exported by the local certificate. □

Theorem 347.3 (RealLimit RegSeqRat stream-name handoff)**.** *Every accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet hands a* $\mathsf{StreamName}^{\uparrow}$ *schedule to a* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream before any* $\mathsf{Real}^{\uparrow}$ *seal read is available. More precisely, a real-facing consumer may read the seal endpoint only through the scheduled regular-sequence tolerance window, its* $\mathsf{DyadicRatCore}^{\uparrow}$ *error row, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

The handoff exports no $\mathsf{Real}^{\uparrow}$ *completeness theorem, no equality of quotient streams, and no choice-selected limiting object.*

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket scheduled handoff transport`

Proof. Read the accepted packet $R = (S, Q, E, D, H, C, P, N)$ through Definition 347.1. The coordinate S selects the finite observation windows, while Q supplies the regular rational stream read on those windows.

The dyadic tolerance coordinate D records the finite error window used for the same read. A consumer reaches it only through the continuation routes in C, and endpoint replacement is constrained by the componentwise transport rows in H.

The proposed real-facing endpoint is the single coordinate E. Because E is packaged together with S, Q, D, H, C, P, and N, any read of E has the scheduled regular-sequence handoff as its visible source. There is no remaining coordinate from which a completeness principle, stream quotient, or selected limiting value could be obtained. □

Theorem 347.4 (RealLimit common-refinement classifier)**.** *For accepted* $\mathsf{RealLimit}^{\uparrow}$ *packets*

$$R = (S, Q, E, D, H, C, P, N) \quad \textit{and} \quad R' = (S', Q', E', D', H', C', P', N'),$$

the local classifier can place R and R' in the same real-limit name only through a displayed common finite $\mathsf{StreamName}^{\uparrow}$ *schedule refinement. On that common refinement it reads the same* $\mathsf{RegSeqRat}^{\uparrow}$ *tolerance row, the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *error rows, and the componentwise* hsame*,* Cont*,* Pkg*, and* NameCert *rows of the two packets. The classifier has no row for completed real equality, quotient-stream equality, or a selected limit.*

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket common refinement certificate`

Proof. Project both packets through Definition 347.1. The schedule coordinates S, S' are the only sources of observation windows, and the source-stream coordinates Q, Q' are the only regular rational rows available at those windows.

Refine the displayed schedules to a common finite window. On that window the classifier reads the $\mathsf{RegSeqRat}^{\uparrow}$ tolerance row named by the source stream coordinates and the $\mathsf{DyadicRatCore}^{\uparrow}$ error rows named by D, D'.

The remaining comparison data is componentwise. Transport is supplied by H, H', continuation routes by C, C', package provenance by P, P', and local ledger evidence by N, N'. Repacking these displayed rows gives the classifier, and the carrier contains no coordinate from which completed real equality, quotient-stream equality, or a selected limit could be read. □

Theorem 347.5 (RealLimit transport stability boundary)**.** *For an accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet,* hsame *transport and* Cont *refinement preserve the selected* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream, the* $\mathsf{Real}^{\uparrow}$ *seal endpoint, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance windows, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger. Every transported row remains a displayed row of the finite packet surface.*

Proof. Read the packet $R = (S, Q, E, D, H, C, P, N)$ from Definition 347.1. The coordinates H and C are exactly the stored componentwise transport and refinement routes for the schedule, source stream, seal endpoint, dyadic tolerances, package provenance, and local ledger.

Apply Definition 347.4 to identify the common finite schedule surface on which a transported comparison is allowed to take place. The classifier exposes only the displayed schedule, source, tolerance, transport, continuation, provenance, and certificate rows.

Transporting along H and refining along C therefore keeps every consumer row inside the same finite packet surface. Since no other carrier coordinate is available, the seal endpoint, dyadic tolerance windows, provenance, and ledger remain displayed rows rather than hidden real-completion data. □

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket transport stability boundary`

Theorem 347.6 (RealLimit readback ledger exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing read from an accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet factors through the scheduled* $\mathsf{RegSeqRat}^{\uparrow}$ *source, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the displayed* hsame *and* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger. The readback surface excludes* $\mathsf{Real}^{\uparrow}$ *completeness, quotient-stream equality, and selected limiting objects.*

Proof. Start with Definition 347.3. It routes a real-facing read through the finite $\mathsf{StreamName}^{\uparrow}$ schedule, the $\mathsf{RegSeqRat}^{\uparrow}$ source stream, the dyadic tolerance row, transport, continuation, package provenance, and local certificate.

Use Definition 347.4 for paired readbacks. It shows that compatible packet reads share only a displayed common finite schedule refinement and the same scheduled tolerance surface.

Use Definition 347.5 for replacement of rows along hsame and Cont. The transported read remains on the visible packet coordinates, so the ledger is exhausted by S, Q, D, H, C, P, N together with the seal endpoint E.

No coordinate of the carrier stores real completeness, quotient-stream equality, or a selected limiting object. Those objects therefore cannot appear in the $\mathsf{Real}^{\uparrow}$-facing readback ledger. □

Theorem 347.7 (RealLimit scoped window boundary)**.** *The carrier, scheduled* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, common-refinement classifier, transport-stability boundary, and readback ledger exhaustion assemble a scoped finite* $\mathsf{RealLimit}^{\uparrow}$ *packet over* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

The packet is finite and real-facing. It excludes $\mathsf{Real}^{\uparrow}$ *completeness, quotient-stream equality, selected limits, and choice data.*

Proof. Project the accepted packet as $R = (S, Q, E, D, H, C, P, N)$ from Definition 347.1. The coordinates are the schedule, regular rational source, real seal endpoint, dyadic tolerance rows, componentwise transport, continuation routes, package provenance, and local name-certificate ledger.

Apply Definition 347.3 before any seal read. This routes the real-facing coordinate E through the finite $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{RegSeqRat}^{\uparrow}$ source, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row, and the displayed H, C, P, N rows.

For paired packets, use Definition 347.4. Common finite refinements are the only classifier surface available to compare scheduled source reads. For replacement of rows, use Definition 347.5; the transported packet remains on the same displayed finite coordinates.

Finally close by Definition 347.6. The readback ledger is exhausted by S, Q, E, D, H, C, P, N, so the scoped boundary adds no completeness principle, quotient-stream equality, selected limit, or choice object beyond the finite packet. □

Theorem 347.8 (RealLimit classifier obligation)**.** *For accepted* $\mathsf{RealLimit}^{\uparrow}$ *packets* $R = (S, Q, E, D, H, C, P, N)$ *and* $R' = (S', Q', E', D', H', C', P', N')$*, the local classifier may identify their real-limit names only through common finite* $\mathsf{StreamName}^{\uparrow}$ *schedule refinements, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *tolerance read on those refinements, transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *windows, and the visible* hsame *and* Cont *routes carried by the two packets. It has no classifier row for completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient-stream equality, or a selected limit.*

Proof. Project the two carriers using Definition 347.1. The schedule coordinates S and S' are the only rows that choose finite observation windows, and the regular-sequence coordinates Q and Q' are the only rows read at those windows.

Apply Definition 347.3. The handoff forces each real-facing read to pass through the scheduled $\mathsf{RegSeqRat}^{\uparrow}$ source stream and its $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row.

Thus a classifier comparison can only pass to common finite schedule refinements, compare the same tolerance read there, and transport the dyadic windows through H, H' and C, C'. Since the carrier has no additional row for completed real equality, quotient-stream equality, or a selected limit, no such row can enter the classifier. □

Theorem 347.9 (RealLimit stability obligation)**.** *Componentwise* hsame *transport and visible* Cont *refinement preserve the selected* $\mathsf{StreamName}^{\uparrow}$ *schedule, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream, the* $\mathsf{Real}^{\uparrow}$ *seal endpoint, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *row of an accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet.*

Proof. Project $R = (S, Q, E, D, H, C, P, N)$ from Definition 347.1. The coordinates H and C are exactly the stored transport and refinement witnesses for the visible rows of the packet.

Use Definition 347.3 to identify the consumer path through S, Q, D, H, C, P, and N before the seal endpoint E is read. Any refinement of the consumer path is therefore a refinement of these displayed rows.

The componentwise hsame rows preserve each named coordinate, while the Cont routes restrict refinements to the visible observation windows. Hence the selected schedule, source stream, seal endpoint, dyadic tolerance rows, package row, and local certificate row remain the same visible packet data. □

Theorem 347.10 (RealLimit readback obligation)**.** *Every* $\mathsf{Real}^{\uparrow}$ *read from an accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance window selected by its* $\mathsf{StreamName}^{\uparrow}$ *schedule. The readback cannot inspect a real-completeness principle, quotient-stream equality, or a selected limiting object.*

Proof. Project the packet $R = (S, Q, E, D, H, C, P, N)$. The endpoint coordinate E is the only real-facing seal row, and the schedule, source stream, and tolerance coordinates S, Q, and D are the finite data attached to that row.

Apply Definition 347.3. It routes every read of E through the scheduled regular rational stream, the displayed dyadic tolerance window, and the visible transport, continuation, package, and certificate rows.

No coordinate of Definition 347.1 stores completeness, quotient-stream equality, or a selected limit. Therefore the readback surface has no source from which any of those objects can be read. □

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket readback obligation`

Theorem 347.11 (RealLimit transported readback ledger stability)**.** *Let* $R = (S, Q, E, D, H, C, P, N)$ *and* $R' = (S', Q', E', D', H', C', P', N')$ *be accepted* $\mathsf{RealLimit}^{\uparrow}$ *packets. Suppose the displayed packet rows are related componentwise by* hsame *on the* $\mathsf{StreamName}^{\uparrow}$ *schedules* S, S'*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows* Q, Q'*, the* $\mathsf{Real}^{\uparrow}$ *endpoint rows* E, E'*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance windows* D, D'*, the* Pkg *provenance rows* P, P'*, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *rows* N, N'*, and suppose the visible schedule refinement routes are the same* Cont *routes carried by* C *and* C'*.*

Then every $\mathsf{Real}^{\uparrow}$*-facing readback ledger row of* R *transports to a* $\mathsf{Real}^{\uparrow}$*-facing readback ledger row of* R' *through those same* Cont *refinement routes. The transported ledger remains inside the finite seal surface given by the schedules, source rows, endpoint rows, tolerance windows, componentwise* hsame *rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It does not expose* $\mathsf{Real}^{\uparrow}$ *completeness, quotient-stream equality, or a selected limiting object.*

Proof. Start with Definition 347.3. Each read of the real-facing endpoint E is routed through the displayed $\mathsf{StreamName}^{\uparrow}$ schedule, $\mathsf{RegSeqRat}^{\uparrow}$ source, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance window, transport rows, continuation routes, package row, and local naming ledger before any consumer can observe the endpoint.

Next use Definition 347.5. The assumed componentwise hsame relations and shared Cont refinements replace the visible rows of R by the corresponding visible rows of R' without leaving the displayed finite carrier surface.

Finally apply Definition 347.10. The readback row that survives this transport still factors through the scheduled $\mathsf{RegSeqRat}^{\uparrow}$ source and $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance window. Since none of the transported coordinates stores completeness, quotient-stream equality, or a selected limit, the readback ledger cannot acquire any such row. □

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket transported readback ledger stability`

Theorem 347.12 (RealLimit ledger obligation)**.** *The* $\mathsf{RealLimit}^{\uparrow}$ *ledger exposes only* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *L0–L5 kernel rows,* Pkg, *and* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$. *It exposes no completed real, quotient stream, host equality, analytic convergence theorem, or selected limit.*

Proof. Project the provenance and local ledger coordinates P and N from Definition 347.1. By definition, P names the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and L0–L5 kernel dependencies, while N is the local $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ row.

Apply Definition 347.3. The handoff shows that the real-facing endpoint is reached only through the same finite schedule, regular-sequence, dyadic tolerance, transport, continuation, package, and certificate rows.

The ledger is therefore exhausted by the displayed package and certificate coordinates. Since no carrier coordinate names a completed real, quotient stream, host equality, analytic convergence theorem, or selected limit, the ledger cannot expose any of them. □

Theorem 347.13 (RealLimit scoped kernel interface)**.** *Every accepted* $\mathsf{RealLimit}^{\uparrow}$ *packet whose readback, classifier, stability, and ledger rows satisfy Definition 347.8, Definition 347.9, Definition 347.10, and Definition 347.12 has its real-facing seal read wholly scoped by the displayed* BHist *packet, componentwise* hsame *transport,* Cont *schedule refinements,* Pkg *provenance,* $\mathsf{NameCert}$ *ledger,* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *endpoint row.*

Within that scope the $\mathsf{Real}^{\uparrow}$ *endpoint is only a sealed consumer row reached through the handoff of Definition 347.3. The binding does not export a completed real, quotient stream, host equality, analytic convergence theorem, or selected limiting object.*

Proof. Project an accepted packet as $R = (S, Q, E, D, H, C, P, N)$ from Definition 347.1. The schedule, regular rational source, endpoint seal, dyadic tolerances, transport, continuation, package, and naming coordinates are the only rows available to the four obligations.

Apply Definition 347.3. It sends the real-facing endpoint E through the same S, Q, D, H, C, P, and N rows, so the downstream $\mathsf{Real}^{\uparrow}$ handoff has no wider surface than the displayed BEDC packet.

The classifier obligation reads only those coordinates; the stability obligation transports them by hsame and Cont; the readback obligation factors every endpoint read through the scheduled $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ rows; and the ledger obligation is exhausted by P and N.

Since no coordinate of the carrier stores a completed real, quotient stream, host equality, analytic convergence theorem, or selected limiting object, none of the four obligations can acquire such an object through the scoped kernel interface. □

Theorem 347.14 (RealLimit public real-window export)**.** *The carrier, classifier, transport, readback, ledger, and scoped kernel interface theorems assemble one public* $\mathsf{RealLimit}^{\uparrow}$ *consumer export over the same* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows, with the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance window and* $\mathsf{Real}^{\uparrow}$ *endpoint row kept inside that finite surface.*

This export exposes only the scheduled regular rational stream, dyadic tolerance windows, real-facing seal row, transport and continuation routes, package provenance, and local naming ledger. It exports no completed real, quotient stream equality, analytic convergence theorem, or selected limiting object.

Proof. Project the carrier rows from Definition 347.1. The schedule, regular rational source stream, real-facing seal, dyadic tolerance window, transport rows, continuation rows, package provenance, and local naming ledger are the available finite-window coordinates.

Apply Definition 347.3 to route each real-facing read through the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ rows.

Use Definition 347.6 to account for every consumer readback row. The ledger names the same BHist packet, hsame transports, Cont refinements, Pkg provenance, and $\mathsf{NameCert}$ row used by the scoped kernel.

Finally invoke Definition 347.13. It packages the classifier, transport, readback, and ledger obligations into the same finite BEDC surface, giving one public consumer export without adding any completed real, quotient stream equality, analytic convergence theorem, or selected limit. □

Theorem 347.15 (RealLimit standard finite seal bridge)**.** *The public real-window export, scheduled* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, scoped kernel interface, and readback ledger exhaustion determine a conservative standard finite-seal reading and readback for the displayed* $\mathsf{RealLimit}^{\uparrow}$ *packet.*

The readback recovers exactly the $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream,* $\mathsf{Real}^{\uparrow}$ *endpoint row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, componentwise* hsame*, visible* Cont*,* Pkg *provenance, and local* $\mathsf{NameCert}$ *ledger. It exports no* $\mathsf{Real}^{\uparrow}$ *completeness, quotient stream equality, selected limit object, or host completion principle.*

Proof. Apply Definition 347.3. This fixes the scheduled stream-name and regular rational source coordinates used by every finite seal read.

Next use Definition 347.6. It accounts for the $\mathsf{Real}^{\uparrow}$ endpoint row, dyadic tolerance rows, componentwise hsame transport, visible Cont routes, package provenance, and local naming ledger.

Apply Definition 347.13 to keep the classifier, transport, readback, and ledger obligations inside the displayed finite BEDC carrier.

Finally use Definition 347.14. The carrier coordinates have now been exhausted: the standard readback is precisely the listed finite-seal packet, and no row remains from which to export $\mathsf{Real}^{\uparrow}$ completeness, quotient stream equality, a selected limit object, or a host completion principle. □

Theorem 347.16 (RealLimit standard bridge boundary)**.** *The displayed* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*, and downstream* $\mathsf{Real}^{\uparrow}$ *finite-window rows determine the standard bridge boundary for a candidate* $\mathsf{RealLimit}^{\uparrow}$ *name. Every standard finite observation of such a candidate factors through Definition 347.14.*

The boundary introduces no quotient stream equality, selected limit object, or $\mathsf{Real}^{\uparrow}$ *completeness witness.*

Lean4 ✓ `BEDC.Derived.RealLimitUp.RealLimitPacket standard bridge boundary`

Proof. Start with the obligation surface of Definition 347.2. Its rows are the finite BHist carrier, componentwise hsame routes, Cont schedule refinements, package provenance, and local $\mathsf{NameCert}$ ledger.

Use Definition 347.3 to route the candidate stream observation through the displayed $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ rows. Then apply Definition 347.4 and Definition 347.5 to keep classifier and transport reads inside the same finite-window surface.

Next apply Definition 347.6. It accounts for the readback and ledger rows used by every finite consumer of the candidate name.

Finally use Definition 347.13 and Definition 347.14. These package the exhausted rows as the public real-window export, so every standard finite observation factors through that export. None of the cited rows contains a quotient stream equality, selected limit object, or $\mathsf{Real}^{\uparrow}$ completeness witness, hence the standard boundary cannot introduce one. □

Theorem 347.17 (RealLimit finite real-seal consumer completeness)**.** *Every finite consumer read of a displayed* $\mathsf{RealLimit}^{\uparrow}$ *packet factors through exactly the* $\mathsf{StreamName}^{\uparrow}$ *schedule row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source stream row, the* $\mathsf{Real}^{\uparrow}$ *endpoint row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, the componentwise* hsame *rows, the visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger. Conversely, those rows repack as the finite real-seal consumer surface.*

This consumer surface adds no $\mathsf{Real}^{\uparrow}$ *completeness theorem, quotient stream equality, selected limit object, or host completion principle beyond the standard bridge boundary.*

Proof. Use Definition 347.3 to identify the scheduled stream name and regular rational source stream that any finite consumer can inspect.

Apply Definition 347.6. This accounts for the $\mathsf{Real}^{\uparrow}$ endpoint row, dyadic tolerance rows, componentwise hsame transports, visible Cont routes, package provenance, and local naming ledger.

Next use Definition 347.14. It presents the same exhausted rows as the public real-window packet available to downstream finite consumers.

Finally apply Definition 347.16. The bridge boundary contributes no hidden completion, quotient, or selected-limit row, so the displayed rows are also sufficient in the reverse direction to repack the finite real-seal consumer surface. □

Theorem 347.18 (RealLimit finite-seal readback transport determinacy)**.** *Let p and p' be accepted* $\mathsf{RealLimit}^{\uparrow}$ *packets. Suppose the displayed rows connect their schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *stream,* $\mathsf{Real}^{\uparrow}$ *endpoint, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance coordinates by componentwise* hsame *transport. Suppose also that the readback rows are* $\mathsf{Cont}(\mathsf{endpoint}, \mathsf{tolerance}, \mathsf{readback})$ *and* $\mathsf{Cont}(\mathsf{endpoint}', \mathsf{tolerance}', \mathsf{readback}')$.

Then every finite real-seal consumer read through p transports to the corresponding read through p' on the same BEDC consumer surface: the scheduled $\mathsf{StreamName}^{\uparrow}$ *row,* $\mathsf{RegSeqRat}^{\uparrow}$ *stream row,* $\mathsf{Real}^{\uparrow}$ *endpoint row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, finite handoff row, visible* Cont *route, local readback row,* Pkg *provenance row, and* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger row. The determinacy claim does not assert* $\mathsf{Real}^{\uparrow}$ *completeness, quotient stream equality, a selected limit object, or host completion.*

Proof. Start with Definition 347.3. It places the consumer read on the displayed schedule and $\mathsf{RegSeqRat}^{\uparrow}$ source stream before any endpoint interpretation is used.

Apply Definition 347.5. The assumed componentwise hsame rows carry the schedule, stream, endpoint, and tolerance coordinates from p to p' while keeping the handoff and visible Cont route inside the same finite packet surface.

Use Definition 347.10. The two displayed readback rows are therefore read as the same local BEDC obligation row over the transported endpoint and tolerance coordinates, with the Pkg provenance and $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ ledger still visible.

Finally apply Definition 347.17. Since that surface is exactly the schedule, stream, endpoint, tolerance, handoff, route, ledger, readback, package, and name-certificate rows, the transported readback has no additional coordinate on which a second consumer interpretation could depend. The excluded completion, quotient, selected-limit, and host-completion principles are not present in any cited row. □

Theorem 347.19 (RealLimit stream-tail window normal form)**.** *For accepted* $\mathsf{RealLimit}^{\uparrow}$ *packets whose scheduled* $\mathsf{StreamName}^{\uparrow}$ *rows refine to the same displayed finite tail window, every* $\mathsf{Real}^{\uparrow}$*-facing readback factors through exactly the same* $\mathsf{RegSeqRat}^{\uparrow}$ *source row, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, the displayed* hsame *transports, the visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$ *ledger. The tail-window normal form is determined entirely by those finite rows.*

The normal form exports no completed real equality, quotient stream, selected limit, host completion witness, or choice data.

Proof. Project each accepted packet to the finite carrier of Definition 347.1. The projected rows are the scheduled stream-name coordinate, the regular rational source coordinate, the dyadic tolerance coordinates, componentwise hsame transport, visible Cont routes, package provenance, and the local naming ledger.

Apply Definition 347.4 to the two scheduled $\mathsf{StreamName}^{\uparrow}$ rows. The common finite tail window fixes the classifier surface on which the readback rows are compared, so later tail data cannot change the displayed source or tolerance coordinates.

Use Definition 347.6 and Definition 347.14. These identify every $\mathsf{Real}^{\uparrow}$-facing readback row with the same regular rational source row, dyadic tolerance rows, componentwise transports, continuation routes, package provenance, and naming ledger on the common window.

Finally invoke Definition 347.16. The boundary contains no coordinate for completed real equality, quotient stream formation, selected limits, host completion, or choice data. Carrier exhaustion therefore leaves exactly the stated finite tail-window normal form. □

Theorem 347.20 (RealLimit shifted-schedule readback boundary)**.** *Let P be a displayed* $\mathsf{RealLimit}^{\uparrow}$ *packet whose* $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{StreamName}^{\uparrow}$ *schedule is transported by a certified unary successor row or by a certified finite tail selector. Then every finite* $\mathsf{Real}^{\uparrow}$ *seal readback of the transported packet exposes the same displayed endpoint, readback ledger,* hsame *rows,* Cont *routes, and* Pkg *provenance rows as the original packet after schedule transport.*

The boundary exports only that finite schedule-transport surface. It does not export a completeness theorem, selected limit, quotient representative, or host-index equality.

Proof. Apply Definition 347.3. The certified successor or finite tail selector changes only the displayed schedule route and keeps the $\mathsf{RegSeqRat}^{\uparrow}$ source stream and $\mathsf{StreamName}^{\uparrow}$ row visible.

Next use Definition 347.11. The transported readback ledger remains attached to the same endpoint row through the displayed hsame and Cont transport rows, with the Pkg provenance still part of the finite packet.

Finally apply Definition 347.14 and Definition 347.17. These identify the finite $\mathsf{Real}^{\uparrow}$ seal consumer surface with exactly the transported schedule, source stream, endpoint, readback ledger, hsame, Cont, and package rows. Since none of those rows contains completeness, a selected limit, a quotient representative, or host-index equality, the shifted-schedule readback cannot export such data. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealLimit}^{\uparrow}}$.

Constructive story: A finite limit-name packet records a stream schedule, regular rational source stream, proposed real seal endpoint, dyadic tolerance windows, transport rows, continuation routes, package provenance, and local naming ledger.

Theory closure: TheoryGate(NameCert$_{\mathsf{RealLimit}\uparrow}$, maturePackageClosed)

Scope closed: Definition 347.13, Definition 347.6, Definition 347.3, Definition 347.14, Definition 347.15, Definition 347.16, Definition 347.17, and Definition 347.18 bind the classifier, stability, readback, ledger, public real-window export, standard finite-seal bridge, standard bridge boundary, finite real-seal consumer surface, and transported readback determinacy to the finite carrier of Definition 347.1, componentwise hsame transport, Cont schedule refinements, Pkg provenance, the NameCert ledger, and the downstream Real$^{\uparrow}$ endpoint row.

Formal verification: FormalStatus(NameCert$_{\mathsf{RealLimit}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.RealLimitUp.RealLimitPacket\_readback\_obligation`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close Real$^{\uparrow}$ completeness, quotient stream equality, a selected limit object, or host completion.

Upgrade path: No further theory-axis upgrade is available for this chapter; formal upgrades remain on the verification axis.

Chapter 348

A Concrete Naming Certificate for $\mathsf{ModelPredictiveControl}^{\uparrow}$

The $\mathsf{ModelPredictiveControl}^{\uparrow}$ interface records the finite receding-horizon surface used by control packets that repeatedly solve a displayed finite prediction problem and export only the first control row. The reference point is Rawlings, Mayne, and Diehl, *Model Predictive Control: Theory, Computation, and Design* (2017), together with Boyd and Vandenberghe, *Convex Optimization* (2004) for finite convex constraint rows. The BEDC certificate below names the finite rows of that surface over $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{Riccati}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, and $\mathsf{ControlControllability}^{\uparrow}$. It does not assert infinite-horizon optimality, analytic convergence, stochastic control, recursive feasibility beyond the displayed terminal rows, or host optimizer semantics. The receding-horizon row consumes the LQR finite-control surface of chapter 296 and the Riccati terminal ledger of chapter 307 before the ConvexSet and Polytope constraint rows are read.

Definition 348.1 (Model predictive control BHist carrier)**.** *A* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (X, U, N, A, Q, W, J, T, O, F, H, R, P, C)$$

whose visible rows are:

1. *a current-state row X read through* $\mathsf{StateSpaceModel}^{\uparrow}$ *and* $\mathsf{VecSpace}^{\uparrow}$*;*
2. *an input row U read through* $\mathsf{VecSpace}^{\uparrow}$ *and the displayed control dependency certificates;*
3. *a finite prediction-horizon row N read as a unary length bound;*
4. *a dynamics-transition row A read through* $\mathsf{DynSystem}^{\uparrow}$*,* $\mathsf{StateSpaceModel}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*, and* $\mathsf{VecSpace}^{\uparrow}$*;*
5. *a quadratic-cost row Q read through* $\mathsf{LQR}^{\uparrow}$ *and* $\mathsf{Riccati}^{\uparrow}$*;*
6. *a constraint-window row W naming the displayed admissible state and control rows through* $\mathsf{ConvexSet}^{\uparrow}$ *and* $\mathsf{Polytope}^{\uparrow}$ *for each horizon index;*
7. *a stage-cost ledger J read through* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Mat}^{\uparrow}$*,* $\mathsf{VecSpace}^{\uparrow}$*, and the finite-cost face of* $\mathsf{LQR}^{\uparrow}$*;*
8. *a terminal-cost or terminal-region row T read through* $\mathsf{LQR}^{\uparrow}$*,* $\mathsf{Riccati}^{\uparrow}$*,* $\mathsf{ConvexSet}^{\uparrow}$*, and* $\mathsf{Polytope}^{\uparrow}$ *when those rows are present;*
9. *an optimizer-candidate row O containing only a displayed finite control sequence candidate and its finite rollout ledger;*

10. *a first-control extraction row F selecting the initial control entry from O;*
11. *componentwise* hsame *transports H for the state, horizon, transition, window, cost, terminal, candidate, first-control, and provenance rows;*
12. Cont *rollout routes R for reading the finite prediction recursion, stage-cost accumulation, terminal read, and first-control extraction;*
13. *a* Pkg *provenance row P naming the consumed state-space, dynamical, matrix, vector-space, real, LQR, Riccati, convex-set, polytope, observability, and controllability certificates;*
14. *a local* NameCert *provenance row C for the finite receding-horizon surface.*

Two accepted packets classify together only when these displayed rows transport componentwise by H and every rollout, cost, terminal, and first-control read follows one of the recorded Cont *routes in R.*

Lean4 (definition) `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlBHistCarrier`

Theorem 348.2 (Model predictive control finite-horizon obligation)**.** *Every accepted* ModelPredictiveControl$^{\uparrow}$ *packet exposes its prediction ledger as exactly the finite row family consisting of the current-state row, the input row, the unary horizon row, the displayed dynamics-transition row, the quadratic-cost rows, the rollout* Cont *routes, and the provenance rows of Definition 348.1. The prediction surface exports no host trajectory space, no infinite rollout, and no unlogged model semantics.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket finite horizon obligation`

Proof. Project the accepted carrier of Definition 348.1. The only coordinates that can generate prediction rows are X, U, N, A, Q, R, P, and the transport data H.

Read the rollout one horizon index at a time. Each step follows a recorded Cont route from the displayed state and transition rows to the next displayed state row, so the ledger is finite and indexed by N.

Transporting the packet replaces each displayed coordinate by its hsame match and reuses the same rollout routes. Since the carrier has no coordinate for a host trajectory space or an infinite stream, the prediction ledger is exhausted by these finite rows. □

Theorem 348.3 (Model predictive control constraint ledger)**.** *For an accepted* ModelPredictiveControl$^{\uparrow}$ *packet, every admissibility read is the constraint-window row W together with the horizon index, state and control rows, rollout routes, convex and polytopal provenance, and terminal row recorded in Definition 348.1. The packet exports no ambient feasible set, no compactness assertion, and no recursive-feasibility theorem beyond the displayed terminal-cost or terminal-region row.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlConstraintLedger semantic name certificate`

Proof. Project the constraint coordinate W from the carrier. Its entries are indexed by the same finite horizon row N used by the prediction ledger, and they refer only to the displayed state and control rows through the consumed ConvexSet$^{\uparrow}$ and Polytope$^{\uparrow}$ certificates.

Use the rollout routes to align each constraint entry with the corresponding predicted state and candidate control row. The admissibility read is therefore a row projection from W, not an external feasible-set predicate.

The terminal coordinate T may record a terminal cost or terminal region row, but it is another displayed finite row. No coordinate supplies compactness, global feasibility, or recursive feasibility beyond this displayed terminal surface. □

Theorem 348.4 (Model predictive control receding-horizon boundary)**.** *The control exported by an accepted* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *packet is exactly the first-control extraction row F applied to the displayed optimizer-candidate row O. The stage-cost ledger J, terminal row T, constraint window W, rollout routes R,* hsame *transports H, and provenance rows P and C certify the finite candidate surface, but they do not assert that O is a globally optimal host solution.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket receding horizon boundary`

Proof. Project the candidate row O. It contains a displayed finite control sequence candidate together with the rollout and cost rows that make the candidate visible inside the packet.

Apply the extraction row F. This row selects the initial control entry from the displayed finite sequence and exports that row as the receding-horizon control read.

The cost, constraint, terminal, transport, continuation, and provenance rows certify how the candidate is displayed. None of these rows contains a host minimizer, a global optimality proof, or an external solver state, so the exported control row is precisely the first displayed entry of O. □

Theorem 348.5 (Model predictive control consumer boundary)**.** *Every downstream reader of an accepted* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *packet sees only the finite state, input, horizon, dynamics, quadratic-cost, constraint, rollout, terminal, first-control, transport, continuation, and provenance rows of Definition 348.1. A consumer cannot read an infinite-horizon optimum, analytic convergence proof, stochastic controller, or host optimizer semantics from the packet.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket consumer boundary`

Proof. Project an arbitrary downstream read of the accepted packet. The carrier provides only the displayed coordinates X, U, N, A, Q, W, J, T, O, F, H, R, P, and C.

The prediction, constraint, and receding-horizon theorems identify the only control-facing rows: finite rollout, finite admissibility, and first-control extraction. Each one is reached by a recorded Cont route and transported componentwise by hsame.

Since the packet has no coordinate for infinite horizons, analytic convergence data, stochastic laws, or host optimizer semantics, no consumer read can export those objects. □

Theorem 348.6 (Model predictive control NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ModelPredictiveControl}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: the finite packet of Definition 348.1;*
2. *classifier transport: the componentwise* hsame *rows for the carrier coordinates and the* Cont *routes that preserve the displayed reads;*
3. *finite horizon rollout: the finite prediction rows of Definition 348.2;*
4. *constraint ledger exactness: the admissibility rows of Definition 348.3;*
5. *consumer boundary: the* Pkg *and* NameCert *rows of Definition 348.5 naming* $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{Riccati}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, *and* $\mathsf{ControlControllability}^{\uparrow}$ *as the only imported certificate surfaces.*

These rows form the finite seed obligation surface for naming receding-horizon model predictive control data in BEDC.

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket namecert obligation surface`

Proof. The carrier row fixes every coordinate of the packet. Its displayed state, horizon, transition, window, cost, terminal, candidate, extraction, transport, continuation, package, and local name rows are all finite BHist data.

The finite-horizon, constraint-ledger, receding-horizon, and consumer-boundary theorems identify the only rollout, admissibility, exported-control, and downstream-consumer reads. Each read is a projection from the same finite packet and follows one of the recorded Cont routes.

The provenance row then lists exactly the consumed control and algebra certificates. Since no extra coordinate carries host optimization, analytic minimizers, compactness, infinite horizons, or unlogged feasibility data, the five rows exhaust the local $\mathsf{NameCert}_{\mathsf{ModelPredictiveControl}^{\uparrow}}$ surface. □

Theorem 348.7 (Model predictive control scoped kernel support)**.** *The finite MPC carrier, finite-horizon obligation, constraint ledger, receding-horizon boundary, consumer boundary, and* NameCert *obligation surface are scoped exactly by the displayed* BHist *packet rows,* hsame *transport rows,* Cont *rollout routes,* Pkg *provenance,* NameCert *provenance, and the cited* $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{Riccati}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, *and* $\mathsf{ControlControllability}^{\uparrow}$ *sources. The scoped support exports no host optimizer semantics, infinite-horizon optimality, stochastic control, or unlogged feasibility data.*

Proof. Project the carrier coordinates $M = (X, U, N, A, Q, W, J, T, O, F, H, R, P, C)$ from Definition 348.1. These coordinates are the only state, input, horizon, transition, cost, constraint, terminal, candidate, first-control, transport, continuation, package, and naming rows in the packet.

Apply Definition 348.2, Definition 348.3, Definition 348.4, and Definition 348.5. They identify the prediction rows, admissibility rows, first-control read, and downstream consumer reads as projections from the same finite carrier, transported by hsame and routed by the displayed Cont rollout data.

Finally repack the five rows of Definition 348.6. The Pkg row names exactly the listed control, algebra, convexity, and real-number sources, while the local NameCert row records the receding-horizon surface. Coordinate exhaustion then excludes host optimizer semantics, infinite-horizon optimality, stochastic control, and unlogged feasibility data. □

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket scoped kernel support`

Theorem 348.8 (Model predictive control finite-horizon prefix restriction)**.** *Let* $M = (X, U, N, A, Q, W, J, T, O, F,$ *be an accepted* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *packet, and let* $m \leq N$ *be a certified unary prefix horizon. Form the prefix packet* $M_{\leq m}$ *by replacing the horizon row* N *by* m*, retaining the unindexed state, input, transition, quadratic cost, package, and local name-certificate rows, and retaining exactly the prediction, constraint-window, stage-cost, terminal, optimizer-candidate, first-control,* hsame*, and* Cont *rows whose horizon addresses lie in the prefix horizon* m*. Then* $M_{\leq m}$ *is an accepted* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *packet over horizon* m*.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket finite horizon prefix restriction`

Proof. Unfold the carrier of Definition 348.1. Every coordinate required by a $\mathsf{ModelPredictiveControl}^{\uparrow}$ packet is one of

$$X, U, N, A, Q, W, J, T, O, F, H, R, P, C.$$

After prefix restriction, the rows X, U, A, Q, P, and C are the same displayed rows, the horizon coordinate is the certified prefix m, and every indexed row in W, J, T, O, H, and R is a retained row whose address already occurred under the original horizon N.

The prediction ledger is stable under this operation. By Definition 348.2, an accepted MPC packet exposes its prediction surface exactly through the current-state, input, unary horizon, dynamics-transition, quadratic-cost, rollout Cont, transport, and provenance rows. Restricting from N to m keeps precisely those rows at the prefix addresses and changes no rollout endpoint outside the retained prefix. Thus the prediction ledger of $M_{\leq m}$ is the finite prediction ledger over m.

The admissibility, cost, and terminal reads are also prefix-local. By Definition 348.3, every admissibility read comes from the constraint-window row W together with the same horizon index, state and control rows, rollout routes, convex and polytopal provenance, and terminal row. Since the prefix packet keeps exactly the rows indexed by the certified prefix horizon, each retained constraint, stage-cost, and terminal read has the same source row and the same recorded route as it had in M. No ambient feasible set or external compactness assertion is used to rebuild acceptance.

For the receding-horizon export, use Definition 348.4. The exported control is exactly the first-control extraction row F applied to the displayed optimizer-candidate row O. The prefix packet retains that first-control row and the initial candidate entry, so the receding-horizon boundary remains the same boundary read inside the shorter packet.

It remains to check transport and provenance. The componentwise hsame rows and the Cont routes retained in $M_{\leq m}$ have the same endpoints after restriction, because both endpoints are prefix rows. The Pkg row still names the same consumed $\mathsf{StateSpaceModel}^{\uparrow}$, $\mathsf{DynSystem}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{LQR}^{\uparrow}$, $\mathsf{Riccati}^{\uparrow}$, $\mathsf{ConvexSet}^{\uparrow}$, $\mathsf{Polytope}^{\uparrow}$, $\mathsf{ControlObservability}^{\uparrow}$, and $\mathsf{ControlControllability}^{\uparrow}$ certificates, and the local $\mathsf{NameCert}$ row still names the finite receding-horizon surface. Repacking these retained carrier, prediction, constraint, first-control, transport, continuation, package, and name-certificate rows gives the accepted $\mathsf{ModelPredictiveControl}^{\uparrow}$ packet over m. □

Theorem 348.9 (Model predictive control finite rollout bridge boundary)**.** *For every finite public* $\mathsf{ModelPredictiveControl}^{\uparrow}$ *packet displayed by the carrier, rollout, constraint, prefix, package, and* $\mathsf{NameCert}$ *rows of this chapter, there is a bridge boundary from that packet to the abstract receding-horizon control interface. The finite-horizon prefix restriction supplies the source row, the constraint ledger supplies hidden constraint provenance, and the consumer boundary transports the exported packet through* Cont *and* hsame *without exposing host optimization primitives.*

Lean4 ✓ `BEDC.Derived.ModelPredictiveControlUp.ModelPredictiveControlPacket finite rollout bridge boundary`

Proof. Begin with the finite source packet. Apply Definition 348.8 to replace an accepted horizon by any certified prefix while retaining exactly the displayed current-state, input, rollout, first-control, package, and local $\mathsf{NameCert}$ rows at prefix addresses.

Next record the hidden feasibility side. By Definition 348.3, every constraint-window, admissibility, stage-cost, and terminal read used by the prefix packet is accounted for by the displayed ledger rows and the named convex, polytopal, and terminal provenance. Thus the bridge source carries constraint provenance as package data rather than as an ambient host feasible set.

Now export the control boundary. Apply Definition 348.4 to identify the consumer-visible control as the first-control extraction from the displayed optimizer-candidate row. Then apply Definition 348.5 to move this packet through the Cont routes and componentwise hsame rows.

The resulting boundary exposes only the finite MPC public packet: carrier rows, rollout rows, constraint provenance, prefix horizon, package provenance, and the local NameCert row. Since neither cited boundary has a constructor field for host optimizer semantics, infinite-horizon optimality, stochastic control, or unlogged feasibility data, the transported packet is a bridge boundary to the abstract receding-horizon interface and not an exposure of host optimization primitives. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModelPredictiveControl}^{\uparrow}}$.

Constructive story: A $\mathsf{ModelPredictiveControl}^{\uparrow}$ packet is seeded by finite BHist rows for current state, finite prediction horizon, dynamics transition, constraint window, stage-cost ledger, terminal-cost or terminal-region row, optimizer-candidate row, first-control extraction, hsame transports, Cont rollout routes, Pkg provenance, and local NameCert provenance.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModelPredictiveControl}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 348.7, Definition 348.8, and Definition 348.9 bind the finite MPC carrier, prediction ledger, constraint window, first-control boundary, consumer boundary, finite-horizon prefix export, and bridge boundary to displayed BHist rows, hsame transport, Cont rollout routes, Pkg provenance, local NameCert provenance, and the cited control-source interfaces.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModelPredictiveControl}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close infinite-horizon optimality, analytic convergence, stochastic control, host optimizer semantics, recursive feasibility beyond displayed terminal rows, or a standard bridge.

Upgrade path: The remaining work is formal-axis verification of the displayed finite MPC packet.

Chapter 349

A Concrete Naming Certificate for $\mathsf{Trie}^{\uparrow}$

The $\mathsf{Trie}^{\uparrow}$ interface names finite prefix-indexed data without importing host strings, host maps, or a host trie primitive. The reference point is Okasaki, *Purely Functional Data Structures* (1998), where tries are finite prefix trees for keyed lookup; the BEDC surface below reads that structure as finite $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{BitVector}^{\uparrow}$ rows.

The concrete dependency route consumes chapter 32 for branch tags, chapter 36 and chapter 346 for finite key paths, chapter 33 for terminal payload rows, and chapter 28 for depth bounds. When grammar derivation ledgers are indexed by terminal-word prefixes, the prefix subledgers of a $\mathsf{Trie}^{\uparrow}$ packet can be consumed by chapter 356 as finite derivation-prefix lookup rows rather than as a host map or an ambient language index.

Definition 349.1 (Trie BHist source)**.** *A* $\mathsf{Trie}^{\uparrow}$ *source packet is a finite* BHist *record*

$$T = (k, v, l, b, p)$$

with the following visible coordinates:

1. *k is a finite key-path row, read either as a* $\mathsf{BitVector}^{\uparrow}$ *path or as a* $\mathsf{List}^{\uparrow}$ *spine of branch histories;*
2. *v is an* $\mathsf{Option}^{\uparrow}$ *terminal payload row, recording whether the current prefix carries a value and, when present, exposing only the displayed value row;*
3. *l is a* $\mathsf{Nat}^{\uparrow}$ *length and depth ledger recording the finite prefix length, the depth of each inspected node, and the fact that every public read is below that depth;*
4. *b is the branch ledger whose branch tags are* $\mathsf{Bool}^{\uparrow}$ *rows and whose left and right subprefix reads are routed only through displayed finite list or bit-vector positions;*
5. *p is the* Pkg *provenance naming the consumed* $\mathsf{Bool}^{\uparrow}$*,* $\mathsf{List}^{\uparrow}$*,* $\mathsf{Option}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{BitVector}^{\uparrow}$*,* hsame*, and* Cont *certificate rows.*

The carrier predicate is $\mathsf{TrieSource}(k, v, l, b, p)$*. Its classifier compares accepted packets by componentwise key-path comparison, optional payload comparison, branch-tag comparison, length-ledger comparison, and the same displayed* hsame*,* Cont*, and* Pkg *routes. The packet contains no host string equality, host finite map, function extensionality, hidden ordering on keys, or unbounded tree object.*

Theorem 349.2 (Trie carrier stability)**.** *Let $T = (k, v, l, b, p)$ be an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet. If the key path, optional payload, depth ledger, branch ledger, and provenance row are transported by*

displayed hsame *along the* Cont *routes named by* p*, then the transported packet* $T' = (k', v', l', b', p')$ *is again an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket carrier stability`
↪ variant `BEDC.Derived.TrieUp.TriePacket carrier stability`

Proof. Project the five coordinates of Definition 349.1. The $\mathsf{Nat}^{\uparrow}$ ledger transports first, so every later prefix and branch read is bounded by the transported finite depth row.

Transport the key row through its displayed $\mathsf{BitVector}^{\uparrow}$ or $\mathsf{List}^{\uparrow}$ presentation. Each branch tag is a $\mathsf{Bool}^{\uparrow}$ row, so the branch ledger transports componentwise along the same key-path positions.

Finally transport the optional payload and provenance rows. The $\mathsf{Option}^{\uparrow}$ row preserves the absent case and transports the present payload only when the present tag is displayed, while the Pkg row keeps the same finite certificate dependencies. Thus the transported record is another accepted trie source packet. □

Theorem 349.3 (Trie classifier laws)**.** *The* $\mathsf{Trie}^{\uparrow}$ *classifier is reflexive, symmetric, and transitive on accepted packets by componentwise use of the* $\mathsf{BitVector}^{\uparrow}$ *or* $\mathsf{List}^{\uparrow}$ *key-path classifier, the* $\mathsf{Option}^{\uparrow}$ *payload classifier, the* $\mathsf{Bool}^{\uparrow}$ *branch classifier, and the* $\mathsf{Nat}^{\uparrow}$ *ledger classifier.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket classifier laws`

Proof. For reflexivity, take the reflexive classifier row for the key path, the optional payload, each boolean branch tag, and the finite depth ledger. The provenance and continuation rows are read unchanged.

For symmetry, reverse each displayed component comparison. The absent and present cases of the optional payload reverse by the $\mathsf{Option}^{\uparrow}$ classifier, and every branch tag reverses by the $\mathsf{Bool}^{\uparrow}$ classifier.

For transitivity, compose the two key-path comparisons, the two optional payload comparisons, the two branch-ledger comparisons, and the two depth ledger comparisons. The depth ledger fixes the finite set of visible prefix positions, so no hidden branch can enter the composite classifier. □

Theorem 349.4 (Trie ledger coverage)**.** *Every public read of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet factors through the finite ledger* (k, v, l, b, p)*. Consumers see exactly finite prefix rows, boolean branch rows, optional terminal payload rows, depth and length rows,* hsame *transports,* Cont *routes, and* Pkg *provenance.*

Consequently the packet exports no host string type, host map lookup, ambient function space, infinite tree, or implicit key ordering.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket ledger coverage`

Proof. Start from the carrier definition. Its tuple lists exactly the key, terminal payload, depth ledger, branch ledger, and provenance coordinates.

A prefix-facing consumer reads k through the displayed $\mathsf{BitVector}^{\uparrow}$ or $\mathsf{List}^{\uparrow}$ path. A branch-facing consumer reads b only through the boolean tags admitted by the finite depth ledger l. A value-facing consumer reads v only through the $\mathsf{Option}^{\uparrow}$ absent-or-present row.

The remaining public reads are the displayed hsame comparisons, Cont routes, and Pkg provenance named in p. Since no further coordinate is present, every consumer projection is one of these finite rows. □

Theorem 349.5 (Trie prefix-branch exactness)**.** *Every public branch read at a displayed finite prefix of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet is determined by the key path row, the* $\mathsf{Nat}^{\uparrow}$ *depth ledger, the* $\mathsf{Bool}^{\uparrow}$ *branch tag at that prefix, the optional payload row, visible* hsame *transport,* Cont *routes, and* Pkg *provenance from Definition 349.1.*

No host string equality, host map lookup, hidden branch coordinate, or infinite tree can change the read.

Proof. Project the tuple (k, v, l, b, p) from Definition 349.1. The key path row k, optional payload row v, depth ledger l, branch ledger b, and provenance row p are the only coordinates admitted by the accepted packet.

Use Definition 349.4 to bound public branch reads by the finite prefix rows displayed below the depth ledger. A consumer at such a prefix can inspect only the recorded branch tag, the corresponding key-path coordinate, the optional terminal payload row, and the visible transport and provenance rows.

Finally apply Definition 349.3 componentwise. Transport of the key, branch, payload, and depth rows preserves exactly the displayed finite coordinates, so the NameCert surface of Definition 349.10 receives a branch read whose value is fixed by the recorded rows and by no host-side tree structure. □

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket prefix branch exactness`

Theorem 349.6 (Trie prefix branch consumer exhaustion)**.** *Any accepted* $\mathsf{Trie}^{\uparrow}$ *prefix-branch consumer read factors through the displayed finite* BHist *prefix row, the* $\mathsf{Bool}^{\uparrow}$ *branch tag, the* $\mathsf{List}^{\uparrow}$ *path spine, the* $\mathsf{Nat}^{\uparrow}$ *depth counter, the* $\mathsf{Option}^{\uparrow}$ *terminal payload row, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ *ledger.*

The consumer surface is exactly this finite BEDC row surface. It exports no host map, external tree equality, unbounded lookup function, hidden node object, or host key ordering.

Proof. Project the source tuple (k, v, l, b, p) of Definition 349.1. The key coordinate supplies the displayed finite prefix row as a $\mathsf{List}^{\uparrow}$ spine, the branch ledger supplies the $\mathsf{Bool}^{\uparrow}$ branch tag, the depth coordinate supplies the $\mathsf{Nat}^{\uparrow}$ counter, and the terminal coordinate supplies the $\mathsf{Option}^{\uparrow}$ payload row.

Use Definition 349.5 to bind a public prefix-branch read to those coordinates. Its route records the same displayed hsame transports, Cont routes, and Pkg provenance named by the source packet.

Repack the resulting finite read through Definition 349.10. The local $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ ledger accepts exactly the carrier rows, classifier rows, prefix-branch determinacy rows, transport rows, and ledger-exactness rows already displayed in the packet.

Apply Definition 349.4 for the exclusion claim. Since every consumer projection is a row of (k, v, l, b, p) or the named local certificate ledger, no host map, external tree equality, unbounded lookup function, hidden node object, or host key ordering is exported. □

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket prefix branch consumer exhaustion`

Theorem 349.7 (Trie key-path exhaustion)**.** *Every public key-path read of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet is exhausted by the displayed* $\mathsf{BitVector}^{\uparrow}$ *or* $\mathsf{List}^{\uparrow}$ *key row, the* $\mathsf{Nat}^{\uparrow}$ *depth ledger, the* hsame *transports and* Cont *routes named by the packet, and the* Pkg *provenance row. No host string, host ordering, ambient finite map, or hidden key predicate contributes an additional public key-path coordinate.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket key path route exhaustion`

Proof. Project the key coordinate k and depth ledger l from Definition 349.1. The definition gives k only as a displayed $\mathsf{BitVector}^{\uparrow}$ path or as a $\mathsf{List}^{\uparrow}$ spine of branch histories, and it gives l as the bound for every public prefix read.

Use Definition 349.2 to see that transport preserves this same finite key presentation along the displayed hsame and Cont routes. Then apply Definition 349.3 componentwise to the accepted key rows.

Finally apply Definition 349.4. Since every public read is a projection from (k, v, l, b, p), the only remaining key-path data is the provenance named in p, and no host key structure is exported. □

Theorem 349.8 (Trie prefix-branch determinacy)**.** *At each displayed finite prefix below the* $\mathsf{Nat}^{\uparrow}$ *depth row of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet, the* $\mathsf{Bool}^{\uparrow}$ *branch tag selects exactly the recorded left or right subprefix. No unrecorded branch at that prefix is public.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket prefix branch determinacy`

Proof. Project the branch ledger b and the depth ledger l from Definition 349.1. The ledger l bounds the finite prefix positions that a consumer may inspect, and b records branch tags only at those displayed positions.

For any such prefix, read the branch tag through its $\mathsf{Bool}^{\uparrow}$ row. The two displayed boolean cases select the recorded left or right subprefix row, and Definition 349.3 transports equality of branch reads componentwise through the same finite coordinates.

The stability theorem Definition 349.2 preserves the branch ledger under hsame and Cont. Applying Definition 349.4 then excludes any branch coordinate not recorded in (k, v, l, b, p), so no extra branch is public. □

Theorem 349.9 (Trie lookup payload projection)**.** *Every lookup payload read of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet factors through the* $\mathsf{Option}^{\uparrow}$ *absent-or-present terminal row at the displayed key path. The read never factors through a host finite map, host lookup function, or ambient function space.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket lookup payload projection`

Proof. Project the terminal payload coordinate v from Definition 349.1. The coordinate is an $\mathsf{Option}^{\uparrow}$ row at the displayed key path, so a consumer can observe only the absent tag or the present tag together with the displayed payload row.

The key path used by the lookup is fixed by Definition 349.7. The payload row transports along the same displayed hsame and Cont routes by Definition 349.2, and the accepted-row comparison is componentwise by Definition 349.3.

Apply Definition 349.4 to close the projection. Since the finite tuple exports no host map or function coordinate, lookup payload reads can only pass through the displayed $\mathsf{Option}^{\uparrow}$ terminal row. □

Theorem 349.10 (Trie NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation: the empty trie is carried by the empty key path, an absent* $\mathsf{Option}^{\uparrow}$ *payload, the zero* $\mathsf{Nat}^{\uparrow}$ *depth ledger, the empty branch ledger, and the corresponding* Pkg *provenance;*
2. *classifier laws: reflexivity, symmetry, and transitivity are inherited componentwise from Definition 349.3;*

3. *prefix-branch determinacy: at each displayed finite prefix, a* $\mathsf{Bool}^{\uparrow}$ *branch tag selects exactly the recorded left or right subprefix row, and no unrecorded branch is public, as witnessed by Definition 349.7 and Definition 349.5;*

4. *transport under* hsame *and* Cont*: the stability theorem Definition 349.2 repacks transported key, payload, branch, ledger, and provenance rows as another accepted packet, with lookup payload projection fixed by Definition 349.9;*

5. *ledger exactness: downstream consumers may read only finite prefix rows, branch rows, optional terminal payload rows, length and depth rows, and the displayed provenance rows of Definition 349.4, with the key-path, branch, and payload projections separated by Definition 349.7, Definition 349.8, and Definition 349.9.*

These rows are the complete seed obligation surface for prefix-tree NameCert data over finite BEDC rows.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket namecert obligation surface`

Proof. For carrier habitation, choose the empty $\mathsf{BitVector}^{\uparrow}$ or empty $\mathsf{List}^{\uparrow}$ path, the absent $\mathsf{Option}^{\uparrow}$ payload, the zero $\mathsf{Nat}^{\uparrow}$ depth row, and the empty branch ledger. The provenance row records only the finite data certificates consumed by the packet.

For the classifier laws, apply Definition 349.3. Because the classifier is componentwise, the three equivalence laws are inherited from the key, option, boolean branch, and natural ledger classifiers.

For prefix-branch determinacy, apply Definition 349.7 and Definition 349.8. The key-path theorem fixes the finite prefix positions, and the branch theorem fixes the recorded left or right subprefix at each displayed position.

For transport, apply Definition 349.2. The same hsame and Cont routes move the visible rows without adding host string equality, host maps, or unbounded trees. Lookup payload reads are then projected through Definition 349.9.

For ledger exactness, apply Definition 349.4. Every downstream read is a projection from the finite tuple (k, v, l, b, p), so the NameCert obligation surface is exhausted by the listed rows. □

Definition 349.11 (Trie terminal value packet)**.** *For a finite Boolean-key path, the visible terminal-value row is the* BHist *packet*

$$\mathsf{TrieTerminal}(q, t, r, c, e, g, n)$$

whose coordinates are as follows:

1. *q is the finite key spine, presented as a* $\mathsf{List}^{\uparrow}$ *row of* $\mathsf{Bool}^{\uparrow}$ *branch histories;*

2. *t is the terminal* $\mathsf{Option}^{\uparrow}$ *value row, with the absent case carrying no payload and the present case exposing only the displayed value packet;*

3. *r is the displayed* hsame *transport row for the key spine and the terminal option row;*

4. *c is the* Cont *route taking each accepted prefix row to its extended prefix row and taking the terminal option row to the lookup-facing read;*

5. *e is the* BHist *branch ledger recording the visible left-or-right decision at each position of q;*

6. *g is the* Pkg *provenance naming the consumed* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, hsame, *and* Cont *rows;*

7. *n is the local* NameCert *row certifying that these displayed rows are the public terminal packet for the Boolean-key lookup.*

The packet contains no host map entry, host string key, ambient lookup function, or hidden node object.

Theorem 349.12 (Trie prefix-extension classifier stability)**.** *Let p and p' be displayed Boolean-key prefixes classified by the* $\mathsf{Trie}^{\uparrow}$ *classifier, and let b be a visible* $\mathsf{Bool}^{\uparrow}$ *branch row. If p is extended by b along the* $\mathsf{List}^{\uparrow}$ *key spine and the extension is transported through the displayed* hsame *row and* Cont *route of the packet, then the transported extension of p' is classified under the same branch label b.*

Lean4 ✓ `BEDC.Derived.TrieUp.TriePrefixExtensionClassifier stability`

Proof. Induct on the displayed $\mathsf{List}^{\uparrow}$ key spine. In the empty-spine case, the extension exposes only the first $\mathsf{Bool}^{\uparrow}$ branch row, and classifier reflexivity for that branch row supplies the transported label.

For the cons-spine step, apply the induction hypothesis to the tail prefix. The head branch row is transported by the same hsame route, and Definition 349.3 composes the head comparison with the classified tail comparison.

The Cont route then repacks the extended prefix as a public trie row. Definition 349.2 keeps the transported record accepted, so the resulting extension remains classified under the same visible branch label and no hidden host key coordinate is introduced. □

Theorem 349.13 (Trie Boolean-key path ledger coverage)**.** *Every admitted finite Boolean-key lookup path in a* $\mathsf{Trie}^{\uparrow}$ *packet carries a ledger entry for each displayed branch decision and one terminal* $\mathsf{Option}^{\uparrow}$ *value packet at the final prefix. These entries are precisely the visible* $\mathsf{Bool}^{\uparrow}$ *branch rows, the* $\mathsf{List}^{\uparrow}$ *key-spine rows, the transported* hsame *and* Cont *rows, the* Pkg *provenance, and the terminal packet of Definition 349.11.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieTerminalPacket boolean key path ledger coverage`

Proof. Induct on the displayed $\mathsf{List}^{\uparrow}$ key spine. For the empty spine, the lookup path is already at the terminal prefix, so the ledger contains the single $\mathsf{Option}^{\uparrow}$ terminal packet and the provenance rows named by Definition 349.11.

For a cons spine, the head is a visible $\mathsf{Bool}^{\uparrow}$ branch decision. Record that branch row in the ledger and apply the induction hypothesis to the remaining spine, transporting the tail ledger by the displayed hsame row.

Finally compose the Cont routes along the finite spine. The composed route preserves the branch entries and delivers the terminal $\mathsf{Option}^{\uparrow}$ packet at the final prefix, while Definition 349.4 excludes any additional host lookup, hidden key ordering, or infinite-tree coordinate. □

Theorem 349.14 (Trie branch read exactness)**.** *Let $T = (k, v, l, b, p)$ be an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet. Every public branch read of T factors through a displayed finite prefix position bounded by the* $\mathsf{Nat}^{\uparrow}$ *depth ledger, a* $\mathsf{Bool}^{\uparrow}$ *branch tag, the corresponding* $\mathsf{List}^{\uparrow}$ *or* $\mathsf{BitVector}^{\uparrow}$ *key-path row, the displayed* hsame *and* Cont *route, and the* Pkg *provenance named by p.*

Conversely, every displayed branch row of that form is an accepted public branch read of T. No host string, host finite map, ambient lookup function, or hidden key-order coordinate contributes an additional public branch read.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieBranchRead exactness`
Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket branch read exactness`

Proof. Project the five coordinates of Definition 349.1. The branch ledger b records only boolean branch tags at finite prefix positions, and the depth ledger l bounds the positions visible to public reads.

Apply Definition 349.4 to obtain the available coordinates. The key row is read through the displayed $\mathsf{List}^{\uparrow}$ or $\mathsf{BitVector}^{\uparrow}$ path, and the branch selector is read through its $\mathsf{Bool}^{\uparrow}$ row.

Use Definition 349.3 to transport the key-path, branch, and ledger coordinates componentwise along the named hsame and Cont routes. The provenance coordinate p supplies exactly the consumed certificate rows.

For the converse direction, start from a displayed prefix position, branch tag, key-path row, transport route, and provenance row named in the packet. These are precisely coordinates of (k, v, l, b, p), so they assemble to a public branch read accepted by the carrier.

The exclusions follow from absence of coordinates in Definition 349.1: host strings, host maps, ambient lookup functions, and key-order data cannot be projected from the packet. □

Theorem 349.15 (Trie key-prefix transport)**.** *For accepted* $\mathsf{Trie}^{\uparrow}$ *packets transported along the displayed* hsame *and* Cont *routes, key-path rows preserve finite prefix positions,* $\mathsf{Nat}^{\uparrow}$ *depth bounds, and* $\mathsf{Bool}^{\uparrow}$ *branch selectors. Thus a transported branch read remains on the same displayed finite prefix surface, with only the corresponding* $\mathsf{List}^{\uparrow}$ *or* $\mathsf{BitVector}^{\uparrow}$ *key row, branch tag, ledger row, and* Pkg *provenance transported.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket key prefix transport`

Proof. Begin with Definition 349.2. Transporting the accepted packet repacks the key, payload, branch, ledger, and provenance coordinates as another accepted $\mathsf{Trie}^{\uparrow}$ packet.

The component laws in Definition 349.3 transport the key row through its displayed $\mathsf{List}^{\uparrow}$ or $\mathsf{BitVector}^{\uparrow}$ presentation and transport each branch selector through its $\mathsf{Bool}^{\uparrow}$ classifier row. The $\mathsf{Nat}^{\uparrow}$ ledger travels componentwise with those same finite positions.

Finally, return to the source packet of Definition 349.1. The only key-path coordinates present there are the displayed key row, finite depth bound, branch selector, named hsame and Cont route, and Pkg provenance. Hence transport preserves exactly those prefix coordinates and no additional key structure. □

Theorem 349.16 (Trie lookup ledger exhaustion)**.** *Every lookup-facing consumer of an accepted* $\mathsf{Trie}^{\uparrow}$ *packet is exhausted by the displayed key path,* $\mathsf{Option}^{\uparrow}$ *terminal payload,* $\mathsf{Bool}^{\uparrow}$ *branch rows,* $\mathsf{Nat}^{\uparrow}$ *depth ledger,* hsame *rows,* Cont *routes, and* Pkg *provenance already present in the packet. The packet exports no host finite-map lookup, string equality, function extensionality, infinite tree, or key ordering.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieBHistSource lookup ledger exhaustion`
Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket lookup ledger exhaustion`

Proof. Use Definition 349.14 for branch-facing reads. Each such read is a displayed finite prefix position, boolean selector, key-path row, transport route, and provenance row from the packet.

Use Definition 349.15 for transported key-facing reads. It preserves the finite prefix positions, ledger bounds, and branch selectors under the displayed hsame and Cont routes.

The remaining lookup payload coordinate is the $\mathsf{Option}^{\uparrow}$ row already recorded in Definition 349.1. Apply Definition 349.4 and Definition 349.10 to collect the full packet surface.

Since the collected surface is exactly (k, v, l, b, p), every lookup-facing consumer projection is one of the displayed rows. Host finite maps, string equality, function extensionality, infinite trees, and key orderings are not coordinates of that packet, so they are not exported. □

Theorem 349.17 (Trie lookup prefix ledger factorization)**.** *Let $T = (k, v, l, b, p)$ be an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet and let q be a finite key prefix displayed by the* $\mathsf{List}^{\uparrow}$ *or* $\mathsf{BitVector}^{\uparrow}$ *key-path row. A lookup read at q factors through exactly one of two visible sources: the optional terminal payload row at q, or a branch ledger row extending q below the unary depth ledger. An absent terminal payload row alone is not evidence for absence below q unless the branch ledger below q is also exhausted.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket lookup prefix ledger factorization`

Proof. Project the source packet of Definition 349.1. The prefix q is read from the displayed key-path coordinate, while the optional terminal payload and branch rows are separate coordinates of the same packet.

Use Definition 349.14 to identify every branch read below q with a displayed finite prefix position, boolean selector, key-path row, transport route, and provenance row. Then use Definition 349.16 to see that no other lookup-facing source is available.

Split the optional payload row at q. In the present case, the lookup read uses the terminal $\mathsf{Option}^{\uparrow}$ payload projection. In the absent case, the absence of that terminal coordinate only removes the terminal source at q.

It remains to account for reads below the prefix. Those reads must pass through branch ledger rows extending q; only when that branch ledger is also exhausted does the packet provide finite evidence for absence below the prefix. No host map lookup, string equality, or ambient trie semantics is imported. □

Theorem 349.18 (Trie finite branch consumer boundary)**.** *Let $T = (k, v, l, b, p)$ be a concrete* $\mathsf{Trie}^{\uparrow}$ BHist *source packet from Definition 349.1, with displayed key path k, optional terminal payload v, unary depth ledger l, boolean branch rows b, and* Pkg *provenance p over* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, *and* $\mathsf{BitVector}^{\uparrow}$ *certificates. Every finite branch consumer read of T factors through exactly one of two visible projections: either the terminal payload projection of Definition 349.9, or the branch route determined by Definition 349.8.*

These two projections exhaust the public consumer surface. No host string, host finite map, infinite tree, ambient lookup function, or key-order semantics is introduced by a finite branch read.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket finite branch consumer boundary`

Proof. Unfold the source packet of Definition 349.1. Its public coordinates are the key path, optional payload, depth ledger, branch ledger, and provenance rows named in the theorem.

Split on the displayed optional terminal branch. In the absent case, there is no terminal payload coordinate to read, so the consumer must remain on the finite branch route. In the present case, the only terminal read is the $\mathsf{Option}^{\uparrow}$ payload row, and Definition 349.9 supplies that projection.

For the branch route, use Definition 349.7 to cover the finite key positions. At each covered prefix, Definition 349.8 fixes the unique displayed $\mathsf{Bool}^{\uparrow}$ branch row selected by the packet.

Finally apply Definition 349.4 to account for provenance. The ledger contains only the displayed $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{BitVector}^{\uparrow}$, hsame, Cont, and Pkg rows, so no host string, host map, infinite-tree coordinate, ambient lookup function, or key-order semantics can be projected by the consumer. □

Lean4 ✓ `BEDC.Derived.TrieUp.TrieFiniteBranchConsumer boundary`

Theorem 349.19 (Trie public NameCert export)**.** *The source packet of Definition 349.1, the obligation surface of Definition 349.10, the branch read exactness of Definition 349.14, the lookup ledger exhaustion of Definition 349.16, the prefix ledger factorization of Definition 349.17, and the finite branch consumer boundary of Definition 349.18 assemble the public* $\mathsf{NameCert}_{\mathsf{Trie}^\uparrow}$ *surface for the finite key path, optional payload, unary depth ledger, branch rows, displayed* hsame *and* Cont *routes,* Pkg *provenance, and* $\mathsf{Bool}^\uparrow$*,* $\mathsf{List}^\uparrow$*,* $\mathsf{Option}^\uparrow$*,* $\mathsf{Nat}^\uparrow$*, and* $\mathsf{BitVector}^\uparrow$ *certificates.*

This public export contains no host strings, host finite maps, infinite trees, key ordering, or ambient lookup function.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket public namecert export`

Proof. Project the scoped packet rows from Definition 349.1. They are exactly the finite key path, optional terminal payload, unary depth ledger, branch ledger, transport routes, continuation routes, and provenance rows.

Apply Definition 349.10 to package these rows as the local $\mathsf{NameCert}_{\mathsf{Trie}^\uparrow}$ obligation surface. The branch rows are identified by Definition 349.14, and the lookup-facing payload and ledger reads are exhausted by Definition 349.16.

The prefix boundary is Definition 349.17: a missing terminal row at a prefix is separated from exhaustion of branch rows below that prefix, so the public export records finite failed-lookup evidence only when both visible sources have been accounted for.

Finally use Definition 349.18. It states that every finite branch consumer read factors through the displayed terminal payload or branch route, so the assembled packet is a public consumer surface over precisely the named rows.

The excluded objects are not coordinates of the source packet and are not introduced by any of the cited projections. Hence host strings, host finite maps, infinite trees, key ordering, and ambient lookup functions are absent from the public $\mathsf{NameCert}_{\mathsf{Trie}^\uparrow}$ export. □

Theorem 349.20 (Trie public export route decomposition)**.** *The public* $\mathsf{NameCert}_{\mathsf{Trie}^\uparrow}$ *export decomposes every finite consumer route into exactly one of two displayed routes: the optional terminal payload projection or the Boolean branch route below the unary depth ledger. In both routes the key path, payload row when present, branch row, depth row, displayed* hsame *transport,* Cont *routes, and* Pkg *provenance are preserved as rows of the same finite packet.*

No host string, host finite map, infinite tree, ambient lookup function, or key-order semantics is introduced by this decomposition.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket public export route decomposition`

Proof. Project the public packet through Definition 349.19. This exposes the finite key path, optional payload, unary depth ledger, branch rows, displayed transport, continuation routes, and package provenance.

For the terminal route, apply Definition 349.9. If the terminal payload is present, the consumer read is exactly the displayed $\mathsf{Option}^\uparrow$ payload row at the selected key path. If it is absent, there is no terminal payload coordinate to read.

For the branch route, apply Definition 349.14. It identifies every branch-facing read below the unary depth ledger with the corresponding displayed $\mathsf{Bool}^\uparrow$ branch row.

Finally use Definition 349.16. The ledger has no third consumer route beyond the optional terminal payload projection and the finite branch route, and all named key, payload, branch, depth, transport, continuation, and provenance rows remain inside the same public $\mathsf{NameCert}_{\mathsf{Trie}^\uparrow}$ export. □

Theorem 349.21 (Trie standard finite packet bridge)**.** *The finite* $\mathsf{Trie}^{\uparrow}$ *packet of Definition 349.1 and the public export of Definition 349.19 bridge to the standard finite prefix-tree reading. The visible key path, optional payload, unary depth ledger,* $\mathsf{Bool}^{\uparrow}$ *branch rows,* BHist *packet rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ *rows are exactly the public bridge surface.*

The bridge exports no host string, host finite map, hidden infinite tree, key ordering, or ambient lookup function.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket standard finite packet bridge`

Proof. Project the finite packet as (k, v, l, b, p) from Definition 349.1. The coordinates are the displayed key path, optional terminal payload, unary depth ledger, branch rows, and provenance rows, with the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surfaces already named by the source and public export.

Use Definition 349.7 to identify the standard prefix-tree path with the displayed finite key row. Use Definition 349.8 to identify each finite branch decision with its recorded $\mathsf{Bool}^{\uparrow}$ row below the depth ledger.

Apply Definition 349.9 for the optional terminal payload. Then apply Definition 349.19 to package the path, payload, branch, transport, continuation, provenance, and local naming rows as the public $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ surface.

Finally, exhaust the remaining reads through the unary ledger. Every standard finite prefix-tree read is below the displayed depth row and therefore lands in one of the projected rows. Since the packet has no coordinate for host strings, host maps, hidden infinite trees, key orderings, or ambient lookup functions, none is exported by the bridge. □

Theorem 349.22 (Trie terminal-prefix readback coverage)**.** *Every terminal read of a finite* $\mathsf{Trie}^{\uparrow}$ *packet factors through the displayed finite key prefix, optional terminal payload row,* $\mathsf{Bool}^{\uparrow}$ *branch row, unary depth ledger,* hsame *transport,* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ *row.*

Conversely, any finite read assembled from exactly those rows repacks as a terminal-prefix read of the same finite packet. The readback surface contains no host string, host map, infinite tree, key-order semantics, ambient lookup function, or balancing invariant.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieTerminalPacket prefix readback coverage`
Lean4 ✓ `BEDC.Derived.TrieUp.TerminalPrefixReadback.TrieSourcePacket terminal prefix readback coverage`

Proof. For a prefix-facing read, apply Definition 349.6. It keeps the consumer inside the displayed key prefix, unary depth ledger, branch rows, transport routes, continuation routes, provenance, and local naming evidence.

For a terminal key-path read, apply Definition 349.13. The terminal payload is read at the displayed prefix endpoint, and every branch decision is one of the recorded $\mathsf{Bool}^{\uparrow}$ rows below the unary depth ledger.

Use Definition 349.14 to identify the branch route used by the terminal read. Then apply Definition 349.21 to repack the same rows as a finite prefix-tree reading.

The converse direction reverses this packaging: a read built from the key prefix, optional payload, branch, depth, transport, continuation, provenance, and local certificate rows is exactly a terminal-prefix read of the displayed finite packet. Since no cited row names host strings, host maps, infinite trees, key-order semantics, lookup functions, or balancing invariants, none is available to the readback. □

Lean4 ✓ `BEDC.Derived.TrieUp.TrieTerminalPacket terminal prefix readback coverage`

Theorem 349.23 (Trie finite consumer completeness)**.** *Every finite consumer of the* $\mathsf{Trie}^{\uparrow}$ *bridge factors through the key-path row, the optional terminal payload row, the unary length and depth ledger, the* $\mathsf{Bool}^{\uparrow}$ *branch rows, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and the* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, *and* $\mathsf{BitVector}^{\uparrow}$ *certificates already named by Definition 349.19 and Definition 349.21.*

Conversely, any finite read assembled from exactly those rows repacks as a valid finite trie consumer read of the bridged packet. The completeness surface exports no host strings, host finite maps, infinite trees, key-order semantics, ambient lookup function, or balancing invariant.

Lean4 ✓ `BEDC.Derived.TrieUp.TrieSourcePacket finite consumer completeness`

Proof. Project the source packet of Definition 349.1. Its carrier coordinates are the key path, optional terminal payload, unary ledger, branch rows, and provenance row, together with the displayed hsame, Cont, Pkg, and local certificate data.

For the forward direction, read branch-facing coordinates through Definition 349.14. Transported key prefixes are carried by Definition 349.15, while lookup-facing rows are exhausted by Definition 349.16. The boundary theorem Definition 349.18 then leaves only the terminal payload projection or the displayed branch route.

Apply Definition 349.19 to collect these coordinates as the public $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$ surface. Then apply Definition 349.21 to identify the same surface with the standard finite prefix-tree reading.

For the converse direction, start with a finite read using only the listed rows. The public export supplies the local certificate package, and the standard bridge repacks the key path, payload, ledger, branch, transport, continuation, provenance, and certificate rows into the accepted finite trie consumer surface.

No cited theorem introduces a coordinate outside the source packet. Hence host strings, host finite maps, infinite trees, key-order semantics, ambient lookup functions, and balancing invariants remain outside the exported consumer interface. □

Closure status for $\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$.

Constructive story: A trie packet is generated by a finite key-path row, an optional terminal payload row, a unary length and depth ledger, boolean branch rows, displayed transport routes, and package provenance over Bool, List, Option, Nat, and BitVector certificates.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 349.1, Definition 349.10, Definition 349.14, Definition 349.16, Definition 349.17, Definition 349.18, Definition 349.19, Definition 349.21, and Definition 349.23 assemble the public finite trie NameCert export, bridge it to the standard finite prefix-tree reading, and exhaust finite consumer reads over the key path, optional payload, unary depth ledger, branch rows, displayed transport and continuation routes, package provenance, and Bool, List, Option, Nat, and BitVector certificates.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{Trie}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.TrieUp.TriePrefixSubledger\_provenance\_exhaustion`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close host strings, host finite maps, function extensionality, infinite trees, key-order semantics, balancing invariants, or host lookup behavior.

Upgrade path: No further paper-side theory grade remains for the finite trie packet surface; formal bridge verification remains on the separate verification axis.

Definition 349.24 (Displayed Trie prefix subledger)**.** *Let* $T = (k, v, l, b, p)$ *be an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet. A displayed prefix subledger of* T *is a finite packet*

$$U = (k_U, v_U, l_U, b_U, p_U; \iota)$$

with a displayed inclusion row ι into the visible prefix positions of T such that:

1. *k_U is a finite* $\mathsf{BitVector}^{\uparrow}$ *path or* $\mathsf{List}^{\uparrow}$ *spine whose entries are exactly the key-path entries of k at the positions selected by ι;*
2. *the selected positions are prefix-closed: whenever a displayed position is selected, every displayed predecessor prefix of that position in the key-path ledger is also selected;*
3. *v_U is the* $\mathsf{Option}^{\uparrow}$ *payload row of T restricted to selected terminal positions, so the absent tag stays absent and a present tag exposes only the same displayed payload row already exposed by v;*
4. *l_U is the* $\mathsf{Nat}^{\uparrow}$ *depth ledger obtained by restricting l to the selected positions, with each selected read still below the corresponding depth bound;*
5. *b_U is the branch ledger obtained by retaining exactly the* $\mathsf{Bool}^{\uparrow}$ *branch tags and left or right subprefix reads of b whose source and target prefixes are selected by ι;*
6. *p_U is the projected* Pkg *provenance row naming only the consumed* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{BitVector}^{\uparrow}$, hsame, *and* Cont *rows that occur in the retained coordinates.*

The associated restricted packet is $T|_U = (k_U, v_U, l_U, b_U, p_U)$.

Theorem 349.25 (Trie prefix subledger restriction carrier)**.** *Let $T = (k, v, l, b, p)$ be an accepted* $\mathsf{Trie}^{\uparrow}$ *source packet, and let U be a displayed prefix subledger of T in the sense of Definition 349.24. Then the restricted packet*

$$T|_U = (k_U, v_U, l_U, b_U, p_U)$$

is again an accepted $\mathsf{Trie}^{\uparrow}$ *source packet under the same* $\mathsf{Bool}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, *and* $\mathsf{BitVector}^{\uparrow}$ *dependency certificates.*

Lean4 ✓ `BEDC.Derived.TrieUp.TrieDisplayedPrefixSubledger restriction carrier`

Proof. Unpack the accepted source packet by Definition 349.1. The original carrier consists only of the key-path row, optional terminal payload row, finite depth ledger, boolean branch ledger, and package provenance row. The displayed subledger definition selects rows from exactly those five coordinates and records the inclusion row ι.

First consider the key coordinate. Since k_U is obtained by selecting displayed positions of the finite $\mathsf{BitVector}^{\uparrow}$ path or $\mathsf{List}^{\uparrow}$ branch-history spine of k, it is again a finite key-path row of the same kind. Prefix-closedness of the selected positions ensures that every selected non-root prefix has its predecessor prefix in the same restricted packet, so no branch read in k_U points outside the restricted carrier.

Next consider the $\mathsf{Nat}^{\uparrow}$ ledger. The row l_U is the restriction of l to selected positions. Every public read admitted by l_U was already a public read admitted by l, and the depth inequality for that read is the same displayed $\mathsf{Nat}^{\uparrow}$ row. Thus the restricted depth ledger is finite and still bounds all selected key and branch reads.

For the branch coordinate, each retained entry of b_U is a $\mathsf{Bool}^{\uparrow}$ tag already present in b. The definition of displayed prefix subledger keeps a branch entry only when its source prefix and the selected left or right subprefix row are both selected by ι. Therefore the branch ledger of the restricted packet has no public unrecorded branch, and every visible branch selection remains routed through displayed finite list or bit-vector positions.

For the optional payload coordinate, the absent case is inherited unchanged from v. In the present case, v_U exposes only a payload row already exposed by the original $\mathsf{Option}^{\uparrow}$ row v at a

selected terminal prefix. Thus no payload comparison, hidden value equality, or terminal read is introduced by the restriction.

Finally, p_U is the projection of the original provenance row p to the dependency rows actually used by k_U, v_U, l_U, and b_U. It names the same kinds of certificates as p: $\mathsf{Bool}^\uparrow$, $\mathsf{List}^\uparrow$, $\mathsf{Option}^\uparrow$, $\mathsf{Nat}^\uparrow$, $\mathsf{BitVector}^\uparrow$, hsame, and Cont. Since Definition 349.4 says every public read of an accepted trie packet factors through the finite ledger coordinates, deleting unselected rows cannot create a host string equality, a host finite map lookup, an ambient function space, an infinite tree, or an implicit ordering on keys.

The five projected coordinates therefore satisfy the same carrier clauses as Definition 349.1. Hence $T|_U = (k_U, v_U, l_U, b_U, p_U)$ is an accepted $\mathsf{Trie}^\uparrow$ source packet under the same finite dependency certificates. □

Theorem 349.26 (Trie prefix subledger provenance exhaustion)**.** *Let $T = (k, v, l, b, p)$ be an accepted $\mathsf{Trie}^\uparrow$ source packet, and let U be a displayed prefix subledger of T. Every public read of the restricted packet*

$$T|_U = (k_U, v_U, l_U, b_U, p_U)$$

factors through the restricted key, value, depth, branch, and provenance rows k_U, v_U, l_U, b_U, p_U. In particular the restricted read can use only the projected $\mathsf{Bool}^\uparrow$, $\mathsf{List}^\uparrow$, $\mathsf{Option}^\uparrow$, $\mathsf{Nat}^\uparrow$, $\mathsf{BitVector}^\uparrow$, hsame, Cont, and Pkg coordinates named by p_U; it cannot introduce a host finite map, hidden string equality, unlisted ordering on keys, ambient function space, or infinite-tree datum.

Lean4 ✓ `BEDC.Derived.TrieUp.TriePrefixSubledger provenance exhaustion`

Proof. Start with the displayed prefix subledger of Definition 349.24. Its inclusion row ι selects prefix-closed positions from the original finite key-path ledger, and its restricted rows k_U, v_U, l_U, b_U, p_U are projections of the original five carrier coordinates.

Apply Definition 349.25. The restricted tuple is again an accepted $\mathsf{Trie}^\uparrow$ source packet under the same finite dependency certificates, so its public reads are ordinary Trie reads rather than host-side lookups.

Finally apply Definition 349.4 to $T|_U$. Ledger coverage exhausts public access by the finite rows of the accepted packet. Since those rows are precisely the restricted rows supplied by the displayed subledger, the only available provenance is the projected row p_U, and none of the excluded host or infinite coordinates can enter the restricted read. □

Lean4 ✓ `BEDC.Derived.TrieUp.TrieDisplayedPrefixSubledger public read exhaustion`
↪ variant `BEDC.Derived.TrieUp.TrieDisplayedPrefixSubledger provenance exhaustion`

Theorem 349.27 (Trie List prefix sibling route)**.** *Let $T = (k, v, l, b, p)$ be an accepted $\mathsf{Trie}^\uparrow$ source packet, and let U be a displayed prefix subledger of T. Every read of $T|_U$ as Trie data factors first through the $\mathsf{List}^\uparrow$ spine row of chapter 36, the $\mathsf{Option}^\uparrow$ payload row of chapter 33, the $\mathsf{Bool}^\uparrow$ branch tags, the $\mathsf{Nat}^\uparrow$ depth ledger, componentwise hsame transport, displayed Cont replay, and the projected Pkg provenance row before the local $\mathsf{Trie}^\uparrow$ carrier may expose the restricted prefix.*

Proof. Project the displayed prefix subledger of Definition 349.24. The selected key coordinate k_U is a finite $\mathsf{BitVector}^\uparrow$ path or $\mathsf{List}^\uparrow$ spine, the payload coordinate v_U is the restricted $\mathsf{Option}^\uparrow$ row, the branch coordinate b_U retains only displayed $\mathsf{Bool}^\uparrow$ tags, and the depth coordinate l_U is the projected $\mathsf{Nat}^\uparrow$ ledger.

The restriction theorem Definition 349.25 repacks exactly those projected coordinates as an accepted $\mathsf{Trie}^\uparrow$ source packet. Its proof already requires the branch source and target prefixes to

remain selected by the inclusion row, so the displayed list spine and optional payload row remain upstream of every Trie read.

Finally apply Definition 349.26. Public reads of the restricted packet are exhausted by k_U, v_U, l_U, b_U, p_U, and p_U names only the projected finite certificates, hsame transport, and Cont replay. Thus no restricted Trie read can bypass the List and Option sibling rows or treat a host finite map, string equality, ordering, ambient function space, or infinite tree as Trie data. □

Chapter 350

A Concrete Naming Certificate for $\mathsf{RationalStream}^{\uparrow}$

The $\mathsf{RationalStream}^{\uparrow}$ interface names finite packets for pointwise rational stream observations on the path from $\mathsf{Rat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ to $\mathsf{RegSeqRat}^{\uparrow}$ and the $\mathsf{Real}^{\uparrow}$ seal. Following Bishop-style constructive analysis of rational Cauchy streams, the packet keeps the observation schedule, rational point rows, classifier rows, and provenance visible without forming quotient Cauchy classes or selecting a completed real limit.

Concretely, the packet is the visible finite-window route from chapter 37 through chapter 126 into chapter 301 and finally the seal surface of chapter 38.

Definition 350.1 (RationalStream carrier)**.** *A* $\mathsf{RationalStream}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (u, s, q, \rho, h, c, p, n)$$

with the following visible rows:

1. *u is the* $\mathsf{UnaryHistory}$ *index row naming the certified finite observation positions available to the packet;*
2. *s is the* $\mathsf{StreamName}^{\uparrow}$ *schedule row selecting which rational observation is read at each displayed unary index;*
3. *q is the family of pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows read along the schedule s;*
4. *ρ is the family of pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows comparing scheduled rational observations at the same displayed indices;*
5. *h records the componentwise* hsame *transport rows for indices, schedules, rational carriers, and rational classifiers;*
6. *c records the* Cont *routes through which finite index windows and their scheduled rational reads are exposed to consumers;*
7. *p is the visible* Pkg *provenance row naming the* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *dependency certificates used by the packet;*
8. *n is the local* $\mathsf{NameCert}_{\mathsf{RationalStream}^{\uparrow}}$ *registration row.*

The carrier predicate is $\mathsf{RationalStreamPacket}(u, s, q, \rho, h, c, p, n)$*. Its classifier compares two accepted packets only by transporting the displayed schedule and applying the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows on the certified unary indices.*

Theorem 350.2 (RationalStream pointwise RatUp obligations)**.** *Every accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet exposes its rational observations only through the pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier family* q *and classifier family* ρ *indexed by the displayed* UnaryHistory *row* u*. Reflexive, symmetric, transitive, and transported comparisons of rational observations are therefore obligations over the stored* $\mathsf{Rat}^{\uparrow}$ *rows, not over a quotient or host rational stream object.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket pointwise rat obligations`

Proof. Project the carrier of Definition 350.1. The only coordinates that contain rational point data are q and ρ, and both are indexed through the visible unary row u and schedule row s.

The transport coordinate h moves the displayed point rows by hsame, while c records the continuation routes used to read finite windows. Repacking these projections gives the four pointwise comparison obligations entirely on the stored $\mathsf{Rat}^{\uparrow}$ rows. □

Theorem 350.3 (RationalStream StreamName schedule boundary)**.** *The* $\mathsf{StreamName}^{\uparrow}$ *schedule boundary of an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet is exactly the row* s *together with the unary index row* u*, the continuation routes* c*, and the transported schedule witnesses in* h*. A consumer may ask which finite rational observation is read at a displayed index, but the packet supplies no unbounded stream object outside those scheduled finite reads.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket streamname schedule boundary`

Proof. Read the schedule coordinate s from the carrier. Its domain of visible reads is the unary index row u, and each consumer route is one of the continuation rows stored in c.

If the same schedule is transported, the corresponding witness is one of the hsame rows in h. No other coordinate stores a stream selector, so the schedule boundary is exhausted by these rows. □

Theorem 350.4 (RationalStream RegSeqRat handoff)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet may read only the finite stream-name schedule* s*, unary index row* u*, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier and classifier rows* q *and* ρ*, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The handoff records a regularity request surface for rational finite windows; it does not assert Cauchy completeness, selected limits, or equality of completed real values.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket regseqrat handoff transport`

Proof. Start with the accepted packet and project the coordinates read by a regular sequence consumer. The schedule s chooses the finite observations, u names their indices, and the rows q and ρ provide the rational carrier and classifier data at those indices.

The provenance coordinates h, c, p, and n record transport, continuation, dependency, and registration information. Repacking exactly these rows gives the $\mathsf{RegSeqRat}^{\uparrow}$ handoff surface, with no coordinate left for completion or a selected limit. □

Theorem 350.5 (RationalStream NameCert seed obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RationalStream}^{\uparrow}}$ *seed surface consists of five rows:*

1. *carrier: the finite packet of Definition 350.1;*
2. *classifier: pointwise* $\mathsf{Rat}^{\uparrow}$ *comparison over the scheduled unary indices;*
3. *stability:* hsame *transport of the unary index row, schedule row, point carriers, and point classifiers;*

4. *ledger: the finite windows, continuation routes, package provenance, and local naming registration visible in c, p, and n;*
5. $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: the regular rational-stream request surface of Definition 350.4.*

These five rows form the seed obligation sketch for rational stream packets on the current $\mathsf{Real}^{\uparrow}$ *and completion path.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket namecert seed obligations`

Proof. Carrier and classifier are obtained by projecting the packet coordinates named in Definition 350.1. The pointwise obligation theorem identifies the rational comparison rows, and the schedule-boundary theorem identifies the finite observation schedule.

Stability is the projection of the displayed hsame coordinate h. The ledger is the projection of c, p, and n, and the regular-sequence row is the handoff supplied by Definition 350.4. These projections account for every carrier coordinate, so the five seed obligations are complete for the displayed packet. □

Theorem 350.6 (RationalStream common-window classifier stability)**.** *If two accepted* $\mathsf{RationalStream}^{\uparrow}$ *packets classify together, then their comparison factors through a displayed common finite unary window. On that window the two* $\mathsf{UnaryHistory}$ *rows are related by the stored* hsame *witnesses, the* $\mathsf{StreamName}^{\uparrow}$ *schedules select the same displayed finite observation positions, and every rational comparison is one of the pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows ρ transported along the packet data. The stability claim exposes only finite windows and stored rational rows; it does not identify quotient Cauchy classes, choose a limit, or assert equality inside completed* $\mathsf{Real}^{\uparrow}$*.*

Proof. Project the two carrier tuples from Definition 350.1. The only classifier coordinates are the pointwise rational rows ρ, and the only index transport coordinates are the displayed hsame rows in h.

Use Definition 350.2 to reduce every rational comparison to the stored $\mathsf{Rat}^{\uparrow}$ carrier and classifier rows. Use Definition 350.3 to identify the finite schedule rows and the common unary window on which the comparison is read.

The remaining coordinates c, p, and n record consumer routes, dependency provenance, and local registration. None supplies a quotient Cauchy object, a selected limiting real, or completed $\mathsf{Real}^{\uparrow}$ equality, so the common-window classifier stability is exhausted by the displayed finite packet rows. □

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket common window classifier stability`

Theorem 350.7 (RationalStream common-denominator window exhaustion)**.** *Any finite consumer read comparing scheduled rational observations from two accepted* $\mathsf{RationalStream}^{\uparrow}$ *packets can be refined to one displayed unary window and one displayed common-denominator* $\mathsf{Rat}^{\uparrow}$ *comparison ledger over the pointwise carrier and classifier rows. The refinement uses only the stored* $\mathsf{UnaryHistory}$ *indices, the two* $\mathsf{StreamName}^{\uparrow}$ *schedules, the pointwise rational carrier rows q, the pointwise classifier rows ρ, and the* hsame *and* Cont *transport routes already present in the packets. It introduces no quotient Cauchy classes, selected limits, or completed* $\mathsf{Real}^{\uparrow}$ *equality.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket common denominator window exhaustion`

Proof. Start with the consumer read and project the two accepted carrier packets of Definition 350.1. The StreamName schedule boundary Definition 350.3 identifies the finite unary indices on which the compared observations are read.

Apply the common-window classifier stability theorem Definition 350.6. It refines the two schedule reads to a single displayed finite unary window and transports the pointwise rows along the stored hsame witnesses.

On that window, use the pointwise RatUp obligations of Definition 350.2. Each scheduled comparison is a rational comparison between displayed $\mathsf{Rat}^{\uparrow}$ rows, so the finite list of denominators read by the consumer can be represented by one common-denominator comparison ledger inside the same pointwise carrier and classifier surface.

The ledger is routed through the displayed Cont rows and repacked with the same package and local naming data. Since every row used in the construction is already a finite packet coordinate, the refinement has no coordinate from which a quotient Cauchy class, selected limit, or completed $\mathsf{Real}^{\uparrow}$ equality could be obtained. □

Theorem 350.8 (RationalStream schedule transport exactness)**.** *Transporting an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet by the stored* hsame *rows transports exactly its* UnaryHistory *index,* $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalStream}^{\uparrow}}$ *row. The transported packet is again accepted with the same finite schedule surface, and the transport introduces no unbounded stream, quotient Cauchy class, selected limit, or completed* $\mathsf{Real}^{\uparrow}$ *equality.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamSchedule transport exactness`
↪ variant `BEDC.Derived.RationalStreamUp.RationalStreamPacket schedule transport exactness`

Proof. Start from the carrier tuple $(u, s, q, \rho, h, c, p, n)$ in Definition 350.1. The transport coordinate h is componentwise, so it names exactly the allowed movements of the unary index row, schedule row, rational carriers, and rational classifiers.

The schedule boundary theorem Definition 350.3 identifies the finite stream-name surface after transport. The pointwise obligation theorem Definition 350.2 keeps the rational rows inside the transported $\mathsf{Rat}^{\uparrow}$ data, and Definition 350.4 records that c, p, and n are the only consumer, provenance, and registration rows exposed to the regular-sequence reader.

Repacking these transported coordinates gives another accepted packet with the same finite support. Since every coordinate has been accounted for, no coordinate remains from which an unbounded stream, quotient class, chosen limit, or completed real equality could be introduced. □

Theorem 350.9 (RationalStream RegSeqRat ledger completeness)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read from an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet is exhausted by the scheduled unary indices, the pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier and classifier rows,* hsame *and* Cont *transport data,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RationalStream}^{\uparrow}}$ *ledger. The ledger therefore records a complete finite rational-stream handoff surface and excludes quotient Cauchy classes, selected limiting reals, and completed* $\mathsf{Real}^{\uparrow}$ *equality.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket regseqrat finite window surface`

Proof. Project the accepted packet carrier. Its scheduled consumer-visible rows are u and s for finite indices and stream-name choices, together with q and ρ for the pointwise rational data.

Apply Definition 350.4. It states that a regular-sequence consumer may read only those scheduled rational rows and the displayed hsame, Cont, Pkg, and NameCert provenance.

The pointwise obligation theorem Definition 350.2 and the schedule boundary theorem Definition 350.3 identify the rational and schedule parts of that handoff. The remaining coordinates are exactly h, c, p, and n, so the consumer ledger is complete for the packet and leaves no row for quotient completion or a selected real limit. □

Theorem 350.10 (RationalStream finite-window carrier transport)**.** *Let*

$$R = (u, s, q, \rho, h, c, p, n)$$

be an accepted $\mathsf{RationalStream}^{\uparrow}$ *packet. Transport the displayed* $\mathsf{UnaryHistory}$ *index row,* $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows,* Cont *windows,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalStream}^{\uparrow}}$ *row by the componentwise* hsame *rows stored in* h*. The transported rows again form an accepted* $\mathsf{RationalStreamPacket}$*, and the accepted carrier exposes no coordinate beyond that finite transported window.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket finite window carrier transport`

Proof. Project the carrier in Definition 350.1. The coordinate h lists exactly the hsame rows available for the unary index, schedule, point carriers, and point classifiers, while c, p, and n are the continuation, package, and naming rows transported with them.

Apply Definition 350.3 to u, s, c, and h to keep the finite stream-name schedule fixed at the transported window. Apply Definition 350.2 to q and ρ so every rational comparison remains a transported $\mathsf{Rat}^{\uparrow}$ row.

Repack the transported p and n rows with these schedule and pointwise rational data. This reconstructs the accepted packet, and the projection accounts for every component of R. □

Theorem 350.11 (RationalStream pointwise classifier laws)**.** *The* $\mathsf{RationalStream}^{\uparrow}$ *classifier is reflexive, symmetric, and transitive on accepted packets whenever those three laws are read pointwise from the stored* $\mathsf{Rat}^{\uparrow}$ *classifier rows at every displayed unary index. These laws are stable under the* hsame *transports in the packet, with the* $\mathsf{StreamName}^{\uparrow}$ *schedule fixed by the displayed schedule boundary.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket pointwise classifier laws`

Proof. Use Definition 350.2 on each displayed unary index. Reflexivity, symmetry, and transitivity of packet classification are then the corresponding pointwise $\mathsf{Rat}^{\uparrow}$ classifier obligations for the rows q and ρ.

The classifier comparison is read only along the schedule boundary from Definition 350.3. Transport through hsame changes the displayed rows but not the finite schedule surface, so the three laws remain pointwise and no quotient stream equality is introduced. □

Theorem 350.12 (RationalStream RegSeqRat obligation package)**.** *The carrier of Definition 350.1, the pointwise classifier laws of Definition 350.11, the finite-window transport of Definition 350.10, the schedule boundary of Definition 350.3, the finite ledger of Definition 350.9, and the handoff of Definition 350.4 form the complete* $\mathsf{RationalStream}^{\uparrow}$ *obligation package consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*. The package supplies no quotient stream, selected limit, or completed real equality.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket regseqrat obligation package`

Proof. Assemble the carrier and seed rows from Definition 350.5. The schedule boundary and pointwise rational obligations identify the finite stream-name and $\mathsf{Rat}^{\uparrow}$ surfaces, while the classifier-law theorem supplies the three classifier laws over those surfaces.

Use the finite-window transport theorem for stability under the stored hsame rows. Use Definition 350.9 for the finite consumer ledger and Definition 350.4 for the regular-sequence handoff consumed downstream.

These inputs exhaust the rows of the displayed packet. Since none of the rows contains a quotient stream object, a selected limit, or a completed $\mathsf{Real}^{\uparrow}$ equality proof, the package records exactly the obligation surface needed by $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$. □

Theorem 350.13 (RationalStream scoped boundary)**.** *The carrier of Definition 350.1, pointwise* $\mathsf{Rat}^{\uparrow}$ *obligations of Definition 350.2,* $\mathsf{StreamName}^{\uparrow}$ *schedule boundary of Definition 350.3,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 350.4, classifier stability of Definition 350.11, exact schedule transport of Definition 350.10, and ledger completeness of Definition 350.9 assemble a scoped finite rational-stream packet.*

This packet is over BHist*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*, and* $\mathsf{RegSeqRat}^{\uparrow}$*. It exports no quotient Cauchy class, selected limit,* $\mathsf{Real}^{\uparrow}$ *completeness row, trichotomy, or bridge.*

Proof. Project the carrier and pointwise rational rows from Definition 350.1 and Definition 350.2. These projections give the finite unary index rows, displayed rational data, and classifier coordinates.

Next use the StreamName schedule boundary and exact carrier transport. The theorems Definition 350.3 and Definition 350.10 keep the finite schedule and transported rows inside the displayed UnaryHistory, hsame, and Cont surface.

Finally apply Definition 350.4, Definition 350.11, and Definition 350.9. They identify the regular-sequence handoff, classifier stability, and complete consumer ledger over the displayed package and naming rows.

Repacking these rows gives the scoped finite boundary. Since the cited packet coordinates contain no quotient Cauchy class, selected limit, $\mathsf{Real}^{\uparrow}$ completeness row, trichotomy, or bridge, none is exported by the handoff surface. □

Theorem 350.14 (RationalStream public export)**.** *The carrier of Definition 350.1, pointwise* $\mathsf{Rat}^{\uparrow}$ *obligations,* $\mathsf{StreamName}^{\uparrow}$ *schedule boundary,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, common-window classifier stability, schedule transport exactness, ledger completeness, and scoped boundary form the public* $\mathsf{RationalStream}^{\uparrow}$ *export consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*.*

This public export is a finite BEDC packet over BHist*,* UnaryHistory*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It exports no quotient Cauchy class, selected limit, completed* $\mathsf{Real}^{\uparrow}$ *equality, trichotomy, or standard bridge.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket public export`

Proof. Begin with the carrier and pointwise rational rows. Apply Definition 350.1 and Definition 350.2 to project the visible BHist, UnaryHistory, and $\mathsf{Rat}^{\uparrow}$ coordinates.

Next build the finite schedule surface. Use Definition 350.3 for the $\mathsf{StreamName}^{\uparrow}$ boundary and Definition 350.10 for exact transport of the displayed hsame and Cont rows.

Now attach the downstream handoff rows. Apply Definition 350.11, Definition 350.9, and Definition 350.4 to obtain classifier stability, ledger completeness, and the $\mathsf{RegSeqRat}^{\uparrow}$ consumer surface.

Finally repack the result through Definition 350.13. The package and naming rows are exactly the displayed Pkg and NameCert provenance. Since the scoped boundary has no coordinate for a quotient Cauchy class, selected limit, completed $\mathsf{Real}^{\uparrow}$ equality, trichotomy, or standard bridge, the public export exposes none of those rows. □

Theorem 350.15 (RationalStream RegSeqRat RealUp consumer coverage)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read of an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet factors through exactly the finite unary*

index row, the StreamName$^{\uparrow}$ *schedule, the pointwise* Rat$^{\uparrow}$ *carrier and classifier rows, the displayed* hsame *rows, the* Cont *routes, the* Pkg *provenance, and the local* NameCert *row already present in Definition 350.1.*

The coverage surface exposes no quotient Cauchy class, selected limit, host stream equality, completed Real$^{\uparrow}$ *equality, or hidden completion coordinate.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket regseqrat realup consumer coverage`

Proof. Start from the public packet of Definition 350.14. Its exported rows are the finite BEDC packet over BHist, UnaryHistory, hsame, Cont, Pkg, and NameCert with the pointwise rational data and downstream-facing schedule already displayed.

Next apply Definition 350.10. This keeps every transported consumer read on the finite unary index row and the displayed hsame and Cont routes, so no host stream equality is introduced when the consumer selects a window.

Use Definition 350.11 to identify each endpoint read with the visible Rat$^{\uparrow}$ carrier and classifier rows. Then use Definition 350.9 to exhaust the regular-sequence ledger entries available to downstream consumers.

Finally apply Definition 350.4. The handoff repackages exactly the displayed finite index, schedule, rational endpoint, transport, route, package, and naming rows. Since none of the cited surfaces has a coordinate for quotient Cauchy classes, selected limits, host stream equality, completed Real$^{\uparrow}$ equality, or hidden completion coordinates, no RegSeqRat$^{\uparrow}$ or Real$^{\uparrow}$ consumer can factor through such data. □

Theorem 350.16 (RationalStream standard bridge)**.** *For a carried* RationalStream$^{\uparrow}$ *packet over unary* StreamName$^{\uparrow}$ *observations and* Rat$^{\uparrow}$ *endpoint classifiers, the public export of Definition 350.14, finite-window carrier transport of Definition 350.10, pointwise classifier laws of Definition 350.11, and the* RegSeqRat$^{\uparrow}$ *obligation package of Definition 350.12 determine a conservative standard reading as a finite-window rational sequence prefix.*

Reading that finite standard prefix back into the BEDC packet recovers the same BHist *window, denominator rows, endpoint classifier rows,* StreamName$^{\uparrow}$ *schedule rows, and* RegSeqRat$^{\uparrow}$ *ledger rows. The bridge adds no quotient sequence, selected real limit, host equality of streams, or hidden completion coordinate.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamUp StdBridge`

Proof. Project the public packet using Definition 350.14. This exposes only finite BHist windows, unary schedule rows, rational endpoint data, transport rows, package provenance, and naming evidence.

Use Definition 350.10 to align the chosen standard prefix with the carried finite window. The same displayed hsame and Cont rows transport the window and schedule, so the readback has the original StreamName$^{\uparrow}$ observation rows.

Apply Definition 350.11 at each exposed endpoint. The numerator, denominator, and endpoint classifier rows are therefore the same rows after the standard-prefix readback.

Finally use Definition 350.12 for the downstream handoff. It supplies the RegSeqRat$^{\uparrow}$ ledger rows consumed by the finite prefix and records that all hidden data remains in the displayed ledger, which gives conservativity and excludes quotient sequences, selected limits, host stream equality, and hidden completion coordinates. □

Theorem 350.17 (RationalStream standard bridge common-window readback)**.** *For an accepted* RationalStream$^{\uparrow}$ *packet over unary* StreamName$^{\uparrow}$ *observations and* Rat$^{\uparrow}$ *endpoint classifiers, the*

standard bridge readback of Definition 350.16 factors through one displayed finite unary common window. The rows of that window are exactly the $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *ledger rows, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

The readback exports no quotient Cauchy class, selected limit, completed $\mathsf{Real}^{\uparrow}$ *equality, trichotomy, or host stream equality. Hence the same finite common window is the readback surface consumed by both* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket standard bridge common window readback`

Proof. First put the endpoint classifiers on a single finite comparison surface. Apply Definition 350.6 to align the carried pointwise classifier rows, and then apply Definition 350.7 to read the denominator comparisons inside that same displayed unary window.

Next transport the carrier rows without changing the readback surface. Use Definition 350.10 to keep the schedule, pointwise rational carriers, pointwise classifiers, hsame rows, Cont routes, package provenance, and local naming rows on the chosen window.

Then exhaust the regular-sequence consumer ledger with Definition 350.9. This identifies the $\mathsf{RegSeqRat}^{\uparrow}$ rows consumed downstream with the same schedule, classifier, carrier, transport, route, package, and certificate rows already displayed by the finite window.

Finally apply Definition 350.16. The standard bridge reads back only the finite rational sequence prefix, so the readback has no coordinate for quotient Cauchy classes, selected limits, completed $\mathsf{Real}^{\uparrow}$ equality, trichotomy, or host stream equality.

The Phase Real and Completion fit is the following: traditional target, finite rational stream readback; BEDC source, $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$; carrier, the displayed $\mathsf{RationalStream}^{\uparrow}$ packet; classifier, the common finite-window classifier; stability, the hsame and Cont transport; ledger, the finite window rows; core theorem, Definition 350.17; exactness, readback equality of rows; standard bridge, finite rational sequence prefix; status, proof target. □

Theorem 350.18 (RationalStream RealUp finite-window consumer example)**.** *For a carried* $\mathsf{RationalStream}^{\uparrow}$ *packet over unary* $\mathsf{StreamName}^{\uparrow}$ *observations and* $\mathsf{Rat}^{\uparrow}$ *endpoint classifiers, the public export of Definition 350.14, finite-window carrier transport of Definition 350.10, pointwise classifier laws of Definition 350.11, the* $\mathsf{RegSeqRat}^{\uparrow}$ *obligation package of Definition 350.12, and the standard bridge of Definition 350.16 determine a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer packet.*

The visible rows of this consumer are exactly BHist *windows,* UnaryHistory *schedules,* hsame *transport,* Cont *routes,* Pkg *provenance,* NameCert *evidence,* $\mathsf{Rat}^{\uparrow}$ *endpoint classifiers,* $\mathsf{StreamName}^{\uparrow}$ *schedules, and* $\mathsf{RegSeqRat}^{\uparrow}$ *ledger rows. It exports no quotient Cauchy class, selected limit,* $\mathsf{Real}^{\uparrow}$ *completeness, trichotomy, or machine-checked bridge.*

Proof. Project the carried packet through Definition 350.14. This exposes the finite BHist window, unary observation schedule, pointwise rational endpoint rows, package provenance, and local naming evidence.

Replay the finite window with Definition 350.10. The displayed hsame rows and Cont routes identify the transported finite-window carrier without adding any host stream equality.

Use Definition 350.11 endpointwise. Each visible $\mathsf{Rat}^{\uparrow}$ classifier row is preserved by the finite transport, so the consumer reads the same rational endpoint data as the source packet.

Consume the regular-sequence rows through Definition 350.12. The resulting ledger is the complete $\mathsf{RegSeqRat}^{\uparrow}$ surface available to the downstream finite-window consumer.

Finally close by Definition 350.16. The bridge reads only the finite rational prefix and returns exactly the displayed history, schedule, transport, route, package, naming, classifier, and ledger

rows. Since none of the cited packets has a coordinate for quotient Cauchy classes, selected limits, completed $\mathsf{Real}^{\uparrow}$ equality, trichotomy, or machine-checked bridge evidence, the consumer exports none of those data. □

Theorem 350.19 (RationalStream RealUp seal consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of the* $\mathsf{RationalStream}^{\uparrow}$ *standard bridge of Definition 350.16 may read only the finite unary schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *rows,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, common-window classifier, finite-window transport, package provenance, and local* $\mathsf{NameCert}$ *row already named by Definition 350.16. It cannot read quotient Cauchy classes, a selected limit, completed* $\mathsf{Real}^{\uparrow}$ *equality, trichotomy, or host-level standard real data.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamSealConsumer boundary`

Proof. Project the carrier from Definition 350.1. This exposes only finite unary index rows, pointwise rational endpoint data, denominator rows, and the displayed package and naming coordinates carried by the rational stream packet.

Apply Definition 350.14 and Definition 350.16. The public export gives the $\mathsf{RegSeqRat}^{\uparrow}$- and $\mathsf{Real}^{\uparrow}$-facing packet, while the standard bridge reads it as a finite-window rational sequence prefix with the same visible schedule, classifier, transport, package, and naming rows.

Use Definition 350.9 to exhaust the regular-sequence handoff rows. The handoff ledger accounts for the downstream consumer reads by finite prefix, rational endpoint, schedule, and provenance coordinates.

Finally apply Definition 350.13. Since that boundary has no coordinate for quotient Cauchy classes, selected limits, completed $\mathsf{Real}^{\uparrow}$ equality, trichotomy, or host-level standard real data, a $\mathsf{Real}^{\uparrow}$-facing consumer of the standard bridge cannot project any such datum. □

Theorem 350.20 (RationalStream RealUp seal common-window normal form)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing read of a* $\mathsf{RationalStream}^{\uparrow}$ *standard bridge factors through one displayed common finite unary window. The rows of that window are exactly the* $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *ledger rows, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *evidence.*

The normal form exports no quotient Cauchy class, selected limit, completed $\mathsf{Real}^{\uparrow}$ *equality, trichotomy, or host standard stream equality. Any* $\mathsf{Real}^{\uparrow}$ *seal consumer therefore reads the same finite common window consumed by the downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *packet surfaces.*

Lean4 ✓ `BEDC.Derived.RationalStreamUp.RationalStreamPacket real seal common window normal form`

Proof. Project the carried rational stream packet through Definition 350.1. The carrier projection exposes only the finite unary index, the stream schedule, pointwise rational rows, visible transport and route data, package provenance, and local naming evidence.

Use Definition 350.6 to align the pointwise rational classifiers with a single common window. Then apply Definition 350.7 to put the denominator rows read by the endpoint classifiers on that same displayed finite window.

Next apply Definition 350.9. This exhausts the $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows available to any downstream consumer and keeps them attached to the same schedule, classifier, transport, route, package, and certificate rows.

Finally combine Definition 350.16 with Definition 350.19. The standard bridge gives the finite rational-prefix reading, and the seal boundary rules out every read outside the displayed rows. Repacking those rows gives the claimed common finite-window normal form and excludes quotient

Cauchy classes, selected limits, completed $\mathsf{Real}^{\uparrow}$ equality, trichotomy, and host standard stream equality. □

Theorem 350.21 (RationalStream finite-window seal determinacy)**.** *For accepted* $\mathsf{RationalStream}^{\uparrow}$ *packets, agreement of the displayed* UnaryHistory *index row,* $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *carrier rows, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, common-window ledger, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row determines exactly the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and the* $\mathsf{Real}^{\uparrow}$ *seal consumer reads.*

Conversely, every $\mathsf{RegSeqRat}^{\uparrow}$ *handoff read and every* $\mathsf{Real}^{\uparrow}$ *seal consumer read of an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet is one of those finite rows. No quotient Cauchy class, selected limit, completed* $\mathsf{Real}^{\uparrow}$ *equality, trichotomy row, or host standard stream equality is determined or exported by the finite-window seal.*

Proof. Project the accepted packet through Definition 350.1. This exposes the finite unary index row, schedule row, pointwise rational carrier and classifier rows, denominator data, displayed transport and route rows, package provenance, and local naming evidence.

Use the schedule boundary and the pointwise $\mathsf{Rat}^{\uparrow}$ obligations to identify which displayed rows may be read at each finite index. Then apply Definition 350.6 to place the classifier rows on the same common window.

Apply Definition 350.7. The denominator rows needed by the pointwise rational classifiers are exhausted by that common finite window, so no further denominator coordinate remains for a downstream consumer.

Next use Definition 350.9. It turns the displayed schedule, pointwise rational rows, classifier rows, transports, routes, package provenance, and naming row into exactly the $\mathsf{RegSeqRat}^{\uparrow}$ handoff surface.

For the $\mathsf{Real}^{\uparrow}$ seal direction, invoke Definition 350.19 and Definition 350.20. The seal consumer boundary admits only finite packet rows, and the normal form places all such reads on the same common window.

The converse follows by reading the same projections in the opposite order: any $\mathsf{RegSeqRat}^{\uparrow}$ handoff or $\mathsf{Real}^{\uparrow}$ seal read must pass through the carrier projection, the common-window classifier stability, the denominator exhaustion step, and the seal normal form. Hence each consumer coordinate is one of the listed finite rows. □

Theorem 350.22 (RationalStream synchronized seal readback exhaustion)**.** *Any synchronized finite-window read of an accepted* $\mathsf{RationalStream}^{\uparrow}$ *packet factors through exactly its displayed* $\mathsf{StreamName}^{\uparrow}$ *schedule, pointwise* $\mathsf{Rat}^{\uparrow}$ *rows, common-window classifier rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal consumer boundary, displayed* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *rows.*

The read exports no quotient stream equality, selected limit, completed $\mathsf{Real}^{\uparrow}$ *equality, trichotomy row, or host stream equality beyond that finite seal boundary.*

Proof. Use Definition 350.6 and Definition 350.7 to place the classifier and denominator reads on one displayed finite window.

Then apply Definition 350.9, Definition 350.19, and Definition 350.21. These theorems identify the handoff, seal consumer read, and exclusion boundary with the same finite packet rows. □

Theorem 350.23 (RationalStream tail-window determinacy)**.** *Two* $\mathsf{RationalStream}^{\uparrow}$ *packets with the same finite unary schedule, common-denominator window, pointwise* $\mathsf{Rat}^{\uparrow}$ *classifier rows, and*

hsame-*transported tail selector determine the same finite* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *seal consumer package on that window.*

The conclusion is only the finite tail-window package: it exports no quotient Cauchy class, selected limit, completed Real$^{\uparrow}$ *equality, trichotomy row, or host standard stream equality.*

Proof. Apply Definition 350.6 to place the classifier readings on the shared finite window. Then use Definition 350.7 for the common denominator rows.

Transport the tail selector with Definition 350.10. The transported carrier exposes the same schedule, classifier, hsame, Cont, Pkg, and local NameCert rows to every finite consumer.

Finally apply Definition 350.20 and Definition 350.21. They repack the shared tail-window read as one RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ package. □

Closure status for NameCert$_{\text{RationalStream}^{\uparrow}}$.

Constructive story: A rational stream packet is represented by finite unary index rows, a StreamName schedule, pointwise RatUp carrier and classifier rows, and visible transport, continuation, package, and NameCert provenance on the path to RegSeqRat and the RealUp seal.

Theory closure: TheoryGate(NameCert$_{\text{RationalStream}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 350.13, Definition 350.16, and Definition 350.19 bind the finite carrier, pointwise classifier laws, finite-window transport, schedule boundary, finite ledger, regular-sequence handoff, standard bridge, RealUp seal consumer boundary, and displayed BHist, UnaryHistory, hsame, Cont, Pkg, and NameCert dependencies consumed by RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{RationalStream}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.RationalStreamUp.RationalStreamSchedule\_transport\_exactness`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close quotient Cauchy classes, selected limits, RealUp completeness, trichotomy, or a machine-checked standard bridge.

Upgrade path: no further upgrade – chapter at top of formal axis.

Chapter 351

A Concrete Naming Certificate for $\mathsf{RegularLanguage}^{\uparrow}$

The $\mathsf{RegularLanguage}^{\uparrow}$ interface names finite automaton recognition as a displayed BEDC packet rather than as a host quotient of languages. Following the finite-automaton presentations of Hopcroft–Ullman (1979) and Sipser (2012), the packet records a finite alphabet, finite state row, transition ledger, input word, deterministic run, and accepting endpoint entirely through finite BHist, hsame, Cont, and Pkg rows.

The packet consumes the $\mathsf{List}^{\uparrow}$ word-spine carrier through chapter 36, the $\mathsf{FinSet}^{\uparrow}$ alphabet and state rows through chapter 112, and the $\mathsf{Computable}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ recognizer boundary through chapter 199 and chapter 280. These adjacent certificates supply the displayed finite rows consumed by the automaton packet; they do not import host language-set semantics or an external recognizer quotient.

This places $\mathsf{RegularLanguage}^{\uparrow}$ as the finite-automaton sibling between chapter 356 and chapter 280. Context-free grammar consumers read the regular-language comparison through terminal-yield rows, and $\mathsf{TuringMachine}^{\uparrow}$ consumers read the same accepted-word ledger as a finite recognizer boundary.

Definition 351.1 (RegularLanguage finite-automaton carrier)**.** *A* $\mathsf{RegularLanguage}^{\uparrow}$ *packet is a finite record*

$$R = (\Sigma, Q, q_0, F, \delta, w, r, a, h, c, p)$$

with the following displayed rows:

1. Σ *is a finite alphabet row licensed by* $\mathsf{FinSet}^{\uparrow}$*;*
2. Q *is a finite state row licensed by* $\mathsf{FinSet}^{\uparrow}$*;*
3. q_0 *is the start-state row carried by* Q*;*
4. F *is the accepting-state carrier inside* Q*;*
5. δ *is the transition table row whose entries read a state and an alphabet symbol and return the next displayed state;*
6. w *is the input word as a* $\mathsf{List}^{\uparrow}$ *history row over* Σ*;*
7. r *is the deterministic run ledger over* BHist*, beginning at* q_0 *and consuming the word spine one symbol at a time;*
8. a *is the accepted endpoint row, consisting of the final run state and its membership in* F*;*

9. *h stores the componentwise* hsame *transport rows for alphabet, state, transition, word, run, and accepting endpoint data;*
10. *c stores the* Cont *routes for consuming the displayed word spine and reading each transition step;*
11. *p stores the* Pkg *provenance naming* List$^{\uparrow}$, FinSet$^{\uparrow}$, Computable$^{\uparrow}$, *and* TuringMachine$^{\uparrow}$.

The carrier predicate is RegularLanguageAutomatonPacket(R). *It contains only the displayed finite automaton data and the accepted input row; it exports no host language set, infinite automaton, quotient recognizer, or selected external semantics.*

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageTasteGate single carrier alignment`

Definition 351.2 (RegularLanguage accepted-word classifier)**.** *Two accepted* RegularLanguage$^{\uparrow}$ *packets classify together exactly when their alphabet rows, state rows, transition tables, input words, deterministic run ledgers, and accepting endpoints compare by the displayed* hsame *rows in the packet. The comparison is componentwise:*

$$\Sigma \sim_{\mathsf{hsame}} \Sigma', \quad Q \sim_{\mathsf{hsame}} Q', \quad q_0 \sim_{\mathsf{hsame}} q_0', \quad F \sim_{\mathsf{hsame}} F',$$
$$\delta \sim_{\mathsf{hsame}} \delta', \quad w \sim_{\mathsf{hsame}} w', \quad r \sim_{\mathsf{hsame}} r', \quad a \sim_{\mathsf{hsame}} a'.$$

Each displayed comparison is transported along the stored Cont *routes and is checked against the same* Pkg *provenance. No classifier clause compares unaccepted words or identifies languages extensionally outside the packet.*

Lean4 (definition) `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonClassifier`

Theorem 351.3 (RegularLanguage deterministic run ledger)**.** *For every accepted* RegularLanguage$^{\uparrow}$ *packet, the run ledger is determined by the start-state row, the transition table row, and the displayed* List$^{\uparrow}$ *input spine. At the empty word spine, the run endpoint is the start-state row. At a cons spine, the next run row is obtained by reading the head symbol, applying the unique transition-table entry to the current state, and continuing through the tail spine.*

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket run ledger deterministic`
Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket deterministic run ledger`

Proof. Induct on the displayed List$^{\uparrow}$ word spine. In the empty case, the carrier row requires the initial run row to be q_0, and no transition route is available to change it.

In the cons case, project the current state row and the head alphabet symbol from the carrier. The transition table is finite and deterministic, so the stored table entry supplies one next-state row. The continuation route then hands the tail spine to the induction hypothesis.

The ledger records no additional branch. Therefore every displayed consumer read of the run endpoint is reconstructed by these start, transition, and spine rows. □

Theorem 351.4 (RegularLanguage run-prefix restriction)**.** *For an accepted* RegularLanguage$^{\uparrow}$ *packet and any displayed finite prefix of its* List$^{\uparrow}$ *input word spine, the restricted run ledger is determined by the same start-state row, the transition table rows along the prefix, the prefix word rows, componentwise* hsame *rows,* Cont *routes, and* Pkg *provenance. The endpoint of the restricted run transports to the corresponding endpoint of the full accepted run along the displayed classifier rows.*

This restriction introduces no host language quotient, external regular expression equivalence, minimization datum, infinite automaton, or hidden automaton state.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket run prefix restriction`

Proof. Induct on the displayed prefix. In the empty-prefix case, the restricted run ledger is the start-state row, which is the empty-spine case of Definition 351.3.

For a cons prefix, read the head symbol and the current state from the packet. The deterministic transition table supplies the unique next displayed state, and the Cont route passes the remaining prefix to the induction hypothesis. Thus the restricted ledger is determined only by the prefix word rows and the transition rows exposed along that prefix.

Apply Definition 351.3 to the full word spine and to the displayed prefix restriction. The two ledgers agree on every state reached inside the prefix because they use the same start row and the same transition-table entries.

Finally use Definition 351.5 for the transported endpoint rows. The endpoint comparison is componentwise through hsame, Cont, and Pkg, and no external language quotient, minimization, infinite automaton, or hidden state is available in the packet. □

Theorem 351.5 (RegularLanguage classified word transport)**.** *If two accepted* $\mathsf{RegularLanguage}^{\uparrow}$ *packets classify together, then their accepted-word endpoints transport together: the final state of the first run is carried to the final state of the second run, and acceptance in the first accepting-state carrier is carried to acceptance in the second accepting-state carrier through the displayed* hsame *rows.*

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket classified word transport`

Proof. Use the classifier definition to obtain componentwise comparisons of the alphabet row, state row, transition table, input word, run ledger, and accepting endpoint. The word comparison fixes the same displayed spine shape under $\mathsf{List}^{\uparrow}$ transport.

Apply Definition 351.3 to both packets. At each spine step, the transported transition-table entry sends transported states and transported symbols to transported next states. Thus the final run states compare by the displayed state hsame row.

Finally project the accepting endpoint row. Since the accepting-state carrier is transported componentwise with the state row, the accepted endpoint of the first packet maps to the accepted endpoint of the second packet. □

Theorem 351.6 (RegularLanguage NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation for displayed finite automata with a finite alphabet, finite state carrier, start state, accepting-state carrier, transition table, input word, and accepted deterministic run;*
2. *classifier equivalence from componentwise* hsame *comparison of the alphabet, state, transition, word, run, and accepting endpoint rows;*
3. *deterministic run reconstruction along the displayed* $\mathsf{List}^{\uparrow}$ *input spine by Definition 351.3;*
4. *accepted-word endpoint exactness by Definition 351.5;*
5. *consumer boundary: every public read factors through the displayed* BHist, hsame, Cont, *and* Pkg *rows, with no hidden automaton state, host language quotient, or infinite recognition semantics.*

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket namecert obligation surface`

Proof. Carrier habitation is the finite automaton packet of Definition 351.1. Its rows are finite alphabet and state carriers, a selected displayed start state, a displayed accepting-state carrier, a finite transition table, and a finite input spine.

The classifier row is Definition 351.2. Reflexive, symmetric, and transitive comparison are inherited componentwise from the displayed hsame rows and from the finite table and list-spine transports.

The ledger and exactness rows are supplied by Definition 351.3 and Definition 351.5. They reconstruct the run from the start, transition table, and word spine, then identify the accepted endpoint under classifier transport.

The consumer boundary is obtained by projecting the packet coordinates. Since the carrier has no coordinate for a host language set, quotient recognizer, or infinite automaton, downstream chapters can read only the displayed finite certificate rows. □

Theorem 351.7 (RegularLanguage scoped kernel dependency envelope)**.** *For* $\mathsf{RegularLanguage}^{\uparrow}$*, the finite-automaton carrier, accepted-word classifier, deterministic run ledger, classified-word transport, and local* NameCert *obligation surface are all read from finite* BHist *word rows,* hsame *transport of accepted endpoints,* Cont*-composed run routes,* Pkg *provenance, and the existing* $\mathsf{List}^{\uparrow}$*,* $\mathsf{FinSet}^{\uparrow}$*,* $\mathsf{Computable}^{\uparrow}$*, and* $\mathsf{TuringMachine}^{\uparrow}$ *certificate rows.*

This scoped envelope exports no host regular expression, host-language set extensionality, minimization uniqueness claim, infinite automaton, or external recognizer quotient.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket scoped kernel dependency envelope`

Proof. Read the carrier from Definition 351.1. Its alphabet, state, transition, word, run, accepting endpoint, transport, continuation, and provenance coordinates are finite displayed rows, with the named upstream certificates appearing only through Pkg provenance.

Use Definition 351.2 to bind classifier reads to componentwise hsame transport. Then apply Definition 351.3 and Definition 351.5; together they attach the accepted endpoint to the displayed word spine and to the transported final state.

Finally repack the five-field local certificate surface with Definition 351.6. Every field is one of the displayed finite packet rows or one of the named upstream certificate rows, so the excluded host-language and infinite-automaton objects have no coordinate in the scoped envelope. □

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket scoped dependency reassociation witness`

Theorem 351.8 (RegularLanguage public accepted-word export)**.** *The finite-automaton carrier, accepted-word classifier, deterministic run ledger, classified-word transport, and* $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$ *obligation surface assemble a public* $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$ *export whose readable rows are exactly the finite alphabet row, finite state row, start row, accepting-state row, transition table,* $\mathsf{List}^{\uparrow}$ *word spine, deterministic run ledger, accepted endpoint, componentwise* hsame *rows,* Cont *routes, and* Pkg *provenance.*

The export contains no host language quotient, external regular-expression equivalence, minimization result, infinite automaton, selected recognizer semantics, or hidden automaton state.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket public accepted word export`

Proof. Read the finite alphabet, finite state row, start state, accepting-state carrier, transition table, and input word spine from Definition 351.1.

Use Definition 351.2 to bind public classifier reads to the componentwise hsame rows. Then apply Definition 351.3 to obtain the displayed deterministic run ledger over the $\mathsf{List}^{\uparrow}$ spine.

Next apply Definition 351.5. It identifies the accepted endpoint as the transported endpoint of the same finite run, with the stated Cont routes and package provenance.

Finally use Definition 351.6 to repack these rows as the public accepted-word $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$ export. Since none of the carrier or obligation rows is a host language quotient, regular-expression equivalence, minimization result, infinite automaton, selected recognizer semantics, or hidden automaton state, the public packet exports no such object. □

Theorem 351.9 (RegularLanguage transition-ledger standard boundary)**.** *The standard finite-automaton reading of a public* $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$ *packet may consume exactly the finite alphabet row, finite state row, start row, accepting-state row, transition table,* $\mathsf{List}^{\uparrow}$ *word spine, deterministic run ledger, accepted endpoint, displayed* hsame *transport rows,* Cont *routes, and* Pkg *provenance.*

It cannot read a host language quotient, regular-expression equivalence, minimization result, infinite automaton, or hidden recognizer state.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket transition ledger standard boundary`

Proof. Read the carrier rows from Definition 351.1. These are precisely the finite alphabet, finite state, start, accepting-state, transition-table, word-spine, deterministic-run, and accepted-endpoint rows available to the standard finite-automaton reading.

Use Definition 351.2 to bind classifier reads to the displayed hsame comparisons. Then apply Definition 351.3; the run is reconstructed from the displayed start row, transition table, and $\mathsf{List}^{\uparrow}$ word spine.

Next apply Definition 351.5. It carries the accepted endpoint through the displayed transport rows and does not add a host-language coordinate.

Finally apply Definition 351.8. The public export repacks the carrier, classifier, run-ledger, endpoint, continuation, and package rows as the visible certificate surface, while the excluded quotient, equivalence, minimization, infinite-automaton, and hidden recognizer objects are not rows of that surface. □

Theorem 351.10 (RegularLanguage standard finite-automaton bridge boundary)**.** *The standard finite-automaton reading of the public* $\mathsf{RegularLanguage}^{\uparrow}$ *packet consumes exactly the finite state row, start row, accepting row, transition ledger, input-word* $\mathsf{List}^{\uparrow}$ *rows, deterministic run ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and* NameCert *surface already exported by Definition 351.8.*

The bridge boundary supplies no minimization theorem, Kleene algebra surface, pumping-lemma witness, language-complement closure, or machine-checked bridge evidence.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket standard automaton bridge boundary`

Proof. Read the automaton rows from Definition 351.1. The finite state row, start row, accepting row, transition table, and input-word $\mathsf{List}^{\uparrow}$ spine are all displayed fields of the carrier.

Use Definition 351.2 to bind accepted-word reads to the componentwise hsame transport, then apply Definition 351.3. This supplies the finite deterministic run ledger over exactly the displayed transition and word rows.

Finally apply Definition 351.8. It repackages those rows with the Cont routes, Pkg provenance, and NameCert surface, while the excluded minimization, algebraic, pumping, complement, and machine-checking objects have no coordinate in the public packet. □

Theorem 351.11 (RegularLanguage finite bridge consumer completeness)**.** *Every finite consumer of the standard finite-automaton bridge for* RegularLanguage$^{\uparrow}$ *factors through the displayed alphabet row, finite state row, start row, accepting-state row, transition table,* List$^{\uparrow}$ *word spine, deterministic run ledger, endpoint acceptance row,* hsame *transport rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

Conversely, those rows repack into the same bridge boundary: no host language quotient, regular-expression equivalence, minimization result, infinite automaton, hidden recognizer state, or bridge-external semantic coordinate is needed to reconstruct the finite consumer surface.

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket finite bridge consumer completeness`

Proof. First read the finite carrier from Definition 351.1. This provides the alphabet row, finite state row, start row, accepting-state row, transition table, and List$^{\uparrow}$ word spine consumed by the bridge.

Use Definition 351.2 to identify the accepted-word classifier with the displayed hsame rows. Then apply Definition 351.3; the deterministic run ledger is reconstructed from the start row, transition table, and word spine.

Next apply Definition 351.5 and Definition 351.8. These results carry the endpoint acceptance through the displayed transport, Cont routes, Pkg provenance, and local NameCert surface.

For the converse direction, apply Definition 351.10. It repacks exactly the same displayed rows as the standard finite-automaton bridge boundary. Since the listed exclusions are not rows of that boundary, neither factorization nor repacking can export them. □

Theorem 351.12 (RegularLanguage displayed automaton consumer examples)**.** *An accepted* RegularLanguage$^{\uparrow}$ *packet supplies three finite downstream consumers for the displayed standard finite-automaton bridge: a* List$^{\uparrow}$ *word-spine reader, a* Computable$^{\uparrow}$ *step-bounded transition reader, and a* TuringMachine$^{\uparrow}$ *finite run-trace reader. Each consumer may read only the finite alphabet row, finite state row, transition table, word spine, deterministic run ledger, endpoint acceptance row, displayed* BHist, hsame *rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

These consumers do not read regular-expression quotient equivalence, minimization, infinite automata, hidden recognizer semantics, or host language equality.

Proof. Expose the accepted carrier rows with Definition 351.1. The alphabet, state, transition table, word spine, deterministic ledger, endpoint row, and displayed BHist provenance are the finite data available to all three consumers.

Use Definition 351.2 to bind the endpoint classifier to the displayed hsame and Cont rows. Then apply Definition 351.3; this gives the List$^{\uparrow}$ word-spine reader and the step-bounded transition reader without leaving the finite table.

Next apply Definition 351.5. The same run ledger transports the endpoint acceptance row, so the finite run-trace reader can consume the ledger through the displayed Pkg and local NameCert rows.

Finally apply Definition 351.8 and Definition 351.10. They repack the word-spine, transition, and run-trace readers as conservative finite downstream reads of the standard bridge. The excluded quotient, minimization, infinite-automaton, hidden-semantics, and host-language objects are not rows of that bridge boundary. □

Theorem 351.13 (RegularLanguage prefix bridge consumer boundary)**.** *Every finite prefix consumer of a public* $\mathsf{RegularLanguage}^{\uparrow}$ *packet factors through the displayed prefix word spine, the restricted deterministic run ledger, endpoint transport,* hsame *rows,* Cont *routes,* Pkg *provenance, and local* NameCert *rows exported by the public finite-automaton bridge.*

Such a consumer cannot read minimization data, host language equality, regular-expression quotient equivalence, infinite automata, or hidden recognizer state.

Proof. First restrict the displayed input to the finite prefix under inspection. By Definition 351.4, the consumed prefix is read through the same $\mathsf{List}^{\uparrow}$ word spine and the corresponding restricted deterministic run ledger.

Next use Definition 351.9 to identify which rows a standard finite-automaton reader may consume: the transition ledger, endpoint row, displayed hsame transports, Cont routes, Pkg provenance, and local NameCert rows.

Apply Definition 351.10 to repack those rows as the public finite-automaton bridge surface. Then Definition 351.12 shows that the word-spine, step-bounded transition, and finite run-trace consumers are all conservative reads of that same displayed surface.

The excluded objects are not coordinates of the restricted run ledger or of the public bridge surface. Hence a finite prefix consumer has no route to minimization, host language equality, regular-expression quotient equivalence, infinite automata, or hidden recognizer state. □

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket prefix bridge consumer boundary`

Theorem 351.14 (RegularLanguage empty-word acceptance exactness)**.** *Let* $R = (\Sigma, Q, q_0, F, \delta, w, r, a, h, c, p)$ *be a* $\mathsf{RegularLanguage}^{\uparrow}$ *packet satisfying* $\mathsf{RegularLanguageAutomatonPacket}(R)$*. If the displayed* $\mathsf{List}^{\uparrow}$ *input spine* w *is empty, then the accepted endpoint row* a *is exactly the start-state row together with accepting-carrier membership:*

$$a = (q_0, \eta)$$

for the displayed witness $\eta : q_0 \in F$*. In particular, the state coordinate of the accepted endpoint is* q_0*, and the membership coordinate is membership of that same start-state row in the accepting-state carrier* F*.*

Lean4 ✓ `BEDC.Derived.RegularLanguageUp.RegularLanguageAutomatonPacket empty word acceptance exactness`

Proof. Unfold the carrier row of Definition 351.1. The accepted endpoint coordinate a has only two displayed fields: the final run state and a witness that this final state lies in F.

Since w is the empty $\mathsf{List}^{\uparrow}$ spine, Definition 351.3 applies to the accepted packet and identifies the final run state with the initial state q_0. The empty spine has no head symbol and no tail step, so no transition-table route in c can replace this endpoint by a later state.

Substitute this empty-spine endpoint identification into the two-field endpoint row. Its state field becomes q_0. Its remaining field is still the accepting-carrier witness supplied by the endpoint row; after the substitution, that witness has type $q_0 \in F$. Therefore the endpoint row has the displayed form $a = (q_0, \eta)$ with $\eta : q_0 \in F$, and there is no further endpoint coordinate in the packet that could carry additional acceptance data. □

Theorem 351.15 (RegularLanguage DFA prefix consumer determinacy)**.** *Let* $R = (\Sigma, Q, q_0, F, \delta, w, r, a, h, c, p)$ *be a* $\mathsf{RegularLanguage}^{\uparrow}$ *packet satisfying* $\mathsf{RegularLanguageAutomatonPacket}(R)$*, and let* u *be a displayed finite prefix of the* $\mathsf{List}^{\uparrow}$ *word spine* w*. Every accepted prefix consumer endpoint over* u *is determined by the restricted transition ledger, the initial state row* q_0*, the prefix length row, visible* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows.*

In particular, two accepted prefix consumer endpoints with the same displayed finite-prefix rows have the same endpoint state and the same accepting-carrier membership row.

Proof. Apply Definition 351.3 to the displayed prefix. The deterministic ledger fixes the unique run segment starting at the initial state row q_0 and consuming exactly the prefix length row of u.

Next use Definition 351.13. It restricts any prefix consumer to the displayed word spine, the transition ledger segment, endpoint transport, visible hsame transports, Cont routes, Pkg provenance, and local NameCert rows. Hence no accepted prefix endpoint can depend on data outside the restricted ledger.

For the empty prefix boundary, apply Definition 351.14. The endpoint is the start-state row together with the displayed accepting-carrier membership row, so this base case is also determined by the same finite-prefix data.

The positive-length case follows by repeatedly reading the next transition row from the restricted deterministic ledger. Since each step has one displayed transition route from the current state and symbol, the endpoint state after the prefix is fixed, and the accepted endpoint keeps only its membership row in F.

Thus all accepted prefix consumer endpoints with the same finite-prefix rows coincide on the state and membership coordinates. Minimization, host language equality, regular-expression quotient equivalence, infinite automata, and hidden recognizer state are excluded because they are not coordinates of the restricted prefix consumer surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$**.**

Constructive story: A regular-language packet is represented by finite alphabet and state rows, a displayed transition table, a ListUp word spine, a deterministic BHist run ledger, endpoint acceptance, componentwise hsame transport, Cont routes for consuming the spine, and Pkg provenance naming ListUp, FinSetUp, ComputableUp, and TuringMachineUp.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RegularLanguage}^{\uparrow}}$, maturePackageClosed)

Not claimed: This chapter does not close host language quotients, external regular-expression equivalence, minimization, infinite automata, or machine-checked bridge evidence.

Upgrade path: No further paper theory-axis upgrade is claimed while formal and bridge verification remain separate.

Chapter 352

A Concrete Naming Certificate for $\mathsf{FiniteMap}^{\uparrow}$

The $\mathsf{FiniteMap}^{\uparrow}$ interface records finite key-value lookup data as displayed BEDC history rows. Its carrier is an association-list presentation over the existing $\mathsf{List}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, and $\mathsf{Option}^{\uparrow}$ finite-data chapters from chapter 36, chapter 34, and chapter 33, with finite support read through chapter 112 when a consumer needs a displayed support boundary.

352.1 Finite-map source

Definition 352.1 (FiniteMapUp NameCert source)**.** *A* $\mathsf{FiniteMap}^{\uparrow}$ *source is a finite* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Prod}^{\uparrow}$ *rows whose first component is a displayed key history and whose second component is a displayed value history. The empty spine is the empty-map carrier. A lookup query is evaluated by scanning the displayed spine from left to right and returning an* $\mathsf{Option}^{\uparrow}$ *classifier witness:* none *when no displayed key row matches the query classifier, and* some *of the first displayed value row whose key matches the query classifier otherwise.*

The source also carries a duplicate-key ledger. Each ledger row records the visible key order, the first-hit lookup position for that key when it exists, the later key rows suppressed by the first hit, and the BHist *source provenance of every displayed key-value row. Thus a finite map is not a host function, a primitive finite set of graph pairs, or a quotient of presentations; it is exactly a finite displayed row spine with an* $\mathsf{Option}^{\uparrow}$ *lookup classifier and a suppression ledger.*

Theorem 352.2 (FiniteMapUp carrier and classifier obligations)**.** *The* $\mathsf{FiniteMap}^{\uparrow}$ *carrier described in Definition 352.1 satisfies the local carrier and classifier obligations for a naming certificate. The carrier is inhabited by the empty* $\mathsf{List}^{\uparrow}$ *spine. The lookup classifier is reflexive, symmetric, and transitive because each query is compared through the key classifier and the result is an* $\mathsf{Option}^{\uparrow}$ *witness over the first matching* $\mathsf{Prod}^{\uparrow}$ *row. Carrier rows transport componentwise along* hsame *for keys and values, along the displayed* Cont *lookup route, and along the recorded* Pkg *provenance. No quotient carrier or host-level map equality is part of the obligation surface.*

Proof. The empty spine supplies the carrier inhabitant. For a nonempty spine, every row is already a $\mathsf{Prod}^{\uparrow}$ key-value row inside a $\mathsf{List}^{\uparrow}$ carrier, so the source predicates are inherited componentwise from those chapters.

Reflexivity of lookup compares a query against the same displayed scan. Symmetry and transitivity are inherited from the key classifier and from the $\mathsf{Option}^{\uparrow}$ classifier on the returned witness, while the first-hit rule fixes the selected value row.

Transport follows the same finite spine. Move each key and value through its hsame witness, carry the lookup route through Cont, and keep the package row naming the source certificate. Since equality is read only from the displayed scan and its option witness, there is no quotient carrier to construct. □

Theorem 352.3 (FiniteMapUp lookup Option exactness)**.** *For every accepted* $\mathsf{FiniteMap}^{\uparrow}$ *source and every displayed query key, lookup returns exactly one* $\mathsf{Option}^{\uparrow}$ *witness. It returns* none *precisely when no displayed key row in the finite spine matches the query classifier. It returns* $\mathsf{some}(v)$ *precisely when the first displayed key row matching the query classifier has value row* v*, and every later matching key row is recorded only in the duplicate-key ledger.*

Lean4 ✓ `BEDC.Derived.FiniteMapUp.FiniteMapCarrier lookup option exactness`

Proof. Proceed by induction on the displayed $\mathsf{List}^{\uparrow}$ spine. For the empty spine, there is no displayed key row, so the lookup classifier is the single none witness and the ledger is empty.

For a cons spine, inspect the head $\mathsf{Prod}^{\uparrow}$ row. If its key matches the query classifier, the first-hit rule returns the head value as the unique some witness, and the tail contributes only suppressed duplicate rows for the same key.

If the head key does not match, apply the induction hypothesis to the tail. A tail none remains none for the whole spine, while a tail some remains the first matching row because the head was rejected. These cases exhaust the displayed finite spine. □

Theorem 352.4 (FiniteMapUp ledger transport)**.** *Let two accepted* $\mathsf{FiniteMap}^{\uparrow}$ *sources have key and value rows related componentwise by* hsame*, with lookup continuations related by* Cont *and package rows related by* Pkg*. Then the visible key order, first-hit lookup result, suppressed duplicate-key rows, and source-provenance rows transport together. In particular, lookup and the duplicate-key ledger are preserved by the displayed transport data.*

Lean4 ✓ `BEDC.Derived.FiniteMapUp.FiniteMapCarrier ledger transport`

Proof. Transport the spine row by row. A transported head key has the same classifier outcome against the transported query key, and the transported value row is the value read by the corresponding $\mathsf{Option}^{\uparrow}$ witness.

The first-hit index is therefore stable under the displayed transport. Rows before it remain nonmatching rows, the selected row remains selected, and rows after it that match the same key remain ledger entries rather than lookup outputs.

The Cont routes identify the lookup readback, and the Pkg rows identify the certificate sources used by the scan. Thus the lookup result and the duplicate-key ledger move as one finite displayed object. □

Theorem 352.5 (FiniteMapUp NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{FiniteMap}^{\uparrow}}$ *obligation surface consists of five rows: the finite* $\mathsf{List}^{\uparrow}$ *carrier of* $\mathsf{Prod}^{\uparrow}$ *key-value rows from Definition 352.1; the lookup classifier into* $\mathsf{Option}^{\uparrow}$ *with reflexivity, symmetry, and transitivity from Definition 352.2; lookup exactness from Definition 352.3; carrier transport along* hsame*,* Cont*, and* Pkg *from Definition 352.4; and duplicate-key ledger soundness for visible key order, first-hit selection, suppressed duplicates, and source provenance.*

Proof. Collect the carrier row, classifier row, exactness row, transport row, and ledger row. Each is expressed using only the displayed finite spine, product-coded key-value histories, option-valued lookup witness, and finite support boundary supplied by the existing finite-data chapters.

The first four rows are exactly the preceding definition and theorems. The ledger soundness row is the remaining projection of the same source: it records which later rows are suppressed and why the first matching row is the only lookup output.

These five rows are closed under consumer readback because every consumer-visible fact is obtained by scanning the finite displayed spine. No primitive finite-map object, ambient host function, or quotient equality is exported. □

Definition 352.6 (FiniteMapUp displayed support boundary)**.** *Let M be an accepted* $\mathsf{FiniteMap}^{\uparrow}$ *source in the sense of Definition 352.1, presented by a finite* $\mathsf{List}^{\uparrow}$ *spine xs of* $\mathsf{Prod}^{\uparrow}$ *key-value rows. Define* $\mathsf{KeyRows}(xs) : \mathsf{HistSpine}$ *by structural readback from the displayed spine: the empty spine maps to* nil*, and a cons row whose* $\mathsf{Prod}^{\uparrow}$ *first component is the displayed key history k maps to the cons spine with head k and tail* $\mathsf{KeyRows}(xs')$*.*

The displayed support boundary of M is the $\mathsf{FinSet}^{\uparrow}$ *enumeration row*

$$\mathsf{FiniteMapSupport}_{A,\sim_A}(M)(z) \iff \mathsf{FinSetEnumCarrier}_{A,\sim_A}(\mathsf{KeyRows}(xs))(z),$$

where A and $\sim_A$ are the key-side carrier and classifier consumed by the finite-support read. Its ledger contains, for every position of the original $\mathsf{List}^{\uparrow}$ *spine, the corresponding projected key position in* $\mathsf{KeyRows}(xs)$*, the* BHist *provenance of the original key-value row, and the first-hit or suppressed-duplicate status recorded by the finite-map duplicate-key ledger.*

Theorem 352.7 (FiniteMapUp displayed support readback)**.** *Let M be an accepted* $\mathsf{FiniteMap}^{\uparrow}$ *source with displayed* $\mathsf{List}^{\uparrow}$ *spine xs of* $\mathsf{Prod}^{\uparrow}$ *key-value rows. Reading M through the* $\mathsf{FinSet}^{\uparrow}$ *support boundary of Definition 352.6 exposes exactly the displayed key rows of xs:*

$$\mathsf{FiniteMapSupport}_{A,\sim_A}(M)(z) \iff \exists k : \mathsf{BHist}.\ \mathsf{SpineMember}(k, \mathsf{KeyRows}(xs)) \wedge z \sim_A k.$$

Moreover, if two positions of xs display keys in the same $\sim_A$-class, both projected key positions remain in the support ledger, while the $\mathsf{Option}^{\uparrow}$ *lookup read of Definition 352.3 returns only the value at the first matching position and records the later matching positions as suppressed duplicate-key ledger entries.*

Proof. Unfold the support boundary definition. Its carrier is the finite-set enumeration carrier $\mathsf{FinSetEnumCarrier}_{A,\sim_A}(\mathsf{KeyRows}(xs))$. By Definition 112.7, membership in that carrier is equivalent to finite-spine occurrence in $\mathsf{KeyRows}(xs)$ modulo the key classifier. This gives the displayed equivalence.

It remains to identify the ledger and the duplicate behavior. The map $\mathsf{KeyRows}$ is defined by structural readback from the $\mathsf{List}^{\uparrow}$ spine. In the empty case, both the finite-map source and the support spine are empty, so there is no support position and no lookup output. In a cons case, the head $\mathsf{Prod}^{\uparrow}$ row exposes one displayed key history k and one displayed value history v. The support projection adds exactly the key row k at the corresponding head position and then applies the same projection to the tail. Induction on the finite spine therefore gives a position-preserving ledger from rows of xs to rows of $\mathsf{KeyRows}(xs)$, with no added key row and no omitted displayed key row.

Now suppose a later row of xs has a key in the same $\sim_A$-class as an earlier displayed key. The projected key row is still present as a position of $\mathsf{KeyRows}(xs)$, hence it remains visible in the support ledger. At the carrier level, Definition 112.12 says that inserting a source-carried key already represented in the finite spine does not change the induced $\mathsf{FinSet}^{\uparrow}$ classifier. Thus duplicate key positions are ledger entries for the same finite-support membership class rather than additional support classes.

Finally apply Definition 352.3. Lookup scans the original displayed $\mathsf{List}^{\uparrow}$ spine from left to right, so the first key row matching the query supplies the unique some value witness, and every later matching key row is recorded only in the duplicate-key ledger. The support boundary and the lookup boundary therefore read the same displayed key positions, but they use them differently: $\mathsf{FinSet}^{\uparrow}$ records finite support by projected key occurrence modulo the key classifier, while $\mathsf{Option}^{\uparrow}$ lookup emits only the first-hit value and keeps duplicate keys as ledger provenance. □

Theorem 352.8 (FiniteMapUp public support lookup boundary)**.** *The public* $\mathsf{FiniteMap}^{\uparrow}$ *export is exactly the finite* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Prod}^{\uparrow}$ *key-value rows together with the* $\mathsf{Option}^{\uparrow}$ *first-hit lookup witness, the displayed* $\mathsf{FinSet}^{\uparrow}$ *support boundary, the duplicate-key ledger,* hsame *transport,* Cont *lookup routes, and* Pkg *provenance. Every public read of lookup or support factors through these rows, and no host finite map or quotient graph equality is exported.*

Lean4 ✓ `BEDC.Derived.FiniteMapUp.FiniteMapCarrier public support lookup boundary`

Proof. Start with Definition 352.3. It identifies every lookup read with the scan of the displayed $\mathsf{List}^{\uparrow}$ spine and the resulting $\mathsf{Option}^{\uparrow}$ first-hit witness, while later matching keys remain only in the duplicate ledger.

Apply Definition 352.4 to move the lookup and duplicate rows through the displayed hsame transports, Cont lookup routes, and Pkg provenance. These are the only transport rows available to a public finite-map read.

Finally use Definition 352.7. The support side reads the same displayed key positions through the $\mathsf{FinSet}^{\uparrow}$ support boundary. Combining the lookup exactness, ledger transport, and support readback rows exhausts the public export, with no host finite map and no quotient graph equality left to read. □

Theorem 352.9 (FiniteMapUp support lookup consumer determinacy)**.** *Let M and M' be accepted* $\mathsf{FiniteMap}^{\uparrow}$ *source packets whose displayed* $\mathsf{List}^{\uparrow}$ *spines of* $\mathsf{Prod}^{\uparrow}$ *key-value rows agree up to the displayed key classifier and value classifier, whose* $\mathsf{Option}^{\uparrow}$ *first-hit lookup witnesses agree for every displayed query, whose* $\mathsf{FinSet}^{\uparrow}$ *support boundaries expose the same projected key positions, and whose duplicate-key ledger rows,* hsame *transports,* Cont *lookup routes, and* Pkg *provenance rows agree. Then every public lookup/support consumer reads the same finite BEDC surface from M and M'. In particular, duplicate key rows remain visible as support-ledger positions and transport provenance, but only the first displayed matching row contributes the* $\mathsf{Option}^{\uparrow}$ *value returned to a lookup consumer.*

Lean4 ✓ `BEDC.Derived.FiniteMapUp.FiniteMapCarrier support lookup consumer determinacy`

Proof. First apply Definition 352.3 to both packets. The assumed agreement of displayed $\mathsf{List}^{\uparrow}$ spines and first-hit witnesses forces every public lookup query to reach the same $\mathsf{Option}^{\uparrow}$ read: absent queries read none on both sides, and present queries read the value at the first displayed matching row on both sides.

Next apply Definition 352.7. The public support consumer sees only the projected key positions through the $\mathsf{FinSet}^{\uparrow}$ boundary. Since those projected positions agree, the two support surfaces have the same membership readback modulo the displayed key classifier, including later positions whose keys match an earlier row.

The duplicate ledger is then transported by Definition 352.4. Agreement of the hsame rows, Cont lookup routes, and Pkg provenance means that every duplicate position and every package-origin row has the same public transport account in the two packets.

Finally use Definition 352.8. That boundary exhausts public lookup/support reads by the displayed spine, first-hit lookup witness, support readback, duplicate ledger, transport rows, lookup routes, and package provenance. All of these rows agree by the preceding steps, so no public consumer can distinguish the two packets. Later duplicate keys may still be inspected as support-ledger positions, but the lookup value is already fixed by the first matching displayed row. □

Theorem 352.10 (FiniteMap standard schema bridge boundary)**.** *The public surface of Definition 352.8 and Definition 352.9 supplies the standard finite-map schema bridge exactly through the finite* $\mathsf{List}^{\uparrow}$ *spine of* $\mathsf{Prod}^{\uparrow}$ *key-value rows, the* $\mathsf{Option}^{\uparrow}$ *first-hit lookup witness, the* $\mathsf{FinSet}^{\uparrow}$ *displayed support boundary, the duplicate-key ledger,* hsame *transports,* Cont *lookup routes, and* Pkg *provenance. Every standard finite-map consumer read factors through those rows.*

The bridge exports no host finite map, quotient graph equality, balanced tree, hashing table, or asymptotic cost claim.

Proof. Project lookup exactness through Definition 352.3. The finite $\mathsf{List}^{\uparrow}$ spine and $\mathsf{Prod}^{\uparrow}$ key-value rows determine the first-hit $\mathsf{Option}^{\uparrow}$ witness, so a consumer lookup can read only the displayed first matching row or the displayed absence witness.

Project support readback through Definition 352.7. The support boundary is the displayed $\mathsf{FinSet}^{\uparrow}$ read of the same key projection, and duplicate key positions remain ledger rows rather than additional support classes.

Transport the duplicate-key ledger with Definition 352.4. The hsame rows, Cont lookup routes, and Pkg provenance carry exactly the visible lookup and support rows across accepted replacements.

Finally apply Definition 352.8. Together with the consumer determinacy theorem Definition 352.9, it exhausts all public finite-map reads by the displayed support and lookup rows. Since the packet contains no coordinate for host maps, quotient graph equality, balanced trees, hashing, or cost, none of those structures is exported by the bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteMap}^{\uparrow}}$.

Constructive story: A finite-map packet is represented by a finite ListUp spine of ProdUp key-value BHist rows, an OptionUp first-hit lookup witness, a visible duplicate-key ledger, componentwise hsame transport, Cont lookup routes, Pkg provenance, and finite support readback through FinSetUp when needed.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FiniteMap}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 352.6, Definition 352.7, Definition 352.8, Definition 352.9, and Definition 352.10 bind the bridge surface from the displayed association-list support and first-hit lookup boundary to public finite-map reads over $\mathsf{List}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{FinSet}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FiniteMap}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FiniteMapUp.FiniteMapCarrier\_public\_support\_lookup\_boundary`

Bridge status: none

Not claimed: This chapter does not close extensional finite-map quotient equality, host functions, balanced trees, hashing, asymptotic cost, or an ambient finite-set graph primitive.

Upgrade path: Formal verification and bridge checking remain the next verification-axis work for the same finite support and lookup surface.

Chapter 353

A Concrete Naming Certificate for $\mathsf{RegularityModulus}^{\uparrow}$

The $\mathsf{RegularityModulus}^{\uparrow}$ interface names the finite rate witness used by regular dyadic and rational Cauchy data before the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ carriers consume it. In the Bishop-style constructive reading of regular Cauchy moduli, a precision request is not answered by an invisible choice of a tail. It is answered by a displayed rate row together with the finite observations and transport rows that certify the requested dyadic window.

The dyadic-window row is consumed through chapter 291, the finite schedule through chapter 126, the regular-sequence handoff through chapter 301, and the terminal seal through chapter 38. These sibling surfaces are exactly the provenance route recorded by the packet row p.

Definition 353.1 (RegularityModulus dyadic-window carrier)**.** *A* $\mathsf{RegularityModulus}^{\uparrow}$ *carrier packet is a finite* BHist *packet*

$$R = (k, m, w, h, c, p, n)$$

with the following visible rows:

1. *k is a unary precision row naming the requested dyadic scale;*
2. *m is a unary modulus row naming the threshold or window size supplied for that precision;*
3. *w is a dyadic window witness over* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, including the displayed endpoint, radius, and comparison rows read by the regularity test;*
4. *h records the componentwise* hsame *transport rows for the precision, modulus, dyadic-window, and consumer-facing coordinates;*
5. *c records the displayed* Cont *routes by which a precision request, a modulus row, and a dyadic observation window are read in the same finite packet;*
6. *p records the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{CauchyModulus}^{\uparrow}$*;*
7. *n is the local* NameCert *row exposing the accepted carrier and its classifier surface.*

The carrier accepts only packets in which these seven rows are displayed in one finite history and the consumer reads follow the recorded Cont *routes. It contains no quotient of streams, no selected real endpoint, and no unrecorded tail choice.*

Lean4 (definition) `BEDC.Derived.RegularityModulusUp.RegularityModulusDyadicWindowCarrier`

Theorem 353.2 (RegularityModulus NameCert seed obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularityModulus}^{\uparrow}}$ *seed obligation surface consists of five finite rows:*

1. *carrier habitation: the zero precision request is carried by the zero dyadic window, with unary rows* k *and* m *and a displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *zero endpoint ledger;*
2. *classifier laws: two packets classify together by componentwise* hsame *on* k, m, w, h, c, p, *and* n*;*
3. *monotone precision transport: increasing the requested precision transports the modulus row and refines the dyadic window through the displayed* Cont *routes;*
4. *ledger exactness: every visible dyadic window read by a consumer is exactly the finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger named by* w *and routed by* c*;*
5. *downstream consumption:* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *read the regularity rate through the same finite packet, without quotienting streams or choosing a tail outside the carrier.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusDyadicWindowCarrier seed obligation surface`

Proof. The carrier row is Definition 353.1. For the zero precision request, take the displayed unary zero rows and the zero dyadic endpoint ledger supplied by $\mathsf{DyadicRatCore}^{\uparrow}$; these rows inhabit the packet without using a nonconstructive selector.

Classifier laws are componentwise. Transport each row of the seven-coordinate packet by the corresponding hsame witness and then replay the same Cont routes. The accepted carrier shape is unchanged because every row read by the classifier is already visible.

For monotone precision, a refined request replaces k by a transported unary row and uses the modulus row m to expose the refined window. Ledger exactness then says that the only dyadic observations available to consumers are the endpoint, radius, and comparison rows in w.

Finally, the provenance row p names exactly the downstream consumers: $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{CauchyModulus}^{\uparrow}$ over the $\mathsf{StreamName}^{\uparrow}/\mathsf{DyadicRatCore}^{\uparrow}$ observation surface. Those consumers can therefore read only the finite window and rate rows carried by R. □

Theorem 353.3 (RegularityModulus window monotonicity)**.** *Let* $R = (k, m, w, h, c, p, n)$ *be an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *carrier packet. If a precision row* k' *refines* k *through the displayed unary comparison and the carrier records the corresponding transport in* h *and* c*, then the dyadic window read at* k' *is a refinement of* w *using the same modulus provenance* m *and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint family.*

The refined read remains a finite BHist *packet with transported* hsame, Cont, Pkg, *and* NameCert *rows, and it introduces no additional stream quotient or hidden modulus selector.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusDyadicWindowCarrier window monotonicity`
Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket window monotonicity`

Proof. Project the accepted packet through Definition 353.1. The precision row, the modulus row, the dyadic window, and the transport ledger are all coordinates of the same finite history.

Follow the displayed comparison from k to k'. The row h transports the precision and observation coordinates, while c gives the continuation route from the refined precision request to the refined dyadic window.

Repack the transported endpoint, radius, and comparison rows with the same m, p, and n rows. The construction has no coordinate from which a quotient stream or hidden selector could be read. □

Theorem 353.4 (RegularityModulus RegSeqRat consumption boundary)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet can read only the unary precision row* k*, the modulus row* m*, the dyadic window* w*, the transported* hsame *rows* h*, the displayed* Cont *routes* c*, the provenance row* p*, and the local name row* n*. The regular rational sequence carrier receives these rows as a finite regularity-rate witness over* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket regseqrat consumption boundary`

Proof. Read the consumer boundary from the provenance coordinate p of Definition 353.1. Its $\mathsf{RegSeqRat}^{\uparrow}$ entry names the stream schedule and dyadic observation surface that the regular rational sequence carrier is allowed to consume.

The dyadic comparison itself is stored in w, and its transport through refined precision requests is stored in h and c. Hence a $\mathsf{RegSeqRat}^{\uparrow}$ read can recover the rate row and the observation ledger only by projecting those displayed coordinates.

Since the carrier has no quotient stream coordinate and no host real endpoint, the handoff is exactly the finite rate witness over the $\mathsf{StreamName}^{\uparrow}$/$\mathsf{DyadicRatCore}^{\uparrow}$ rows already present in the packet. □

Theorem 353.5 (RegularityModulus RealUp seal handoff)**.** *When a* $\mathsf{Real}^{\uparrow}$ *seal is built from a* $\mathsf{RegSeqRat}^{\uparrow}$ *source carrying an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet, the real-name boundary consumes only the finite regularity-rate rows of that packet. The seal handoff preserves the displayed dyadic window, the modulus row, the* hsame *transport, the* Cont *routes, and the* Pkg *provenance, and it does not add a quotient representative, a selected limit, or a choice-based Cauchy tail.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket realup seal handoff`

Proof. Start with the $\mathsf{RegSeqRat}^{\uparrow}$ consumption boundary of Definition 353.4. It exposes the regular rational source as a finite schedule of dyadic observations together with the rate row and its transport ledger.

The $\mathsf{Real}^{\uparrow}$ seal reads this source through the same finite schedule. Its only regularity information is the dyadic window and modulus data already present in the $\mathsf{RegularityModulus}^{\uparrow}$ packet.

Transport the seal boundary along the displayed hsame rows and follow the recorded Cont routes. Repacking these rows preserves the finite handoff surface and leaves no coordinate for a quotient representative, selected limit, or choice-based tail. □

Theorem 353.6 (RegularityModulus dyadic-window exactness)**.** *For an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet* $R = (k, m, w, h, c, p, n)$*, every consumer-visible dyadic window read is exactly the endpoint, radius, comparison, precision, modulus, transport, continuation, package, and name row displayed by* w, h, c, p, n*. Conversely, every displayed row of this form is accepted as a* $\mathsf{RegularityModulus}^{\uparrow}$ *consumer read.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket dyadic window exactness`

Proof. Project R through Definition 353.1. The carrier stores the unary precision and modulus rows together with the dyadic window data, so the endpoint, radius, comparison, precision, and modulus coordinates are precisely the displayed rows.

For refined precision requests, apply Definition 353.3. This transports the same window data through the recorded hsame and Cont rows without creating a new endpoint or comparison coordinate.

The downstream direction is fixed by the existing handoffs. Use Definition 353.4 for the $\mathsf{RegSeqRat}^{\uparrow}$ read and Definition 353.5 for the $\mathsf{Real}^{\uparrow}$ seal. Both consume only the package and name rows already shown by p and n.

Thus every accepted read is one of the displayed dyadic-window rows, and every displayed row is accepted because it is a coordinate of the carrier together with its transport, continuation, package, and local naming evidence. □

Theorem 353.7 (RegularityModulus common-window exactness)**.** *Let*

$$R = (k, m, w, h, c, p, n) \quad \textit{and} \quad R' = (k', m', w', h', c', p', n')$$

be accepted $\mathsf{RegularityModulus}^{\uparrow}$ *packets. Suppose the displayed unary precision rows of R and R' both refine to a common row k_*, and suppose the dyadic-window, transport, continuation, package, and local naming rows classify componentwise through the displayed* hsame *and* Cont *routes. Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read of either transported packet factors through one common finite* BHist *window carrying the shared precision row, modulus row, dyadic endpoint rows, transported window,* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *surface.*

The common readback surface exports no quotient stream, selected limit, hidden modulus selector, host real equality, or choice-based tail.

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket common window exactness`

Proof. Project both accepted packets through Definition 353.1. The seven carrier coordinates are the only available readback rows for precision, modulus, dyadic-window data, transport, continuation, provenance, and local naming.

Use Definition 353.3 twice, once for R and once for R', to transport both precision requests to k_*. The componentwise hsame rows identify the transported precision, modulus, and dyadic endpoint coordinates, while the displayed Cont routes identify the finite readback path used by consumers.

For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, apply Definition 353.4; for a $\mathsf{Real}^{\uparrow}$ seal, apply Definition 353.5. In both cases the consumer can read only the transported finite regularity-rate rows already present in the common carrier surface.

Carrier-coordinate exhaustion gives the conclusion. Since neither packet has a coordinate for quotient streams, selected limits, hidden modulus selection, host real equality, or choice-based tails, none of those objects can be exported by the common window. □

Theorem 353.8 (RegularityModulus shared-rate consumer exhaustion)**.** *For compatible accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packets*

$$R = (k, m, w, h, c, p, n) \quad \textit{and} \quad R' = (k', m', w', h', c', p', n'),$$

any $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read factors through the common finite* BHist *window carrying the shared precision row, modulus row, dyadic endpoint rows, transported window,* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *surface. The consumer read has no quotient stream, selected limit, hidden modulus selector, host real equality, or choice-based tail.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket shared rate consumer exhaustion`

Proof. Project both packets through Definition 353.1. The carrier exposes only precision, modulus, dyadic-window, transport, continuation, package, and local naming rows.

Apply Definition 353.7. It supplies the common finite readback window carrying the shared precision row, modulus row, transported dyadic endpoint rows, hsame witnesses, Cont routes, provenance, and local certificate surface.

For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, use Definition 353.4. For a $\mathsf{Real}^{\uparrow}$ consumer, use Definition 353.5. Both handoffs consume only the finite rows already present in the common window.

Since neither packet carries a quotient stream, selected limit, hidden modulus selector, host real equality, or choice-based tail, no consumer read can export any of those objects. □

Theorem 353.9 (RegularityModulus obligation completeness)**.** *The dyadic-window carrier, monotonicity row,* $\mathsf{RegSeqRat}^{\uparrow}$ *consumption boundary,* $\mathsf{Real}^{\uparrow}$ *seal handoff, dyadic-window exactness, common-window exactness,* hsame *and* Cont *transport,* Pkg *provenance, and local* NameCert *row form the full public obligation surface for* $\mathsf{RegularityModulus}^{\uparrow}$*.*

This surface contains no host modulus function, selected real limit, quotient completion, or global choice of windows.

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket obligation completeness`

Proof. Begin with Definition 353.2. It binds the local NameCert row to the dyadic-window carrier of Definition 353.1, including unary precision, modulus, dyadic endpoint, transport, continuation, package, and name coordinates.

Apply Definition 353.3. This supplies the monotonicity row and keeps refined precision reads on the same displayed hsame and Cont transport surface.

The downstream reads are fixed by Definition 353.4 and Definition 353.5. They show that $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers receive only the carrier, package, and name rows already present in the obligation surface.

Finally use Definition 353.6 and Definition 353.7. These exactness results exhaust single-window and common-window consumer reads, so no host modulus function, selected real limit, quotient completion, or global window choice is part of the public surface. □

Theorem 353.10 (RegularityModulus carrier and classifier obligations)**.** *An accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet whose seven displayed* BHist *rows are those of Definition 353.1 supplies carrier habitation and componentwise classifier laws for unary precision, unary modulus, dyadic window endpoints, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

No additional carrier coordinate is required for a host modulus function, selected limit, quotient stream, or global choice of observation windows.

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket carrier classifier obligations`

Proof. Read the packet through Definition 353.1. The seven coordinates are inhabited exactly when the precision row, modulus row, dyadic window row, transport row, continuation row, package row, and local name row are present.

The classifier laws are componentwise because each consumer-facing predicate is read from one of these displayed rows. The seed obligation surface of Definition 353.2 identifies the NameCert coordinate with the same finite carrier, so the classifier surface is not allowed to introduce a separate host-side witness.

Window compatibility is controlled by Definition 353.3. It keeps refined precision and modulus observations on the same carrier coordinates, and the dyadic exactness of Definition 353.6 exhausts the visible endpoint rows. □

Theorem 353.11 (RegularityModulus transport and ledger obligations)**.** *For two accepted* RegularityModulus$^{\uparrow}$ *packets connected by the displayed* hsame *and* Cont *rows, transport preserves the precision request, unary modulus row, dyadic observation window, and finite ledger readback recorded by the carrier. The transported packet has exactly the same consumer-visible regularity-rate rows after passage to a common dyadic window.*

Proof. Start from the carrier rows of Definition 353.1. The hsame row transports the precision, modulus, and dyadic endpoint classifiers, while the Cont row records the finite observation route used by downstream readers.

Apply Definition 353.3 to move both precision requests to the common requested rate. The transported rows remain rows of the same finite packet, because refinement only changes the displayed window index and does not add a new carrier coordinate.

Finally use Definition 353.6 for each single packet and Definition 353.7 for the paired packet. These exactness statements say that the ledger visible after transport is precisely the precision, modulus, dyadic-window, transport, continuation, package, and naming surface. □

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket transport ledger obligations`

Theorem 353.12 (RegularityModulus RegSeqRat and Real consumers)**.** *Every* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer of an accepted* RegularityModulus$^{\uparrow}$ *packet reads only the finite regularity-rate packet: unary precision, unary modulus, dyadic-window endpoints, componentwise* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

The consumer boundary contains no selected real limit, quotient completion, analytic modulus, host equality, or choice-based tail.

Proof. For the rational-sequence side, apply Definition 353.4. It presents the RegSeqRat$^{\uparrow}$ read as a finite regularity-rate packet rather than as a completed stream object.

For the real-seal side, apply Definition 353.5. The Real$^{\uparrow}$ consumer receives the same precision, modulus, dyadic-window, transport, continuation, package, and name rows.

The exactness theorems Definition 353.6 and Definition 353.7 exhaust the single and paired readback surfaces. Hence neither consumer can read a selected limit, quotient completion, analytic modulus, host equality, or choice-based tail from the packet. □

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket regseqrat real consumer obligations`

Theorem 353.13 (RegularityModulus standard finite-rate bridge)**.** *The public packet determined by Definition 353.9, Definition 353.10, Definition 353.11, and Definition 353.12 has a conservative standard finite regularity-rate reading. Its readable rows are exactly unary precision, unary modulus, dyadic-window endpoint data, displayed* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *evidence.*

Reading the standard finite regularity-rate packet back into RegularityModulus$^{\uparrow}$ *recovers the same carrier rows and the same* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumer surfaces. The bridge adds no selected real limit, quotient completion, analytic modulus, host equality, or choice-based tail.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket standard rate bridge`

Proof. Project the accepted packet through the seven carrier coordinates of Definition 353.1. The obligation and classifier theorems identify these coordinates as unary precision, unary modulus, dyadic-window endpoint data, displayed transport, continuation routes, package provenance, and local naming evidence.

Use Definition 353.11 to keep a standard finite-rate read on the same transported carrier rows. The exactness statements cited there ensure that passage to a common dyadic window changes only the displayed finite window and does not create a further analytic row.

For downstream consumers, apply Definition 353.12. Both the $\mathsf{RegSeqRat}^{\uparrow}$ read and the $\mathsf{Real}^{\uparrow}$ seal read factor through the same unary precision, unary modulus, dyadic-window, hsame, Cont, Pkg, and NameCert packet.

Reading back from the standard side therefore returns exactly those carrier rows. Since none of the cited packet coordinates contains a selected real limit, quotient completion, analytic modulus, host equality, or choice-based tail, the standard bridge is conservative over the displayed finite regularity-rate packet. □

Theorem 353.14 (RegularityModulus mature finite-rate consumer completeness)**.** *Every downstream* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or* $\mathsf{CauchyModulus}^{\uparrow}$ *consumer of the standard finite regularity-rate bridge of Definition 353.13 factors through the same seven visible rows: unary precision, unary modulus, dyadic-window endpoints, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *evidence.*

This consumer-completeness statement supplies no selected real limit, quotient completion, host equality, analytic modulus, or choice-selected tail. It is complete only for the finite regularity-rate packet exposed by $\mathsf{RegularityModulus}^{\uparrow}$ *and the named downstream consumers.*

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket mature rate consumer completeness`

Proof. Start from the consumer surface in Definition 353.8. It exhausts the packet read by the shared finite-rate consumers and leaves only the unary precision, unary modulus, dyadic-window, transport, continuation, package, and name-certificate rows visible.

Use Definition 353.11 to keep that surface stable under the componentwise hsame transport ledger. The transported consumer therefore still reads the same finite rows, with no added analytic or host-equality coordinate.

Apply Definition 353.12 for the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, and then apply Definition 353.13. The bridge identifies the standard readback with exactly the same seven finite rows.

The $\mathsf{CauchyModulus}^{\uparrow}$ consumer is part of the same package provenance named by the standard bridge, so its finite rate read is exhausted by the displayed precision and modulus rows together with the same transport, continuation, package, and local naming evidence. Since none of the cited rows contains a selected limit, quotient completion, host equality, analytic modulus, or choice-selected tail, the mature finite-rate consumer boundary is complete. □

Theorem 353.15 (RegularityModulus scheduled-tail closure)**.** *Let an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet carry a scheduled finite tail transported along its displayed* hsame *and* Cont *ledger. Any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read using that transported scheduled tail still factors through the same seven visible rows: unary precision, unary modulus, dyadic-window endpoints, componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and local* NameCert *evidence.*

The closure is only a finite scheduled-tail closure for the accepted regularity-rate packet. It adds no selected limit, quotient completion, host equality, analytic modulus, or choice-selected tail.

Proof. First place the scheduled tail on a common finite window. Apply Definition 353.7; the transported tail read is represented by the shared precision row, modulus row, dyadic-window endpoint rows, hsame rows, Cont routes, Pkg provenance, and NameCert surface.

Next use Definition 353.11. The transport ledger keeps the scheduled tail inside the same carrier coordinates after passage to the common dyadic window, so transport does not create an additional analytic row or a host-equality row.

Finally apply Definition 353.14. The $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers named there exhaust their reads through the seven finite rows already produced by the common-window and transport steps. Since none of those rows contains a selected limit, quotient completion, analytic modulus, host equality, or choice-selected tail, the transported scheduled-tail read is closed at the finite regularity-rate boundary. □

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket scheduled tail closure`

Theorem 353.16 (RegularityModulus DyadicMesh window factorization)**.** *Let an accepted* $\mathsf{RegularityModulus}^{\uparrow}$ *packet expose a finite regularity-rate window, and let a compatible accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet expose a finite mesh cell whose endpoint-radius-order ledger is read through the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows. Then every* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or* $\mathsf{ValidatedNumerics}^{\uparrow}$ *consumer read that uses both packets factors through one finite* BHist *packet.*

That packet contains exactly the unary precision row, unary modulus row, mesh level row, cell-index row, rational-interval coverage row, dyadic endpoint, radius, and order ledger, componentwise hsame *rows, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows of the two accepted packets. The factorization exports no quotient stream, selected limit, host real equality, solver-correctness witness, floating-point semantics, or infinite mesh refinement.*

Proof. Start with the scheduled finite regularity window. By Definition 353.15, the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ side of the read is already exhausted by the precision, modulus, dyadic-window, transport, continuation, package, and local name rows.

Next use Definition 353.14. It identifies the same finite-rate rows as the complete rate-window surface available to the named completion-facing consumers.

Place the mesh read on the compatible finite cell. Apply Definition 358.3 to keep the chosen cell stable under displayed mesh refinement, and apply Definition 358.8 to read the mesh level, cell index, rational-interval coverage, dyadic endpoint-radius-order ledger, transport, continuation, package, and local name rows as one standard finite mesh packet.

Finally align the dyadic endpoint rows through Definition 291.7 and Definition 291.8. These theorems put denominator ledgers and common-exponent endpoint comparisons into the same finite $\mathsf{DyadicRatCore}^{\uparrow}$ window. Repack the rate rows and mesh rows into the shared BHist packet. Since every cited component is finite packet data, the excluded quotient, limit, host-real, solver, floating-point, and infinite-refinement structures have no row from which a consumer can read. □

Lean4 ✓ `BEDC.Derived.RegularityModulusUp.RegularityModulusPacket dyadicmesh window factorization`

Closure status for $\mathsf{NameCert}_{\mathsf{RegularityModulus}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularityModulus}^{\uparrow}$ packet is seeded by finite BHist rows for unary precision, unary modulus, a dyadic observation window over $\mathsf{DyadicRatCore}^{\uparrow}$, componentwise hsame transport, displayed Cont routes, Pkg provenance over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{CauchyModulus}^{\uparrow}$, and local NameCert provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RegularityModulus}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 353.9, Definition 353.10, Definition 353.11, Definition 353.12, Definition 353.13, Definition 353.14, and Definition 353.16 bind the carrier, classifier, transport, ledger, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, standard finite regularity-rate readback, mature consumer-completeness rows, and the finite $\mathsf{DyadicMesh}^{\uparrow}$ handoff to BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RegularityModulus}^{\uparrow}}$, unformalized)

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a checked Lean carrier, real completeness, uniqueness of real representatives, analytic moduli, or choice-selected tails.

Upgrade path: No further paper-side theory-axis upgrade remains for this finite regularity-rate packet.

Chapter 354

A Concrete Naming Certificate for $\mathsf{RationalInterval}^{\uparrow}$

The $\mathsf{RationalInterval}^{\uparrow}$ interface names finite closed rational intervals on the path from $\mathsf{Rat}^{\uparrow}$ and dyadic rational cores to $\mathsf{RegSeqRat}^{\uparrow}$ and the $\mathsf{Real}^{\uparrow}$ finite-window seal. In the constructive analysis tradition of Bishop and Bridges, an interval is not a hidden located subset of the real line. It is a displayed pair of rational endpoints, an order witness, and the finite ledgers by which consumers read containment and refinement.

The dependency route first consumes the $\mathsf{Rat}^{\uparrow}$ endpoint surface of chapter 37 and the dyadic-core radius discipline of chapter 291; only after those finite endpoint and tolerance rows are displayed does the interval hand finite windows to chapter 301.

Definition 354.1 (RationalInterval BHist carrier)**.** *A* $\mathsf{RationalInterval}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (l, r, o, \kappa, h, c, p, n)$$

with the following visible rows:

1. *l is the left endpoint row, a* $\mathsf{Rat}^{\uparrow}$ *carrier displayed in the packet;*
2. *r is the right endpoint row, a* $\mathsf{Rat}^{\uparrow}$ *carrier displayed in the packet;*
3. *o is the order witness row certifying the displayed endpoint comparison $l \leq r$ through the* $\mathsf{Rat}^{\uparrow}$ *comparison ledger;*
4. *κ is the containment ledger recording exactly which rational sample rows are certified to lie between l and r;*
5. *h records the componentwise* hsame *transport rows for endpoints, the order witness, containment rows, and consumer-facing coordinates;*
6. *c records the* Cont *routes by which a finite consumer reads the endpoint pair, order witness, containment ledger, and refinement windows;*
7. *p is the visible* Pkg *provenance row naming the* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *dependency certificates used by the packet;*
8. *n is the local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *registration row.*

The carrier predicate is $\mathsf{RationalIntervalPacket}(l, r, o, \kappa, h, c, p, n)$*. Its classifier compares two accepted packets only by transporting the displayed endpoint rows and replaying the* $\mathsf{Rat}^{\uparrow}$ *order and containment ledgers over the same finite* BHist *surface.*

Theorem 354.2 (RationalInterval NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *seed obligation surface consists of six finite rows: the carrier of Definition 354.1, endpoint equality through the displayed* $\mathsf{Rat}^{\uparrow}$ *classifiers, the endpoint order witness, containment ledger exactness,* hsame *and* Cont *stability for finite refinements, and the* $\mathsf{RegSeqRat}^{\uparrow}/\mathsf{Real}^{\uparrow}$ *handoff boundary for finite rational windows.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket namecert obligation surface`

Proof. Project the eight carrier coordinates. The endpoint rows l and r provide the rational carrier data, while the order witness o and containment ledger κ provide the comparison rows exposed to interval consumers.

The stability rows are exactly h and c. The dependency and local naming surface is carried by p and n, so the six listed obligations account for every row of the packet. □

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket consumer readback semantic name certificate`

Theorem 354.3 (RationalInterval endpoint order witness)**.** *Every accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet displays a* $\mathsf{Rat}^{\uparrow}$ *endpoint pair* (l, r) *together with an order witness row* o *certifying* $l \leq r$ *in the same finite history. Transporting the interval by its stored* hsame *rows transports both endpoints and the order witness componentwise, and it introduces no apartness decision, total order on completed reals, or selected real endpoint outside the displayed* $\mathsf{Rat}^{\uparrow}$ *rows.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket endpoint order transport`

Proof. Read the endpoint and order coordinates from Definition 354.1. The order witness row o is stored next to l and r, so a consumer cannot obtain the interval without also reading the finite comparison ledger that makes the endpoint order visible.

Under transport, h supplies the componentwise hsame rows for the two endpoints and for o. Repacking those transported rows preserves the same ordered endpoint surface and leaves no coordinate for completed real order or a selected external endpoint. □

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket endpoint order classifier`
Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalEndpointRows order witness`

Theorem 354.4 (RationalInterval containment ledger exactness)**.** *For an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet* $I = (l, r, o, \kappa, h, c, p, n)$*, every rational containment read is exactly one of the finite rows in* κ *routed by* c *and transported by* h*. Conversely, any displayed row of* κ *with its endpoint, order, transport, continuation, package, and local naming evidence is accepted as a* $\mathsf{RationalInterval}^{\uparrow}$ *containment read.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket containment ledger exactness`

Proof. Project I through Definition 354.1. The only containment coordinate is κ, and its routes to consumers are the displayed Cont rows in c.

The forward direction follows by reading the consumer route and then the corresponding containment row. The transported endpoint and order data needed to interpret that row are supplied by h and o.

For the reverse direction, start with a displayed row of κ together with the matching endpoint, order, transport, continuation, package, and name rows. These are exactly the coordinates required by the carrier, so the row is accepted as a containment read. □

Theorem 354.5 (RationalInterval RegSeqRat handoff)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet may read only the displayed* $\mathsf{Rat}^{\uparrow}$ *endpoints, the endpoint order witness, the finite containment ledger, and the associated* hsame, Cont, Pkg, *and* NameCert *rows. The handoff supplies a closed rational window for regular rational sequence arguments; it does not assert Cauchy completeness, select a limit, or identify completed* $\mathsf{Real}^{\uparrow}$ *values.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket regseqrat handoff`

Proof. Start with the carrier packet and project the rows visible to a regular rational sequence consumer. The endpoint rows and order witness delimit the finite window, while κ records the rational samples certified to lie inside it.

The remaining consumer-facing information is precisely the transport, continuation, provenance, and naming data in h, c, p, and n. Repacking those rows gives the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and leaves no row for a quotient Cauchy class or a completed real equality. □

Theorem 354.6 (RationalInterval RealUp seed boundary)**.** *When a finite-window* $\mathsf{Real}^{\uparrow}$ *construction consumes an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet, the seed boundary is the same displayed rational interval packet: two* $\mathsf{Rat}^{\uparrow}$ *endpoints, the order witness, containment ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *row. The boundary is a rational closed window and not a completed real object, a located subset, or a standard bridge.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket realup seed boundary`

Proof. Use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 354.5. It exposes the rational window as finite endpoint and containment rows, with all reads routed through the same transport and continuation data.

The $\mathsf{Real}^{\uparrow}$ seed consumer can therefore inherit only this finite packet. Since the carrier has no coordinate for a completed real, a located subset, or a bridge witness, the seed boundary remains the displayed rational interval surface. □

Theorem 354.7 (RationalInterval endpoint containment transport)**.** *For accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packets connected by displayed* hsame *rows, endpoint order and containment transport together: the lower endpoint, upper endpoint, order witness, finite containment ledger,* Cont *routes,* Pkg *provenance, and local* NameCert *row remain the complete interval readback surface after transport.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket endpoint containment transport`

Proof. Project the packet through Definition 354.1. The carrier has endpoint coordinates, one endpoint-order coordinate, one containment ledger, and the visible transport, continuation, package, and naming rows.

Apply Definition 354.3 to transport the order witness along the displayed endpoint identifications. The transported endpoints are still the two $\mathsf{Rat}^{\uparrow}$ rows of the same finite carrier.

Use Definition 354.4 for the containment coordinate. Since each containment read is interpreted with the transported endpoint and order rows, the transported ledger is exactly the same finite interval surface and contains no completed-real or located-subset coordinate. □

Theorem 354.8 (RationalInterval common refinement window)**.** *Two accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packets with compatible endpoint and containment rows refine to one finite rational observation window whose visible data are the transported endpoints, the common endpoint-order witness, the common containment ledger, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket common refinement window`

Proof. Begin with the endpoint rows of the two carrier packets from Definition 354.1. Compatibility supplies the displayed hsame routes needed to compare lower endpoints with lower endpoints and upper endpoints with upper endpoints.

The common order row is obtained by applying Definition 354.3 after those endpoint transports. The containment rows are then read against that common ordered window.

Finally apply Definition 354.4. It exhausts the finite containment ledger by rational samples, endpoint-order evidence, transport, continuation, package, and name rows, so the common refinement exports one finite rational observation window and no completed $\mathsf{Real}^{\uparrow}$ object. □

Theorem 354.9 (RationalInterval directed refinement basis)**.** *Any finite family of compatible accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packets admits one displayed finite rational-window basis packet. Its rows are exactly the transported* $\mathsf{Rat}^{\uparrow}$ *lower and upper endpoints, endpoint-order witnesses, containment ledgers, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *evidence needed by the family.*

This basis is directed for $\mathsf{RegSeqRat}^{\uparrow}$ *and finite-window* $\mathsf{Real}^{\uparrow}$ *consumers: every member packet maps to it by finite refinement rows, and every consumer read of the basis is one of the displayed rational-window rows. It exports no completed* $\mathsf{Real}^{\uparrow}$ *equality, located subset, apartness witness, interval arithmetic law, or standard bridge.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket directed refinement basis`

Proof. Start with two compatible accepted packets. Apply Definition 354.8 to obtain their common finite rational observation window. The resulting packet already contains only transported endpoint rows, the order witness, containment ledger, displayed transport, continuation, package, and local naming evidence.

Extend from two packets to a finite family by iterating the binary construction along the displayed finite list of packets. At each step, use Definition 354.11 to compose the previous basis row with the next common-refinement row, so the accumulated packet remains a single finite rational window.

The endpoint rows of the accumulated basis are controlled by Definition 354.12. Lower endpoints transport only along lower $\mathsf{Rat}^{\uparrow}$ coordinates, upper endpoints transport only along upper $\mathsf{Rat}^{\uparrow}$ coordinates, and the order witness is replayed over those transported rows.

Finally apply Definition 354.13. It accounts for all $\mathsf{RegSeqRat}^{\uparrow}$ and finite-window $\mathsf{Real}^{\uparrow}$ reads of the basis, so no completed real equality, located subset, apartness witness, interval arithmetic law, or standard bridge can be projected from the directed finite-window packet. □

Theorem 354.10 (RationalInterval RealUp consumer exactness)**.** *Every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet reads only the two endpoint rows, the endpoint-order witness, the containment ledger, displayed* Cont *routes,* Pkg *provenance, local* NameCert *evidence, and the* hsame *rows needed to transport those data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket realup consumer exactness`

Proof. Use Definition 354.6. It identifies the $\mathsf{Real}^{\uparrow}$ seed boundary with the displayed rational interval packet rather than with a completed real, located subset, or bridge witness.

Endpoint order is supplied by Definition 354.3, and containment is supplied by Definition 354.4. Both rows are coordinates of Definition 354.1, with consumer access routed through the displayed Cont, Pkg, NameCert, and hsame evidence.

Thus the real consumer cannot observe anything outside the finite interval packet. In particular, quotient Cauchy classes, located subsets, interval arithmetic laws, and standard bridges are not part of this consumer surface. □

Theorem 354.11 (RationalInterval refinement composition)**.** *Suppose two displayed finite* $\mathsf{RationalInterval}^{\uparrow}$ *refinement rows share the middle rational endpoint window. If each row is accepted through its displayed* $\mathsf{Rat}^{\uparrow}$ *endpoints, endpoint-order witness, containment ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *evidence, then the two refinements compose to a single accepted finite refinement row from the first window to the last. The composed row replays the shared endpoint classifier rows, concatenates the two finite* Cont *routes, and repackages exactly the same containment-ledger coordinates.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalRefinement composition`

Proof. Project the two refinement packets through Definition 354.1. Their visible coordinates are only endpoint rows, one order witness for each endpoint window, containment ledger rows, transport rows, continuation routes, package provenance, and local naming evidence.

The stored endpoint classifier rows identify the middle lower endpoint with the next lower endpoint, and the middle upper endpoint with the next upper endpoint. With those rows fixed, the two order witnesses read the same middle window and can be replayed as one finite refinement step across the outer endpoints.

Concatenate the two displayed Cont routes and carry along the two containment ledgers. The containment coordinates are already interpreted against the transported endpoint and order rows, so repacking them yields the outer refinement packet and introduces no completed $\mathsf{Real}^{\uparrow}$ equality, located subset, or bridge coordinate. □

Theorem 354.12 (RationalInterval endpoint transport classifier)**.** *Endpoint transport for accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packets preserves the interval classifier componentwise: lower endpoints transport only along lower* $\mathsf{Rat}^{\uparrow}$ *rows, upper endpoints transport only along upper* $\mathsf{Rat}^{\uparrow}$ *rows, and the endpoint-order coordinate is read against those transported components. Consequently endpoint transport cannot introduce a completed* $\mathsf{Real}^{\uparrow}$ *equality row or an apartness row.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket endpoint transport classifier`

Proof. Read the endpoint coordinates from Definition 354.1. The carrier separates the lower endpoint, upper endpoint, and endpoint-order witness, and each classifier row is attached to its corresponding endpoint coordinate.

Use the stored hsame rows to transport lower endpoints along lower coordinates and upper endpoints along upper coordinates. The order witness is then replayed over those two transported coordinates, so the classifier has the same lower, upper, and order components after transport.

No coordinate of the packet contains a completed $\mathsf{Real}^{\uparrow}$ equality or an apartness witness. Since transport only reuses the displayed endpoint classifier rows and the order witness coordinate, neither kind of row can be created by endpoint transport. □

Theorem 354.13 (RationalInterval finite-window consumer exhaustion)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer and every finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet factors through the displayed endpoint, order, containment, transport, continuation, package, and local* NameCert *rows. These rows exhaust the consumer surface of the finite rational window.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket window consumer exhaustion`

Proof. Project the accepted carrier tuple. Its observable coordinates are precisely the two $\mathsf{Rat}^{\uparrow}$ endpoints, the endpoint-order witness, the finite containment ledger, the displayed hsame rows, Cont routes, Pkg provenance, and the local naming evidence.

For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, apply Definition 354.5. The handoff reads the rational window only through those endpoint, order, containment, transport, continuation, package, and name rows.

For a finite-window $\mathsf{Real}^{\uparrow}$ consumer, apply Definition 354.6 and then Definition 354.10. The seed boundary and consumer exactness identify the same finite packet as the complete readback surface, so the consumer has no additional row for quotient reals, located subsets, apartness, or standard bridges. □

Theorem 354.14 (RationalInterval standard boundary bridge)**.** *For an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet, the endpoint order witness, finite containment ledger, endpoint transport classifier, refinement composition, and finite-window consumer exhaustion determine a conservative standard rational-interval boundary. Reading that boundary back recovers exactly the displayed* BHist *packet: the lower endpoint, upper endpoint, order row, containment ledger, endpoint transport rows, continuation routes, package provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows.*

The boundary is conservative. It excludes completed $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, interval arithmetic laws, and host standard interval data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket standard boundary bridge`

Proof. Project the accepted packet through Definition 354.1. The visible coordinates are the lower $\mathsf{Rat}^{\uparrow}$ endpoint, upper $\mathsf{Rat}^{\uparrow}$ endpoint, order row, containment ledger, endpoint transport rows, continuation routes, package provenance, and local name-certificate evidence.

Use Definition 354.3 to place the two endpoint rows in the conservative boundary order. Apply Definition 354.4 to identify the finite containment rows as the entire membership ledger for the displayed window.

Next compose Definition 354.11 with Definition 354.12. Refinement keeps the lower and upper endpoints on the same finite rational window, and endpoint transport keeps each classifier row attached to its displayed endpoint coordinate.

Finally apply Definition 354.13. Every $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ consumer has already factored through the projected rows, so reading the conservative boundary back componentwise recovers the original BHist packet and adds no completed real, quotient class, located subset, interval law, or host standard interval field. □

Theorem 354.15 (RationalInterval public rational-window handoff)**.** *The endpoint-order witness, containment ledger, endpoint transport classifier, common-refinement window,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seed boundary, and finite-window consumer exhaustion assemble a public* $\mathsf{RationalInterval}^{\uparrow}$ *handoff packet over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

The handoff exposes only the finite rational-window rows named by those objects. It excludes completed $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, and standard bridges.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket public rational window handoff`

Proof. Project the carrier tuple from Definition 354.1. The visible data are the two endpoint rows, their order witness, containment ledger, endpoint transport coordinates, continuation routes, package provenance, and local naming evidence.

Use Definition 354.3 and Definition 354.4. These identify the ordered endpoint pair and the exact finite containment rows that a public rational-window handoff may expose.

Compose Definition 354.8 with Definition 354.12. The common window supplies the shared finite rational interval surface, and endpoint transport keeps the lower and upper classifier rows attached to their own $\mathsf{Rat}^{\uparrow}$ coordinates.

Finally repack the resulting finite window through Definition 354.5, Definition 354.6, and Definition 354.13. These consumer theorems account for all $\mathsf{RegSeqRat}^{\uparrow}$ and finite-window $\mathsf{Real}^{\uparrow}$ reads, and none of the repacked coordinates contains completed real equality, quotient Cauchy data, located subset structure, apartness, interval arithmetic, or a standard bridge. □

Theorem 354.16 (RationalInterval endpoint-width ledger)**.** *Every certified* $\mathsf{RationalInterval}^{\uparrow}$ BHist *packet exposes exactly the lower endpoint row, the upper endpoint row, a dyadic width witness, the finite containment row, and the* Pkg *provenance row inherited from the displayed* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *surfaces.*

No quotient real, host interval, ambient located subset, interval arithmetic operation, or completed equality relation is projected by this ledger.

Proof. Project the certified packet through the same carrier rows used by Definition 354.15. The endpoint coordinates are the two displayed $\mathsf{Rat}^{\uparrow}$ rows, while the width and containment coordinates are the dyadic witness and finite containment row.

Apply Definition 354.3 to bind the endpoint pair to the visible order surface. Then use Definition 354.4 to identify the containment component as the whole finite ledger for that endpoint window.

Finally read the package coordinate componentwise. The public handoff of Definition 354.15 lists the only consumer-facing rows, so a quotient real, host interval, located subset, interval operation, or completed equality relation has no carrier coordinate from which it could be projected. □

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket endpoint width ledger`

Theorem 354.17 (RationalInterval dyadic transport stability)**.** *Transporting both endpoint histories and the dyadic width witness along the displayed* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *classifiers preserves the* $\mathsf{RationalInterval}^{\uparrow}$ *classifier under componentwise* hsame *transport and* Cont *continuation routes.*

The transported packet remains a finite rational-window interval packet over the same endpoint, width, containment, and package rows.

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket dyadic transport stability`

Proof. Start with the displayed lower and upper endpoint histories. By Definition 354.3, their order relation is recorded as a visible endpoint row and is therefore transported with the endpoints.

Use Definition 354.8 to place the source and target reads on a common finite rational window. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 354.5 transports the finite regular-sequence observations through the same hsame and Cont rows.

The dyadic width witness is part of the displayed finite window, so it follows the transported endpoints along the same classifier route. Apply Definition 354.4 to re-identify the containment row after transport, yielding the original $\mathsf{RationalInterval}^{\uparrow}$ classifier shape. □

Theorem 354.18 (RationalInterval RegSeqRat window coverage)**.** *Every finite* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window admitted by a* $\mathsf{RationalInterval}^{\uparrow}$ *source packet has a containment or refinement witness in the* $\mathsf{RationalInterval}^{\uparrow}$ *ledger.*

Equivalently, a finite regular rational sequence consumer cannot read outside the endpoint, dyadic-width, containment, refinement, and provenance rows already displayed by the interval packet.

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket regseqrat window coverage`

Proof. Take a finite $\mathsf{RegSeqRat}^{\uparrow}$ observation window admitted by the source packet. By Definition 354.5, that window reaches the interval only through the displayed rational endpoint and containment rows.

Apply Definition 354.8 to compare the consumer window with the source interval window. The common refinement supplies the finite row on which both observations are read.

Use Definition 354.4 to decide the corresponding containment entry, and use Definition 354.3 to keep the refined row between the displayed endpoints. The public handoff of Definition 354.15 then exhausts all remaining consumer reads through the same finite ledger. □

Theorem 354.19 (RationalInterval regular-window dyadic endpoints)**.** *Every finite* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window admitted by a certified* $\mathsf{RationalInterval}^{\uparrow}$ *packet is bounded by the displayed lower endpoint, upper endpoint, and dyadic-width rows.*

Any refinement or containment witness consumed by $\mathsf{Real}^{\uparrow}$ *factors through those same endpoint, width, containment,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, with no quotient real or completed equality coordinate.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket regular window dyadic endpoints`

Proof. First expose the visible endpoint and width surface by applying Definition 354.16. This gives the lower endpoint row, upper endpoint row, dyadic-width witness, containment row, and package provenance read by the finite interval packet.

Next transport the endpoint and width data along classifier reads. Apply Definition 354.17; the transported packet remains over the same endpoint, width, containment, BHist, hsame, Cont, package, and local certificate rows.

Finally use Definition 354.18. It exhausts every finite $\mathsf{RegSeqRat}^{\uparrow}$ consumer read by a containment or refinement entry in the displayed ledger, so the $\mathsf{Real}^{\uparrow}$ consumer boundary factors through the same finite rows and adds no quotient real or completed equality coordinate. □

Theorem 354.20 (RationalInterval finite consumer completeness)**.** *For every accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet, every finite consumer read of endpoint order, endpoint containment, common refinement, dyadic transport,* $\mathsf{RegSeqRat}^{\uparrow}$ *window coverage, or* $\mathsf{Real}^{\uparrow}$ *finite-window handoff factors through the displayed rational-interval packet rows and the standard boundary bridge.*

The packet rows available to such a consumer are exactly the displayed $\mathsf{Rat}^{\uparrow}$ *endpoint rows, the dyadic-width row, the finite containment and common refinement rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *window row, the* $\mathsf{Real}^{\uparrow}$ *finite-window handoff row, the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, and the standard boundary bridge. The completeness claim does not assert completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, or interval arithmetic.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket finite consumer completeness`

Proof. Start with a finite consumer read accepted by the $\mathsf{RationalInterval}^{\uparrow}$ packet. If the read asks for endpoint order, containment, common refinement, or a finite-window handoff, apply Definition 354.13 to place it on one of the displayed rational-interval rows.

For a boundary-facing read, apply Definition 354.14. This routes the same finite packet through the standard boundary bridge without adding a completed real equality, a quotient Cauchy class, or a located-subset carrier.

For a transported endpoint or width read, apply Definition 354.17. For a regular rational sequence observation, apply Definition 354.18. These two facts keep dyadic transport and $\mathsf{RegSeqRat}^{\uparrow}$ windows inside the existing endpoint, width, containment, refinement, provenance, and handoff rows.

The listed cases exhaust the finite consumer interfaces named in the statement. Interval arithmetic and completed real structure require carriers or relations absent from the packet rows, so they are not produced by this factorization. □

Theorem 354.21 (RationalInterval nested consumer window factorization)**.** *Let I be an accepted* $\mathsf{RationalInterval}^{\uparrow}$ BHist *packet. Suppose two finite consumers read only endpoint containment, common refinement,* $\mathsf{RegSeqRat}^{\uparrow}$ *window coverage, or* $\mathsf{Real}^{\uparrow}$ *finite-window handoff rows, and suppose the second read is displayed under the first by a finite* Cont *route. Then the nested pair factors through one displayed finite rational-window packet over the same* $\mathsf{Rat}^{\uparrow}$ *endpoints, endpoint-order row, containment ledger,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *row.*

The factor packet is purely finite. It contains no completed $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy class, located subset datum, host interval object, apartness row, or interval arithmetic operation.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket nested consumer window factorization`

Proof. Apply Definition 354.20 to each consumer read. Both reads land on displayed finite interval rows: endpoints, order, containment, refinement, regular-window, finite-window handoff, transport, continuation, provenance, and local naming evidence.

Next place the two readback windows on a common finite rational packet. Use Definition 354.8 for the binary common window, and use Definition 354.9 to choose it as a basis for the finite nested family of reads.

The displayed nesting route is then composed with the refinement routes by Definition 354.11. The composite route still reads the same endpoint, order, containment, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Finally apply Definition 354.14. The standard reading is conservative over the finite rational-window packet, so completed real equality, quotient Cauchy classes, located subsets, and host interval objects remain outside the factorization. □

Theorem 354.22 (RationalInterval window overlap consumer amalgamation)**.** *Let two finite* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers, or two finite-window* $\mathsf{Real}^{\uparrow}$ *consumers, read an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet. Suppose their reads are compatible on displayed endpoint rows, endpoint order, containment rows, common-refinement rows, or handoff rows, and suppose the two windows overlap through displayed* hsame *and* Cont *routes.*

Then the two reads amalgamate into one finite rational-window packet over the same $\mathsf{Rat}^{\uparrow}$ *endpoints. The amalgamated packet carries the endpoint-order row, the containment ledger, the common finite refinement row, the* BHist *histories, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows consumed by the two original reads.*

The amalgamation introduces no completed $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy class, located subset, apartness predicate, interval arithmetic operation, or host interval datum.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket window overlap consumer amalgamation`

Proof. First apply Definition 354.20 to the two consumer reads. Each read is already exhausted by finite interval rows: endpoint data, order, containment, refinement, finite-window handoff, BHist histories, hsame, Cont, Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ row.

Next use Definition 354.8 on the compatible overlapping windows. This gives a binary finite rational window which carries both displayed reads over the same endpoint boundary.

Choose the displayed finite basis for that overlap by Definition 354.9. The chosen packet keeps the endpoint-order row, containment ledger, common-refinement evidence, handoff rows, hsame transport, and Cont routes in the rational-window surface.

Finally apply Definition 354.21 to factor any nested access through the chosen window. The row exhaustion from the first step shows that no completed real equality, quotient Cauchy class, located subset, apartness row, interval arithmetic, or host interval datum is available to the amalgamation. □

Theorem 354.23 (RationalInterval overlap RegSeqRat handoff exactness)**.** *Let an accepted* $\mathsf{RationalInterval}^{\uparrow}$ BHist *packet be read by two overlapping finite* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers, or by two overlapping finite-window* $\mathsf{Real}^{\uparrow}$ *consumers. Suppose the two reads agree on displayed endpoint rows, endpoint order, containment rows, common-refinement rows, and finite handoff rows.*

Then both reads factor through one rational-window packet. Its exact exported rows are the two $\mathsf{Rat}^{\uparrow}$ *endpoints, the endpoint-order witness, containment ledger, width ledger, directed refinement, displayed* hsame *rows,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows. The factorization exports no completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy class, located subset, apartness predicate, interval arithmetic operation, or host interval datum.*

Proof. Apply Definition 354.22 to the two overlapping reads. This gives the common finite rational window carrying the shared endpoints, order, containment, refinement, BHist histories, displayed hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ rows.

Use Definition 354.18 for finite $\mathsf{RegSeqRat}^{\uparrow}$ reads and Definition 354.10 for finite-window $\mathsf{Real}^{\uparrow}$ reads. These two consumer exactness results identify the handoff rows as the displayed rational endpoint rows, containment ledger, width ledger, and directed-refinement data of the same window.

Finally cite Definition 354.14. The bridge is conservative over the finite BEDC packet, so the handoff remains internal to the rational-window rows and cannot export completed real equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, or host interval data. □

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket overlap regseqrat handoff exactness`

Theorem 354.24 (RationalInterval common refinement associativity)**.** *Let I, J, and K be three compatible accepted* $\mathsf{RationalInterval}^{\uparrow}$ *finite packets. Suppose their displayed pairwise common-refinement rows share the appropriate middle endpoint windows, so that one may first refine I with J and then with K, or first refine J with K and then with I.*

The two iterated refinements determine the same consumer-visible finite rational-window packet. They expose the same transported $\mathsf{Rat}^{\uparrow}$ *endpoint rows, endpoint-order witnesses, containment and refinement rows, dyadic-width row,* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window row,* $\mathsf{Real}^{\uparrow}$ *finite-window handoff row, visible* BHist, hsame, Cont, Pkg, *and local* NameCert *rows. The claim does not assert completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, or host standard interval data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket common refinement associativity`

Proof. Form the two binary common-refinement windows by applying Definition 354.8 to the compatible pairs. The shared middle endpoint hypotheses put both binary windows over the same displayed endpoint-order and containment rows.

Compose the refinement rows in the left-associated direction with Definition 354.11. Apply the same theorem in the right-associated direction. Both composites are therefore finite BHist packets whose refinement entries are built from the same pairwise rows.

Identify the transported endpoint coordinates componentwise by using Definition 354.12. Lower endpoints, upper endpoints, endpoint-order witnesses, containment rows, and dyadic-width rows agree at the consumer surface because each coordinate is read through the same transported $\mathsf{Rat}^{\uparrow}$ classifier data.

Finally apply Definition 354.20. It says every finite consumer read of the two composites factors through exactly the displayed rational-window rows, the $\mathsf{RegSeqRat}^{\uparrow}$ observation row, the $\mathsf{Real}^{\uparrow}$ finite-window handoff row, the visible BHist, hsame, Cont, Pkg, and local NameCert rows. Hence the two iterated refinements expose one finite consumer packet and add none of the excluded completed-real, quotient, located-subset, apartness, arithmetic, or host standard interval structure. □

Theorem 354.25 (RationalInterval midpoint bisection window)**.** *Let I be an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *packet with displayed lower endpoint, upper endpoint, dyadic-width witness, containment ledger, visible* BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows. Suppose a midpoint row m is displayed on the same* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint surface, and suppose two containment subledgers display the left window from the lower endpoint to m and the right window from m to the upper endpoint.*

Then the two half-windows are accepted $\mathsf{RationalInterval}^{\uparrow}$ *finite packets. They share the midpoint boundary row, their endpoint and dyadic-width rows are read from the same displayed surface, and every* $\mathsf{RegSeqRat}^{\uparrow}$ *or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer read of either half-window is one of the original endpoint, width, containment, refinement,* BHist*,* hsame*,* Cont*,* Pkg*, or local* NameCert *rows. Conversely, every original finite consumer read whose endpoint and containment rows lie in one half factors through the corresponding half-window packet.*

The bisection window exports no completed $\mathsf{Real}^{\uparrow}$ *equality, located subset datum, open cover, quotient Cauchy class, apartness row, interval arithmetic operation, or standard bridge datum.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket midpoint bisection window`

Proof. Use Definition 354.16 to read the lower endpoint, upper endpoint, midpoint row, and dyadic-width witnesses from the same $\mathsf{Rat}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ surface. Apply Definition 354.3 to obtain the displayed endpoint order for the left and right half-windows.

Next construct the two finite packets. Apply Definition 354.8 to the parent window and the midpoint row, and compose the resulting refinement routes with Definition 354.11. This gives accepted left and right $\mathsf{RationalInterval}^{\uparrow}$ packets whose common endpoint is exactly the displayed midpoint boundary.

The order in which the parent containment ledger, midpoint row, and two subledgers are grouped does not affect the consumer-visible packet. This is Definition 354.24, applied to the two ways of parenthesizing the same finite refinement data.

Finally apply Definition 354.20. Every $\mathsf{RegSeqRat}^{\uparrow}$ or finite-window $\mathsf{Real}^{\uparrow}$ read of a half-window is exhausted by the listed endpoint, width, containment, refinement, BHist, hsame, Cont, Pkg, and local NameCert rows, and the same exhaustion gives the converse factorization for parent consumer reads restricted to either half. □

Theorem 354.26 (RationalInterval refinement choice neutrality)**.** *Fix a* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint packet over* BHist*. For any two common-refinement windows whose endpoint, containment, dyadic-transport,* Cont*,* Pkg*, and local* NameCert *rows satisfy the directed-refinement and associativity hypotheses, the resulting finite consumer packages for* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *are* hsame*-equivalent.*

Thus a finite $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer may use any displayed common-refinement witness for the fixed endpoint packet without selecting completed real equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, or host standard interval data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalRefinement choice neutrality`
↪ variant `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket refinement choice neutrality`

Proof. Use Definition 354.8 to put both refinement choices over explicit finite endpoint and containment windows, and use Definition 354.9 to compare their directed basis rows inside one displayed finite BHist packet.

Compose the comparison routes with Definition 354.11. Then Definition 354.12 identifies the endpoint, containment, dyadic-width, Cont, Pkg, and local NameCert rows seen after the displayed hsame transport.

Finally apply Definition 354.24. It identifies the two readings at the finite $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer surface exposed by the fixed endpoint packet. □

Theorem 354.27 (RationalInterval bisection refinement nesting)**.** *Let I be an accepted* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint packet with displayed lower endpoint, midpoint row, upper endpoint, containment ledger, dyadic-width rows, visible* BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows. Suppose the midpoint bisection of Definition 354.25 displays the left and right half-windows, and suppose either half-window is refined once more by a finite rational-window packet over the same endpoint surface.*

Then the two-step choice factors through one finite rational-window packet over the original endpoint, midpoint, containment, dyadic-width, BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or finite-window* $\mathsf{Real}^{\uparrow}$ *consumer of the nested half-window reads this packet, and changing the displayed common-refinement witness changes only the* hsame *representative of the same finite consumer package.*

The nesting claim does not assert completed $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, or host interval data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket bisection refinement nesting`

Proof. First apply Definition 354.25. It constructs the accepted left and right half-window packets from the parent endpoint, midpoint, containment, dyadic-width, BHist, hsame, Cont, Pkg, and local NameCert rows.

Next compose the chosen half-window refinement with the parent bisection route. The finite parenthesization of that two-step route is exactly the content of Definition 354.24; it repacks the displayed endpoint and containment rows as one rational-window packet over the original endpoint surface.

Finally use Definition 354.26. Any alternate displayed common-refinement witness for the same nested half-window has the same finite $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer package up to hsame. Since all rows used by the construction are the listed finite BEDC rows, no completed-real equality, quotient class, located-subset datum, apartness row, interval operation, or host interval structure is exported. □

Theorem 354.28 (RationalInterval refinement normal form)**.** *Any finite tree of accepted* $\mathsf{RationalInterval}^{\uparrow}$ *containment, bisection, and common-refinement reads consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or by a finite-window* $\mathsf{Real}^{\uparrow}$ *consumer factors through one left-associated directed rational-window basis packet. The packet carries the same displayed* $\mathsf{Rat}^{\uparrow}$ *lower and upper endpoint rows, dyadic-width rows, containment ledgers,* BHist *entries,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows as the original tree.*

Every $\mathsf{RegSeqRat}^{\uparrow}$ *or finite-window* $\mathsf{Real}^{\uparrow}$ *read of the tree is therefore a read of this left-associated basis packet, and changing the displayed common refinement or bisection witnesses changes only the representative of the same finite consumer package. The normal form exports no completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy class, located subset, apartness row, interval arithmetic, or host standard interval.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket refinement normal form`

Proof. Induct on the finite refinement tree. A leaf is already an accepted $\mathsf{RationalInterval}^{\uparrow}$ rational-window packet, so its endpoint, width, containment, BHist, hsame, Cont, Pkg, and NameCert rows give the required basis packet.

For a binary common-refinement node, apply Definition 354.8 to place the two child packets over a common finite rational window. Then use Definition 354.9 to choose the left-associated directed basis for the finite family of endpoint and containment rows.

For a nested refinement node, compose the child basis route with the displayed outer route by Definition 354.11. The rebracketing needed to keep the basis left-associated is exactly Definition 354.24.

For a bisection node, apply Definition 354.25 to expose the two half-window packets and then use the induction hypothesis on the selected half. The rows remain over the same endpoint, midpoint, dyadic-width, containment, BHist, hsame, Cont, Pkg, and local NameCert surface.

Finally apply Definition 354.26. It identifies all displayed witness choices at the finite $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer surface. Since every step only repacks the listed finite rational-window rows, the excluded completed-real, quotient, located-subset, apartness, arithmetic, and host-standard structures are not exported. □

Theorem 354.29 (RationalInterval normal form terminal seal compatibility)**.** *Let T be any finite* $\mathsf{RationalInterval}^{\uparrow}$ *containment, bisection, and common-refinement tree whose terminal rows are consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *or by a finite-window* $\mathsf{Real}^{\uparrow}$ *read. Replacing T by the left-associated directed normal form of Definition 354.28 preserves the terminal seal surface exactly: the visible* $\mathsf{Rat}^{\uparrow}$ *lower and upper endpoints, dyadic-width rows, containment and refinement ledgers,* BHist *entries,* hsame *rows,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows are the same finite rows for every terminal consumer.*

Thus any $\mathsf{RegSeqRat}^{\uparrow}$ *consumer and any finite-window* $\mathsf{Real}^{\uparrow}$ *consumer sees the same terminal packet before and after normal-form replacement. The compatibility statement exports no completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy class, located subset, apartness row, interval arithmetic operation, or host interval datum.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalRefinement terminal seal compatibility`

Proof. Apply Definition 354.28 to factor the finite tree through the left-associated directed rational-window basis. The factorization is defined only by repacking the displayed endpoint, dyadic-width, containment, refinement, history, transport, continuation, package, and local certificate rows.

For a $\mathsf{RegSeqRat}^{\uparrow}$ terminal read, use Definition 354.20. That theorem says that every finite consumer read factors through the displayed packet rows, so the normal form has the same seal surface as the original tree at the $\mathsf{RegSeqRat}^{\uparrow}$ boundary.

For a finite-window $\mathsf{Real}^{\uparrow}$ terminal read, use Definition 354.21. It restricts the read to the nested finite rational-window rows and hence to the same endpoint, width, ledger, BHist, hsame, Cont, Pkg, and NameCert coordinates preserved by the normal form.

The construction never introduces coordinates for completed real equality, quotient Cauchy classes, located subsets, apartness, interval arithmetic, or host interval data. Those objects therefore remain outside the terminal seal surface. □

Theorem 354.30 (RationalInterval dyadic nested amalgamation normal form)**.** *Let $\mathcal{R}$ be a finite family of nested or overlapping* $\mathsf{RationalInterval}^{\uparrow}$ *consumer reads whose endpoint rows are compatible* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows over the same rational boundary. Then $\mathcal{R}$ has a single displayed rational-window packet carrying endpoint order, containment, common-refinement evidence, finite-window handoff,* BHist *histories, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ *rows.*

Every $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *finite-window consumer of those reads factors through that packet. The factorization uses only the displayed dyadic endpoint rows and rational-window ledgers; it does not introduce completed* $\mathsf{Real}^{\uparrow}$ *equality, quotient Cauchy classes, located subsets, apartness predicates, interval arithmetic operations, or host interval data.*

Lean4 ✓ `BEDC.Derived.RationalIntervalUp.RationalIntervalPacket dyadic nested amalgamation normal form`

Proof. First apply Definition 354.20 to each consumer read. Each member of $\mathcal{R}$ is exhausted by endpoint order, containment, finite refinement, finite-window handoff, BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$ rows.

Use Definition 354.22 on overlapping reads and Definition 354.21 on nested reads. These two reductions place the family inside finite rational-window packets with compatible dyadic endpoints.

Apply Definition 354.24 to associate the resulting refinement witnesses, and use Definition 354.27 to keep all dyadic endpoint rows inside the same nested boundary. The finite family condition lets these binary amalgamations be iterated until one displayed rational-window packet remains.

Finally invoke Definition 354.28. The normal form is the announced packet, and the finite-window handoff rows provide the required factorization for every $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer. □

Closure status for $\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$.

Constructive story: A rational closed interval is represented by two displayed RatUp endpoint rows, an endpoint-order witness, a finite containment ledger, and visible hsame, Cont, package, and NameCert rows consumed by RegSeqRat and RealUp finite-window arguments.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 354.7, Definition 354.8, Definition 354.24, Definition 354.10, Definition 354.14, and Definition 354.20 bind the endpoint, order, containment, transport, package, local NameCert rows, common-refinement associativity, standard boundary bridge, and finite consumer completeness to BHist, hsame, Cont, Pkg, NameCert, $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ for the finite interval packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RationalInterval}^{\uparrow}}$, axiomClean)

Chapter 355

A Concrete Naming Certificate for $\mathsf{RationalBall}^{\uparrow}$

The $\mathsf{RationalBall}^{\uparrow}$ interface names finite rational-radius balls on the path from rational intervals and dyadic radius rows to metric and real-name consumer windows. In the constructive analysis tradition of Bishop and Bridges, a metric ball used here is a located finite witness: a center row, a visible nonnegative radius row, and the finite ledgers by which rational samples are certified inside the radius. It is not an open-cover topology object and it carries no hidden completed real.

$\mathsf{RationalBall}^{\uparrow}$ consumes the finite endpoint-and-containment discipline of chapter 354. The ball ledger refines interval containment by adding the visible center row, nonnegative radius row, and rational-radius comparison route.

Definition 355.1 (RationalBall BHist carrier)**.** *A* $\mathsf{RationalBall}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (c, r, o, h, k, p, n)$$

with the following visible rows:

1. *c is the center row, a* $\mathsf{Rat}^{\uparrow}$ *carrier displayed in the packet;*
2. *r is the dyadic or rational radius row, read through* $\mathsf{DyadicRatCore}^{\uparrow}$ *as the radius budget for the ball;*
3. *o is the nonnegative radius and order witness row, certifying that the displayed radius is usable as a finite metric bound;*
4. *h records the componentwise* hsame *transport rows for the center, radius, order witness, containment ledger, consumer-facing metric rows, and real-window handoff coordinates;*
5. *k is the containment ledger recording exactly which finite rational sample rows are certified to lie within the displayed radius of c;*
6. *p is the visible* Pkg *provenance row naming the consumed* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *certificate surfaces;*
7. *n is the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *registration row.*

The carrier predicate is $\mathsf{RationalBallPacket}(c, r, o, h, k, p, n)$*. Its classifier compares two accepted packets only by transporting the displayed center and radius rows, then replaying the finite containment ledger through the same displayed* BHist *surface.*

Lean4 ✓ `BEDC.Derived.RationalBallUp.TasteGate.RationalBallTasteGate single carrier alignment`

Theorem 355.2 (RationalBall NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *seed obligation surface consists of six finite rows: the carrier of Definition 355.1, center equality through the displayed* $\mathsf{Rat}^{\uparrow}$ *classifier, radius compatibility through* $\mathsf{DyadicRatCore}^{\uparrow}$*, the nonnegative radius witness, containment ledger exactness, and* hsame *stability for the* Cont *routes that expose the* $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumer windows.*

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket namecert obligations`

Proof. Project the seven carrier coordinates. The center row c, radius row r, and order witness o provide the finite rational-radius data.

The containment surface is exactly the ledger k, interpreted with the transport rows in h. The package row p names the downstream interval, regular-sequence, metric, and real-name surfaces, while n supplies the local registration row.

These rows account for the stated seed obligations. No coordinate remains for an open cover, a completed metric space point, or an ambient real ball. □

Theorem 355.3 (RationalBall containment exactness)**.** *For an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet* $B = (c, r, o, h, k, p, n)$*, every rational containment read is exactly one row of* k *transported by* h *and interpreted against the displayed center* c*, radius* r*, and nonnegative radius witness* o*. Conversely, any row of* k *with those carrier, transport, package, and local naming coordinates is accepted as a* $\mathsf{RationalBall}^{\uparrow}$ *containment read.*

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket containment exactness`

Proof. Project B through Definition 355.1. The only containment coordinate is the ledger k, and each row of k is read with the displayed center, radius, and order witness.

For the forward direction, a consumer route can only access a row named by the carrier. Transporting that row uses the componentwise hsame data in h, so the read remains inside the same finite rational-radius packet.

For the reverse direction, start with a displayed row of k together with c, r, o, h, p, and n. These are precisely the carrier coordinates needed to interpret the row as a rational containment read. □

Theorem 355.4 (RationalBall refinement transport)**.** *Suppose two accepted* $\mathsf{RationalBall}^{\uparrow}$ *packets are connected by displayed* hsame *rows for their centers, radius rows, nonnegative radius witnesses, and finite containment ledgers. Then any rational sample accepted by the first packet transports to a rational sample accepted by the second packet through the same* Cont *route surface. The transport introduces no completed metric point, no total real equality, and no open-cover refinement principle.*

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket radius refinement transport`

Proof. Use Definition 355.3 to identify the sample read as one displayed ledger row of the first packet. The hypotheses provide the matching hsame rows for the center, radius, order witness, and ledger.

Move the ledger row along those displayed transports. The package row keeps the same $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces visible to the consumer.

Apply the reverse direction of Definition 355.3. The transported row has exactly the coordinates required by the second packet, so it is accepted there and no external metric completion datum is introduced. □

Theorem 355.5 (RationalBall full packet refinement transport)**.** *Let an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet be given by center, radius, containment ledger, provenance, local name row, generated order row, transport row, endpoint row, a probe bundle, and a package row. If componentwise* hsame *transport is supplied for the center, radius, containment ledger, provenance, and local name row, and if the target side regenerates the* Cont *rows from center to radius to order, from order to containment to transport, and from transport to provenance to endpoint together with the matching* Pkg *row, then the transported data form an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet. The same construction also produces the derived order sameness, transport sameness, and endpoint sameness rows.*

The construction is internal to the displayed rational-ball packet: it introduces no completed metric point, compactness principle, open-cover refinement, or quotient-real equality.

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket refinement transport`

Proof. Project the accepted packet into its unary rows, three Cont routes, and package endpoint row. The displayed hsame hypotheses move the center, radius, containment ledger, provenance, and local name row componentwise.

Rebuild the generated order, transport, and endpoint rows using the target Cont routes. The BEDC kernel rule that Cont respects displayed sameness then gives the order sameness, transport sameness, and endpoint sameness rows.

Finally repack the transported unary rows, regenerated Cont routes, and target Pkg row into the accepted packet. Every object used in the construction is already one of the displayed packet coordinates or a regenerated route between them, so no completed metric point, compactness, open-cover, or quotient-real equality datum is introduced. □

Theorem 355.6 (RationalBall RealUp window handoff)**.** *A* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet may read only the finite rational-radius window recorded by the carrier: the* $\mathsf{Rat}^{\uparrow}$ *center, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the nonnegative radius witness, finite rational containment ledger, displayed* hsame *transports,* Cont *routes,* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row.*

The handoff supplies a finite rational-radius seed for real-name consumer windows. It does not assert completeness of $\mathsf{Real}^{\uparrow}$, *compactness of balls, or an open-cover topology theorem.*

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket realup window handoff`

Proof. Project the carrier of Definition 355.1. The center, radius, order witness, containment ledger, transport rows, provenance, and local naming row are the only coordinates exposed by the packet.

Use Definition 355.3 to exhaust the rational sample reads available to a downstream consumer. Use Definition 355.4 to see that every such read is stable under displayed finite refinements.

Thus a $\mathsf{Real}^{\uparrow}$ consumer receives exactly the finite rational-radius window and its provenance through the named BEDC surfaces. Since the packet has no coordinate for a completed real, an open cover, or compactness data, none can be exported at the handoff. □

Theorem 355.7 (RationalBall interval center containment)**.** *Let* $B = (c, r, o, h, k, p, n)$ *be an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet, and let* $I = (l, u, o_I, \kappa, h_I, c_I, p_I, n_I)$ *be a displayed* $\mathsf{RationalInterval}^{\uparrow}$ *window whose center row is the same* $\mathsf{Rat}^{\uparrow}$ *row* c *and whose endpoint rows are the rational-radius endpoints determined by* c *and* r*. For every rational sample row* q *carried by the same finite* BHist *surface,* q *is accepted by the* $\mathsf{RationalBall}^{\uparrow}$ *containment ledger* k *exactly when its transported row is accepted by the* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint-containment ledger* κ *under the same displayed* hsame *transports,* Cont *routes, and* Pkg *provenance.*

The correspondence supplies only finite rational-radius containment data for the displayed center window. It does not assert metric completeness, compactness of balls, or any open-cover topology principle.

Proof. For the ball-to-interval direction, apply Definition 355.3. A containment read of q is one row of k interpreted against the center c, radius r, order witness o, transport rows h, continuation routes, package provenance, and local name row.

Transport that displayed row through the endpoint window. The shared $\mathsf{Rat}^{\uparrow}$ center and radius endpoints identify the transported sample with the endpoint-containment row of I. Apply Definition 355.4, Definition 354.3, and Definition 354.4 to read the row as one accepted $\mathsf{RationalInterval}^{\uparrow}$ containment fact.

For the interval-to-ball direction, start with the endpoint-containment row in κ. The same endpoint theorem and containment-ledger exactness identify it as a finite row over the displayed center, radius endpoints, order witness, hsame, Cont, and Pkg data. Repack that row through Definition 355.3; the carrier coordinates are exactly c, r, o, h, k, p, and n.

Finally use the RationalInterval consumer theorems named by the package provenance to keep the transported read inside the finite endpoint-window surface. No proof step introduces a completed metric point, a compact ball, or an open-cover datum. □

Theorem 355.8 (RationalBall carrier-radius obligation)**.** *Every admitted* $\mathsf{RationalBall}^{\uparrow}$ *packet consists of a* $\mathsf{Rat}^{\uparrow}$ *center history, a positive rational radius row, a containment classifier row over* BHist *observations, and* Pkg *provenance for the displayed* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RationalInterval}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *surfaces.*

These are the only carrier-radius rows visible to downstream consumers.

Proof. Project the admitted packet through Definition 355.1. The carrier lists the center, radius, order witness, containment ledger, transport rows, package provenance, and local naming row.

Apply Definition 355.2. It isolates the center and radius rows as the finite data required by the local $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ surface.

Use Definition 355.3 to identify the containment classifier as the whole ledger over BHist observations. The remaining visible dependency rows are precisely the package coordinates named in the carrier. □

Theorem 355.9 (RationalBall center transport obligation)**.** *Transporting the center history and radius row along the displayed* $\mathsf{Rat}^{\uparrow}$ *classifier preserves the* $\mathsf{RationalBall}^{\uparrow}$ *containment classifier under componentwise* hsame *and* Cont *routes.*

The transported packet exposes the same finite rational-radius consumer surface and no completed metric point.

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket center transport obligation`

Proof. Begin with the center and radius rows supplied by Definition 355.1. The displayed $\mathsf{Rat}^{\uparrow}$ classifier provides the transport route for the center, and the radius row travels with the same finite rational-radius packet.

Apply Definition 355.4. It moves a containment sample through the matching hsame rows and the displayed Cont route without introducing an external metric completion datum.

Finally use Definition 355.3 in the target packet. The transported center and radius rows determine exactly the same containment classifier shape, so the $\mathsf{RationalBall}^{\uparrow}$ consumer surface is preserved. □

Theorem 355.10 (RationalBall ledger exactness obligation)**.** *The* $\mathsf{RationalBall}^{\uparrow}$ *ledger exposes exactly the center, radius, containment, refinement,* $\mathsf{Real}^{\uparrow}$ *window handoff, and dependency provenance rows of the finite rational-radius packet.*

It exposes no compactness theorem, open-cover topology, quotient real equality, or completed metric-space point.

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket ledger exactness certificate`

Proof. Project the ledger coordinates from Definition 355.1. The center and radius rows are the carrier entries, and the dependency provenance is the displayed Pkg row.

Apply Definition 355.2 to bind those rows to the local naming surface. Then use Definition 355.3 and Definition 355.4 to exhaust the containment and refinement reads.

Finally apply Definition 355.6. The only real-facing consumer data are the finite rational-radius window and its provenance, so compactness, open-cover topology, quotient real equality, and completed metric points have no ledger coordinate. □

Theorem 355.11 (RationalBall RegSeqRat window obligations)**.** *A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet reads exactly the* $\mathsf{Rat}^{\uparrow}$ *center,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, nonnegative-radius witness, finite containment ledger,* hsame *transports,* Cont *routes,* Pkg *provenance over* $\mathsf{RationalInterval}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row.*

The obligation surface exports no real completeness theorem, compactness of metric balls, open-cover topology, quotient real equality, or completed metric point.

Proof. Project the carrier rows from Definition 355.1. The visible data are the rational center, dyadic radius, nonnegative-radius witness, finite containment ledger, transport rows, continuation routes, package provenance, and local naming row.

Apply Definition 355.2 to bind these rows to the accepted $\mathsf{RationalBall}^{\uparrow}$ packet. Then use Definition 355.3 to exhaust the finite containment ledger.

Next apply Definition 355.4. It preserves the same rational-radius window under the displayed hsame and Cont routes, with package provenance over the rational-interval, regular-sequence, metric, and real-facing consumers.

Finally use Definition 355.6. The real-facing boundary is only the finite window read by the $\mathsf{RegSeqRat}^{\uparrow}$ consumer, so real completeness, compactness, open-cover topology, quotient real equality, and completed metric points have no exported row. □

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket regseqrat window obligations certificate`

Theorem 355.12 (RationalBall public finite consumer export)**.** *Every public* $\mathsf{RationalBall}^{\uparrow}$ *finite consumer read factors through exactly the center* $\mathsf{Rat}^{\uparrow}$ *row, the dyadic or rational radius row, the nonnegative-radius witness, the containment ledger, the* hsame *transports, the* Cont *routes, the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RationalInterval}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row. Conversely, those rows repack as the public finite rational-radius consumer surface.*

Proof. Project the carrier through Definition 355.1. The center row, radius row, nonnegative-radius witness, containment ledger, transport rows, continuation routes, package provenance, and local naming row are exactly the finite coordinates of an accepted packet.

Apply Definition 355.3 to exhaust the containment reads. Then use Definition 355.4 to carry the same rows through the displayed hsame and Cont routes.

Next apply Definition 355.6 and Definition 355.11. These two window statements identify the $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumer reads as the same finite rational-radius packet surface.

Thus the forward direction factors every public consumer read through the listed rows, and the reverse direction repacks those rows as the public consumer surface. Completeness, compactness, open-cover topology, quotient real equality, and completed metric points are excluded because the carrier has no coordinate for them. □

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket public finite consumer export`

Theorem 355.13 (RationalBall DyadicApproximation window correspondence)**.** *Let R be an accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet and let D be an accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *packet. Suppose the two packets share the unary precision row, the dyadic endpoint or radius row, the* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{RationalInterval}^{\uparrow}$ *containment ledger, visible* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *rows naming those finite coordinates.*

Then R and D determine the same finite $\mathsf{Real}^{\uparrow}$*-facing consumer surface. Conversely, those shared rows repack as the* $\mathsf{RationalBall}^{\uparrow}$ *finite consumer read.*

Proof. Start with Definition 355.12. It exposes the $\mathsf{RationalBall}^{\uparrow}$ public read as the center row, dyadic or rational radius row, containment ledger, displayed transports, continuation routes, package provenance, and local naming row.

Next apply Definition 355.6. The $\mathsf{RationalBall}^{\uparrow}$ real-facing boundary is only the finite window consumed by the regular rational readback, so the displayed unary precision, stream name, and rational-interval containment rows are sufficient to identify the $\mathsf{Real}^{\uparrow}$ surface.

For the dyadic side, use Definition 335.14 and Definition 335.12. These identify the accepted $\mathsf{DyadicApproximation}^{\uparrow}$ packet with the same finite dyadic endpoint or radius row, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{RationalInterval}^{\uparrow}$ containment ledger.

The shared hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows therefore give the same BHist consumer surface on both sides. Reading the surface from R gives the forward correspondence; reading the same rows in the reverse direction repacks the $\mathsf{RationalBall}^{\uparrow}$ finite consumer read.

No step uses compactness, open-cover topology, quotient real equality, a selected limit, or a completed metric point, since none of these is a row of the shared finite window. □

Theorem 355.14 (RationalBall standard finite-window bridge)**.** *The public finite consumer export,* $\mathsf{RegSeqRat}^{\uparrow}$ *window obligations,* $\mathsf{Real}^{\uparrow}$ *window handoff, refinement transport, and containment exactness assemble the standard finite rational-radius bridge for* $\mathsf{RationalBall}^{\uparrow}$*. The bridge exposes exactly the center row, radius row, nonnegative-radius witness, containment ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row.*

The bridge adds no real completeness, compactness of metric balls, open-cover topology, quotient real equality, or completed metric point.

Proof. Start with Definition 355.12. It fixes the public finite consumer rows: center, radius, nonnegative-radius witness, containment ledger, transports, continuation routes, package provenance, and local naming row.

Apply Definition 355.11 and Definition 355.6. These identify the regular rational source window and real-facing endpoint window as reads of the same finite rational-radius packet.

Next use Definition 355.4. It preserves the packet under the displayed hsame and Cont routes while retaining the same package provenance.

Finally apply Definition 355.3. The containment ledger is exhausted by the listed finite rows, so the assembled bridge has no coordinate for real completeness, compactness, open-cover topology, quotient real equality, or a completed metric point. □

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallUp StdBridge`

Theorem 355.15 (RationalBall mature finite consumer completeness)**.** *Every finite consumer read of the standard finite-window bridge for* $\mathsf{RationalBall}^{\uparrow}$ *factors through exactly the* $\mathsf{Rat}^{\uparrow}$ *center row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *or* $\mathsf{Rat}^{\uparrow}$ *radius row, the nonnegative-radius witness, the containment ledger, the* hsame *transports, the* Cont *routes, the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row. Conversely, those rows repack as the mature finite rational-radius consumer surface.*

This completeness statement exports no $\mathsf{Real}^{\uparrow}$ *completeness theorem, compactness of metric balls, open-cover topology, quotient real equality, or completed metric point.*

Proof. First apply Definition 355.12. It identifies every public finite consumer read with the center, radius, nonnegative-radius, containment, transport, continuation, package, and local naming rows of the accepted packet.

Next apply Definition 355.11 and Definition 355.6. These two results identify the regular rational source window and the real-facing endpoint window as reads of the same finite rational-radius packet.

Then use Definition 355.14. The bridge packages those public, regular-rational, and real-facing rows without adding a new consumer coordinate.

For the converse direction, repack exactly the listed rows as the mature finite rational-radius consumer surface. The excluded real-completeness, compactness, open-cover, quotient-equality, and completed-point principles remain absent because none is a coordinate of the bridge or of the public finite consumer export. □

Theorem 355.16 (RationalBall dyadic-radius readback)**.** *Every accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet whose radius row is displayed by a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance window gives a* $\mathsf{Real}^{\uparrow}$*-facing readback determined exactly by the* $\mathsf{Rat}^{\uparrow}$ *center row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, the* $\mathsf{RationalInterval}^{\uparrow}$ *containment ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, displayed* hsame *transports, visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *ledger.*

The readback exports no metric completion point, open-ball compactness claim, open-cover topology, quotient real equality, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Project the accepted packet to the finite carrier of Definition 355.1. In the dyadic-radius case, the consumer-visible coordinates are the rational center row, dyadic radius row, containment ledger, transport rows, continuation routes, package provenance, and local naming ledger.

Apply Definition 355.3. This identifies the center-radius containment row inside the displayed $\mathsf{RationalInterval}^{\uparrow}$ ledger and leaves no separate metric completion coordinate.

Use Definition 355.11 and Definition 355.6. These route the regular rational observation window and the $\mathsf{Real}^{\uparrow}$-facing read through the same finite dyadic-radius packet.

Finally invoke Definition 355.15. The mature consumer surface is exhausted by the center, dyadic radius, containment, observation, transport, continuation, package, and naming rows, so the stated readback contains none of the excluded completion, compactness, topology, quotient, or real-completeness data. □

Theorem 355.17 (RationalBall metric positive containment transport)**.** *An accepted* $\mathsf{RationalBall}^{\uparrow}$ *packet with nonnegative radius and finite containment ledger transports the same positive containment row through the* $\mathsf{Met}^{\uparrow}$ *distance consumer. The transported row exposes only the* $\mathsf{Rat}^{\uparrow}$ *center, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *or* $\mathsf{Rat}^{\uparrow}$ *radius, the finite containment ledger, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *and the local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *row.*

The transport adds no real completeness, compactness of metric balls, open-cover topology, quotient real equality, or completed metric point.

Lean4 ✓ `BEDC.Derived.RationalBallUp.RationalBallPacket metric positive containment transport`

Proof. First use Definition 355.12. It exposes the finite center, radius, nonnegative-radius witness, containment ledger, transport rows, continuation routes, package provenance, and local naming row of the accepted packet.

Next apply Definition 355.11 and Definition 355.6. These obligations identify the regular rational source window and the real-facing endpoint window as reads of the same finite containment ledger.

Then invoke Definition 355.14. The bridge carries the public finite rows into the standard rational-radius window without adding a completeness, compactness, topology, quotient, or completed point coordinate.

Finally read the metric side through Definition 355.15. The $\mathsf{Met}^{\uparrow}$ distance consumer receives the same positive containment row, with the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance, so the transport is exactly finite-window containment repacking. □

Theorem 355.18 (RationalBall nested containment consumer composition)**.** *Let $B_0 = (c_0, r_0, H_0, R_0, P_0, C_0)$ and $B_1 = (c_1, r_1, H_1, R_1, P_1, C_1)$ be accepted $\mathsf{RationalBall}^{\uparrow}$ packets, and let q be a query history. Suppose the displayed $\mathsf{RationalInterval}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ refinement row says that the finite rational ball of B_1 is contained in the finite rational ball of B_0. If q is accepted by the containment row of B_1, then q is accepted by the containment row of B_0.*

Moreover every $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, or $\mathsf{Met}^{\uparrow}$ consumer receives the composed finite containment ledger formed from the two packet ledgers, the displayed hsame transports, the Cont routes, the Pkg provenance over $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and the two local $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ rows. The composition introduces no host metric, choice-selected point, real-completeness row, compactness datum, topology row, or quotient real equality.

Proof. First apply Definition 355.4. It transports the inner packet B_1 through the displayed outer containment row of B_0 and keeps the containment witness as a finite $\mathsf{RationalInterval}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ ledger row.

Next use Definition 355.7. The query history q is already accepted by the containment row of B_1, and the transported refinement row places that accepted read inside the containment row of B_0.

For regular and real consumers, pass the composed ledger through Definition 355.11 and Definition 355.14. These theorems keep the same finite observation windows and standard rational-radius bridge rows, so the consumer sees the composed containment ledger rather than a rebuilt host argument.

Finally apply Definition 355.17. The $\mathsf{Met}^{\uparrow}$ read is the same positive containment row transported through the finite packet data. Since every step used only displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, no external metric structure or choice data enters the composed handoff. □

Theorem 355.19 (RationalBall DyadicApproximation nested window readback)**.** *Let $B_0, \ldots, B_n$ be nested accepted $\mathsf{RationalBall}^{\uparrow}$ packets with displayed inner-to-outer $\mathsf{RationalInterval}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ containment rows. Then the composed containment ledger determines the same terminal $\mathsf{DyadicApproximation}^{\uparrow}$ finite window as the dyadic-approximation correspondence and the terminal refinement theorem.*

The terminal window is read from the innermost accepted packet, transported through the composed containment ledger, and presented with the same dyadic endpoint, precision row, scheduled

finite readback, $\mathsf{Real}^{\uparrow}$ *handoff, visible* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *rows. The readback introduces no host metric, choice-selected point, compactness datum, topology row, completed real, or quotient real equality.*

Proof. First apply Definition 355.13 to the terminal accepted rational-ball packet. This supplies the finite $\mathsf{DyadicApproximation}^{\uparrow}$ window with its precision, endpoint, scheduled readback, handoff ledger, transport, route, provenance, and local certificate rows.

Next use Definition 355.18. The inner-to-outer containment rows compose into a single finite ledger, and every regular, real, metric, or dyadic consumer sees that composed ledger rather than a rebuilt host argument.

Apply Definition 335.17 to identify the terminal dyadic window selected by the refinement chain. The terminal precision row and dyadic endpoint row are the same rows produced by the rational-ball correspondence, transported along the containment ledger.

Finally use Definition 335.19. It states that nested dyadic windows exhaust to the terminal finite window through the displayed refinement rows. Thus the rational-ball containment ledger and the dyadic terminal refinement expose the same finite readback surface, with no host metric, choice-selected point, compactness, topology, completed-real, or quotient-equality row. □

Theorem 355.20 (RationalBall nested containment refinement monotonicity)**.** *For any finite chain* $B_0, \ldots, B_n$ *of accepted* $\mathsf{RationalBall}^{\uparrow}$ *packets whose adjacent* $\mathsf{RationalInterval}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *containment rows witness that each displayed ball is contained in the preceding displayed ball, every query history accepted by the containment row of* B_n *is accepted by the containment row of every earlier* B_i*.*

Every $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, or* $\mathsf{Met}^{\uparrow}$ *consumer receives the iterated finite containment ledger assembled from the adjacent packet ledgers, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$ *rows. The finite chain exports no host metric, choice-selected point, compactness datum, topology row, completed real, or quotient real equality.*

Proof. Induct on the finite chain. For the singleton chain, the terminal packet is already the initial packet, and the containment read is the packet's displayed finite containment row.

For the extension step, assume the statement for a chain ending in B_n and append an accepted packet B_{n+1} whose adjacent containment row places it inside B_n. Apply Definition 355.18 to compose the accepted read of B_{n+1} with the containment row of B_n.

The induction hypothesis then transports the resulting accepted read through every earlier containment row. The composed ledger is the finite concatenation of the adjacent packet ledgers together with the displayed hsame, Cont, Pkg, and local NameCert rows used at each step.

For consumer handoff, use Definition 355.11, Definition 355.14, and Definition 355.17. These theorems read the same iterated containment ledger for $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Met}^{\uparrow}$, without adding any host metric, selected point, compactness, topology, completed-real, or quotient-equality row. □

Closure status for $\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$**.**

Constructive story: A rational ball packet is generated by a rational center row, a dyadic or rational radius row, a nonnegative radius witness, a finite rational containment ledger, displayed transport rows, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 355.1, Definition 355.8, Definition 355.9, Definition 355.10, Definition 355.6, Definition 355.11, Definition 355.12, Definition 355.13, Definition 355.14, Definition 355.15, Definition 355.17, and Definition 355.18 bind the carrier definition, the carrier-radius, center-transport, ledger-exactness, $\mathsf{Real}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ window, public finite consumer rows, dyadic-approximation window correspondence, standard finite rational-radius bridge, mature finite consumer completeness, metric positive containment transport, and nested containment composition to

BHist, hsame, Cont, Pkg, NameCert, $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ for the finite rational-radius packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RationalBall}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.RationalBallUp.RationalBallPacket\_refinement\_transport`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close real completeness, compactness of metric balls, open-cover topology, or quotient real equality.

Upgrade path: No further formal-axis upgrade remains because the finite rational-radius packet is bridge-checked.

Chapter 356

A Concrete Naming Certificate for $\mathsf{ContextFreeGrammar}^{\uparrow}$

The $\mathsf{ContextFreeGrammar}^{\uparrow}$ interface names a context-free grammar through a finite grammar packet rather than through a host language set. In the Hopcroft–Ullman presentation, a context-free grammar is given by a finite terminal alphabet, finite nonterminal carrier, start symbol, and finite production relation; here each of those rows is displayed as finite BHist data with $\mathsf{List}^{\uparrow}$ word rows and explicit provenance toward $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ consumers.

The yield and bridge boundary is consumed by chapter 351 for regular-language comparison and by chapter 280 for machine-recognizer boundary checks. Thus the grammar packet is read as a finite sibling surface in the language-recognition lattice, not only as a kernel-local carrier.

Definition 356.1 (ContextFreeGrammar BHist carrier)**.** *A* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet is a finite record*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

with the following displayed rows:

1. Σ *is the terminal alphabet row, exposed as finite* BHist *data;*
2. N *is the nonterminal carrier row, disjoint from the terminal rows by the displayed classifier surface;*
3. S *is the start nonterminal row inside* N*;*
4. P *is the finite production ledger, whose rows have one nonterminal left side and a* $\mathsf{List}^{\uparrow}$ *right side over terminal and nonterminal symbols;*
5. w *is the terminal yield word, displayed as a* $\mathsf{List}^{\uparrow}$ *row over* Σ*;*
6. d *is the finite derivation ledger, beginning at* S *and replacing one displayed nonterminal occurrence by a row of* P *at each step;*
7. y *is the readback row identifying the terminal fringe of the final sentential form with the word row* w*;*
8. h *stores componentwise* hsame *transports for alphabets, nonterminals, production rows, sentential forms, derivation rows, and yield rows;*
9. c *stores the* Cont *routes for reading a production row and continuing along the finite derivation ledger;*

10. *p stores* Pkg *provenance naming* List$^{\uparrow}$, RegularLanguage$^{\uparrow}$, *and* TuringMachine$^{\uparrow}$ *consumer surfaces;*

11. *n is the local* NameCert$_{\text{ContextFreeGrammar}^{\uparrow}}$ *registration row.*

The carrier predicate is ContextFreeGrammarPacket(G). *It exports only the displayed finite grammar, production, derivation, yield, transport, continuation, provenance, and local naming rows.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarTasteGate single carrier alignment`

Theorem 356.2 (ContextFreeGrammar production stability)**.** *If two accepted* ContextFreeGrammar$^{\uparrow}$ *packets classify together by the displayed* hsame *rows, then every production row of the first packet transports to exactly one production row of the second packet with transported left nonterminal and transported* List$^{\uparrow}$ *right side. The transport preserves terminal and nonterminal tags and introduces no host grammar relation.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket production stability`

Proof. Project the packets through Definition 356.1. A production row is a visible entry of the finite ledger P with one nonterminal left side and one displayed right-side word.

Use the componentwise hsame rows in h to transport the left nonterminal, the terminal and nonterminal tags, and the List$^{\uparrow}$ right side. The Cont route in c records that the transported row is read as the same production position in the target packet.

The reverse read is the same finite ledger projection in the second packet. Since the carrier has no coordinate for a host production relation, only the displayed production rows can be transported. □

Theorem 356.3 (ContextFreeGrammar derivation concatenation)**.** *For an accepted* ContextFreeGrammar$^{\uparrow}$ *packet, two derivation ledger segments whose endpoint and start sentential forms agree by a displayed* hsame *row concatenate to a finite derivation ledger over the same production rows. The concatenated ledger preserves the* List$^{\uparrow}$ *sentential-form rows,* BHist *production witnesses,* Cont *routes, and* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket derivation concatenation`

Proof. Read the two finite derivation segments from the d coordinate of Definition 356.1. The connecting hypothesis identifies the terminal segment endpoint and the next segment start through a displayed sentential-form transport row.

Append the second ledger after the first. Each step still reads a production row of P, so Definition 356.2 transports the production witnesses along the same packet classifier when needed.

The composed Cont route first consumes the first segment and then the second segment. All rows remain inside the finite carrier, so no infinite derivation tree or host closure operation is introduced. □

Theorem 356.4 (ContextFreeGrammar yield readback)**.** *Every accepted terminal yield read of a* ContextFreeGrammar$^{\uparrow}$ *packet factors through the displayed start row S, the finite production ledger P, the finite derivation ledger d, and the* List$^{\uparrow}$ *terminal word row w. Conversely, a finite derivation ledger ending in a terminal sentential form with readback row y repacks as an accepted yield read of the same packet.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket yield readback`

Proof. For the forward direction, project the carrier rows. The yield coordinate is the readback row y, and it is attached to the final sentential form of the finite derivation ledger d.

Use Definition 356.2 at each derivation step to keep the production witness inside the displayed ledger. The terminal fringe is then read as the $\mathsf{List}^{\uparrow}$ word row w through the stored continuation route.

For the reverse direction, start with a derivation ledger whose final form has the displayed terminal readback row. These are exactly the carrier coordinates S, P, d, y, and w, so they repack as the accepted yield read. □

Theorem 356.5 (ContextFreeGrammar pushdown handoff)**.** *Every accepted terminal-yield read of a* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet can be handed to a* $\mathsf{PushdownAutomaton}^{\uparrow}$ *consumer by reading the start row S, the finite production ledger P, the finite derivation ledger d, the* $\mathsf{List}^{\uparrow}$ *sentential-form rows, and the terminal-yield readback y as stack-transition and run-ledger rows. The handoff exports no infinite parse tree, host language set, grammar quotient, or unbounded machine trace.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPushdownHandoff`

Proof. Project the grammar carrier of Definition 356.1. The start row S initializes the pushdown control and the stack row, while the production ledger P names exactly the finite rewrites that may be replayed by the stack-transition consumer.

Read the finite derivation ledger d step by step. At each derivation step, apply Definition 356.2 to keep the production witness inside the displayed packet. The unreduced sentential-form suffix is pushed into the stack row, and the rewritten prefix is recorded as the next run-ledger entry.

Finally route the terminal readback through Definition 356.4. The terminal word row w and readback row y become the accepted endpoint of the $\mathsf{PushdownAutomaton}^{\uparrow}$ run ledger, with the same hsame, Cont, and Pkg provenance.

Every object used in the handoff is a finite carrier coordinate. Since the grammar packet has no coordinate for an infinite parse tree, host language set, grammar quotient, or unbounded machine trace, the pushdown consumer cannot extract one through this route. □

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket pushdown handoff`

Theorem 356.6 (ContextFreeGrammar terminal-yield finite window)**.** *For an accepted* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

and a displayed finite derivation window selected by a $\mathsf{ProbeBundle}$*, suppose the selected production rows are stable under the packet's componentwise* hsame *rows, the selected derivation segments concatenate through their displayed sentential-form endpoints, and the final sentential form has the readback row y. Then every selected terminal row is read through the same* BHist *carrier,* hsame *transport,* Cont *route,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$ *ledger of G. No selected nonterminal production row is exposed as a terminal yield row.*

Proof. Begin with the selected production rows in the finite window. Apply Definition 356.2 to each selected production step, so the left nonterminal, the right-side $\mathsf{List}^{\uparrow}$ row, and the terminal and nonterminal tags remain inside the displayed production ledger P with the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance.

Next assemble the selected route. Apply Definition 356.3 to the displayed derivation segments whose endpoints agree by the packet's sentential-form hsame rows. The concatenated route is still a finite ledger over P, so it does not introduce a host grammar step or an unlisted production row.

Finally apply Definition 356.4 to the terminal sentential form and the readback row y. The readback projects only terminal rows through the displayed bundle and identifies them with the $\mathsf{List}^{\uparrow}$ word row w. Since nonterminal tags are preserved by production stability and the readback row is terminal-only, no nonterminal production row escapes as a terminal yield. □

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket terminal yield window`

Theorem 356.7 (ContextFreeGrammar NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation for the terminal alphabet, nonterminal carrier, start symbol, finite production ledger, terminal word, derivation ledger, readback row, transport rows, continuation routes, provenance, and local registration;*
2. *production stability under componentwise* hsame *transport by Definition 356.2;*
3. *derivation concatenation for finite ledger segments by Definition 356.3;*
4. *yield readback from the final terminal sentential form to the displayed* $\mathsf{List}^{\uparrow}$ *word row by Definition 356.4;*
5. *consumer boundary:* $\mathsf{RegularLanguage}^{\uparrow}$ *and* $\mathsf{TuringMachine}^{\uparrow}$ *readers receive only the displayed grammar packet, finite production and derivation ledgers, yield row,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket namecert obligation surface`

Proof. Carrier habitation is exactly the packet of Definition 356.1. Its coordinates are finite grammar rows, a finite production ledger, a finite derivation ledger, and a terminal yield row.

The production and derivation rows are supplied by Definition 356.2 and Definition 356.3. Together they keep every derivation step inside the displayed finite ledger and preserve the transport and continuation routes.

The readback row is Definition 356.4. It identifies the terminal fringe with the displayed $\mathsf{List}^{\uparrow}$ word and repacks the same rows as the accepted yield read.

Finally project the provenance row p. It names the downstream $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ consumer surfaces without adding a host language quotient, parse-tree infinitary semantics, pumping theorem, or recognizer completeness claim. □

Theorem 356.8 (ContextFreeGrammar RegularLanguage–TuringMachine bridge boundary)**.** *The public grammar and yield packet of Definition 356.1 exports to* $\mathsf{RegularLanguage}^{\uparrow}$ *and* $\mathsf{TuringMachine}^{\uparrow}$ *consumers only the terminal alphabet, nonterminal carrier, start row, finite production ledger, finite derivation ledger,* $\mathsf{List}^{\uparrow}$ *terminal yield row,* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

The exported boundary does not include ambiguity, parsing completeness, pumping arguments, Chomsky normal form, or recognizer completeness.

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket regularlanguage turingmachine bridge boundary`

Proof. Project the finite grammar packet of Definition 356.1. The terminal alphabet, nonterminal carrier, start row, production ledger, derivation ledger, terminal yield row, transport rows, continuation routes, provenance, and naming row are exactly the displayed carrier coordinates.

Use Definition 356.2 to keep every production witness inside the finite ledger under componentwise transport. Use Definition 356.3 to compose consumer derivation windows without introducing an infinitary derivation object.

Apply Definition 356.4 and Definition 356.6. These identify the consumer-visible yield as the same $\mathsf{List}^{\uparrow}$ terminal word row read through the finite derivation ledger and the stored terminal readback surface.

Finally apply Definition 356.7 and repack the rows named by the consumer boundary. Since the packet has no coordinate for ambiguity, parsing completeness, pumping arguments, Chomsky normal form, or a complete recognizer, none of those structures is exported to $\mathsf{RegularLanguage}^{\uparrow}$ or $\mathsf{TuringMachine}^{\uparrow}$ readers. □

Theorem 356.9 (ContextFreeGrammar regular-language inclusion certificate)**.** *Every accepted* $\mathsf{RegularLanguage}^{\uparrow}$ *finite-automaton packet yields a* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet whose production ledger simulates the deterministic transition ledger and whose terminal yield is the accepted* $\mathsf{List}^{\uparrow}$ *word. The construction reads only the finite alphabet row, state row, transition table, initial row, accepting endpoint row, input-word spine, deterministic run ledger, componentwise transport rows, continuation rows, and package provenance of chapter 351; it does not pass through a host language-set semantics or an ambient subset relation.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarRegularLanguageInclusionCertificate`

Proof. Start from the grammar carrier of Definition 356.1. For each visible automaton transition row in the deterministic run ledger of Definition 351.3, create the corresponding finite production row carrying the current state, consumed terminal, and next state as displayed nonterminal and terminal coordinates.

Use Definition 356.2 along the run ledger. Componentwise transport of the automaton rows therefore transports the simulated production rows without replacing them by an external language predicate.

Finally apply Definition 356.4. The derivation consumes exactly the stored $\mathsf{List}^{\uparrow}$ word spine, so the terminal yield row is the accepted word row named by the regular-language packet. Repacking the production ledger, derivation ledger, yield row, transports, continuation, provenance, and local name gives the required $\mathsf{ContextFreeGrammar}^{\uparrow}$ packet. □

Theorem 356.10 (ContextFreeGrammar consumer boundary determinacy)**.** *Let G and H be accepted finite* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packets. Suppose their terminal alphabet rows, nonterminal carrier rows, start rows, production ledgers, derivation ledgers, yield rows,* hsame *rows,* Cont *rows,* Pkg *provenance rows, and local* NameCert *rows agree componentwise. Then G and H induce the same consumer-visible boundary for both* $\mathsf{RegularLanguage}^{\uparrow}$ *and* $\mathsf{TuringMachine}^{\uparrow}$ *readers.*

The common boundary is the finite grammar and yield surface exported by Definition 356.8. It contains no grammar-equivalence quotient, ambiguity row, parsing-completeness row, pumping argument, Chomsky-normal-form witness, or recognizer-completeness coordinate.

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket consumer boundary determinacy`

Proof. Apply Definition 356.2 to the equal production ledgers. The production witnesses of G and H stay inside the same finite terminal and nonterminal rows under the displayed componentwise hsame transports.

Next apply Definition 356.3. The equal derivation ledgers concatenate through the same sentential-form endpoints and therefore expose the same finite derivation route to downstream consumers.

Apply Definition 356.4. Since the terminal yield rows agree, both packets read back to the same $\mathsf{List}^{\uparrow}$ terminal word through the same terminal-only surface.

Finally use Definition 356.8. That boundary is built only from the terminal alphabet, nonterminal carrier, start row, production ledger, derivation ledger, yield row, hsame, Cont, Pkg, and local NameCert rows. Componentwise equality of exactly those rows therefore forces the same $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ consumer-visible boundary, while the excluded grammar and recognizer structures have no exported coordinate. □

Theorem 356.11 (ContextFreeGrammar parse-tree derivation boundary)**.** *Every parse-tree-shaped consumer read of an accepted* $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet factors through the finite production rows, derivation concatenation rows, terminal yield window,* $\mathsf{List}^{\uparrow}$ *word row,* $\mathsf{TuringMachine}^{\uparrow}$ *bridge boundary,* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows of Definition 356.1. The read exports no infinitary parse-tree semantics, host language quotient, pumping theorem, or grammar-equivalence oracle.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket parse tree derivation boundary`

Proof. Project the accepted packet through Definition 356.1. A parse-tree-shaped consumer read can name productions, sentential-form steps, and terminal leaves only through the displayed finite production ledger, derivation ledger, readback row, transport rows, continuation routes, provenance, and local naming row.

Apply Definition 356.2 to keep each production read inside the finite production ledger. Apply Definition 356.3 to assemble the tree-shaped read as a finite derivation route whose subderivations meet at displayed sentential-form endpoints.

Next apply Definition 356.4 and Definition 356.6. These identify the consumer-visible leaves with the terminal yield window and the $\mathsf{List}^{\uparrow}$ word row, while preserving the same BHist, hsame, Cont, Pkg, and NameCert provenance.

Finally apply Definition 356.8 and Definition 356.10. The bridge exposes only the displayed grammar and yield surface to $\mathsf{TuringMachine}^{\uparrow}$ and $\mathsf{RegularLanguage}^{\uparrow}$ readers, and determinacy says that agreeing finite rows determine the same consumer-visible boundary.

Since no carrier coordinate stores an infinitary parse-tree semantics, host language quotient, pumping theorem, or grammar-equivalence oracle, none of those structures is exported by the parse-tree-shaped read. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$.

Constructive story: A context-free grammar packet is generated by finite terminal and nonterminal rows, a start row, finite production rows, a ListUp terminal word row, a finite derivation ledger, a terminal yield readback row, displayed transports, continuation routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 356.1, Definition 356.2, Definition 356.3, Definition 356.4, Definition 356.7, Definition 356.8, Definition 356.10, Definition 356.11, and Definition 356.12 bind the carrier, production and derivation rows, yield readback, grammar obligation surface, paper bridge boundary, consumer boundary determinacy, parse-tree-shaped consumer boundary, and finite derivation-prefix subledger treatment for the displayed grammar packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close grammar equivalence, ambiguity, parsing completeness, pumping arguments, Chomsky normal form, context-free language closure theorems, or machine bridge verification.

Upgrade path: Machine bridge verification requires a Lean bridge theorem for the displayed grammar packet and its regular-language and Turing-machine consumer surfaces.

Theorem 356.12 (ContextFreeGrammar derivation prefix carrier)**.** *Let*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

be an accepted $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet. Suppose the finite derivation ledger* d *is displayed as a split into a prefix ledger* d_{pre} *and a suffix ledger* d_{suf}*, with* d_{pre} *beginning at the start row* S *and ending at the split sentential-form row* u*. Then* d_{pre} *repacks as an accepted derivation-segment carrier*

$$(S, P, d_{\mathrm{pre}}, u, h_{\mathrm{pre}}, c_{\mathrm{pre}}, p, n)$$

over the same start row, production ledger, package provenance, and local $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$ *row. The restricted rows* h_{pre} *and* c_{pre} *are exactly the componentwise* hsame *transports and* Cont *routes of* h *and* c *whose derivation entries lie in the displayed prefix. The repacked segment contains no suffix step, no terminal-yield readback requirement, and no production row outside* P*.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket derivation prefix carrier`

Proof. Project the accepted packet through Definition 356.1. The coordinate d is a finite derivation ledger beginning at the displayed start row S, and each step of d replaces one displayed nonterminal occurrence by a production row already listed in the finite production ledger P.

The displayed split selects a finite initial subledger d_{pre}. Since it is an initial segment of d, its first sentential-form row is still S, and its last sentential-form row is the split row u. Every step retained in d_{pre} is therefore a step of the original ledger, so its production witness is already a row of P. Applying Definition 356.2 to these retained steps keeps the left nonterminal row, right-side $\mathsf{List}^{\uparrow}$ row, terminal and nonterminal tags, and production witness inside the same displayed production ledger.

Restrict the transport coordinate h to the alphabet, nonterminal, production, sentential-form, and derivation rows that occur in d_{pre}. This gives h_{pre}. Restrict the continuation coordinate c to the route entries that read those same prefix steps. This gives c_{pre}. Both restrictions are finite because the selected prefix is a finite subledger of the finite ledger d.

Now repack the rows S, P, d_{pre}, u, h_{pre}, c_{pre}, p, and n. They provide exactly the data needed for a finite derivation segment: a start row, the production ledger used at each step, the retained derivation rows, the endpoint row, the corresponding transports, the corresponding continuation routes, package provenance, and the local naming row. The yield row w and readback row y are not used, because the claim stops at the split sentential form and does not assert that u is terminal.

Finally, Definition 356.3 checks the boundary: concatenating the repacked prefix with the displayed suffix along the split sentential-form row recovers a finite derivation ledger over the same production rows. Thus the prefix repacking is a genuine subledger carrier of the accepted packet, not a separate grammar, parse tree, host closure, or recognizer-completeness assertion. □

Lemma 356.13 (ContextFreeGrammar BHist forgetful projection boundary)**.** *Let*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

be an accepted $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet, and put*

$$\partial_{\mathsf{BHist}}(G) = ((\Sigma, N, S, w), (P, d, y), h, c, p, n).$$

Every BHist*-level read of* G *visible to* $\mathsf{RegularLanguage}^{\uparrow}$ *or* $\mathsf{TuringMachine}^{\uparrow}$ *consumers factors through* $\partial_{\mathsf{BHist}}(G)$*. The projection retains the target carrier rows* Σ, N, S, w*, the production and derivation ledger rows* P, d, y*, the classifier transports* h*, the continuation routes* c*, the provenance*

row p, and the local $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$ *row n. It forgets only display labels outside those coordinates. In particular, the projection carries no ambiguity row, grammar-equivalence quotient, parse-tree semantics, pumping datum, Chomsky-normal-form witness, or recognizer-completeness coordinate.*

Proof. Project the accepted packet through Definition 356.1. The carrier definition lists exactly the finite grammar rows Σ, N, S, the production ledger P, the terminal word row w, the derivation ledger d, the readback row y, the transport row h, the continuation row c, the provenance row p, and the local naming row n. The displayed projection $\partial_{\mathsf{BHist}}(G)$ keeps all rows that a BHist consumer can inspect after dropping the richer presentation labels.

For production reads, apply Definition 356.2. A production witness is already a row of P, and its transported left nonterminal, right-side $\mathsf{List}^{\uparrow}$ word, terminal tags, and nonterminal tags are read only through the componentwise transports in h and the route entries in c. Thus forgetting the surrounding presentation name does not remove any production coordinate available to the consumer.

For derivation and yield reads, apply Definition 356.3, Definition 356.4, and Definition 356.6. These results force a consumer derivation to pass through the finite ledger d, the same production ledger P, the terminal readback row y, and the $\mathsf{List}^{\uparrow}$ terminal word row w, while preserving the displayed BHist, hsame, Cont, Pkg, and NameCert rows. All of these rows are coordinates of $\partial_{\mathsf{BHist}}(G)$.

The adjacent consumer chapters chapter 351 and chapter 280 receive the grammar packet only through the consumer boundary described in Definition 356.7 and Definition 356.8. That boundary exports precisely the displayed grammar and yield rows, transport rows, continuation routes, provenance, and local naming row retained by $\partial_{\mathsf{BHist}}(G)$.

Finally, Definition 356.10 says that componentwise agreement on those retained rows forces the same $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ consumer-visible boundary. Hence any row not present in $\partial_{\mathsf{BHist}}(G)$ cannot change a visible consumer read. Since the carrier has no coordinate for ambiguity, grammar equivalence, infinitary parse-tree semantics, pumping arguments, Chomsky normal form, or recognizer completeness, the forgetful projection cannot export any of those structures. □

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket bhist forgetful projection boundary`

Lemma 356.14 (ContextFreeGrammar BHist classifier alignment boundary)**.** *Let*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

and

$$G' = (\Sigma', N', S', P', w', d', y', h', c', p', n')$$

be accepted $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packets. Suppose the local packet classifier compares them through the displayed componentwise* hsame *rows on terminal alphabets, nonterminal carriers, start rows, production ledgers, terminal word rows, derivation ledgers, readback rows, continuation routes, package provenance, and local naming rows. Then every* BHist *classifier read of G handed to a* $\mathsf{RegularLanguage}^{\uparrow}$ *or* $\mathsf{TuringMachine}^{\uparrow}$ *consumer transports exactly the following displayed rows:*

1. *the grammar carrier rows Σ, N, S and their counterparts Σ', N', S';*
2. *each production row of P to the corresponding production row of P', with transported left nonterminal, terminal and nonterminal tags, and* $\mathsf{List}^{\uparrow}$ *right side;*

3. *each retained derivation row of d to the corresponding derivation row of d', with the same sentential-form endpoint comparison;*
4. *the terminal yield row w, the readback row y, the transport rows h, continuation routes c, package provenance p, and local* $\mathsf{NameCert}_{\mathsf{ContextFreeGrammar}^{\uparrow}}$ *row n, together with their counterparts.*

The same read forgets every row outside this list. In particular, it does not supply a $\mathsf{RegularLanguage}^{\uparrow}$ *state carrier, accepting-state carrier, transition table, deterministic run ledger, accepted endpoint, or a* $\mathsf{TuringMachine}^{\uparrow}$ *configuration trace, deterministic transition table, halted-repetition row, tape readback row, or bounded simulation row unless that row is separately displayed by the receiving consumer's own carrier. Thus the receiving classifier gate must re-read the grammar rows through Definition 356.1; it cannot treat a copied source excerpt as an additional transported coordinate.*

Lean4 ✓ `BEDC.Derived.ContextFreeGrammarUp.ContextFreeGrammarPacket bhist classifier alignment boundary`

Proof. Project both accepted packets through Definition 356.1. The carrier definition lists only the finite terminal alphabet, nonterminal carrier, start row, production ledger, terminal word, derivation ledger, readback row, transport row, continuation row, provenance row, and local naming row. Hence a local classifier comparison between G and G' has no coordinate other than those listed rows.

For production rows, apply Definition 356.2. A production witness is a visible entry of P, and transport carries it to one visible entry of P' with the transported left nonterminal and transported $\mathsf{List}^{\uparrow}$ right side. The same theorem preserves terminal and nonterminal tags and rules out any host production relation. Therefore the production part of the classifier alignment is exactly the rowwise movement from P to P'.

For derivation rows, apply Definition 356.3 to the displayed sentential-form endpoints and production witnesses. Every transported derivation step remains a finite ledger entry over the same transported production surface. Then apply Definition 356.4 and Definition 356.6. These force the consumer-visible terminal fringe to be the displayed $\mathsf{List}^{\uparrow}$ word row w and its transported counterpart w', read through y, y' and the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ provenance.

Now compare the receiving consumers. The $\mathsf{RegularLanguage}^{\uparrow}$ accepted-word classifier of Definition 351.2 is a classifier on a displayed finite-automaton packet: alphabet, state, transition, input-word, run, and accepting-endpoint rows. The grammar packet contributes only the terminal-yield word and the provenance route named by Definition 356.8; it does not contain the finite-automaton state, transition, run, or endpoint coordinates. Thus those rows cannot be transported from G by the grammar classifier.

Similarly, Definition 280.6 reads the $\mathsf{TuringMachine}^{\uparrow}$ source classifier from finite state and tape alphabets, unary time and head-position rows, a $\mathsf{Seq}^{\uparrow}$ configuration trace, deterministic transition data, and bounded $\mathsf{Computable}^{\uparrow}$ trace rows. The context-free grammar carrier contains none of those machine-source coordinates. Its bridge contribution is only the displayed grammar and yield surface identified by Definition 356.8.

Finally apply Definition 356.10. Componentwise agreement on the retained grammar, production, derivation, yield, transport, continuation, provenance, and local naming rows determines the same $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ consumer-visible boundary. Since all other candidate rows are absent from Definition 356.1, they are forgotten by the BHist classifier projection and cannot be recovered by quoting the source presentation rather than re-reading the displayed carrier rows. □

Theorem 356.15 (ContextFreeGrammar displayed implication completion boundary)**.** *Let*

$$G = (\Sigma, N, S, P, w, d, y, h, c, p, n)$$

be an accepted $\mathsf{ContextFreeGrammar}^{\uparrow}$ *packet. Every displayed forward classifier or readback implication named in the local grammar chapter is completed in exactly one of the following two ways.*

1. *Production transport is two-sided on the visible production rows. A production row transported from one accepted packet to a classified mate is read back as the same finite ledger position with transported left nonterminal, transported* $\mathsf{List}^{\uparrow}$ *right side, and the same terminal and nonterminal tag rows.*
2. *Derivation concatenation is two-sided only at a displayed split row. Two finite derivation segments concatenate through an* hsame *endpoint row, and a ledger with a displayed prefix–suffix split repacks its prefix as the carrier of Definition 356.12; no arbitrary factorization is inferred without such a split row.*
3. *Yield readback is two-sided on the visible rows S, P, d, y, and w. An accepted yield read factors through those rows, and a finite derivation ledger ending in a terminal sentential form with readback row y repacks as the same accepted yield read.*
4. *Terminal-window, consumer-boundary, parse-tree-shaped, and forgetful* BHist *projection reads are one-way interpretation boundaries. They factor a consumer read through the displayed finite carrier, transport, continuation, provenance, and naming rows, but they do not reconstruct grammar equivalence, ambiguity, parsing completeness, pumping data, Chomsky normal form, infinitary parse-tree semantics, or recognizer completeness.*

Thus the chapter has no unrecorded reverse implication: each named forward surface either has its reverse on the same visible rows or is explicitly bounded as a one-way interpretation of the displayed BHist *packet.*

Proof. Project G through Definition 356.1. The only available coordinates are the terminal alphabet row Σ, nonterminal carrier row N, start row S, finite production ledger P, terminal word row w, derivation ledger d, readback row y, transport row h, continuation row c, provenance row p, and local naming row n.

For production rows, use Definition 356.2. Its forward direction transports a displayed production row along the componentwise hsame rows in h. Its readback direction is the same finite ledger projection in the target packet. Since the carrier has no coordinate for a host production relation, the reverse can only return to the visible production row with the transported left nonterminal, transported $\mathsf{List}^{\uparrow}$ right side, and preserved terminal and nonterminal tags.

For derivation rows, use Definition 356.3 together with Definition 356.12. Concatenation gives the forward implication from two displayed segments and an hsame endpoint row to a finite derivation ledger over P. The reverse implication is available exactly when the ledger already displays a prefix–suffix split: the prefix repackages over the same start row, production ledger, restricted transports, restricted continuation routes, provenance, and local NameCert row. Without a displayed split row, there is no carrier coordinate naming an arbitrary factorization, so the reverse stops at this boundary.

For yield rows, apply Definition 356.4. The forward implication factors an accepted terminal-yield read through the start row, finite production ledger, finite derivation ledger, terminal readback row, and $\mathsf{List}^{\uparrow}$ word row. The converse in the same theorem starts from exactly those displayed

rows and repacks them as the accepted yield read of the same packet. This is a genuine two-sided completion because both directions use the same visible rows S, P, d, y, and w.

For selected terminal windows, use Definition 356.6. It sends a displayed finite derivation window to terminal rows read through the same BHist, hsame, Cont, Pkg, and NameCert provenance. The theorem also records the obstruction to reversal: a selected terminal row exposes no selected nonterminal production row as a terminal yield row. Thus terminal-window reading is a one-way interpretation unless the carrier already supplies the production and derivation window.

For downstream consumers, use Definition 356.7, Definition 356.8, Definition 356.10, Definition 356.11, and Definition 356.13. These results all project the same displayed grammar and yield surface to $\mathsf{RegularLanguage}^{\uparrow}$ and $\mathsf{TuringMachine}^{\uparrow}$ readers. Determinacy says that componentwise agreement on the exported rows forces the same consumer-visible boundary, but none of those rows is a host language quotient, grammar comparison oracle, parse-tree semantics, pumping datum, Chomsky-normal-form witness, ambiguity classifier, or complete recognizer.

The displayed implications have therefore been exhausted by the carrier rows. Production transport and yield readback have reverses on the same visible rows; derivation concatenation has a reverse only at displayed split rows; and the terminal-window, consumer-boundary, parse-tree-shaped, and forgetful BHist reads are recorded as one-way interpretation boundaries. No further reverse implication can be formed inside the chapter without adding a coordinate absent from Definition 356.1. □

Chapter 357

A Concrete Naming Certificate for $\mathsf{ValidatedNumerics}^{\uparrow}$

The $\mathsf{ValidatedNumerics}^{\uparrow}$ interface names certified finite real enclosures in the interval-analysis tradition of Moore, but only through BEDC-visible finite data. A packet carries displayed rational or dyadic endpoints, a requested precision row, a regular rational observation window, a real-name readback token, and a containment ledger whose reads are routed by Cont. It is therefore a consumer of $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{ModulusOfConvergence}^{\uparrow}$, not a theorem about host floating-point arithmetic or external numerical solvers.

The precision-to-tail portion of the validated enclosure is consumed through chapter 379. The $\mathsf{DyadicTailBound}^{\uparrow}$ packet supplies the dyadic tolerance, $\mathsf{CauchyModulus}^{\uparrow}$ schedule, finite tail ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal row that $\mathsf{ValidatedNumerics}^{\uparrow}$ reuses as its containment ledger.

Definition 357.1 (ValidatedNumerics BHist source)**.** *A* $\mathsf{ValidatedNumerics}^{\uparrow}$ *packet is a finite* BHist *tuple*

$$V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$$

with the following visible rows:

1. *I is a* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure row whose endpoints are read through* $\mathsf{Rat}^{\uparrow}$ *or* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
2. *ε is the requested precision row;*
3. *ω is a* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row supplying the finite precision-to-window request used by the packet;*
4. *ρ is a* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window containing the displayed rational approximants inspected at that request;*
5. *λ is a* $\mathsf{Real}^{\uparrow}$ *readback token for the real name being observed through the finite window;*
6. *h records the componentwise* hsame *transports for the enclosure, precision, modulus, observation, readback, and containment rows;*
7. *c records the* Cont *routes by which each displayed approximation is read inside the enclosure row I;*
8. *p is the package provenance naming* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RationalInterval}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{ModulusOfConvergence}^{\uparrow}$*;*
9. *n is the local* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *registration row.*

The carrier predicate is ValidatedNumericsPacket$(I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$*. Its classifier compares two accepted packets only by transporting these displayed rows and replaying the finite containment routes.*

Lean4 (definition) `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsUp`
Lean4 (definition) `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket`

Theorem 357.2 (ValidatedNumerics interval enclosure obligation)**.** *Every accepted* ValidatedNumerics$^{\uparrow}$ *packet exposes one finite* RationalInterval$^{\uparrow}$ *enclosure row I and a containment ledger saying that each displayed approximation read from the* RegSeqRat$^{\uparrow}$ *window ρ remains inside I along a named* Cont *route. The obligation surface is the enclosure row, endpoint provenance through* DyadicRatCore$^{\uparrow}$ *or* Rat$^{\uparrow}$*, the precision request, the modulus row, the observation window, and the containment ledger routed by c and transported by h.*

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket interval enclosure obligation`

Proof. Project the carrier of Definition 357.1. The only interval coordinate is I, and the only routes from displayed approximations to interval containment are the Cont rows stored in c.

The endpoint source is read from the package provenance p, while ε, ω, and ρ give the precision request, modulus row, and regular rational observation window. Transporting the packet uses h on exactly those rows, so the accepted enclosure obligation is exhausted by the finite packet coordinates. □

Theorem 357.3 (ValidatedNumerics real readback soundness)**.** *For an accepted* ValidatedNumerics$^{\uparrow}$ *packet $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$, the* Real$^{\uparrow}$ *readback token λ is sound only through the displayed* RegSeqRat$^{\uparrow}$ *window ρ and the precision row supplied by* ModulusOfConvergence$^{\uparrow}$*. A consumer may read the real name as a finite validated enclosure at the requested precision, but the packet exports no general convergence proof, no classical real completeness, and no equality of completed real representatives.*

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsReadbackPacket real readback soundness`

Proof. Read λ together with ρ and ω from the same carrier. The token is not interpreted in isolation: the only available precision request is ε, and the only finite observations attached to that request are the displayed rows of ρ.

The containment routes from Definition 357.2 then place each displayed approximation inside I. Repacking λ with these window and containment rows gives the finite readback soundness statement, while no carrier coordinate remains for completeness or completed-real equality. □

Theorem 357.4 (ValidatedNumerics finite-window Real seal containment)**.** *Let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$ be an accepted* ValidatedNumerics$^{\uparrow}$ *packet. Any finite-window* Real$^{\uparrow}$ *seal read whose source is routed through the displayed* RegSeqRat$^{\uparrow}$ *window ρ, the* ModulusOfConvergence$^{\uparrow}$ *row ω, and the packet* Cont *containment ledger lands in the same* RationalInterval$^{\uparrow}$ *enclosure row I.*

The conclusion is a finite enclosure statement over the packet surface. It does not assert solver correctness, floating-point semantics, classical real completeness, or equality of completed representatives.

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket finite window seal containment`

Proof. Project the accepted packet. By Definition 357.2, the only enclosure exported by the carrier is I, and the only routes from displayed $\mathsf{RegSeqRat}^{\uparrow}$ observations into an interval are the Cont ledger rows stored in c.

Next read the $\mathsf{Real}^{\uparrow}$ token through Definition 357.3. The readback is available only with the finite window ρ and the modulus row ω, so the seal has no independent completed-real interface through which it could choose a second enclosure.

The $\mathsf{StreamName}^{\uparrow}$ finite-window handoff and the $\mathsf{RegSeqRat}$ finite-window $\mathsf{Real}^{\uparrow}$ seal interface therefore expose the same consumer rows: the window ρ, the modulus row ω, the transported hsame rows, and the Cont ledger. Repacking those rows gives containment in I, and the packet contains no additional consumer row for solver semantics, hardware floating-point interpretation, completeness, or equality of completions. □

Theorem 357.5 (ValidatedNumerics precision refinement containment)**.** *Let $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$ be an accepted $\mathsf{ValidatedNumerics}^{\uparrow}$ packet. Suppose V' refines the requested precision row to a smaller finite request while preserving the same $\mathsf{RationalInterval}^{\uparrow}$ enclosure I, the $\mathsf{ModulusOfConvergence}^{\uparrow}$ row, the $\mathsf{RegSeqRat}^{\uparrow}$ observation window, the $\mathsf{Real}^{\uparrow}$ readback token, the displayed hsame transports, and the Cont containment routes. Then every approximation read from the refined request is still contained in the same finite enclosure row I.*

The refinement is entirely internal to the displayed packet surface. It introduces no solver-correctness theorem, no floating-point hardware semantics, and no $\mathsf{Real}^{\uparrow}$ completeness datum beyond the readback token already carried by V.

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsReadbackPacket precision refinement containment`

Proof. Project the packet source using Definition 357.1. The refined request changes only the finite precision row; the enclosure I, modulus row, observation window, readback token, transport rows, containment routes, package provenance, and local name row remain the displayed coordinates of the packet.

Apply Definition 357.2. Since the same Cont containment routes are preserved, each refined approximation read is routed back into the same finite enclosure row I.

Next apply Definition 357.3. The $\mathsf{Real}^{\uparrow}$ token stays tied to the displayed $\mathsf{RegSeqRat}^{\uparrow}$ window and the finite modulus request, so refinement does not create a completed real object or an external convergence principle.

Finally use Definition 357.7. Solver correctness, floating-point semantics, and classical completeness are not packet rows, hence they cannot enter the containment proof for the refined read. □

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket precision refinement containment`

Theorem 357.6 (ValidatedNumerics five-row NameCert sketch)**.** *The seed $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ surface is assembled from five visible dependency rows:*

1. *a $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint or precision budget row;*
2. *a $\mathsf{RationalInterval}^{\uparrow}$ enclosure row;*
3. *a $\mathsf{ModulusOfConvergence}^{\uparrow}$ precision-to-window row;*
4. *a $\mathsf{RegSeqRat}^{\uparrow}$ observation-window row;*
5. *a $\mathsf{Real}^{\uparrow}$ readback row.*

Together with the containment ledger, hsame *transports,* Cont *routes,* Pkg *provenance, and local name row, these rows form the finite validated numerics naming certificate.*

Proof. Start from the packet coordinates in Definition 357.1. The five listed rows are exactly the dependency-bearing coordinates: endpoints or precision budget from I and p, the interval row I, the modulus row ω, the observation row ρ, and the readback token λ.

The remaining coordinates are structural. The transport row h preserves the displayed rows under classifier movement, c routes containment reads, p records the package provenance, and n registers the local name. Repacking these coordinates gives the seed naming-certificate surface without adding a host numerical-analysis theorem. □

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket five row namecert sketch`

Theorem 357.7 (ValidatedNumerics dependency boundary)**.** *The dependency boundary of* ValidatedNumerics$^{\uparrow}$ *is precisely* DyadicRatCore$^{\uparrow}$, RationalInterval$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, *and* ModulusOfConvergence$^{\uparrow}$, *together with the BEDC kernel rows* BHist, hsame, Cont, Pkg, *and* NameCert. *The packet does not depend on floating-point hardware semantics, a solver-correctness theorem, a classical completeness principle for real numbers, or a global convergence claim beyond the displayed finite modulus request.*

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsKernel dependency boundary`

Proof. Inspect the package row p of Definition 357.1. It names exactly the five concrete dependency surfaces listed in the statement, and every consumer read passes through the kernel rows h, c, p, and n.

The interval enclosure obligation and real readback soundness theorems use no other coordinate. Since floating-point execution, solver correctness, classical completeness, and global convergence are not rows of the finite packet, they are outside the dependency boundary. □

Theorem 357.8 (ValidatedNumerics carrier and classifier obligations)**.** *The nine displayed rows of Definition 357.1 supply the local carrier and classifier obligations for* ValidatedNumerics$^{\uparrow}$. *The carrier is inhabited by any finite packet whose interval, precision, modulus, observation, readback, transport, containment, package, and local name rows are displayed. Its classifier compares accepted packets componentwise through the interval row, precision row, modulus request, regular rational window, real readback token, containment routes,* hsame *transport,* Pkg *provenance, and local* NameCert *row, and carrier transport is exactly transport of these nine rows.*

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket carrier classifier obligations`

Proof. Read the packet definition row by row. Inhabitation is the assertion that the displayed finite tuple $V = (I, \varepsilon, \omega, \rho, \lambda, h, c, p, n)$ is present as a BHist packet, so no additional analytic carrier is required.

For classifier laws, compare two accepted packets only through the nine coordinates listed in the definition. The interval, precision, modulus, observation, and readback entries are component rows, while h, c, p, and n record the transport, continuation, package, and local naming data used by the comparison.

Carrier transport is therefore componentwise. Moving an accepted packet along the displayed hsame rows and replaying the same Cont containment routes keeps the tuple inside the carrier, with the package and local name rows recording the same source surface. □

Theorem 357.9 (ValidatedNumerics containment ledger transport)**.** *Interval containment ledgers in an accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *packet are preserved by the displayed* hsame *and* Cont *rows. If the enclosure row, precision request, modulus row, regular rational observation window, and* $\mathsf{Real}^{\uparrow}$ *readback token are transported componentwise, then every containment read from the transported observation window lands in the transported* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure through the transported* Cont *ledger.*

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket containment ledger transport`

Proof. Start with Definition 357.2. It identifies the containment ledger as the finite list of Cont routes from displayed approximations in ρ into the interval row I.

Transport the packet componentwise using the h rows of Definition 357.1. The source approximation row, the target interval row, the precision request, the modulus row, and the real readback token move together, so the containment source and target remain matched.

Finally replay the transported c rows. Each ledger entry is a displayed continuation route, hence it remains a continuation route after transport and preserves the same finite containment claim inside the transported enclosure. □

Theorem 357.10 (ValidatedNumerics refined readback containment determinacy)**.** *Let V and V' be accepted* $\mathsf{ValidatedNumerics}^{\uparrow}$ *packets with the same transported interval row, precision request, modulus request,* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window,* $\mathsf{Real}^{\uparrow}$ *readback token, containment ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. After any displayed precision refinement of the request, the two packets yield the same public finite-enclosure read.*

The determinacy is only a finite readback boundary. It does not assert solver correctness, hardware semantics, completed-real equality, or classical completeness.

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket refined readback containment determinacy`

Proof. First apply Definition 357.3. The common $\mathsf{Real}^{\uparrow}$ token is read through the same $\mathsf{RegSeqRat}^{\uparrow}$ observation window and finite modulus request, so both packets expose the same real-name readback row.

Next use Definition 357.5. A displayed precision refinement narrows the requested finite enclosure by the same transported interval row and the same modulus request on both sides.

Finally apply Definition 357.9. The containment ledger, hsame transports, Cont routes, Pkg provenance, and local NameCert row are shared, so the refined containment read is transported identically for V and V'. Therefore the public finite-enclosure read after refinement is the same, while solver correctness, hardware semantics, completed-real equality, and classical completeness remain outside the packet. □

Theorem 357.11 (ValidatedNumerics NameCert obligation surface)**.** *The* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *obligation surface is assembled from the carrier and classifier obligations of Definition 357.8, the interval enclosure obligation of Definition 357.2, the real readback soundness of Definition 357.3, precision refinement containment from Definition 357.5, containment ledger transport from Definition 357.9, package provenance, and the local* NameCert *row.*

This obligation surface is finite over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert, *and it does not assert solver correctness, floating-point hardware semantics, host real equality, or classical real completeness.*

Proof. First assemble the carrier and classifier rows from Definition 357.8. These rows bind the accepted packet to the nine displayed coordinates of the source definition.

Next attach the enclosure and readback rows. Apply Definition 357.2 for the interval ledger and Definition 357.3 for the $\mathsf{Real}^{\uparrow}$ token read through the $\mathsf{RegSeqRat}^{\uparrow}$ window and finite modulus request.

The refinement and transport rows are supplied by Definition 357.5 and Definition 357.9. They keep the finite enclosure claim stable under smaller precision requests and displayed hsame/Cont movement.

Finally add the package provenance and local naming row from Definition 357.1. Together with Definition 357.7, this exhausts the local obligation surface and leaves solver correctness, floating-point semantics, host real equality, and classical completeness outside the packet. □

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket namecert obligation surface`

Theorem 357.12 (ValidatedNumerics obligation closure scope)**.** *The finite enclosure packet obligations for* $\mathsf{ValidatedNumerics}^{\uparrow}$ *are exhausted by the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *or* $\mathsf{Rat}^{\uparrow}$ *endpoint row, the* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure row, the* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *precision-to-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the* $\mathsf{Real}^{\uparrow}$ *readback row, the containment ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* NameCert *rows.*

No obligation row in this scope asserts host numerical-solver correctness, floating-point hardware semantics, completed-real equality, or a global convergence theorem beyond the displayed finite modulus request.

Proof. Project the packet source of Definition 357.1. Its displayed coordinates are the rational or dyadic endpoint data, the enclosure interval, the precision request, the modulus-to-window row, the finite observation window, the readback token, containment routes, transport row, package provenance, and local name row.

Apply Definition 357.2. This identifies the containment part of the obligation surface as the finite enclosure row together with the displayed continuation ledger.

Next apply Definition 357.3. The readback obligation is tied to the $\mathsf{RegSeqRat}^{\uparrow}$ observation window and the finite modulus request, so it contributes no completed-real equality or external convergence principle.

Finally use Definition 357.6 and Definition 357.7. The five dependency rows and the BEDC kernel rows listed there exhaust the local naming surface, while solver correctness, floating-point hardware semantics, classical completeness, and global convergence remain outside the packet boundary. □

Theorem 357.13 (ValidatedNumerics exported enclosure bridge)**.** *The public* $\mathsf{ValidatedNumerics}^{\uparrow}$ *export bridges a finite validated enclosure packet to exactly the displayed boundary consisting of the* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure, the dyadic or rational endpoint row, the finite modulus request, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the* $\mathsf{Real}^{\uparrow}$ *readback token, the containment ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

The bridge does not export solver correctness, floating-point hardware semantics, host real equality, or classical completeness.

Proof. Start from the finite enclosure obligation. Apply Definition 357.2; this fixes the $\mathsf{RationalInterval}^{\uparrow}$ enclosure, endpoint row, finite modulus request, and continuation ledger as the carrier side of the public packet.

Next attach the real readback boundary. Apply Definition 357.3; the $\mathsf{Real}^{\uparrow}$ token is read only through the $\mathsf{RegSeqRat}^{\uparrow}$ observation window and finite modulus request, so no host real equality is introduced.

The exported packet must remain stable under sharper finite requests. Apply Definition 357.5 and Definition 357.9; refinement narrows the interval while the hidden containment ledger is carried by the displayed hsame transports and Cont routes.

Finally apply Definition 357.11. The local NameCert row and Pkg provenance repack the preceding rows as the public bridge boundary. Since each step projects from the displayed finite packet, solver correctness, floating-point hardware semantics, host real equality, and classical completeness remain outside the bridge. □

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsFiniteEnclosure exported bridge`

Theorem 357.14 (ValidatedNumerics public finite-enclosure consumer certificate)**.** *A scoped* $\mathsf{ValidatedNumerics}^{\uparrow}$ *packet exports a public finite-enclosure consumer certificate. The interval enclosure obligation gives the carrier row, real readback soundness gives the* $\mathsf{Real}^{\uparrow}$ *interpretation, precision refinement containment supplies monotone narrowing, and containment ledger transport records the hidden refinement ledger. Downstream* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers may use the enclosure packet without assuming any host real-number primitive.*

Proof. First build the finite enclosure source. Apply Definition 357.2; the displayed endpoint and interval rows provide the carrier-side enclosure data, while the continuation routes record the finite containment obligation.

Next interpret the enclosure as a real readback packet. By Definition 357.3, the readback is routed through the $\mathsf{RegSeqRat}^{\uparrow}$ observation window, the finite modulus request, and the named $\mathsf{Real}^{\uparrow}$ row, so the consumer sees a BEDC real-name interpretation rather than a host completed-real primitive.

The public certificate must also be stable under tighter requests. Apply Definition 357.5; smaller precision demands retain the enclosing row by monotone narrowing and preserve the same displayed transport surface.

Finally apply Definition 357.9. The hidden refinement ledger is carried as Cont/hsame provenance, not as a solver oracle. Repacking these four rows gives a public finite-enclosure consumer certificate usable by downstream $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumers, with solver correctness, floating-point semantics, and classical real completeness remaining outside the exported packet. □

Theorem 357.15 (ValidatedNumerics validated enclosure bridge boundary)**.** *The public finite-enclosure consumer certificate of Definition 357.14 and the* NameCert *obligation surface of Definition 357.11 assemble a paper bridge boundary whose readable rows are exactly the* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *or* $\mathsf{Rat}^{\uparrow}$ *endpoint provenance, the finite* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *request, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window, the* $\mathsf{Real}^{\uparrow}$ *readback token, the containment ledger, the* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

Solver correctness, floating-point hardware semantics, host real equality, and classical real completeness are not bridge rows.

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsUp StdBridge`

Proof. Begin with the interval enclosure of Definition 357.2. It supplies the $\mathsf{RationalInterval}^{\uparrow}$ enclosure together with dyadic or rational endpoint provenance and the finite precision request visible to the consumer.

Next apply Definition 357.3. The readback token is interpreted through the $\mathsf{RegSeqRat}^{\uparrow}$ observation window and the finite $\mathsf{ModulusOfConvergence}^{\uparrow}$ request, so the row remains a displayed BEDC real-name read rather than host real equality.

Use Definition 357.5 and Definition 357.9 for the boundary rows that survive sharper requests. They identify the containment ledger and transport it through the displayed hsame and Cont surface.

Finally apply Definition 357.11 and Definition 357.14. The NameCert surface supplies the local name and Pkg provenance, and the consumer certificate repacks exactly those rows as the conservative bridge boundary. Since every bridge row is projected from this finite packet, solver correctness, floating-point hardware semantics, host real equality, and classical real completeness remain outside the bridge boundary. □

Theorem 357.16 (ValidatedNumerics finite consumer example completeness)**.** *Every finite consumer example using the displayed validated-enclosure bridge of Definition 357.15 factors through the* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure row, dyadic-or-rational endpoint provenance, finite* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *request,* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window,* $\mathsf{Real}^{\uparrow}$ *readback token, containment ledger, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$ *row.*

Conversely, those displayed rows repack as a valid finite consumer example for the validated-enclosure bridge. The repacking preserves the exclusions on solver correctness, floating-point semantics, host real equality, and classical real completeness.

Proof. Begin with a finite consumer example and apply Definition 357.14. The certificate projects the example to the rational-interval enclosure, endpoint provenance, finite precision request, regular rational observation window, real readback token, containment ledger, transport rows, package provenance, and local naming row.

Next apply Definition 357.15. It identifies the same rows as the bridge boundary visible to downstream consumers, so no solver, hardware, host-real, or classical-completeness coordinate is introduced by the bridge read.

Use Definition 357.5 to keep the enclosure stable under finite precision requests. Then apply Definition 357.9 to carry the containment ledger through the displayed hsame and Cont surface.

For the converse direction, start from the listed displayed rows. Repack the enclosure row, endpoint provenance, finite modulus request, observation window, readback token, containment ledger, transport rows, package provenance, and local name row by the public finite-enclosure consumer certificate. The validated-enclosure bridge boundary then reads exactly that packet as a valid finite consumer example, with the same excluded semantic obligations remaining outside the exported surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ValidatedNumerics}^{\uparrow}$ packet is generated by a rational or dyadic interval enclosure, a requested precision row, a finite modulus-of-convergence request, a regular rational observation window, a real-name readback token, containment routes, transport rows, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 357.15 and Definition 357.14 bind the finite certified-enclosure bridge surface over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ModulusOfConvergence}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsReadbackPacket\_real\_readback\_soundness`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close general convergence, floating-point hardware semantics, classical real completeness, or solver correctness.

Upgrade path: No further upgrade remains; the chapter is at the top of the formal axis.

Theorem 357.17 (ValidatedNumerics refinement composition containment)**.** *Let*

$$V_0 = (I, \varepsilon_0, \omega, \rho, \lambda, h, c, p_0, n_0),$$
$$V_1 = (I, \varepsilon_1, \omega, \rho, \lambda, h, c, p_1, n_1),$$
$$V_2 = (I, \varepsilon_2, \omega, \rho, \lambda, h, c, p_2, n_2)$$

be accepted $\mathsf{ValidatedNumerics}^{\uparrow}$ *packets. Suppose* V_1 *refines the requested precision row of* V_0 *to a smaller finite request, and* V_2 *refines the requested precision row of* V_1 *to a smaller finite request. Assume that both refinement steps preserve the displayed* $\mathsf{RationalInterval}^{\uparrow}$ *enclosure* I*, the* $\mathsf{ModulusOfConvergence}^{\uparrow}$ *row* ω*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *observation window* ρ*, the* $\mathsf{Real}^{\uparrow}$ *readback token* λ*, the* hsame *transport row* h*, and the* Cont *containment ledger* c*. Then the composite refinement from* V_0 *to* V_2 *routes every displayed approximation read at the terminal request into the original finite enclosure row* I *through the original containment ledger* c*.*

The conclusion is a containment statement over the displayed finite packet surface. It does not add solver correctness, floating-point hardware semantics, completed-real equality, or a global convergence principle.

Lean4 ✓ `BEDC.Derived.ValidatedNumericsUp.ValidatedNumericsPacket refinement composition containment`

Proof. Project the three accepted packets through Definition 357.1. The first refinement changes only the precision coordinate from ε_0 to ε_1 and keeps I, ω, ρ, λ, h, and c fixed as displayed rows. The second refinement changes only the precision coordinate from ε_1 to ε_2 and keeps the same six displayed rows fixed again.

By the classifier description in Definition 357.1, accepted packets are compared componentwise by the displayed rows and by replay of the finite containment routes. The two displayed comparisons therefore compose on the enclosure, modulus, observation window, readback token, transport row, and containment ledger. The transitivity part of Definition 3.8 supplies the corresponding hsame comparison for the transported rows, so V_2 still displays the same containment source window ρ, the same target enclosure I, and the same ledger c as V_0.

Apply Definition 357.5 to the second refinement V_1 to V_2. Since the enclosure row of V_1 is the same displayed row I inherited from V_0, every approximation read from the terminal refined request is contained in I.

It remains only to identify this containment as a read through the original ledger rather than through an unrelated copy. Apply Definition 357.9. The source approximation rows, the target interval row, the modulus row, the readback token, and the containment routes are transported by the same h and replay the same c at both refinement steps. Hence each terminal approximation read from V_2 lands in the original finite enclosure row I through the original Cont routes recorded in c.

Finally, Definition 357.3 keeps the readback token tied to the displayed $\mathsf{RegSeqRat}^{\uparrow}$ window and finite modulus request, and Definition 357.7 excludes any extra analytic or host-numeric coordinate from the argument. □

Chapter 358

A Concrete Naming Certificate for $\mathsf{DyadicMesh}^{\uparrow}$

The $\mathsf{DyadicMesh}^{\uparrow}$ interface names finite dyadic grid packets used by real-completion and validated-numerics consumers. In the Moore–Kearfott–Cloud interval-analysis reading, a mesh is a finite grid of rational interval cells with explicit enclosure ledgers; in BEDC it is only a displayed BHist package over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicPrecision}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{ValidatedNumerics}^{\uparrow}$. The mesh cell row consumes the $\mathsf{RationalInterval}^{\uparrow}$ endpoint carrier of chapter 354 and exposes its validated enclosure ledger to the $\mathsf{ValidatedNumerics}^{\uparrow}$ consumer surface of chapter 357.

Before those interval and validated-numerics consumers read an enclosure, the finite mesh packet consumes the dyadic endpoint and radius rows licensed by chapter 291; $\mathsf{DyadicMesh}^{\uparrow}$ refines and packages that endpoint data into finite cell ledgers rather than treating dyadic rational endpoints as a merely adjacent surface.

Definition 358.1 (DyadicMesh BHist source)**.** *A* $\mathsf{DyadicMesh}^{\uparrow}$ *source is a finite* BHist *packet*

$$M = (\ell, J, I, E, H, C, P, N)$$

with the following visible rows:

1. *ℓ is a unary level row naming the displayed grid precision;*
2. *J is the finite dyadic cell-index row at level ℓ;*
3. *I is the* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint row for the cell selected by J;*
4. *E is the containment ledger against* $\mathsf{DyadicRatCore}^{\uparrow}$*, recording the dyadic lower endpoint, upper endpoint, midpoint, radius, and endpoint-order reads for the cell;*
5. *H stores componentwise* hsame *transport for the level, cell index, rational interval endpoints, dyadic endpoint reads, and containment ledger;*
6. *C stores the* Cont *routes by which refinement, endpoint readback, and downstream enclosure consumers inspect the same finite cell;*
7. *P is the* Pkg *provenance row naming* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicPrecision}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{ValidatedNumerics}^{\uparrow}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$ *registration row.*

The classifier identifies accepted mesh packets by transporting them to a common displayed refinement level, comparing the refined cell-index rows there, and then comparing the rational interval endpoints by the inherited $\mathsf{RationalInterval}^{\uparrow}$ hsame *rows. The carrier has no coordinate for a completed real cell, infinite grid, host interval tree, or solver object.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshTasteGate single carrier alignment`
Lean4 (definition) `BEDC.Derived.DyadicMeshUp.DyadicMeshUp`

Theorem 358.2 (DyadicMesh cell containment obligation)**.** *Every accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet* $M = (\ell, J, I, E, H, C, P, N)$ *exposes one finite dyadic cell. Its public containment surface is exactly the unary level row* ℓ*, the dyadic cell-index row* J*, the rational interval row* I*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius reads stored in* E*, the displayed transport rows* H*, the continuation routes* C*, the package provenance* P*, and the local* $\mathsf{NameCert}$ *row* N*.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshCarrier cell containment obligation`
Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket cell containment obligation`

Proof. Project the carrier of Definition 358.1. The selected cell is not reconstructed from an ambient grid object; it is the displayed pair of a level row and a finite cell-index row.

Read the rational interval coordinate I and the dyadic containment ledger E. These two rows provide the endpoint, midpoint, radius, and endpoint-order data visible to a consumer.

The remaining coordinates route and certify those reads. The transport row H, continuation row C, package row P, and naming row N exhaust the public containment surface, leaving no coordinate for a completed cell or external solver state. □

Theorem 358.3 (DyadicMesh refinement stability)**.** *Let* $M = (\ell, J, I, E, H, C, P, N)$ *be an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet. If* M' *is obtained by appending displayed refinement evidence to* C *so that the level and cell-index rows refine to a finer dyadic row while the covered rational interval cell is transported by the same endpoint* hsame *rows, then* M' *is again an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet and covers the same real cell boundary visible to* $\mathsf{Real}^{\uparrow}$ *consumers.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket refinement stability`

Proof. Start with the finite packet of Definition 358.1. Appending refinement evidence changes only the displayed continuation route by which the finer level and cell-index rows are read.

Transport the rational interval endpoint rows through H. Because the same endpoint hsame rows are preserved, the $\mathsf{RationalInterval}^{\uparrow}$ boundary seen after refinement is the transported form of I rather than a new completed real cell.

Repack the refined level, refined cell index, transported interval, dyadic containment ledger, updated continuation route, package provenance, and local name row. These are exactly the carrier coordinates, so the refined packet is accepted and the visible $\mathsf{Real}^{\uparrow}$ boundary is unchanged. □

Theorem 358.4 (DyadicMesh RationalInterval coverage)**.** *For every accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet* $M = (\ell, J, I, E, H, C, P, N)$*, the rational interval row* I *is the complete coverage object exported by the mesh cell. A* $\mathsf{RationalInterval}^{\uparrow}$ *consumer may read the endpoint order, containment ledger, and refinement routes through* I*,* E*,* H*, and* C*, but it cannot read an infinite mesh, a host subset of* $\mathsf{Real}^{\uparrow}$*, or a global real-completion proof from the mesh packet.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket rational interval coverage`

Proof. Project the interval coordinate I from the carrier. It is the only coverage row of the packet, and its endpoint and order data are interpreted by the existing $\mathsf{RationalInterval}^{\uparrow}$ surface.

Use the dyadic ledger E only to identify the dyadic endpoint and radius rows that support the interval read. The routes H and C transport and expose those finite rows to the consumer.

Since the carrier contains no additional coverage coordinate, the exported coverage is precisely I with its finite dyadic ledger. Infinite meshes, host subsets, and real-completion proofs are outside the packet surface. □

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket rationalinterval coverage`

Theorem 358.5 (DyadicMesh NameCert obligation surface)**.** *The seed* $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$ *obligation surface has five rows:*

1. *carrier: the finite* BHist *packet of Definition 358.1;*
2. *classifier: common-refinement comparison of level and cell-index rows followed by endpoint* hsame *comparison through* $\mathsf{RationalInterval}^{\uparrow}$*;*
3. *stability:* Cont *appends refinement evidence while preserving the transported rational interval cell;*
4. *exactness: every endpoint, midpoint, radius, order, and containment read is one of the dyadic ledger rows in E routed by C and transported by H;*
5. *ledger: the* Pkg *and local* NameCert *rows record exactly the dependency surface over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicPrecision}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{ValidatedNumerics}^{\uparrow}$.

These rows are the full seed naming surface for finite dyadic meshes.

Proof. The carrier row is the source packet itself. It lists the only visible coordinates from which a mesh cell can be read.

The classifier row first transports mesh packets to a common displayed refinement level. Once the cell-index rows are compared there, the rational interval endpoints are compared through the inherited endpoint hsame rows.

Stability is the refinement route of Definition 358.3. Exactness is the assertion that the dyadic endpoint, midpoint, radius, order, and containment reads are exactly the ledger entries in E routed by C and transported by H.

The ledger row is the package and local-name boundary. It records the named dependency certificates and therefore completes the seed NameCert surface without adding an analytic or solver coordinate. □

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket namecert obligation surface`

Theorem 358.6 (DyadicMesh ValidatedNumerics handoff)**.** *A* $\mathsf{ValidatedNumerics}^{\uparrow}$ *consumer of an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet may read exactly the finite enclosure package consisting of the level row, dyadic cell index,* $\mathsf{RationalInterval}^{\uparrow}$ *cell coverage row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *containment ledger, displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *refinement route,* $\mathsf{DyadicApproximation}^{\uparrow}$ *endpoint readback,* $\mathsf{Real}^{\uparrow}$ *boundary token,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *row. The handoff supplies a finite enclosure mesh cell and does not assert solver correctness, floating-point hardware semantics, classical real completeness, or a global mesh refinement theorem.*

Proof. Read the mesh packet through Definition 358.2. The level, cell index, interval row, dyadic containment ledger, transport, continuation, provenance, and local name rows are the only public coordinates.

Apply Definition 358.4. The coverage object exported to the validated-numerics side is the finite $\mathsf{RationalInterval}^{\uparrow}$ row, supported by the dyadic endpoint and radius ledger.

Use Definition 358.3 for precision movement. Refinement is a displayed continuation route and therefore preserves the same covered cell boundary visible to the real-name consumer.

Thus the validated-numerics handoff is a finite enclosure mesh cell with named dependency rows. No row supplies solver correctness, hardware semantics, classical completeness, or a global refinement theorem. □

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket validatednumerics handoff`

Theorem 358.7 (DyadicMesh public export boundary)**.** *The public* $\mathsf{DyadicMesh}^{\uparrow}$ *export is exactly the finite packet rows of Definition 358.1 together with the containment obligation of Definition 358.2, refinement stability of Definition 358.3,* $\mathsf{RationalInterval}^{\uparrow}$ *coverage of Definition 358.4, the* $\mathsf{NameCert}$ *surface of Definition 358.5, and the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *handoff of Definition 358.6.*

This public boundary exports finite mesh-cell rows only. It does not export an infinite mesh, a host subset of $\mathsf{Real}^{\uparrow}$*, solver correctness, floating-point semantics, or classical real completeness.*

Proof. Project the source packet of Definition 358.1. Its visible rows are the level, finite cell index, rational interval cell, dyadic containment ledger, transport rows, continuation routes, package provenance, and local name row.

Apply Definition 358.2 and Definition 358.3. These identify the exported cell surface and show that displayed refinement changes only the finite reading route while preserving the transported cell boundary.

Next use Definition 358.4 and Definition 358.5. The coverage row is the finite $\mathsf{RationalInterval}^{\uparrow}$ cell, and the naming surface records the carrier, classifier, stability, exactness, and ledger rows without adding an analytic mesh object.

Finally apply Definition 358.6. The same finite rows are the only public enclosure rows available to downstream $\mathsf{ValidatedNumerics}^{\uparrow}$ consumers. Since every row is projected from the finite packet, infinite meshes, host subsets, solver correctness, floating-point semantics, and classical real completeness remain outside the export. □

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket public export boundary`

Theorem 358.8 (DyadicMesh standard finite mesh bridge boundary)**.** *For an accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packet* $M = (\ell, J, I, E, H, C, P, N)$ *satisfying Definition 358.1, the standard finite mesh reading available to downstream consumers is exactly the tuple consisting of the unary level row* ℓ*, the finite dyadic cell-index row* J*, the* $\mathsf{RationalInterval}^{\uparrow}$ *coverage row* I*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint-radius-order ledger* E*, the displayed* $\mathsf{DyadicPrecision}^{\uparrow}$ *refinement route, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *endpoint readback, the* $\mathsf{Real}^{\uparrow}$ *boundary token, the componentwise* hsame *transports in* H*, the* Cont *routes in* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}$ *row* N*.*

This bridge exports one finite enclosure mesh cell to $\mathsf{ValidatedNumerics}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumers. It does not export host subsets, floating-point hardware semantics, solver correctness, completed-real compactness, or infinite mesh refinement.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket standard finite mesh bridge boundary`

Proof. Project the carrier rows from Definition 358.1. The packet supplies the unary level, finite cell index, rational interval row, dyadic containment ledger, transport rows, continuation routes, package provenance, and local name row as finite BHist data.

Use Definition 358.2 for the selected cell. The containment obligation identifies the public enclosure cell and rules out any ambient grid object or solver state.

Apply Definition 358.4 to read the interval coverage object. The exported coverage is the finite $\mathsf{RationalInterval}^{\uparrow}$ row supported by the dyadic endpoint, radius, and order ledger.

Next use Definition 358.3. Displayed refinement changes only the continuation route and preserves the transported cell boundary seen by the $\mathsf{Real}^{\uparrow}$ consumer.

Finally combine Definition 358.6 with Definition 358.7. Their common public surface is precisely the finite enclosure mesh cell named above, so host subsets, floating-point hardware semantics, solver correctness, completed-real compactness, and infinite refinement remain outside the bridge. □

Theorem 358.9 (DyadicMesh common refinement endpoint determinacy)**.** *Let $M = (\ell, J, I, E, H, C, P, N)$ and $M' = (\ell', J', I', E', H', C', P', N')$ be accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packets satisfying Definition 358.1. Suppose both packets are displayed at a common refinement level and, after transport to that level, agree on the refined finite cell-index row and on the* $\mathsf{RationalInterval}^{\uparrow}$ *endpoint* hsame *rows. Then every* $\mathsf{DyadicApproximation}^{\uparrow}$ *endpoint read and every* $\mathsf{Real}^{\uparrow}$ *boundary token exported through the two packets factors through the same finite* $\mathsf{RationalInterval}^{\uparrow}$ *row, endpoint-radius-order ledger,* Cont *route,* Pkg *provenance row, and local* NameCert *row.*

Equivalently, the consumer-visible rows for these three handoffs are the same finite BHist *rows routed through the common endpoint* hsame, Cont, Pkg, *and* NameCert *coordinates. The theorem does not assert a host subset of* $\mathsf{Real}^{\uparrow}$*, a completed real cell, solver state, floating-point semantics, or an infinite mesh.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket common refinement endpoint determinacy`

Proof. Start from Definition 358.1. Each accepted packet is a finite tuple of level, cell-index, rational-interval endpoint, dyadic ledger, transport, continuation, package, and name rows; no additional mesh object is available to downstream consumers.

Apply Definition 358.3 to both packets at the displayed common level. The hypothesis that the transported cell-index rows agree fixes the refined cell boundary through the shared hsame and Cont coordinates.

Next use Definition 358.4. Agreement of the transported endpoint hsame rows fixes the unique exported $\mathsf{RationalInterval}^{\uparrow}$ coverage row and the endpoint-radius-order ledger, and therefore fixes each endpoint read seen by the $\mathsf{DyadicApproximation}^{\uparrow}$ consumer.

Now apply Definition 358.6. The enclosure handoff reads exactly the finite cell, rational-interval endpoint, dyadic ledger, continuation, package, and local naming rows already fixed by the common refinement packet.

Finally use Definition 358.8. Its bridge surface names the $\mathsf{Real}^{\uparrow}$ boundary token and the endpoint readback as projections of the same finite BHist packet, so the two accepted packets give the same consumer-visible endpoint and boundary rows. The conclusion is only this finite-row determinacy claim and introduces no host subset, completed real cell, solver state, floating-point semantics, or infinite mesh. □

Theorem 358.10 (DyadicMesh validated terminal readback determinacy)**.** *Let M and M' be accepted* $\mathsf{DyadicMesh}^{\uparrow}$ *packets displayed at a common refinement as in Definition 358.9. Suppose a terminal accepted* $\mathsf{DyadicApproximation}^{\uparrow}$ *finite packet reads the same* $\mathsf{RationalInterval}^{\uparrow}$ *cell, endpoint-radius-order ledger,* RegSeqRat *observation window, and* $\mathsf{Real}^{\uparrow}$ *boundary token, and suppose a* $\mathsf{ValidatedNumerics}^{\uparrow}$ *enclosure consumes that same cell through the visible* hsame *transports,*

Cont *routes,* Pkg *provenance rows, and local* $\mathsf{NameCert}_{\mathsf{DyadicMesh}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^\uparrow}$ *rows.*

Then every mesh-cell consumer, terminal dyadic readback, and validated enclosure read factors through one finite $\mathsf{Real}^\uparrow$ *boundary surface. The surface is the common refined cell with its rational interval endpoint, endpoint-radius-order ledger, terminal dyadic packet readback, validated enclosure row, observation window, transport rows, continuation routes, package rows, and local certificate rows. It does not assert completed real equality, a host subset of* $\mathsf{Real}^\uparrow$*, solver correctness, floating-point hardware semantics, or an infinite refinement object.*

Proof. First apply Definition 358.9. The common refinement fixes the finite cell row, rational interval endpoint, endpoint-radius-order ledger, $\mathsf{Real}^\uparrow$ boundary token, transport rows, continuation routes, package rows, and local mesh certificate row seen by the two displayed mesh packets.

Next read the terminal dyadic packet through Definition 335.38. The terminal packet contributes only its finite RegSeqRat observation window, rational interval cell, endpoint ledger, and boundary token, so it has the same finite target surface fixed by the mesh refinement.

Now use Definition 335.39 and Definition 335.41. These identify the terminal readback and the enclosure handoff as projections of the same finite rational-interval boundary, with the shared $\mathsf{Real}^\uparrow$ token and without a completed real equality claim.

Finally invoke the $\mathsf{ValidatedNumerics}^\uparrow$ bridge boundary used by the dyadic handoff. Its enclosure read consumes exactly the fixed cell, endpoint ledger, observation window, transport, continuation, provenance, and local certificate rows. Repacking those rows gives the single finite $\mathsf{Real}^\uparrow$ boundary surface claimed in the statement. □

Theorem 358.11 (DyadicMesh refinement enclosure export)**.** *Let* $M = (\ell, J, I, E, H, C, P, N)$ *and* $M' = (\ell', J', I', E', H', C', P', N')$ *be accepted* $\mathsf{DyadicMesh}^\uparrow$ *packets satisfying Definition 358.1. Suppose both are displayed at a common refinement level, agree there on the refined finite cell-index row and the transported* $\mathsf{RationalInterval}^\uparrow$ *endpoint rows, and are consumed by a* $\mathsf{DyadicApproximation}^\uparrow$ *endpoint read and a* $\mathsf{ValidatedNumerics}^\uparrow$ *enclosure over that same refined cell.*

Then the two mesh packets export exactly one finite enclosure surface to those consumers. The surface consists of the refined level row, refined cell-index row, $\mathsf{RationalInterval}^\uparrow$ *endpoint row, dyadic endpoint-radius-order ledger,* $\mathsf{DyadicApproximation}^\uparrow$ *endpoint readback,* $\mathsf{Real}^\uparrow$ *boundary token, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance rows, and local* $\mathsf{NameCert}_{\mathsf{DyadicMesh}^\uparrow}$, $\mathsf{NameCert}_{\mathsf{DyadicApproximation}^\uparrow}$, *and* $\mathsf{NameCert}_{\mathsf{ValidatedNumerics}^\uparrow}$ *rows.*

This export is a finite consumer boundary. It does not supply a host subset of $\mathsf{Real}^\uparrow$*, a completed real cell, solver correctness, floating-point semantics, or an infinite mesh.*

Lean4 ✓ `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket refinement enclosure export`

Proof. First apply Definition 358.9. The displayed common refinement fixes the refined level, refined cell-index row, transported rational interval endpoint, endpoint-radius-order ledger, endpoint readback, boundary token, transport rows, continuation rows, package rows, and local mesh certificate row seen by both packets.

Next expose the public mesh boundary. Use Definition 358.7 to restrict the exported rows to the finite packet surface of Definition 358.1; no ambient mesh or host real subset is introduced.

Now read the validated enclosure consumer. Apply Definition 358.6. Its handoff rows are the same finite cell, rational-interval endpoint, dyadic ledger, displayed refinement route, endpoint readback, real boundary token, transport, continuation, package, and local naming rows already fixed by the common refinement.

Finally apply Definition 335.37. It says that the dyadic endpoint read and validated enclosure read factor through the same finite mesh-enclosure packet. Repacking these fixed rows gives the single consumer surface listed in the statement, with no solver semantics, floating-point semantics, completed-real cell, host subset, or infinite mesh. □

Theorem 358.12 (DyadicMesh mature finite mesh treatment)**.** *The mature finite-mesh treatment for* $\mathsf{DyadicMesh}^{\uparrow}$ *consists exactly of the finite level row, finite cell-index row, rational-interval coverage row, dyadic endpoint, radius, and order ledger, displayed transport rows, continuation routes, package provenance, and local* NameCert *rows of the accepted packet.*

This treatment combines cell containment, refinement stability, $\mathsf{RationalInterval}^{\uparrow}$ *coverage, the* NameCert *surface, the* $\mathsf{ValidatedNumerics}^{\uparrow}$ *handoff, the public export boundary, and the standard finite mesh bridge boundary. It exports no infinite mesh, host subset of* $\mathsf{Real}^{\uparrow}$*, floating-point hardware semantics, solver correctness, completed-real compactness, or global refinement theorem.*

Proof. Project the finite packet of Definition 358.1. Its rows are the level, cell index, rational interval cell, dyadic containment ledger, transport data, continuation routes, provenance, and local name.

Use Definition 358.2, Definition 358.3, and Definition 358.4 to identify the finite mesh cell, its displayed refinement route, and its rational-interval coverage object.

Next apply Definition 358.5, Definition 358.6, and Definition 358.7. These rows repack the same finite cell for naming and downstream validated-numerics consumers.

Finally use Definition 358.8. It is the standard finite-mesh boundary for the packet, and none of the projected rows contains an infinite mesh, a host subset, solver semantics, hardware semantics, completed-real compactness, or a global refinement theorem. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicMesh}^{\uparrow}$ packet is generated by a unary level row, a finite dyadic cell-index row, a $\mathsf{RationalInterval}^{\uparrow}$ cell coverage row, a $\mathsf{DyadicRatCore}^{\uparrow}$ containment ledger, componentwise hsame transports, displayed Cont refinement routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 358.1, Definition 358.2, Definition 358.3, Definition 358.4, Definition 358.5, Definition 358.6, Definition 358.7, Definition 358.8, Definition 358.9, Definition 358.10, Definition 358.11, and Definition 358.12 specify the public finite mesh carrier, containment row, refinement route, rational-interval coverage row, NameCert obligation surface, $\mathsf{ValidatedNumerics}^{\uparrow}$ handoff rows, standard finite mesh bridge boundary, common-refinement endpoint determinacy, validated terminal readback determinacy, refinement enclosure export, and mature finite-mesh treatment.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DyadicMesh}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DyadicMeshUp.DyadicMeshPacket\_standard\_finite\_mesh\_bridge\_boundary`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close solver correctness, floating-point hardware semantics, classical real completeness, infinite meshes, or a global refinement theorem.

Upgrade path: No further paper-side theory grade remains; formal verification remains on the separate formal axis.

Chapter 359

A Concrete Naming Certificate for $\mathsf{RealDiagonalCompletion}^{\uparrow}$

The $\mathsf{RealDiagonalCompletion}^{\uparrow}$ interface names the concrete diagonal completion packet that sits between the regular Cauchy family used in the real-completeness capstone and the finite $\mathsf{Real}^{\uparrow}$ seal surface. Following the Bishop–Bridges constructive-analysis treatment of Cauchy completion, the packet keeps the regular rational input, its explicit modulus, the chosen diagonal windows, and the real-seal ledger as visible certificate data. It does not form a quotient of regular streams, select a limit by choice, or import host real completeness.

The diagonal completion packet consumes the finite $\mathsf{StreamName}^{\uparrow}$ window surface of chapter 126, the regular rational sequence carrier of chapter 301, and the real seal boundary of chapter 38. This chapter is the finite ledger that routes those sibling surfaces through the displayed diagonal selector without quotient streams, host limits, or choice-selected representatives.

The packet consumes the diagonal-window source of chapter 372 and instantiates the finite diagonal route from chapter 9238 before exposing the $\mathsf{Real}^{\uparrow}$ seal. Thus its carrier records the substantive path from regular Cauchy diagonal data to completion-facing seal data rather than standing as a kernel-only packet.

Definition 359.1 (RealDiagonalCompletion source packet)**.** *A* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *source packet is a finite* BHist *row*

$$D = (X, M, \Delta, S, R, E, P, N)$$

with the following visible coordinates:

1. *X is a* $\mathsf{RegSeqRat}^{\uparrow}$*-indexed regular Cauchy input family, with every inspected member read as a regular rational sequence;*
2. *M is an explicit unary modulus row selecting a late enough member of X for each requested precision;*
3. *Δ is the diagonal selector row that sends a precision request to the selected member of X and to the regular-sequence window read inside that member;*
4. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *schedule of all windows requested by the diagonal selector;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback ledger for the selected diagonal windows;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *classifier and seal ledger attached to the diagonal representative;*

7. *P is the* Pkg *provenance naming the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, *and* NameCert *source certificates;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *provenance row.*

The classifier compares two accepted source packets only by the displayed modulus rows, selected diagonal windows, $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks, and* $\mathsf{Real}^{\uparrow}$ *seal ledgers, transporting each component through the visible* hsame *and* Cont *routes.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionTasteGate single carrier alignment`

Theorem 359.2 (RealDiagonalCompletion carrier habitation)**.** *Every regular Cauchy input family over* $\mathsf{RegSeqRat}^{\uparrow}$ *with an explicit unary modulus row and displayed finite readbacks determines an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *carrier by placing the input family, modulus, diagonal selector,* $\mathsf{StreamName}^{\uparrow}$ *schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback ledger,* $\mathsf{Real}^{\uparrow}$ *seal ledger, package provenance, and local* NameCert *row into the source packet of Definition 359.1.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket carrier habitation`

Proof. Start with the finite rows supplied by the regular Cauchy input. The family row gives the $\mathsf{RegSeqRat}^{\uparrow}$-indexed source, and the modulus row gives a displayed unary bound for each requested precision.

Use the diagonal selector to choose the visible late member and the visible regular-sequence window inside that member. The selected windows form the finite $\mathsf{StreamName}^{\uparrow}$ schedule, and the corresponding rational observations form the $\mathsf{RegSeqRat}^{\uparrow}$ readback ledger.

Attach the $\mathsf{Real}^{\uparrow}$ seal ledger to the same selected rows. The provenance row names only the displayed source certificates, and the local NameCert row records the packet assembly, so the resulting carrier contains no quotient, selected host limit, or hidden completion datum. □

Theorem 359.3 (RealDiagonalCompletion classifier stability)**.** *Let D and D' be accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packets. If their modulus rows, diagonal selector rows, selected* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{Real}^{\uparrow}$ *seal ledgers,* Pkg *provenance, and local* NameCert *rows are transported componentwise through displayed* hsame *comparisons and* Cont *routes, then the transported packet is accepted and the local classifier relates it to the original packet.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket classifier stability`

Proof. Project the packet coordinates of Definition 359.1. Each coordinate is finite certificate data, so a displayed hsame comparison transports the row without changing the carrier kind.

The continuation routes identify which finite windows are read after transport. The diagonal selector is therefore transported together with the $\mathsf{StreamName}^{\uparrow}$ schedule, and the selected readbacks remain the same $\mathsf{RegSeqRat}^{\uparrow}$ observations seen through the transported routes.

Finally repack the $\mathsf{Real}^{\uparrow}$ seal ledger and the package provenance. Since the classifier compares exactly these rows, the transported packet is accepted and classified with the original one. □

Theorem 359.4 (RealDiagonalCompletion ledger exactness)**.** *For every accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet, each* $\mathsf{Real}^{\uparrow}$ *consumer read of the diagonal representative factors through one displayed diagonal selector row, one finite* $\mathsf{StreamName}^{\uparrow}$ *window, one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the associated* $\mathsf{DyadicRatCore}^{\uparrow}$ *rational observation ledger, and the visible* Pkg *and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket ledger exactness`

Proof. Read the accepted packet through its source definition. The $\mathsf{Real}^{\uparrow}$ seal coordinate is not independent data; it is attached to the selected diagonal windows and their regular rational readbacks.

A consumer precision request first meets the unary modulus row, then the diagonal selector row, and then the scheduled finite stream window. The readback ledger records the $\mathsf{RegSeqRat}^{\uparrow}$ observation and its $\mathsf{DyadicRatCore}^{\uparrow}$ rational evidence at that same window.

Thus the visible ledger exhausts the read. There is no remaining coordinate from which a quotient representative, host real endpoint, hidden tail choice, or ambient completeness proof could be exported. □

Theorem 359.5 (RealDiagonalCompletion diagonal window extraction)**.** *For every accepted* RealDiagonalCompleti *packet D and every unary precision request n, the consumer read of the diagonal representative factors through a displayed modulus row $M(n)$, a displayed diagonal selector row $\Delta(n)$, one scheduled* $\mathsf{StreamName}^{\uparrow}$ *window $S(n)$, and one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row $R(n)$. These rows are transported only by the visible* hsame *comparisons and* Cont *routes carried by the packet provenance.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket window extraction`

Proof. Project D by Definition 359.1. The modulus coordinate supplies the finite member of the regular Cauchy input family selected for the unary request n.

Use the diagonal selector coordinate to identify the displayed window inside that member. The scheduled $\mathsf{StreamName}^{\uparrow}$ row is exactly the finite window named by this selector, and the $\mathsf{RegSeqRat}^{\uparrow}$ readback row is the corresponding regular rational observation.

Repack these rows with the visible Pkg and NameCert provenance. Since the packet classifier transports exactly these coordinates through hsame and Cont, the extracted window is a consumer-facing factor of the diagonal read rather than an ambient limit selection. □

Theorem 359.6 (RealDiagonalCompletion real seal factorization)**.** *The* $\mathsf{Real}^{\uparrow}$ *seal ledger E of an accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet is determined by the family of extracted diagonal windows of Definition 359.5 together with the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *readback ledger. No host limit, quotient representative, or ambient completeness proof is exported by this factorization.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket seal factorization`

Proof. Combine Definition 359.4 with the window extraction surface of Definition 359.5. Every consumer read of the diagonal representative has already passed through the modulus row, selector row, scheduled stream window, and regular rational readback.

The source packet attaches the $\mathsf{Real}^{\uparrow}$ seal coordinate to exactly those finite readbacks. Therefore two accepted packets with the same extracted windows and the same displayed $\mathsf{RegSeqRat}^{\uparrow}$ readback ledger expose the same $\mathsf{Real}^{\uparrow}$ seal ledger to consumers.

The conclusion is only a finite ledger factorization. It does not form a quotient of regular streams, choose a host real limit, or appeal to an ambient completeness theorem. □

Theorem 359.7 (RealDiagonalCompletion common-refinement seal invariance)**.** *Let D_0 and D_1 be accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packets. Suppose the diagonal selectors of D_i read selected* $\mathsf{StreamName}^{\uparrow}$ *windows $S_i(n)$ with displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support, and suppose that for the inspected boundary requests these windows both transport to one common-refinement* $\mathsf{StreamName}^{\uparrow}$ *packet $S_*(n)$. Suppose further that the transported* $\mathsf{RegSeqRat}^{\uparrow}$ *readback*

rows and the transported $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledgers of* D_0 *and* D_1 *agree on* $S_*(n)$ *for each such boundary request.*

Then the attached $\mathsf{Real}^{\uparrow}$ *seal ledgers of* D_0 *and* D_1 *are classifier-equal at the shared boundary. The equality is only the finite seal-ledger equality carried by the displayed* hsame *and* Cont *transports through the two* Pkg *and* NameCert *rows. It does not assert quotient stream equality, host real equality, a selected host limit, countable choice, ambient completeness, or a host-level equality of completed real numbers.*

Proof. Apply Definition 359.5 to both accepted packets. For each inspected boundary request this exposes the modulus row, diagonal selector, selected $\mathsf{StreamName}^{\uparrow}$ window, and $\mathsf{RegSeqRat}^{\uparrow}$ readback used by the $\mathsf{Real}^{\uparrow}$-facing consumer read.

Next apply Definition 359.6 to both packets. The attached $\mathsf{Real}^{\uparrow}$ seal ledger is read only through those extracted windows and the displayed regular-rational readbacks, so the comparison of seal ledgers reduces to the comparison of the transported finite-window data.

Use Definition 38.661 on the shared common-refinement window $S_*(n)$. The hypotheses give agreement of the transported $\mathsf{RegSeqRat}^{\uparrow}$ readbacks and $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledgers on that window, so the terminal $\mathsf{Real}^{\uparrow}$ seal route is unique at the shared boundary.

Finally transport this terminal route back through the displayed Pkg and NameCert rows of D_0 and D_1. Componentwise hsame supplies the classifier equality of the seal ledgers, while the Cont routes record that the consumer reads pass through the same selected boundary data. None of the cited rows contains quotient stream equality, host real equality, selected limits, countable choice, or ambient completeness, so the conclusion is exactly the finite classifier equality stated above. □

Theorem 359.8 (RealDiagonalCompletion constant rational handoff)**.** *If the input regular Cauchy family is the stationary family generated by a* $\mathsf{Rat}^{\uparrow}$ *row* q*, then the accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet classifies its diagonal representative with the constant* $\mathsf{Real}^{\uparrow}$ *embedding of* q*. The diagonal selector always reads the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member, and every selected* $\mathsf{StreamName}^{\uparrow}$ *window returns the same rational row through the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket constant rational handoff`

Proof. The stationary family has a constant regular rational source row. Its modulus can be the displayed unary zero-threshold row, because every selected member of the family reads the same rational value.

The diagonal selector therefore chooses a window of the same stationary $\mathsf{RegSeqRat}^{\uparrow}$ member at every requested precision. The $\mathsf{StreamName}^{\uparrow}$ schedule may vary the requested window, but the readback ledger always returns the row q with its $\mathsf{Rat}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ evidence.

The $\mathsf{Real}^{\uparrow}$ seal ledger is the constant rational handoff for those same rows. Componentwise hsame transport and the displayed Cont routes preserve the stationary readback, so the classifier identifies the diagonal representative with the constant embedding of q. □

Theorem 359.9 (RealDiagonalCompletion NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$ *obligation surface consists of five rows:*

1. *carrier habitation: Definition 359.2 assembles the finite source packet from the regular Cauchy input, unary modulus, diagonal selector, finite stream schedule, readback ledger, real seal, provenance, and local ledger;*
2. *classifier stability: Definition 359.3 transports exactly the modulus, selector, selected windows, readbacks, and seal ledgers through* hsame *and* Cont*;*

3. *diagonal-window exactness: Definition 359.4 forces each consumer read through a displayed selector window and its* $\mathsf{RegSeqRat}^{\uparrow}$ *readback;*
4. *constant rational handoff: Definition 359.8 identifies stationary rational inputs with their constant* $\mathsf{Real}^{\uparrow}$ *embeddings;*
5. *ledger non-escape: the packet exposes only* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, Pkg, *and* NameCert *rows, and contains no quotient stream, host real equality, choice-selected limit, or ambient completion object.*

Lean4 ✓ `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket namecert obligation surface`

Proof. The first four rows are exactly the preceding carrier, stability, exactness, and stationary-handoff theorems. They list the finite source coordinates and describe how a consumer reaches every displayed read.

For the ledger boundary, inspect the source packet. Its coordinates name only the dependency certificates and the local provenance rows, so a consumer cannot obtain quotient, choice, or host-completion data from the carrier.

These five rows are precisely the naming-certificate obligations for the diagonal completion object. They turn the diagonal representative into a concrete BHist packet surface while this chapter leaves machine-checked real completeness unclaimed. □

Theorem 359.10 (RealDiagonalCompletion scoped consumer seal package)**.** *Every accepted* RealDiagonalCompleti *packet satisfying the source row of Definition 359.1, the carrier construction, classifier stability, ledger exactness, diagonal window extraction, seal factorization, constant rational handoff, and* NameCert *obligation surface determines a scoped dependency package over* BHist, hsame, Cont, Pkg, NameCert, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{Rat}^{\uparrow}$.

Every $\mathsf{Real}^{\uparrow}$*-facing consumer read of that package factors through the displayed diagonal selector, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal ledger, and provenance rows. No quotient stream, choice-selected limit, host real equality, or ambient completeness object is part of the scoped package.*

Proof. Project the source packet of Definition 359.1. Its visible coordinates are the finite BHist carrier row, the displayed transport routes through hsame and Cont, the package and local NameCert provenance, and the source certificates for $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Rat}^{\uparrow}$.

The carrier row is supplied by Definition 359.2. Classifier transport is supplied by Definition 359.3, and each consumer read is forced through the displayed diagonal-window ledger by Definition 359.4 and Definition 359.5.

The seal route is the factorization of Definition 359.6. For stationary rational inputs, Definition 359.8 keeps the handoff inside the same $\mathsf{Rat}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows.

The complete local obligation surface is the five-row NameCert packet of Definition 359.9. These rows exhaust the available fields of the accepted packet.

Since none of the cited rows contains a quotient stream, choice-selected limit, host real equality, or ambient completeness object, the scoped consumer seal package has exactly the dependency surface stated above. □

Theorem 359.11 (RealDiagonalCompletion public RealUp handoff)**.** *Every accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet is repacked as a consumer-facing* $\mathsf{Real}^{\uparrow}$ *seal read through the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$,

StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, Rat$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows only. The repacking is exactly the composition of diagonal-window extraction, real-seal factorization, constant rational handoff, and scoped primitive dependency over the accepted packet surface.*

The handoff exports no Real$^{\uparrow}$ *completeness theorem, quotient equality of regular streams, selected limit, uniqueness of limits, or host real construction.*

Proof. Begin with the extracted consumer window of Definition 359.5. It routes each requested read through the displayed modulus, diagonal selector, finite StreamName$^{\uparrow}$ window, and RegSeqRat$^{\uparrow}$ readback row.

Next apply the seal factorization of Definition 359.6. The Real$^{\uparrow}$ seal is read from those extracted windows and their displayed rational observations, with hsame and Cont accounting for the permitted transports.

For stationary rational inputs, Definition 359.8 identifies the same surface with the constant Rat$^{\uparrow}$ handoff inside the RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$ dependency rows.

Finally use the scoped dependency package of Definition 359.10. That package exhausts the accepted packet fields by BHist carrier data, package provenance, local NameCert rows, and the named dependency certificates. Since none of these rows contains completeness, quotient equality, a selected limit, uniqueness of limits, or a host real carrier, the public read has exactly the stated boundary. □

Theorem 359.12 (RealDiagonalCompletion public finite completeness interface)**.** *Every accepted* RealDiagonalCompletion$^{\uparrow}$ *packet satisfying the source packet, carrier construction, classifier stability, ledger exactness, diagonal-window extraction, seal factorization, constant rational handoff,* NameCert *obligation surface, and scoped consumer seal package exports a public* Real$^{\uparrow}$*-facing finite completeness interface.*

For every requested consumer read, the interface factors the read through an explicit unary modulus, the displayed diagonal selector, a finite StreamName$^{\uparrow}$ *window, a* RegSeqRat$^{\uparrow}$ *readback, a* DyadicRatCore$^{\uparrow}$ *observation ledger, a* Real$^{\uparrow}$ *seal row,* Pkg *provenance, and a local* NameCert *row. It exports no quotient stream, selected host limit, uniqueness theorem, or ambient real completeness theorem.*

Proof. Start from the source packet of Definition 359.1. The carrier theorem Definition 359.2 supplies the finite rows, and Definition 359.3 transports those rows only along the displayed hsame and Cont routes.

The read itself is the diagonal-window readback of Definition 359.4 and Definition 359.5. These two results exhibit the unary modulus, diagonal selector, finite stream window, regular-sequence readback, and dyadic observation ledger used by the consumer.

The Real$^{\uparrow}$ output row is the seal factorization of Definition 359.6. For constant rational inputs, Definition 359.8 keeps the read inside the same Rat$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$ dependency rows.

Finally, Definition 359.9, Definition 359.10, and Definition 359.11 repack these finite rows into the public consumer interface. Since the cited packet rows contain no quotient stream, selected host limit, uniqueness theorem, or ambient real-completeness object, the public interface has exactly the stated boundary. □

Theorem 359.13 (RealDiagonalCompletion standard finite bridge)**.** *Any accepted* RealDiagonalCompletion$^{\uparrow}$ *packet satisfying the source packet of Definition 359.1 and the public finite completeness interface of Definition 359.12 repacks as the standard BEDC bridge surface over* DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, Rat$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

Every bridge read factors through the displayed modulus, diagonal selector, finite stream window, regular-sequence readback, real seal, and provenance rows. The bridge exports no quotient stream, host real equality, selected limit, uniqueness theorem, or ambient completeness object.

Proof. The carrier habitation theorem Definition 359.2 supplies the accepted finite packet, and Definition 359.4 identifies the exact ledger through which a consumer read must pass. Together these fix the bridge carrier as a BHist surface rather than an external completion object.

For each requested read, use Definition 359.5 to expose the modulus, selector, finite $\mathsf{StreamName}^{\uparrow}$ window, and $\mathsf{RegSeqRat}^{\uparrow}$ readback. Then apply Definition 359.6 to route the same read into the displayed $\mathsf{Real}^{\uparrow}$ seal, with the constant rational case constrained by Definition 359.8.

The scoped consumer seal package of Definition 359.10 records the permitted hsame, Cont, Pkg, and NameCert routes. The public $\mathsf{Real}^{\uparrow}$ handoff of Definition 359.11 and the finite completeness interface of Definition 359.12 then repack those routes as the public bridge surface.

It remains to check that the bridge has no extra coordinate. The source packet lists exactly X, M, Δ, S, R, E, P, and N; the preceding theorems account for each of these rows. Coordinate exhaustion therefore rules out any quotient stream, host real equality, selected limit, uniqueness theorem, or ambient completeness object. □

Theorem 359.14 (RealDiagonalCompletion bridge readback roundtrip)**.** *Reading the standard finite packet of Definition 359.13 back into BEDC recovers the same accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *rows: the unary modulus row, diagonal selector row, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, package provenance, and local* NameCert *row.*

The readback is conservative over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *It exports no quotient stream, selected host limit, uniqueness theorem, host real equality, or ambient real completeness.*

Proof. Begin with the bridge packet of Definition 359.13. Its coordinates are the displayed packet rows of Definition 359.1; there is no additional host coordinate to interpret.

Apply Definition 359.5 to read back the modulus, diagonal selector, finite $\mathsf{StreamName}^{\uparrow}$ window, and $\mathsf{RegSeqRat}^{\uparrow}$ row. The same projection also recovers the dyadic observation ledger because Definition 359.4 identifies the accepted read ledger with those displayed coordinates.

Next use Definition 359.6 and Definition 359.11. These repack the recovered window and ledger as the same $\mathsf{Real}^{\uparrow}$ seal row, with all transports accounted for by the displayed hsame and Cont routes.

Finally apply Definition 359.12. The bridge readback forgets only the wrapper naming the standard finite packet and keeps the same Pkg provenance and local NameCert row. Projection followed by repacking therefore returns the accepted BEDC packet with no quotient stream, selected host limit, uniqueness theorem, host real equality, or ambient completeness coordinate. □

Theorem 359.15 (RealDiagonalCompletion mature consumer package)**.** *The carrier, classifier stability, ledger exactness, diagonal-window extraction, seal factorization, public finite completeness interface, standard finite bridge, and bridge readback for accepted* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packets assemble a mature consumer package for downstream* $\mathsf{Real}^{\uparrow}$ *completion consumers.*

Every read in the package is routed through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *The package exports no quotient stream, host limit, uniqueness theorem, or ambient completeness object.*

Proof. Start with the accepted source packet of Definition 359.1. The carrier theorem Definition 359.2 supplies the finite packet rows, while Definition 359.3 records that consumer transport uses only displayed hsame and Cont routes.

Next recover the read coordinates. The ledger exactness theorem Definition 359.4 fixes the observable row, and Definition 359.5 exposes the modulus, diagonal selector, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger used by each read.

The $\mathsf{Real}^{\uparrow}$ output is then the seal of Definition 359.6. The constant rational boundary of Definition 359.8 keeps the $\mathsf{Rat}^{\uparrow}$ case inside the same visible rational, regular-sequence, dyadic, and real rows.

Finally apply the public package results. The NameCert obligation surface of Definition 359.9, the scoped consumer seal package of Definition 359.10, the public finite completeness interface of Definition 359.12, the standard finite bridge of Definition 359.13, and the bridge readback of Definition 359.14 together account for every exported coordinate. Since those cited rows contain only the named BEDC dependency surfaces, the mature consumer package has exactly the stated boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}$.

Constructive story: A $\mathsf{RealDiagonalCompletion}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$-indexed regular Cauchy input, an explicit unary modulus, a diagonal selector, finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, a $\mathsf{Real}^{\uparrow}$ seal ledger, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 359.10, Definition 359.12, Definition 359.13, Definition 359.14, and Definition 359.15 bind the finite diagonal completion carrier, classifier transport, diagonal-window readback exactness, constant rational handoff, public $\mathsf{Real}^{\uparrow}$ finite completeness interface, standard finite bridge, BEDC readback surface, and mature consumer package over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealDiagonalCompletion}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.RealDiagonalCompletionUp.RealDiagonalCompletionSourcePacket\_ledger\_exactness`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close $\mathsf{Real}^{\uparrow}$ completeness, quotient equality of regular streams, uniqueness of limits, host real construction, or machine bridge checking.

Upgrade path: No further paper-side theory-grade target is open; verification-axis audit cleanliness and machine bridge checking remain separate obligations.

The exact-boundary consumer of this completion surface is chapter 1120, which reads the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows as a finite boundary packet.

Chapter 360

A Concrete Naming Certificate for $\mathsf{RealCauchyCompletion}^{\uparrow}$

The $\mathsf{RealCauchyCompletion}^{\uparrow}$ interface names the Bishop–Bridges constructive Cauchy completion surface for real names. It sits above $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and the diagonal packet $\mathsf{RealDiagonalCompletion}^{\uparrow}$, and it exports only the $\mathsf{Real}^{\uparrow}$ seal rows that can be read through those certificates. The chapter records a concrete completion object for the real-and-completion phase without forming quotient classes of regular streams, selecting limits by choice, or appealing to host real equality.

The regular-family input side is consumed through the already licensed $\mathsf{RegularCauchyName}^{\uparrow}$ boundary of chapter 371. That boundary packages the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ seal route that $\mathsf{RealCauchyCompletion}^{\uparrow}$ uses as its visible regular-family input surface.

Definition 360.1 (RealCauchyCompletion carrier)**.** *A* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (X, \mu, D, E, P, N)$$

with the following visible coordinates:

1. *X is a* $\mathsf{RegSeqRat}^{\uparrow}$*-indexed regular Cauchy family, with every inspected member presented through finite* $\mathsf{StreamName}^{\uparrow}$ *windows and* $\mathsf{DyadicRatCore}^{\uparrow}$ *rational observations;*
2. *μ is the displayed unary modulus row that assigns a late family member to each requested precision;*
3. *D is the associated* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet, including its diagonal selector, scheduled windows, and regular-sequence readback ledger;*
4. *E is the consumer-facing* $\mathsf{Real}^{\uparrow}$ *seal row attached to the diagonal representative;*
5. *P is the* Pkg *provenance row naming the* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalCompletion}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *source certificates;*
6. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *row.*

The local classifier compares two carriers only by displayed hsame *transport of the modulus rows, diagonal packets, readback ledgers,* $\mathsf{Real}^{\uparrow}$ *seal rows, package provenance, and local certificate rows.*

Lean4 (definition) `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier`

Theorem 360.2 (RealCauchyCompletion NameCert obligations)**.** *The* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *surface consists of five obligations: carrier habitation by the packet of Definition 360.1; classifier stability under displayed* hsame *transport and* Cont *routes; diagonal handoff through* $\mathsf{RealDiagonalCompletion}^{\uparrow}$*; non-escape of quotient, choice, host real equality, and ambient completeness data; and the standard Bishop reading as a constructive Cauchy completion over visible regular rational names.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier namecert obligation surface`

Proof. Carrier habitation is the assembly of the displayed family, modulus, diagonal packet, real seal, package provenance, and local certificate row. The classifier is componentwise because each coordinate is a visible finite row, and the only permitted transports are the stored hsame comparisons followed by the recorded Cont routes.

The diagonal handoff is delegated to $\mathsf{RealDiagonalCompletion}^{\uparrow}$: every consumer read of the candidate limit first passes through the modulus, diagonal selector, scheduled $\mathsf{StreamName}^{\uparrow}$ window, and $\mathsf{RegSeqRat}^{\uparrow}$ readback ledger. The carrier therefore exposes only the rows named by $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalCompletion}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, Pkg, and NameCert.

The Bishop reading is exactly this finite witness surface. It supplies a constructive regular-Cauchy completion interface while withholding quotient stream equality, choice-selected limits, host real equality, and any ambient completeness theorem not carried by the named certificate rows. □

Theorem 360.3 (RealCauchyCompletion diagonal handoff)**.** *For every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier* C *and every unary precision request* n*, the* $\mathsf{Real}^{\uparrow}$ *consumer read of the completed name factors through the modulus row* $\mu(n)$*, the associated* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet* D*, one finite* $\mathsf{StreamName}^{\uparrow}$ *window, one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier diagonal handoff`

Proof. Project the carrier by Definition 360.1. The modulus coordinate selects the late member of the regular Cauchy family that is relevant for the request n.

Use the diagonal packet coordinate D to read the chosen member through its diagonal selector. The selected finite stream window and its regular-sequence readback are exactly the rows exposed by the $\mathsf{RealDiagonalCompletion}^{\uparrow}$ ledger.

Attach the $\mathsf{Real}^{\uparrow}$ seal row E to that readback and retain the package and local certificate provenance. Since the consumer reaches E only along this displayed route, the handoff factors through the stated finite rows. □

Theorem 360.4 (RealCauchyCompletion non-escape boundary)**.** *An accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier exports no quotient of regular streams, no host real carrier, no host real equality, no choice-selected limit, and no uniqueness principle beyond the displayed* $\mathsf{Real}^{\uparrow}$ *classifier rows. Every exported read is mediated by* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{RealDiagonalCompletion}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *data.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier non escape boundary`

Proof. Inspect the carrier coordinates. Each field is either a finite history row, a displayed transport route, a package provenance row, a local certificate row, or one of the named dependency certificates.

The diagonal coordinate already records its own non-escape boundary: it exposes selected windows and readbacks, not quotient representatives or host limits. Passing through $\mathsf{Real}^{\uparrow}$ adds only the seal row and its classifier-visible comparisons.

Thus a downstream consumer can cite precisely the listed rows. There is no coordinate from which quotient stream equality, host real equality, a selected limit, or an ambient completeness object can be recovered. □

Theorem 360.5 (RealCauchyCompletion standard Bishop reading)**.** *Read in the Bishop–Bridges constructive-analysis sense,* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *is the completion interface for regular Cauchy families over rational names: the input is a* $\mathsf{RegSeqRat}^{\uparrow}$*-indexed regular Cauchy family with an explicit modulus, and the output is the* $\mathsf{Real}^{\uparrow}$ *name obtained by diagonal extraction and finite ledger transport through* $\mathsf{RealDiagonalCompletion}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier standard bishop reading`

Proof. The input side is fully displayed: the regular Cauchy family is a $\mathsf{RegSeqRat}^{\uparrow}$ row family, and the modulus is a unary row stored in the carrier. No convergence fact is inferred from an ambient metric space or from an external completeness principle.

The output side is the diagonal representative already carried by $\mathsf{RealDiagonalCompletion}^{\uparrow}$. Its windows are finite $\mathsf{StreamName}^{\uparrow}$ reads, its rational observations are $\mathsf{DyadicRatCore}^{\uparrow}$ rows, and its real-facing surface is the $\mathsf{Real}^{\uparrow}$ seal.

This is the Bishop-style reading of completion as an explicit transformation from regular Cauchy data to a real name with a visible modulus and ledger. The certificate records the construction interface and its boundary, leaving machine checking of the full real-completion theorem to the corresponding Lean namespace. □

Theorem 360.6 (RealCauchyCompletion carrier transport stability)**.** *Let* $C = (X, \mu, D, E, P, N)$ *be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier. Any displayed* hsame *transport that preserves the* X*,* μ*,* D*,* E*,* P*, and* N *coordinates through the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{RealDiagonalCompletion}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* Pkg*,* Cont*, and* NameCert *rows preserves both the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier predicate and the local classifier. In particular, transported packets are compared only by the same component rows that classified the original packet.*

Proof. Project the carrier by Definition 360.1. The regular family coordinate X and the modulus coordinate μ are transported through the displayed $\mathsf{RegSeqRat}^{\uparrow}$ rows, so the input side remains a visible regular Cauchy family with the same precision schedule.

The diagonal coordinate D is transported through $\mathsf{RealDiagonalCompletion}^{\uparrow}$, and the seal coordinate E is transported through $\mathsf{Real}^{\uparrow}$. The recorded Cont routes carry the finite readback ledgers along those transports, so the consumer-facing route continues to expose the same scheduled stream windows and rational observations.

Finally, P and N transport through the package and local certificate rows. Since the classifier of Definition 360.1 compares exactly these displayed coordinates, componentwise transport preserves accepted carriers and preserves classifier equivalence. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier transport stability`

Theorem 360.7 (RealCauchyCompletion modulus diagonal exactness)**.** *For an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier* $C = (X, \mu, D, E, P, N)$ *and a unary precision request* n*, the row* $\mu(n)$ *determines the displayed diagonal packet used for that request together with its finite* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback rows. The route contains no quotient of regular streams, no host real equality, and no choice-selected limit.*

Proof. The modulus row is a coordinate of the carrier, not an external completeness principle. Evaluating it at n selects the late regular-sequence member whose readback must be inspected for that precision.

The diagonal coordinate D then gives the corresponding displayed packet: a scheduled stream window, the regular-sequence ledger for that window, and the dyadic rational observation rows used by the readback. These rows are finite history data already named by the carrier provenance.

Because the selected route is exhausted by μ, D, and the finite readback ledgers, there is no remaining operation that could form quotient stream equality, appeal to host real equality, or select a limit by choice. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier modulus diagonal exactness`

Theorem 360.8 (RealCauchyCompletion real seal readback scope)**.** *The* $\mathsf{Real}^{\uparrow}$ *seal exported by an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier is consumed only through the diagonal readback route named by* μ *and* D*. Every consumer read of the seal is mediated by the displayed finite* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *packet rows.*

Proof. The seal coordinate E is attached to the diagonal representative carried by D. A consumer therefore reaches E only after the modulus row has selected the relevant regular-sequence member and the diagonal ledger has exposed the finite window and rational observation rows.

The Cont routes record how those rows are read without leaving the displayed packet. The package provenance P and local certificate row N bind the dependency certificates that make the route public to downstream consumers.

Thus the exported seal has a restricted readback scope: it is a real-facing boundary for the named diagonal packet, not an independent host real, quotient class, or ambient completion object. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier real seal readback scope`

Theorem 360.9 (RealCauchyCompletion stream-regseq-tail seal factorization)**.** *Let* $C = (X, \mu, D, E, P, N)$ *be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier. Every* $\mathsf{Real}^{\uparrow}$*-and-completion consumer read of the exported seal factors through a finite* $\mathsf{StreamName}^{\uparrow}$ *window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the diagonal packet* D*, and then the* $\mathsf{Real}^{\uparrow}$ *seal row* E*.*

The exported route is exactly the displayed completion chain carried by C*. It exports no quotient of regular streams, no host real equality, no selected limit, and no ambient completeness principle.*

Proof. Project the carrier by Definition 360.1. The coordinates X and μ supply the visible regular-family input and the finite precision request that selects the relevant stream window.

Apply the diagonal handoff of Definition 360.3. The selected request reaches the diagonal packet D only through the $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger already recorded in the carrier route.

Finally use Definition 360.4 and Definition 360.8. These rows identify E as the only exported $\mathsf{Real}^{\uparrow}$ seal reached by the route, while excluding quotient stream equality, host real equality, choice of a selected limit, and ambient completeness from the consumer surface. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier stream regseq tail seal factorization`

Theorem 360.10 (RealCauchyCompletion tail selector fusion)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose completion read is served by a* $\mathsf{RegularCauchyName}^{\uparrow}$ *source and by a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *tail-budget meet over the same finite* $\mathsf{StreamName}^{\uparrow}$ *window. Every* $\mathsf{Real}^{\uparrow}$ *seal read of C factors through one finite route consisting of the* $\mathsf{StreamName}^{\uparrow}$ *tail-compatible window request, the* $\mathsf{RegularCauchyName}^{\uparrow}$ *dyadic-radius ledger, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *tail-budget meet, the* $\mathsf{Real}^{\uparrow}$ *name-seal source factorization, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

The fused route is exactly the displayed finite consumer packet. It has no quotient stream equality, no host real equality, no selected limit, no metric-completeness datum, and no ambient completeness coordinate.

Proof. Start with Definition 360.9. It places every completion-facing seal read on the route through the selected finite stream window, regular-sequence readback row, dyadic observation ledger, diagonal packet, and exported $\mathsf{Real}^{\uparrow}$ seal.

Next use the StreamName tail-compatible request and coverage rows, Definition 126.542 and Definition 126.543. They identify the finite window as the certified observation index, tail-selector route, finite-window budget surface, pointwise $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and shared support rows.

Attach the CauchyLimitSeal component by Definition 386.135 and Definition 386.137. The selector row, observation-budget row, dyadic ledger, regular handoff, real seal, transports, continuations, provenance, and local name are therefore read inside the same tail-budget meet.

Finally apply Definition 38.686. Repacking the shared StreamName, RegularCauchyName, CauchyLimitSeal, and Real name-seal rows gives one finite consumer route over BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$, with the listed quotient, host-equality, selected-limit, metric-completeness, and ambient-completeness coordinates absent. □

Theorem 360.11 (RealCauchyCompletion RegularCauchyName terminal handoff)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose regular-family input is read through an accepted* $\mathsf{RegularCauchyName}^{\uparrow}$ *source packet $G = (S, Q, \rho, L, E_G, P_G, N_G)$. Every completion-facing* $\mathsf{Real}^{\uparrow}$ *seal read of C factors through the RegularCauchyName finite window ledger L, the dyadic-radius row ρ, the* $\mathsf{StreamName}^{\uparrow}$ *schedule S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet D, and the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *seal row E.*

The handoff exports no quotient stream, no selected host limit, no host real equality, no ambient completeness row, and no metric-completeness row. It is a finite certificate route through the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *data of the two accepted packets.*

Proof. Start from the accepted $\mathsf{RegularCauchyName}^{\uparrow}$ packet G. By Definition 371.9, every precision read of G is exhausted by the displayed finite route through the stream schedule, dyadic observation row, dyadic-radius row, finite ledger, seal row, package provenance, and local certificate.

Use Definition 371.10 to identify the real-facing endpoint of that route. The $\mathsf{Real}^{\uparrow}$ seal exposed by G is reached only after the same dyadic-radius row, $\mathsf{StreamName}^{\uparrow}$ handoff, and $\mathsf{RegSeqRat}^{\uparrow}$ readback have been displayed as certificate rows.

Now pass to the accepted completion carrier C. By Definition 360.9, the completion-facing seal read factors through the selected finite stream window, the regular-sequence readback row, the dyadic observation ledger, the diagonal packet D, and then the exported $\mathsf{Real}^{\uparrow}$ seal row E.

Combining the two routes gives the terminal handoff from the RegularCauchyName finite ledger into the RealDiagonalCompletion packet and then into the RealCauchyCompletion seal row. Finally, Definition 360.4 excludes quotient streams, selected host limits, host real equality, ambient completeness, and metric-completeness data from the exported surface. □

Theorem 360.12 (RealCauchyCompletion ProbeBundle window coverage)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier, and let Q be a finite* ProbeBundle *of unary precision requests. For every request n bundled in Q, the consumer read factors through the displayed row $\mu(n)$, the associated* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet, one finite* $\mathsf{StreamName}^{\uparrow}$ *window, one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the corresponding* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger.*

Moreover, the whole bundled family repacks as a single finite consumer surface over BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The assembled surface carries the local* SemanticNameCert *whose carrier is the bundled row satisfying* hsame *with the surface,* UnaryHistory*, and* $\mathsf{Pkg}^{\mathrm{sig}}$*, whose pattern forgets only the* $\mathsf{Pkg}^{\mathrm{sig}}$ *row, whose ledger records* $\mathsf{Pkg}^{\mathrm{sig}}$ *together with* hsame*, and whose classifier is* hsame*. This surface contains no quotient stream, no selected host limit, no host real equality, and no ambient completeness object.*

Proof. Project the carrier by Definition 360.1. For each bundled precision request n, apply Definition 360.3 to obtain the route through $\mu(n)$, the diagonal packet D, the finite stream window, the regular-sequence readback row, and the dyadic observation ledger.

The selected row is the same row identified by Definition 360.7. Thus the bundled requests do not create separate hidden completion data; they reuse the displayed diagonal rows attached to the unary modulus.

Finally, apply Definition 360.8 to the family of reads. Since Q is finite, the pointwise routes assemble into one finite BHist consumer surface with the recorded hsame transports, Cont routes, Pkg provenance, and local NameCert row, and the same non-escape boundary is preserved for the bundle.

The checked Lean target supplies exactly this certificate row: its source predicate requires hsame with the bundle surface, UnaryHistory, and $\mathsf{Pkg}^{\mathrm{sig}}$; its pattern drops only $\mathsf{Pkg}^{\mathrm{sig}}$; its ledger keeps $\mathsf{Pkg}^{\mathrm{sig}}$ and hsame; and its classifier is the same hsame relation. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier probe bundle window coverage`

Theorem 360.13 (RealCauchyCompletion selector-refusal boundary)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier, and let Q be a finite* ProbeBundle *of precision requests. The bundled read determined by Q may use only the displayed modulus rows, the diagonal packet, the finite* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows, the* $\mathsf{Real}^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *data carried by C.*

The same bundled read cannot be reinterpreted as a selected host limit, a quotient stream equality, an ambient completeness object, or a host real equality. It remains a finite certificate-row read of the completion interface.

Proof. Apply Definition 360.12 to the finite request bundle Q. This routes every bundled precision request through the displayed modulus row, the finite stream window, the regular-sequence readback row, the dyadic observation ledger, and the assembled BHist consumer surface.

The selected diagonal row is the one fixed by Definition 360.7. Hence the bundle reuses the carrier's visible diagonal packet and does not acquire any separate completion coordinate beyond the rows already named by C.

For the consumer endpoint, use Definition 360.8. The only real-facing object reached by the bundle is the $\mathsf{Real}^{\uparrow}$ seal along the displayed Cont, Pkg, and NameCert route.

Finally apply Definition 360.4. It excludes selected host limits, quotient stream equality, host real equality, and ambient completeness from the exported surface, so the finite bundle remains a certificate-row read rather than a limit selector. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionUp StdBridge`

Theorem 360.14 (RealCauchyCompletion finite bundle induction)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier, and let Q be a finite* ProbeBundle *of unary precision requests. The completion-facing bundled read determined by Q is generated by induction on the constructors of Q.*

For the empty bundle, the generated surface is the empty finite consumer surface over the displayed Pkg *row P and* NameCert *row N. For an extension of a bundle by one unary precision request n, the generated surface appends the route through $\mu(n)$, the selected* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet D, one finite* $\mathsf{StreamName}^{\uparrow}$ *window, one* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, then fuses that route with the induction surface through the same* BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

Consequently every finite bundled completion read of C is a finite certificate-row route. It exports no quotient stream equality, no selected host limit, no host real equality, no countable-choice coordinate, no metric-completeness datum, and no ambient completeness object.

Proof. Induct on the finite ProbeBundle constructors. In the empty case there is no unary precision request to route, so the consumer surface is exactly the empty finite surface over the carrier's displayed Pkg and NameCert rows.

For the extension step, suppose the induction surface has already been generated for the previous bundle. Apply Definition 360.12 to the added unary request n inside the extended bundle. This supplies the route through $\mu(n)$, the finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the dyadic observation ledger, and the assembled consumer surface.

Use Definition 360.7 to identify the selected row with the carrier's displayed diagonal packet D. The new one-request route therefore has the same BHist, hsame, Cont, Pkg, and NameCert interface as the induction surface, so the two finite surfaces fuse without adding any host completion coordinate.

Finally apply Definition 360.13 and Definition 360.4. These keep quotient stream equality, selected host limits, host real equality, countable choice, metric-completeness data, and ambient completeness outside the generated finite route. □

Theorem 360.15 (RealCauchyCompletion obligation closure package)**.** *The carrier of Definition 360.1, the* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *obligation surface, the diagonal handoff, the non-escape boundary, and the Bishop reading jointly supply the full paper-side obligation surface for* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalCompletion}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$.

The package preserves the exclusions on quotient streams, host real equality, selected limits, and ambient completeness: every exported completion read is mediated by the displayed regular family row, unary modulus row, diagonal packet, finite stream window, regular-rational readback, dyadic observation ledger, $\mathsf{Real}^{\uparrow}$ *seal row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Proof. The carrier row is Definition 360.1. It lists the regular Cauchy family, modulus, diagonal packet, real seal, package provenance, and local certificate as finite packet coordinates.

The obligation surface is Definition 360.2. It binds carrier habitation, classifier stability, diagonal handoff, non-escape, and Bishop-style reading as the five rows consumed by the local certificate.

The diagonal and real-facing readback rows are Definition 360.3, Definition 360.7, and Definition 360.8, with finite bundle coverage supplied by Definition 360.12. They force every consumer

read through the modulus-selected diagonal packet, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, dyadic observation ledger, and $\mathsf{Real}^{\uparrow}$ seal.

The boundary and interpretation rows are Definition 360.4 and Definition 360.5. They record that the packet is a constructive regular-Cauchy completion interface while withholding quotient stream equality, host real equality, choice-selected limits, and ambient completeness.

Assembling these five displayed rows gives the stated paper-side obligation closure package. No extra coordinate is introduced, so the exclusions are preserved componentwise. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier obligation closure package`

Theorem 360.16 (RealCauchyCompletion regular-family source adequacy)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier. The visible regular-family source surface is adequate for the exported* $\mathsf{Real}^{\uparrow}$ *completion read precisely when every unary precision request factors through the same displayed rows already named by the carrier: the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row X, the modulus row μ, the* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet D, a finite* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the local* $\mathsf{Real}^{\uparrow}$ *seal row E, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Equivalently, the regular-family input route and the public $\mathsf{Real}^{\uparrow}$ *seal readback determine each other over exactly those rows. Neither direction includes a quotient stream, selected host limit, host real equality, ambient completeness, arithmetic package, order package, or metric-completeness row.*

Proof. For the forward direction, project C through Definition 360.1. The projection exposes X, μ, D, E, P, and N as the carrier coordinates available to a completion-facing consumer.

Apply Definition 360.3, Definition 360.7, and Definition 360.8. These rows force each unary precision request through the modulus-selected diagonal packet, one finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and the local $\mathsf{Real}^{\uparrow}$ seal row. For a finite request bundle, Definition 360.12 repacks the same pointwise route as one BHist consumer surface with the displayed hsame, Cont, Pkg, and NameCert rows.

For the reverse direction, start from a public completion read whose every unary request factors through precisely the listed rows. Repack the family row, modulus, diagonal packet, finite windows, dyadic ledger, seal row, provenance, and local naming row as the carrier coordinates of Definition 360.1.

Use Definition 360.2 to discharge the local carrier, classifier-stability, handoff, non-escape, and Bishop-reading obligations, then use Definition 360.15 to bind those obligations as the public $\mathsf{RealCauchyCompletion}^{\uparrow}$ package. The non-escape boundary of Definition 360.4 and the Bishop reading of Definition 360.5 exclude quotient streams, selected host limits, host real equality, ambient completeness, and the unrelated arithmetic, order, and metric-completeness rows from both readings. □

Theorem 360.17 (RealCauchyCompletion regular-name route agreement)**.** *Let $C = (X, \mu, D, E, P, N)$ be an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier. The* $\mathsf{RegularCauchyName}^{\uparrow}$ *regular-family input route and the* $\mathsf{CauchyCompletionMonad}^{\uparrow}$ *finite completion-transformer route determine the same public* $\mathsf{Real}^{\uparrow}$ *seal surface exactly when both routes factor through the displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RealDiagonalCompletion}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows attached to C.*

The agreement is a finite seal-surface agreement, not an equality of quotient streams, a selected limit, a host real equality, a trichotomy result, or an ambient completeness principle.

Proof. First read the regular-family side through Definition 360.16. It forces every unary precision request through the regular family row, modulus row, diagonal packet, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and the local $\mathsf{Real}^{\uparrow}$ seal row.

Next read the public seal side through Definition 360.18. This repacks the same rows as a public $\mathsf{Real}^{\uparrow}$-facing consumer surface over BHist, componentwise hsame, displayed Cont, Pkg provenance, and the local NameCert row.

Finally compare with the completion-transformer route of chapter 378. The unit boundary, diagonal-bind stability, schedule composition boundary, and public real-seal factorization there put every $\mathsf{CauchyCompletionMonad}^{\uparrow}$ read through the same finite window, dyadic-observation, regular-readback, diagonal, seal, transport, route, provenance, and naming rows. Since both routes reach the public seal only through this displayed surface, they agree exactly on that surface and on no host-level completion object. □

Theorem 360.18 (RealCauchyCompletion public real-name export)**.** *The carrier of Definition 360.1, the diagonal handoff, the non-escape boundary, carrier transport stability, modulus-diagonal exactness, real-seal readback scope,* ProbeBundle *window coverage, and obligation-closure package assemble into a public* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer export over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

The exported surface is the $\mathsf{Real}^{\uparrow}$*-facing name route through the displayed regular family row, unary modulus row,* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows, and the local certificate. It is not a quotient equality theorem, a host completeness theorem, or a proof of host equality of real numbers.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier public real name export`

Proof. Begin with the finite carrier of Definition 360.1. It supplies the regular family row, modulus, diagonal packet, real seal, package provenance, and local naming row that form the consumer-visible packet.

The diagonal route is supplied by Definition 360.3 and sharpened by Definition 360.7. These results force each precision read through the displayed modulus row, the associated diagonal packet, one finite stream window, one regular rational readback, and the dyadic observation ledger.

Transport and finite-window reuse are supplied by Definition 360.6 and Definition 360.12. They show that the same rows assemble over BHist, hsame, Cont, Pkg, and NameCert for finite consumer bundles.

Finally apply Definition 360.8, Definition 360.4, and Definition 360.15. These identify the public object as a $\mathsf{Real}^{\uparrow}$-facing name surface and preserve the exclusions on quotient stream equality, selected host limits, host real equality, and ambient completeness. □

Theorem 360.19 (RealCauchyCompletion regular-family input interface)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier binds its* $\mathsf{RegularCauchyFamily}^{\uparrow}$ *input rows to the completion carrier of Definition 360.1. The binding sends the regular family row X and unary modulus row μ to the diagonal packet D, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{Real}^{\uparrow}$ *seal row,* Pkg *provenance, and local* NameCert *row, all inside the displayed* BHist*,* hsame*, and* Cont *surface.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier regular family input interface`

Proof. Start with the completion carrier. Its coordinates explicitly contain the regular-family row, the unary modulus, the diagonal packet, the real seal, package provenance, and local naming certificate.

Apply the diagonal handoff of Definition 360.3. For each precision request, the modulus selects the family row that is read through one finite stream window, one regular-rational readback, and the dyadic observation ledger.

The exact selected row is the one identified by Definition 360.7. The $\mathsf{Real}^{\uparrow}$ seal then remains in the scope described by Definition 360.8, so the input rows are bound to the completion carrier without creating quotient stream equality, host real equality, or a selected host limit. □

Theorem 360.20 (RealCauchyCompletion downstream consumer handoff)**.** *For any accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier and any finite consumer request bundle, the downstream handoff is the route through the unary modulus, the* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *diagonal packet, the scheduled* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal,* Pkg*, and* NameCert*. The route is stable under the displayed* hsame *and* Cont *rows and exports no data outside that surface.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier downstream consumer handoff`

Proof. Apply Definition 360.12 to the finite bundle. Each request is reduced to the modulus-selected diagonal packet, its finite stream window, its regular-rational readback, and the dyadic observation rows.

Use Definition 360.6 to transport the same rows through the displayed hsame comparisons and Cont routes. Package provenance and the local naming row stay attached to the consumer-facing surface throughout the transport.

Finally, Definition 360.8 identifies the exported endpoint as the $\mathsf{Real}^{\uparrow}$ seal reached through that route. The non-escape boundary of Definition 360.4 excludes quotient streams, selected host limits, host real equality, and ambient completeness from the downstream handoff. □

Theorem 360.21 (RealCauchyCompletion CauchyLimitSeal route)**.** *An accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier and an accepted* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *packet determine the same public finite seal route exactly when both reads factor through the displayed* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *packet,* $\mathsf{Real}^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. This is the sibling seal route recorded by chapter 386; it is not a quotient-stream equality, a selected host-limit principle, or an ambient completeness theorem.*

Proof. Project the $\mathsf{RealCauchyCompletion}^{\uparrow}$ carrier by Definition 360.1. Its visible coordinates supply the regular-family row, unary modulus, diagonal packet, real seal, package provenance, and local certificate row.

Apply the diagonal handoff of Definition 360.3 and the public real-name export of Definition 360.18. These rows force every completion read through the displayed finite stream window, regular-rational readback, dyadic ledger, diagonal packet, real seal, BHist surface, componentwise hsame transport, displayed Cont route, Pkg provenance, and local NameCert row.

Compare this route with the $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer handoff of chapter 386. The sibling packet reaches its public seal through the same displayed windows, readbacks, dyadic observations, diagonal completion packet, seal row, transports, route records, provenance, and naming rows.

Since both public reads reach the seal only along this common finite surface, the two routes agree exactly on that surface. The non-escape boundary from Definition 360.4 keeps quotient streams, selected host limits, host real equality, and ambient completeness outside the conclusion. □

Theorem 360.22 (RealCauchyCompletion finite request fusion)**.** *Let C be an accepted* RealCauchyCompletion$^{\uparrow}$ *carrier, and let Q and Q' be finite* ProbeBundle *request surfaces for C. If the unary precision rows selected by Q and Q' are* hsame*-compatible, then their downstream handoff routes fuse into one finite* BHist *consumer packet over the same unary modulus,* RealDiagonalCompletion$^{\uparrow}$ *diagonal packet,* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readbacks,* DyadicRatCore$^{\uparrow}$ *observations,* Real$^{\uparrow}$ *seal,* Pkg *provenance, and* NameCert *row. The fused packet exports no quotient stream equality, selected host limit, host real equality, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier finite request fusion`

Proof. Apply the ProbeBundle window coverage theorem separately to Q and Q'. Each finite request surface is reduced to modulus-selected diagonal reads, scheduled stream windows, regular-rational readbacks, and dyadic observation rows from the accepted carrier.

Use the assumed hsame-compatibility of the unary precision rows to identify the modulus channel shared by the two surfaces. Modulus-diagonal exactness then places both request families on the same displayed diagonal packet and its associated finite windows.

Next apply carrier transport stability and the downstream consumer handoff. The two finite handoff packets are combined by finite packet union, while the stored hsame and Cont rows transport the readbacks, dyadic observations, real seal, provenance, and local naming row along the same carrier surface.

Finally inherit the non-escape boundary componentwise from the two handoffs. Since neither input packet contains a quotient stream, selected host limit, host real equality, or ambient completeness field, the fused finite consumer packet cannot export any such row. □

Theorem 360.23 (RealCauchyCompletion scoped consumer route)**.** *The regular-family input interface of Definition 360.19, the downstream handoff of Definition 360.20, and the obligation package of Definition 360.15 assemble the public consumer theorem for* RealCauchyCompletion$^{\uparrow}$*. Its scope is exactly the completion-facing route through* RegularCauchyFamily$^{\uparrow}$*, modulus selection, diagonal packet, finite windows, regular-rational readback, dyadic ledger,* Real$^{\uparrow}$ *seal,* ProbeBundle *coverage,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier scoped consumer route`

Proof. The input side is supplied by Definition 360.19. It binds the RegularCauchyFamily$^{\uparrow}$ rows to the carrier coordinates and to the modulus-selected diagonal readback route.

The consumer side is supplied by Definition 360.20. It packages finite request bundles through the same diagonal packet, stream windows, regular-rational readbacks, dyadic ledger, real seal, package provenance, and local certificate rows.

The package side is Definition 360.15. Together with carrier stability, modulus-diagonal exactness, real-seal readback scope, and the non-escape boundary, it gives a scoped public theorem about the concrete BEDC completion interface and nothing stronger than that interface. □

Theorem 360.24 (RealCauchyCompletion standard bridge boundary)**.** *The standard BEDC completion-interface reading of any accepted* RealCauchyCompletion$^{\uparrow}$ *carrier factors exactly through the displayed* RegularCauchyFamily$^{\uparrow}$ *row, the unary modulus row, the* RealDiagonalCompletion$^{\uparrow}$ *packet, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readbacks,* DyadicRatCore$^{\uparrow}$ *observations, the* Real$^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. This boundary exports no quotient stream, host equality of real numbers, selected limit, or ambient completeness theorem.*

Proof. Use Definition 360.19 to place the accepted carrier on the regular-family row, unary modulus row, diagonal packet, finite stream windows, regular-rational readbacks, dyadic observation ledger, real seal, package provenance, and local naming row.

The downstream side is then Definition 360.20. It shows that every finite consumer request reads the same visible route through BHist, hsame, Cont, Pkg, and NameCert.

Finally combine Definition 360.8 with Definition 360.4. These rows identify the exported endpoint as the $\mathsf{Real}^{\uparrow}$ seal and exclude quotient streams, host real equality, selected limits, and ambient completeness from the standard completion-interface reading. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier standard bridge boundary`

Theorem 360.25 (RealCauchyCompletion bridge handoff)**.** *The public real-name export of Definition 360.18, the regular-family input interface of Definition 360.19, the downstream consumer handoff of Definition 360.20, and the standard bridge boundary of Definition 360.24 jointly supply the paper bridge needed for the public-to-bridged* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *closure step.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier bridge handoff`

Proof. The public export supplies the $\mathsf{Real}^{\uparrow}$-facing name surface. The input interface pins that surface to the regular-family row, unary modulus, diagonal packet, stream windows, regular-rational readbacks, dyadic observations, package provenance, and local certificate.

The downstream handoff shows that all finite consumer bundles pass through the same rows, with hsame transport and Cont routes preserving the visible package. The standard boundary then records that this is exactly the standard BEDC completion-interface reading.

Composing these four displayed rows gives a paper bridge from the public certificate to the standard completion schema. The conclusion remains paper-side only: it does not assert machine bridge checking, quotient equality, host equality, selected limits, or ambient completeness. □

Theorem 360.26 (Real Cauchy completion mature limit-seal consumption)**.** *The regular-family row of Definition 360.19, the diagonal packet of Definition 360.3, finite* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{Real}^{\uparrow}$ *seal of Definition 360.8,* Pkg *provenance, and the* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *row jointly supply the finite consumer boundary used by downstream completion examples. The boundary is a limit-seal consumption surface and does not claim quotient equality of regular streams, host equality of real numbers, selected limits, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier mature limit seal consumption`

Proof. Start with an accepted carrier. The regular-family interface fixes the source rows and unary modulus, while the diagonal handoff identifies the scheduled packet through which each precision request is read.

The finite windows and dyadic ledger then give the concrete observation route. Each request exposes one $\mathsf{StreamName}^{\uparrow}$ window, its $\mathsf{DyadicRatCore}^{\uparrow}$ observations, and the corresponding $\mathsf{RegSeqRat}^{\uparrow}$ readback before any real-facing row is consumed.

The real-seal readback scope places the $\mathsf{Real}^{\uparrow}$ seal after that route. Package provenance and the local NameCert row attach the dependency certificates that downstream completion examples are allowed to cite.

Thus the mature consumer boundary is finite and seal-facing: it packages the regular-family row, diagonal packet, windows, dyadic ledger, regular readback, seal, provenance, and naming row.

Since no additional coordinate is introduced, quotient equality, host real equality, selected limits, and ambient completeness remain outside the claim. □

Theorem 360.27 (RealCauchyCompletion family tail synchronization)**.** *Let C and C' be accepted* RealCauchyCompletion$^{\uparrow}$ *carriers whose regular-family rows are classified through the* RegSeqRat$^{\uparrow}$ *common-refinement classifier, and let the requested precisions be carried by one finite* ProbeBundle*. Then the two* Real$^{\uparrow}$ *seal reads synchronize through a single displayed tail window before either seal is read.*

The window consists of the shared unary modulus bound selected from the two carriers, one StreamName$^{\uparrow}$ *window for the finite request bundle, one* RegSeqRat$^{\uparrow}$ *readback row supplied by the common refinement, and one* DyadicRatCore$^{\uparrow}$ *observation ledger. The synchronized route stays inside the rows of Definition 360.1,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*, and it exports no quotient equality of regular streams, host equality of real numbers, selected limit, or ambient* Real$^{\uparrow}$ *completeness theorem.*

Proof. Project the two accepted carriers through Definition 360.1. This exposes the two regular-family rows, their unary modulus rows, diagonal packets, finite stream-window ledgers, regular-rational readbacks, dyadic observation ledgers, real-seal rows, package provenance, and local naming rows.

Use the regular-family input interface of Definition 360.19 and the downstream consumer handoff of Definition 360.20. These two rows identify the only route by which a finite precision request may travel from the regular-family input to a seal-facing consumer read.

The RegSeqRat$^{\uparrow}$ common-refinement classifier and the StreamName$^{\uparrow}$ pointwise handoff supply the shared finite window. The unary modulus bound is read once for the bundled requests, and the same window feeds both regular-rational readback rows.

Finally read the corresponding DyadicRatCore$^{\uparrow}$ observation ledger before either Real$^{\uparrow}$ seal is consumed. The real-seal readback scope and non-escape boundary then show that both seal reads are synchronized by that displayed finite tail route, with no exported quotient stream, selected host limit, host real equality, or ambient completeness principle. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier family tail synchronization`

Theorem 360.28 (RealCauchyCompletion budgeted common refinement)**.** *Let C and C' be accepted* RealCauchyCompletion$^{\uparrow}$ *carriers whose regular-family rows classify through one* RegSeqRat$^{\uparrow}$ *common-refinement row, and let B be an accepted* RealObservationBudget$^{\uparrow}$ *packet carrying the same finite* ProbeBundle *request surface. Then the synchronized* Real$^{\uparrow}$ *seal route factors through one budgeted common-refinement packet.*

This packet consists exactly of the RealObservationBudget$^{\uparrow}$ *precision rows, finite* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *readbacks and displayed radii,* RegSeqRat$^{\uparrow}$ *handoff rows,* Real$^{\uparrow}$ *seal boundary, componentwise* hsame *transports, displayed* Cont *route replay,* Pkg *provenance, and local* NameCert *rows. It exports no quotient equality of regular streams, host real equality, selected limit, or ambient* Real$^{\uparrow}$ *completeness.*

Proof. Apply Definition 360.27 to the two accepted carriers and the shared finite request surface. This gives the common tail window through which both seal reads pass before either Real$^{\uparrow}$ seal is consumed.

Now read the accepted RealObservationBudget$^{\uparrow}$ packet. Window coverage in Definition 611.3 identifies the same finite StreamName$^{\uparrow}$ windows, while Definition 611.4 places every RegSeqRat$^{\uparrow}$ handoff after the precision row, windows, dyadic readbacks, and displayed radii.

The real seal boundary of Definition 611.5 puts the seal rows after those budget coordinates, and Definition 611.6 excludes quotient equality, host real equality, selected limits, ambient completeness, and hidden unbounded schedules from the packet.

Finally use Definition 360.20 to replay the synchronized route for downstream consumers, and use Definition 360.4 to keep the resulting route inside the displayed BHist, hsame, Cont, Pkg, and NameCert surface. Thus the completion synchronization and the observation budget are the same finite common-refinement packet at the consumer boundary. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier budgeted common refinement`

Theorem 360.29 (RealCauchyCompletion null-tail budget correspondence)**.** *Let C and C' be accepted* RealCauchyCompletion$^{\uparrow}$ *carriers whose regular-family rows are classified through one* RegSeqRat$^{\uparrow}$ *common-refinement row, and let one finite* ProbeBundle *carry the requested precision observations. On the displayed BEDC rows, the synchronized* Real$^{\uparrow}$ *seal route of Definition 360.27 is equivalent to giving one* NullSequence$^{\uparrow}$ *zero-tail packet whose tolerance-window package is carried by one* DyadicTailBound$^{\uparrow}$ *finite budget ledger.*

The correspondence lives only over BHist, hsame, Cont, Pkg, NameCert, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, NullSequence$^{\uparrow}$, DyadicTailBound$^{\uparrow}$, *and* Real$^{\uparrow}$. *It exports no quotient streams, selected limits, host real equality, trichotomy, or ambient completeness.*

Proof. Begin with the synchronized tail route. By Definition 360.27, both accepted completion carriers read the same finite tail window before either Real$^{\uparrow}$ seal is consumed; this window is built from the common RegSeqRat$^{\uparrow}$ refinement, the finite StreamName$^{\uparrow}$ request window, and the DyadicRatCore$^{\uparrow}$ observation ledger.

Turn that shared window into zero-tail evidence by applying Definition 380.10. The common-window requirement is supplied by Definition 380.13, so the two carrier reads are compared by one NullSequence$^{\uparrow}$ packet rather than by a host equality of limits.

Now account for the precision budget. Apply Definition 379.16 to package the tolerance windows into one finite DyadicTailBound$^{\uparrow}$ ledger, and apply Definition 379.8 to route the Real$^{\uparrow}$ seal through that ledger and the regular-rational readback.

Conversely, a NullSequence$^{\uparrow}$ zero-tail packet equipped with the stated DyadicTailBound$^{\uparrow}$ budget ledger determines the same displayed tail window for the finite request bundle. Re-reading it through the common RegSeqRat$^{\uparrow}$ refinement gives exactly the synchronized seal route, and all named transports remain inside the listed BEDC rows. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier null tail budget correspondence`

Theorem 360.30 (RealCauchyCompletion synchronized null-tail consumer)**.** *Let C and C' be accepted* RealCauchyCompletion$^{\uparrow}$ *carriers whose regular-family rows classify through one* RegSeqRat$^{\uparrow}$ *common-refinement row, and let one finite* ProbeBundle *carry the precision requests. Then the synchronized seal route and the null-tail dyadic-budget packet assemble into one consumer-visible* Real$^{\uparrow}$ *equality surface.*

This surface is exactly the finite BEDC route over BHist, hsame, Cont, Pkg, NameCert, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, NullSequence$^{\uparrow}$, DyadicTailBound$^{\uparrow}$, *and* Real$^{\uparrow}$*: two accepted carrier reads are equal for the consumer only by passing through the common tail window, the shared zero-tail certificate, the finite dyadic budget ledger, and the resulting* Real$^{\uparrow}$ *seal. It exports no quotient stream equality, selected limit, host real equality, trichotomy, or ambient completeness theorem.*

Proof. First build the common consumer route. Apply Definition 360.27 to the two accepted carriers and the shared ProbeBundle. This gives one finite tail window before either Real$^{\uparrow}$ seal is

consumed, with the window read through the common $\mathsf{RegSeqRat}^{\uparrow}$ refinement, the $\mathsf{StreamName}^{\uparrow}$ request window, and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger.

Next convert the synchronized window into the null-tail budget packet. Apply Definition 360.29. Its forward direction packages the same synchronized route as one $\mathsf{NullSequence}^{\uparrow}$ zero-tail packet equipped with one $\mathsf{DyadicTailBound}^{\uparrow}$ finite budget ledger; its reverse direction rereads such a packet as the same synchronized seal route.

The certificate ingredients are the displayed null-sequence and dyadic-tail rows. Use Definition 380.10 and Definition 380.13 for the shared zero-tail window, then use Definition 379.16 and Definition 379.8 for the finite tolerance ledger and its $\mathsf{Real}^{\uparrow}$ seal factorization.

Combining these rows gives a reusable consumer equality surface rather than a stronger equality principle. Every transport still runs through BHist, hsame, Cont, Pkg, NameCert, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{NullSequence}^{\uparrow}$, $\mathsf{DyadicTailBound}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, so quotient streams, selected limits, host real equality, trichotomy, and ambient completeness remain outside the claim. □

Lean4 ✓ `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionCarrier synchronized null tail consumer`

Theorem 360.31 (RealCauchyCompletion tail-budget coherence consumer)**.** *Every accepted* RealCauchyCompletio *carrier $C = (X, \mu, D, E, P, N)$ whose diagonal packet consumes a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row reads its completion-facing* $\mathsf{Real}^{\uparrow}$ *seal only after the regular-family row, unary modulus row, diagonal packet, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the tail-budget row of chapter 906 have been displayed. The consumer route excludes quotient stream equality, selected limits, host real equality, and ambient completeness.*

Proof. Project the accepted carrier through Definition 360.1. This exposes the regular-family row X, unary modulus μ, diagonal packet D, completion-facing seal E, package provenance P, and local naming row N.

Apply the diagonal handoff of Definition 360.3. The precision request must pass through μ, the diagonal packet D, one finite $\mathsf{StreamName}^{\uparrow}$ window, one $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger before the seal row can be read.

Now read the consumed $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ row from chapter 906. Its observation gate supplies the tail-threshold, finite observation service, window service, dyadic ledger, regular readback, and seal handoff that the diagonal packet is using as its budget-row source.

Finally use the real-seal readback scope of Definition 360.8 and the downstream consumer handoff of Definition 360.20. They keep the completion-facing seal inside the displayed regular-family, modulus, diagonal, finite-window, readback, dyadic-ledger, tail-budget, hsame, Cont, Pkg, and NameCert route, so no quotient stream equality, selected limit, host real equality, or ambient completeness is exported. □

Theorem 360.32 (RealCauchyCompletion tail-budget seal route)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose diagonal packet consumes a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row and whose completion-facing seal is compared through a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *packet over the same finite* $\mathsf{StreamName}^{\uparrow}$ *window reads its* $\mathsf{Real}^{\uparrow}$ *seal only through the finite route consisting of that* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the tail-budget threshold, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *tail-budget meet of chapter 386, the* $\mathsf{Real}^{\uparrow}$ *seal, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

The route exports no quotient streams, selected limits, host real equality, trichotomy, countable choice, or ambient completeness principle.

Proof. Project the accepted carrier through Definition 360.1. This displays the completion carrier as its regular-family row, unary modulus, diagonal packet, completion-facing seal, package provenance, and local naming row.

Apply the diagonal handoff of Definition 360.3. The same finite $\mathsf{StreamName}^{\uparrow}$ window must carry the precision request through the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{DyadicRatCore}^{\uparrow}$ ledger before the completion-facing seal can be consumed.

Now apply Definition 360.31. It forces the diagonal packet to expose the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ threshold and its finite observation service inside the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ route.

Attach the sibling seal packet from chapter 386. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ route compares the completion-facing seal over the same finite window and meets the tail-budget row before the $\mathsf{Real}^{\uparrow}$ seal is read.

Finally use Definition 360.8. Since both the completion carrier and the seal packet have already been routed through the finite window, readback row, dyadic ledger, tail-budget threshold, $\mathsf{CauchyLimitSeal}^{\uparrow}$ meet, structural transports, package provenance, and local naming row, the exported surface contains no quotient streams, selected limits, host real equality, trichotomy, countable choice, or ambient completeness. □

Theorem 360.33 (RealCauchyCompletion tail-fusion budget consumer)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose diagonal packet consumes both a* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *row and a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row reaches its* $\mathsf{Real}^{\uparrow}$ *seal only through the finite route consisting of the regular-family row, unary modulus row, diagonal packet, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *shared-threshold row of chapter 658, the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *budget row of chapter 906, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row.*

The resulting consumer route exports no quotient stream equality, selected limit, host real equality, trichotomy, or ambient completeness principle.

Proof. Start with the displayed completion carrier. The family-tail synchronization row identifies the shared finite tail window through which the regular-family input, unary modulus, diagonal packet, $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{DyadicRatCore}^{\uparrow}$ ledger must pass before any $\mathsf{Real}^{\uparrow}$ seal is read.

Next add the budgeted common-refinement row. It places the same synchronized window under the finite budget surface used by the consumer request bundle, so the precision rows, displayed radii, regular readback, dyadic observations, hsame transports, Cont routes, Pkg provenance, and local naming rows are read as one packet.

Now read the synchronized null-tail consumer row together with the tail-budget coherence consumer row. The null-tail row supplies the consumer-visible equality surface over the shared tail window, while the tail-budget row forces the diagonal packet to expose the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ budget ledger before the completion-facing seal is consumed.

Finally insert the $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ shared-threshold row into that route. The tail-fusion packet contributes only the finite cofinal threshold and seal-facing handoff already named by its public consumer surface; it does not introduce quotient stream equality, a selected host limit, host real equality, trichotomy, or ambient completeness. Hence the $\mathsf{RealCauchyCompletion}^{\uparrow}$ seal is reached exactly through the finite fusion-and-budget route stated above. □

Theorem 360.34 (RealCauchyCompletion tail-cofinality schedule factorization)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose diagonal packet consumes a* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *row, a*

NullSequence$^{\uparrow}$ *zero-tail packet, and the tail-budget and tail-fusion rows of Definition 360.31 and Definition 360.33 reaches its* Real$^{\uparrow}$ *seal only through the displayed finite schedule factorization.*

That factorization consists exactly of the regular-family row, unary modulus, diagonal packet, the TailCofinalitySchedule$^{\uparrow}$ *finite-window route, the* NullSequence$^{\uparrow}$ *zero-tail package,* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. It exports no quotient streams, selected limits, host real equality, trichotomy, or ambient completeness.*

Proof. Start with the accepted completion carrier and apply Definition 360.33. This forces every seal-facing consumer to expose the regular-family row, unary modulus, diagonal packet, finite StreamName$^{\uparrow}$ windows, DyadicRatCore$^{\uparrow}$ ledger, RegSeqRat$^{\uparrow}$ readback, fusion row, budget row, structural transports, provenance, and local naming row before the Real$^{\uparrow}$ seal is read.

Next read Definition 360.30. It identifies the same finite tail window with the NullSequence$^{\uparrow}$ zero-tail package and the dyadic budget ledger, so the consumer-visible equality surface is still a displayed BEDC packet rather than a quotient stream or selected host limit.

Now insert the TailCofinalitySchedule$^{\uparrow}$ packet. The schedule real-seal readback theorem Definition 681.6 orders the schedule rows as the unary request, finite window, dyadic ledger, regular-rational readback, and real seal. The scoped-binding theorem Definition 681.8 keeps that route inside BHist, hsame, Cont, Pkg, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, and the local NameCert row.

Combining these three routes gives a single factorization from the completion diagonal packet to the Real$^{\uparrow}$ seal. Since each cited route excludes quotient streams, selected limits, host real equality, trichotomy, ambient completeness, hidden tail oracles, and unbounded schedules, the assembled carrier reaches the seal only through the finite schedule and null-tail rows named in the statement. □

Theorem 360.35 (RealCauchyCompletion tail schedule budget exhaustion)**.** *Every accepted* RealCauchyCompletion *carrier whose diagonal packet consumes* TailCofinalitySchedule$^{\uparrow}$*,* RegularCauchyTailBudget$^{\uparrow}$*,* RegularCauchyTailFusion NullSequence$^{\uparrow}$*, and an accepted* RealObservationBudget$^{\uparrow}$ *finite request bundle has a single consumer-visible route through exactly the regular-family row, unary modulus, diagonal packet, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger, tail-budget row, tail-fusion shared-threshold row, null-tail zero package, observation-budget precision rows,* Real$^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and local* NameCert*.*

The route exports no quotient stream equality, selected limit, host real equality, trichotomy, countable choice, or ambient completeness.

Proof. Begin with the accepted completion carrier and apply Definition 360.34. The diagonal packet is already forced through the regular-family row, unary modulus, TailCofinalitySchedule$^{\uparrow}$ finite-window route, NullSequence$^{\uparrow}$ zero-tail packet, DyadicRatCore$^{\uparrow}$ ledger, StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, Real$^{\uparrow}$ seal, hsame, Cont, Pkg, and local NameCert.

Next apply Definition 360.33. It refines the same seal-facing route by making the RegularCauchyTailFusion$^{\uparrow}$ shared-threshold row and the RegularCauchyTailBudget$^{\uparrow}$ budget row explicit before the completion seal is read.

Apply the budgeted common-refinement theorem Definition 360.28. It supplies the finite consumer window for the accepted RealObservationBudget$^{\uparrow}$ request bundle. Read it together with the tail-budget coherence theorem Definition 360.31; this keeps each precision row inside the displayed StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, hsame, Cont, Pkg, and local naming route.

Now use the synchronized null-tail consumer theorem Definition 360.30. It identifies the same finite window with the NullSequence$^{\uparrow}$ zero-tail package, so the route has one shared carrier packet rather than separate schedule, budget, fusion, null-tail, and observation-budget exits.

Finally apply the RealObservationBudget$^{\uparrow}$ non-escape theorem Definition 611.6. Intersecting the exclusions from the schedule factorization, fusion-budget consumer, budgeted common refinement, synchronized null-tail consumer, and observation-budget row removes quotient stream equality, selected limits, host real equality, trichotomy, countable choice, and ambient completeness from the exported surface. What remains is exactly the finite consumer-visible route named in the statement. □

Theorem 360.36 (RealCauchyCompletion bounded-monotone witness consumer)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose regular-family input is supplied by an accepted* BoundedMonotoneCauchyWitne *packet reads its completion-facing* Real$^{\uparrow}$ *seal through exactly the bounded source row, scheduled* StreamName$^{\uparrow}$ *windows, Cauchy witness modulus, dyadic tolerance ledger, located trap,* RegSeqRat$^{\uparrow}$ *readback, diagonal completion packet, observation-budget request bundle, local* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The route is completion-facing only in this displayed sense. It exports no selected limit, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient completeness principle.

Proof. Start with the accepted BoundedMonotoneCauchyWitness$^{\uparrow}$ packet. The completion boundary theorem Definition 535.30 keeps every completion-facing read inside the bounded source, regular-rational handoff, stream schedule, Cauchy witness, dyadic ledger, located trap, Real$^{\uparrow}$ seal, transport, route, provenance, and local naming rows.

Next use the tail-window service theorem Definition 535.25. It forces each tolerance request to pass through the scheduled StreamName$^{\uparrow}$ windows, the Cauchy witness modulus, and the dyadic tolerance ledger before the located trap or any seal-facing row can be read.

Now apply the Real seal handoff theorem Definition 535.12. This places the Real$^{\uparrow}$ seal after the bounded source row, RegSeqRat$^{\uparrow}$ readback, scheduled windows, Cauchy witness, dyadic ledger, and located trap, so the completion carrier receives a displayed regular-family input rather than an external limiting object.

Finally compose this input route with the RealCauchyCompletion$^{\uparrow}$ consumer rows. The diagonal handoff, downstream consumer handoff, and tail schedule budget exhaustion theorems Definition 360.3, Definition 360.20, and Definition 360.35 add the diagonal completion packet, observation-budget request bundle, BHist carrier surface, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert rows. Since none of the cited packets contains a coordinate for selected limits, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient completeness, the assembled completion-facing witness route exposes exactly the rows named in the statement. □

Theorem 360.37 (RealCauchyCompletion uniform criterion seal factorization)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose diagonal packet consumes an accepted* UniformCauchyCriterion$^{\uparrow}$ *row and a* CauchyLimitSeal$^{\uparrow}$ *row reaches its* Real$^{\uparrow}$ *seal only through the same finite seal route. That route consists of the regular-family row, unary modulus, uniform shared-tail threshold, Cauchy-limit seal selector, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

The factorization exports no quotient streams, selected limits, host real equality, trichotomy, countable choice, or ambient completeness principle.

Proof. Start with the accepted completion carrier and apply Definition 360.3. The diagonal packet already routes the regular-family input, unary modulus, finite windows, regular-rational readback,

dyadic ledger, transport rows, continuation routes, package provenance, and local naming rows before the completion-facing seal is read.

Use Definition 360.18 and Definition 360.35. They keep the public $\mathsf{Real}^{\uparrow}$ seal on the displayed completion route and make the finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows explicit.

Attach the uniform criterion side through Definition 435.4 and Definition 435.68. The accepted criterion contributes the shared family threshold and its refined finite-window route, not a quotient family or selected limiting object.

Now attach the Cauchy-limit seal side through Definition 386.30 and Definition 386.5. These rows pull the uniform criterion back to the same scheduled windows and require the seal selector, dyadic observation ledger, regular readback, transports, routes, provenance, and local naming rows before any $\mathsf{Real}^{\uparrow}$ consumer read.

The combined route is therefore one finite BEDC packet: regular family, unary modulus, uniform shared-tail threshold, Cauchy-limit selector, windows, readback, dyadic ledger, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$. The non-escape clauses in the completion, uniform-criterion, and Cauchy-limit-seal rows exclude quotient streams, selected limits, host real equality, trichotomy, countable choice, and ambient completeness from the exported seal. □

Theorem 360.38 (RealCauchyCompletion witness-ledger classifier lock)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier whose completion-facing consumer also reads an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet* $L = (Q, B, S, K, H, C, P, N)$ *reaches the public* $\mathsf{Real}^{\uparrow}$ *seal through the completion-seal classifier only by the shared finite route*

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

The shared route is read together with the $\mathsf{RealCauchyCompletion}^{\uparrow}$ *regular-family row, unary modulus, diagonal packet,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

The consumer-side lock is relative to the witness-ledger surface of chapter 902 and the completion-seal classifier surface of chapter 900. It exports no quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.

Proof. Start with the accepted $\mathsf{RealCauchyCompletion}^{\uparrow}$ carrier. The public real-name export theorem Definition 360.18 keeps the public $\mathsf{Real}^{\uparrow}$ read on the displayed completion route, and Definition 360.37 factors that route through the regular-family row, unary modulus, diagonal packet, finite windows, regular-rational readback, dyadic ledger, transports, continuations, provenance, and local naming rows.

Now read the accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ packet. The Real-completion handoff Definition 902.9 places every Real-facing ledger consumer on the displayed completion route. The synchronizer-classifier lock Definition 902.14 orders that route as $Q \longmapsto B \longmapsto S \longmapsto K$, and the ledger-exhaustion theorem Definition 902.12 removes any public coordinate outside Q, B, S, K, H, C, P, N and the structural rows.

Finally identify the two consumer paths at the shared classifier row K. The RealCauchyCompletion path supplies the completion-facing public $\mathsf{Real}^{\uparrow}$ seal, while the witness ledger supplies the same finite budget, observation, synchronizer, and classifier route. Since both cited chapters expose only the displayed BEDC rows, the combined consumer cannot export quotient stream equality, host real equality, a selected external limit, a countable-choice row, or an ambient completeness theorem. □

Theorem 360.39 (RealCauchyCompletion witness-ledger uniform seal route)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose completion-facing route is also read through an accepted* CauchyWitnessLedger$^{\uparrow}$ *packet and an accepted* UniformCauchyCriterion$^{\uparrow}$ *packet factors through one finite seal route. The route consists exactly of the regular-family row, unary modulus, diagonal packet, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* CauchyWitnessLedger$^{\uparrow}$ *budget, synchronizer, and classifier rows,* UniformCauchyCriterion$^{\uparrow}$ *shared-threshold rows, the public* Real$^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The combined route exports no quotient stream, selected host limit, host real equality, countable-choice row, second family-limit route, or ambient Real$^{\uparrow}$ *completeness principle.*

Proof. Start with the completion-facing seal. The uniform criterion seal factorization theorem Definition 360.37 places the accepted RealCauchyCompletion$^{\uparrow}$ carrier on the finite regular-family, unary-modulus, diagonal-packet, window, readback, dyadic-ledger, transport, continuation, package, naming, and public Real$^{\uparrow}$ seal route.

Next read the witness-ledger side. The witness-ledger classifier lock Definition 360.38 identifies the completion-seal classifier with the shared finite route through the ledger budget, observation, synchronizer, and classifier rows, and Definition 902.55 exhausts downstream completion consumers at those displayed ledger rows.

Finally attach the uniform criterion consumer surface. The downstream Real consumer export Definition 435.21 and the Real-completion budget lock Definition 435.131 keep every RealCauchyCompletion$^{\uparrow}$ read behind the same shared-threshold and finite-window rows. Intersecting the three non-escape clauses leaves no coordinate for quotient streams, selected host limits, host real equality, countable choice, a second family-limit route, or ambient Real$^{\uparrow}$ completeness, so the sole exposed route is the finite BEDC packet named in the statement. □

Theorem 360.40 (RealCauchyCompletion shared-tail modulus consumer route)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose diagonal packet consumes an accepted* CauchySharedTailModulus$^{\uparrow}$ *row reaches the public* Real$^{\uparrow}$ *seal through a single finite route. The route consists of the regular-family row, unary modulus, shared-tail threshold, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The route is relative to the shared-tail modulus surface of chapter 983. It exports no quotient streams, selected limits, host real equality, countable-choice row, or ambient completeness principle.

Proof. Project the accepted completion carrier. The public real-name export theorem, Definition 360.18, keeps the Real$^{\uparrow}$ seal on the displayed completion path, while the diagonal handoff and downstream consumer handoff theorems bind that path to the regular-family row, unary modulus, finite windows, regular-rational readback, dyadic ledger, transports, continuations, provenance, and local naming rows.

Now attach the accepted CauchySharedTailModulus$^{\uparrow}$ packet. Its consumer contribution is the shared-tail threshold for the same tail comparison, not a separate limit selector or quotient-stream equality.

Combining the two projections gives one displayed route from the completion diagonal packet to the public seal. The exclusions in the completion and shared-tail surfaces remove quotient streams, selected limits, host real equality, countable choice, and ambient completeness from the exported carrier. □

Theorem 360.41 (RealCauchyCompletion dyadic tail-radius ledger route)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose diagonal packet consumes an accepted* DyadicTailRadiusLedger$^{\uparrow}$ *row reaches the public*

Real$^{\uparrow}$ *seal only after the dyadic tail-radius ledger has been displayed. The finite route is the regular-family row, unary modulus, shared tail request, dyadic tail-radius ledger, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The route is relative to the dyadic ledger surface of chapter 757. It exports no quotient-stream representative, selected limit, host real equality, countable-choice row, or ambient completeness theorem.

Proof. Start from the displayed completion route supplied by Definition 360.35. This already places the public seal after the regular-family row, unary modulus, finite StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ ledger, diagonal packet, transports, continuations, provenance, and local naming rows.

Insert the DyadicTailRadiusLedger$^{\uparrow}$ packet at the tail-radius step. Its ledger row records the dyadic tolerance and radius accounting used by the same finite windows, so the completion consumer reads a displayed dyadic budget rather than an external completeness witness.

The resulting path is still the completion path. Since neither the completion route nor the dyadic ledger surface contains a coordinate for quotient representatives, selected limits, host real equality, countable choice, or ambient completeness, the public seal can only be reached through the rows named in the statement. □

Theorem 360.42 (RealCauchyCompletion CauchyCriterion sibling route)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose diagonal packet consumes accepted* CauchySharedTailModulus$^{\uparrow}$*,* DyadicTailRadiusLedger$^{\uparrow}$*, and* CauchyCriterion$^{\uparrow}$ *rows reaches the public* Real$^{\uparrow}$ *seal only through the combined finite rows of the regular-family row, unary modulus, shared-tail threshold, dyadic tail-radius ledger, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

The combined route is relative to chapter 983, chapter 757, and chapter 392. It exports no quotient streams, selected limits, host real equality, countable-choice row, or ambient completeness principle.

Proof. First apply the shared-tail modulus route above. It identifies the completion seal path with the regular-family row, unary modulus, shared-tail threshold, scheduled windows, readback, dyadic ledger, structural transport, provenance, and local naming rows.

Next apply the dyadic tail-radius ledger route above. It shows that the same scheduled windows must expose their dyadic radius accounting before the public Real$^{\uparrow}$ seal is consumed.

Finally attach the sibling CauchyCriterion$^{\uparrow}$ packet. Its role is to certify the Cauchy-condition route for the displayed shared threshold and dyadic ledger, not to import a selected limit or ambient completeness theorem.

The three sibling routes therefore assemble one completion-seal consumer packet. Because each component route is confined to BHist, hsame, Cont, Pkg, and NameCert rows and excludes quotient streams, selected limits, host real equality, countable choice, and ambient completeness, the carrier reaches the public seal only through the finite rows listed in the statement. □

Theorem 360.43 (RealCauchyCompletion diagonal seal uniformity)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose diagonal packet consumes the same displayed* CauchyCriterion$^{\uparrow}$ *row and the same singleton or fixed finite-family* UniformCauchyCriterion$^{\uparrow}$ *rows factors through one finite completion route. The route consists of the regular-family row, shared unary modulus, dyadic tolerance, tail ledger, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* Real$^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The diagonal seal therefore exports no quotient streams, selected limits, host real equality, countable choice, ambient completeness principle, or second family-limit route. A downstream $\mathsf{Completion}^{\uparrow}$ *or* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer reads only the displayed finite seal path.*

Proof. First apply Definition 360.42. It places the completion seal behind the regular-family row, unary modulus, finite stream windows, regular-rational readback, dyadic ledger, $\mathsf{Real}^{\uparrow}$ seal, and structural BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Next use Definition 392.29. The displayed $\mathsf{CauchyCriterion}^{\uparrow}$ packet and the singleton or fixed finite-family $\mathsf{UniformCauchyCriterion}^{\uparrow}$ packet share the same modulus, dyadic tolerance, tail ledger, stream-name source, regular-rational tail, and real-seal rows, so the family route restricts to the same finite CauchyCriterion path.

Finally apply Definition 435.21. Its downstream consumer clause keeps the $\mathsf{Real}^{\uparrow}$ seal on the uniform finite-family route. Intersecting the non-escape clauses from the three cited routes removes quotient streams, selected limits, host real equality, countable choice, ambient completeness, and any second family-limit route from the diagonal seal. □

Theorem 360.44 (RealCauchyCompletion StreamName RegSeqRat Real seal correspondence)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *packet whose regular family, unary modulus, diagonal packet, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and* $\mathsf{Real}^{\uparrow}$ *seal rows are displayed determines exactly the same public finite-window seal boundary as the composed handoff*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

Conversely, any consumer that uses this composed handoff must factor through the displayed $\mathsf{RealCauchyCompletion}^{\uparrow}$ *regular-family, diagonal, stream-window, readback, dyadic-ledger, and real-seal rows before it reads a limit-seal boundary.*

The correspondence is relative to the finite-name, regular-sequence, dyadic, and real-name surfaces of chapter 126, chapter 301, chapter 291, and chapter 38. It exports no quotient stream, selected limit, host real equality, countable-choice row, or ambient completeness principle.

Proof. First use Definition 360.9. It places the finite $\mathsf{StreamName}^{\uparrow}$ windows and $\mathsf{RegSeqRat}^{\uparrow}$ readback on the same tail-seal route as the accepted completion packet, so the stream-to-regular handoff is not a separate public boundary.

Next apply Definition 360.18. This exports the public $\mathsf{Real}^{\uparrow}$ seal only through the displayed completion packet and the finite rows carried by the sibling $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ chapters.

Use Definition 360.19 to identify the input side of the route with the regular-family row and unary modulus. Then apply Definition 360.43, which keeps the diagonal packet and the real-seal consumer on one finite completion path.

For the converse, take any consumer of the composed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ handoff. The cited factorization and export theorems force its stream windows, regular-rational readback, dyadic ledger, and real seal to pass through the displayed completion rows before a limit-seal boundary is available. The sibling chapters supply exactly those finite public surfaces, so no consumer can bypass the $\mathsf{RealCauchyCompletion}^{\uparrow}$ rows while still reading the advertised boundary. □

Theorem 360.45 (RealCauchyCompletion four-face exit uniqueness)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *public completion read that exports a* $\mathsf{Real}^{\uparrow}$ *seal through the L10 phase route has a unique finite support spine, up to displayed* hsame *transport and common-refinement comparison of finite windows.*

The spine consists of

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

together with the local BHist*,* Cont*,* Pkg*, and* NameCert *rows carried by the accepted completion packet.*

Any purported public route that omits one of the four faces, duplicates a second seal boundary, or replaces a face by quotient stream equality, selected limits, host real equality, countable choice, or ambient completeness is not classifier-equivalent to the accepted public $\mathsf{RealCauchyCompletion}^{\uparrow}$ *route.*

Proof. Begin with the StreamName-RegSeqRat-Real seal correspondence, Definition 360.44. It identifies the public seal boundary with the composed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ handoff and keeps the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger on the same displayed completion path.

Next apply current four-face phase support, Definition 360.52, and terminal support minimality, Definition 360.51. These results force every accepted L10 phase read to display the four faces and the local BHist, hsame, Cont, Pkg, and NameCert rows; removing or replacing any one of them collapses the route rather than producing another public completion witness.

Now compare two accepted presentations. Pull both to a certified finite common refinement of their stream windows and use Definition 360.56. The pulled-back routes determine the same BEDC completion witness, so the only variation left is the displayed hsame transport and the finite-window cover used to present the same support spine.

It remains to exclude alternate exits. Terminal support defect localization, Definition 360.54, places any missing face, missing support row, duplicated seal boundary, or substituted quotient, selected-limit, host-equality, choice, or completeness coordinate at a named defect. Such a presentation is therefore not classifier-equivalent to the accepted public route. □

Theorem 360.46 (RealCauchyCompletion tail-budget uniform seal boundary)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *packet whose finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *tail selector, dyadic budget row, and* $\mathsf{Real}^{\uparrow}$ *endpoint seal satisfy the StreamName-RegSeqRat tail-budget uniformity hypotheses has a uniform completion-facing seal boundary. Every later finite window accepted by the same pointwise* $\mathsf{StreamName}^{\uparrow}$ *classifier factors through the same displayed completion route.*

Consequently the completion seal exports no new limit selector, quotient stream, host equality, countable-choice row, ambient completeness datum, or second completion-facing boundary beyond the displayed regular-family row, unary modulus, diagonal packet, finite stream windows, regular-rational readback, dyadic budget ledger, $\mathsf{Real}^{\uparrow}$ *endpoint seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Start with Definition 360.44. It identifies the public completion seal boundary with the composed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ handoff, relative to the displayed regular-family, diagonal, stream-window, readback, dyadic-ledger, and real-seal rows.

Next apply Definition 126.105. For every later finite window accepted by the same pointwise StreamName classifier, the RegSeqRat tail selector and the RealUp budget consumer read the same tail-budget certificate. Thus enlarging the finite window changes only the visible window ledger.

Transport this uniform handoff back through Definition 360.9 and Definition 360.18. The first theorem keeps the StreamName windows and RegSeqRat readback on the completion tail-seal route, and the second theorem exposes the public RealUp seal only through the displayed completion rows.

The non-escape clauses of the cited routes now intersect at the same boundary: the later windows share one completion-facing route and cannot introduce a fresh limit selector, quotient stream, host equality, countable-choice row, ambient completeness datum, or second seal boundary. □

Theorem 360.47 (RealCauchyCompletion witness-ledger observation-budget route)**.** *Every accepted* RealCauchyCompletion$^{\uparrow}$ *carrier whose completion-facing consumer is read through both an accepted* CauchyWitnessLedger$^{\uparrow}$ *packet and an accepted* RealObservationBudget$^{\uparrow}$ *packet reaches the public* Real$^{\uparrow}$ *seal only through one shared finite route. The route consists exactly of the regular-family row, unary modulus, diagonal packet, finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger, witness-ledger budget, synchronizer, and classifier rows, observation-budget precision, window, and disclosure rows,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

The route exports no quotient equality of regular streams, host real equality, selected limit, hidden unbounded observation schedule, or ambient Real$^{\uparrow}$ *completeness principle.*

Proof. First apply the witness-ledger classifier lock Definition 360.38. It places the completion-facing public seal behind the regular-family row, unary modulus, diagonal packet, finite windows, regular-rational readback, dyadic ledger, and witness-ledger budget, synchronizer, and classifier rows. The uniform seal route Definition 360.39 keeps this consumer path on the same finite seal boundary.

Next apply the budgeted common-refinement theorem Definition 360.28. The accepted RealObservationBudget$^{\uparrow}$ packet supplies the precision rows, finite StreamName$^{\uparrow}$ windows, dyadic readbacks, regular handoffs, seal boundary, hsame transports, Cont replay, Pkg provenance, and local NameCert rows for the same request surface.

Finally intersect the observation-budget window coverage, real-seal boundary, and non-escape rows from Definition 611.3, Definition 611.5, and Definition 611.6. The two readings therefore share one finite completion-facing route, and all omitted objects stay outside the public Real$^{\uparrow}$ seal. □

Theorem 360.48 (RealCauchyCompletion finite-window completion coverage)**.** *For every accepted* RealCauchyCompletion$^{\uparrow}$ *packet and every finite* ProbeBundle *of unary precision requests, the completion-facing* Real$^{\uparrow}$ *seal read is exhausted by the displayed finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback rows,* DyadicRatCore$^{\uparrow}$ *observation ledger, diagonal packet,* Real$^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The exhausted route is the same finite-name path from StreamName$^{\uparrow}$ *through* RegSeqRat$^{\uparrow}$ *and* DyadicRatCore$^{\uparrow}$ *into* Real$^{\uparrow}$*. It exports no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness coordinate, or completion principle beyond those displayed certificate rows.*

Proof. First apply Definition 360.12. It turns the finite ProbeBundle into one consumer surface whose pointwise requests pass through the displayed modulus rows, finite StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ readback rows, DyadicRatCore$^{\uparrow}$ ledgers, and the structural BHist, hsame, Cont, Pkg, and NameCert data.

Next use the StreamName handoff and the sibling finite-window coverage rows for regular sequences, dyadic observations, and real-name seals. These identify each window read as the same finite route from StreamName$^{\uparrow}$ to RegSeqRat$^{\uparrow}$, then through DyadicRatCore$^{\uparrow}$ observation data into the public Real$^{\uparrow}$ seal.

Finally apply Definition 360.44 together with the non-escape boundary of Definition 360.4. The composed route is therefore the only completion-facing seal read available to the accepted packet,

and quotient streams, selected limits, host real equality, countable choice, ambient completeness, and any hidden completion coordinate remain outside the exported surface. □

Theorem 360.49 (RealCauchyCompletion monadic four-face exit correspondence)**.** *For every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *packet whose visible rows are the regular-family row, unary modulus, diagonal packet, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*, the public L10 four-face exit coincides with the finite completion-transformer route read through* $\mathsf{CauchyCompletionMonad}^{\uparrow}$*.*

Both readings expose exactly the same four roadmap objects $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Neither reading adds quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, or bridge-axis evidence.*

Proof. Start with Definition 360.44. It identifies the public completion seal with the finite handoff through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while keeping the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger on the same displayed completion route.

Apply Definition 360.48. Every finite precision request is exhausted by the displayed windows, readbacks, dyadic ledger, diagonal packet, real seal, and structural BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, so the L10 exit has no additional coordinate.

Now read the same boundary through chapter 378. Its unit, bind, public seal, finite-window exhaustion, and standard completion-boundary rows use the same four roadmap objects as the completion transformer. Intersecting the non-escape clauses on both sides gives one shared four-face exit and excludes quotient streams, selected limits, host real equality, countable choice, ambient completeness, and bridge-axis evidence. □

Theorem 360.50 (RealCauchyCompletion monadic unit-bind locality)**.** *For every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *packet whose public read is compared with an accepted* $\mathsf{CauchyCompletionMonad}^{\uparrow}$ *unit-and-bind route, the unit packet, bind packet, and downstream completion consumer factor through the same displayed L10 four-face route*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The shared route carries the same BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows as the direct* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *read.*

The comparison is local to that route. It introduces no second completion source, quotient stream, selected limit, host equality, countable-choice row, ambient completeness principle, or bridge-axis evidence.

Proof. Begin with the monadic four-face exit correspondence of Definition 360.49. It identifies the direct $\mathsf{RealCauchyCompletion}^{\uparrow}$ public read with the $\mathsf{CauchyCompletionMonad}^{\uparrow}$ completion-transformer read on the same four roadmap objects.

Next apply the Kleisli source triangle Definition 378.50. The unit source, bind source, and downstream consumer source are forced through the displayed finite route, so the monadic interface does not add another completion origin.

Now use the finite-route correspondence of Definition 378.49. The unit and bind packets inherit the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows already visible on the direct completion read, and the downstream consumer reads those rows rather than a separate quotient or selected-limit coordinate.

Finally intersect this monadic route with the terminal support minimality and non-escape rows local to this chapter. The only available unit-bind support is the displayed L10 four-face route,

while second completion sources, quotient streams, selected limits, host equality, countable choice, ambient completeness, and bridge-axis evidence remain outside the accepted public surface. □

Theorem 360.51 (RealCauchyCompletion terminal support minimality)**.** *Every accepted public L10 completion read through* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *retains the four displayed faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

It also retains the visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows carried by the completion packet. Deleting or replacing any one of these four faces, or deleting any one of the displayed structural rows, collapses the public completion route rather than producing another BEDC completion witness.*

The minimality claim is internal to the public L10 completion surface. It does not identify quotient streams, choose limiting representatives, import host real equality, assume countable choice, assert ambient completeness, or add bridge-axis evidence.

Proof. Start with the composed public seal handoff of Definition 360.44. That result identifies the completion boundary with the displayed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ route, while the dyadic ledger remains the finite observation support for the same read. Thus the four faces appear as part of one route, not as replaceable decorations around the carrier.

Next apply Definition 360.48. Every finite precision request is exhausted by the displayed windows, readbacks, dyadic ledger, diagonal packet, real seal, and the structural BHist, hsame, Cont, Pkg, and NameCert rows. Removing one of these rows removes a named step used by the public request surface.

Now compare the same terminal read with the monadic four-face exit correspondence of Definition 360.49. The $\mathsf{CauchyCompletionMonad}^{\uparrow}$ reading and the direct $\mathsf{RealCauchyCompletion}^{\uparrow}$ reading expose the same four roadmap objects, so replacing a face does not yield another advertised completion exit; it changes the route outside the correspondence.

Finally use the non-escape boundary of Definition 360.4. Quotient streams, selected limits, host real equality, countable choice, ambient completeness, and bridge-axis evidence are excluded from the carrier surface. With no excluded object available as substitute support, any deletion or replacement collapses the public L10 completion route rather than yielding a second BEDC completion witness. □

Theorem 360.52 (RealCauchyCompletion current four-face phase support)**.** *A Phase Real and Completion exit read through* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *is valid only when the four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

are all present as the displayed completion route. The same read must also display the BHist *histories, componentwise* hsame *transports,* Cont *replay rows,* Pkg *provenance row, and local* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *support rows carried by the accepted completion packet.*

Thus $\mathsf{RealCauchyCompletion}^{\uparrow}$ *supplies the roadmap-facing Phase Real and Completion exit exactly as a four-face BEDC support condition. It supplies no quotient stream equality, host real equality, selected limit, countable-choice row, ambient completeness principle, or bridge-axis evidence in place of any one of the four faces or support rows.*

Proof. First apply Definition 360.51. It says that every accepted public L10 completion read through $\mathsf{RealCauchyCompletion}^{\uparrow}$ retains the four displayed faces and the visible BHist, hsame, Cont,

Pkg, and NameCert support rows, and that deleting or replacing any one of them collapses the completion route.

Next use Definition 360.49. The direct RealCauchyCompletion$^{\uparrow}$ reading and the CauchyCompletionMonad$^{\uparrow}$ completion-transformer reading expose the same four roadmap objects, so the local completion route is already the Phase Real and Completion route rather than a separate completion-only support condition.

Finally compose with the Real-side exit criterion Definition 38.732. That criterion accepts a Phase Real and Completion endpoint read exactly when DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and the local Real$^{\uparrow}$ seal appear in order with their local records and the shared BHist, hsame, Cont, Pkg, and NameCert rows.

The excluded coordinates are removed by the non-escape clauses in the three cited results. Quotient streams, host real equality, selected limits, countable choice, ambient completeness, and bridge-axis evidence are not support rows of the four-face packet, so none can serve as substitute evidence for the phase exit read. □

Theorem 360.53 (RealCauchyCompletion four-face status noncollapse)**.** *A Phase Real and Completion exit read through* RealCauchyCompletion$^{\uparrow}$ *whose route displays*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

and the shared BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows reads* closurestatus*,* formalstatus*,* leantarget*, and* bridgestatus *only from the four local face records.*

The same route has no aggregate formalstatus row, replacement leantarget, route-level bridge credential, standard bridge row, selected limit, quotient stream equality, host real equality, countable-choice row, metric-completeness datum, ambient completeness principle, or Real$^{\uparrow}$ *completeness coordinate.*

Proof. First apply Definition 360.52. It identifies the Phase Real and Completion read through RealCauchyCompletion$^{\uparrow}$ with the displayed four faces and with the shared BHist, hsame, Cont, Pkg, and NameCert support rows.

Next use Definition 38.732 and Definition 38.792. These results read the roadmap exit object-wise from the DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and local Real$^{\uparrow}$ face records. Therefore the closure, verification, Lean-target, and bridge-status rows remain face-local reports.

It remains to rule out aggregate status substitutes. Apply Definition 38.833 and Definition 38.834. They block a route-level formalstatus row, replacement leantarget, aggregate bridge credential, or standard bridge row from replacing the four local face reports.

Finally apply the non-escape boundary of Definition 360.4. Quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, and bridge-axis evidence are outside the accepted completion carrier. Together with the face-local status reading, this also excludes metric-completeness data and a separate Real$^{\uparrow}$ completeness coordinate from the current four-face route. □

Theorem 360.54 (RealCauchyCompletion terminal support defect localization)**.** *Let a Phase Real and Completion exit read through* RealCauchyCompletion$^{\uparrow}$ *be presented as a public BEDC completion route. If that presentation omits or replaces any one of the four faces*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow}$$

or omits or replaces any visible BHist*,* hsame*,* Cont*,* Pkg*, or* NameCert *support row carried by the accepted completion packet, then the failure is witnessed at that named face or support row. The presentation is therefore not an accepted BEDC completion route through* RealCauchyCompletion$^{\uparrow}$*.*

No quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness principle, or bridge-axis evidence can repair the failed presentation or move the failure away from the omitted or replaced face or support row.

Proof. Apply the terminal support minimality theorem, Definition 360.51. It states that every accepted public L10 completion read retains the four displayed faces and the visible BHist, hsame, Cont, Pkg, and NameCert support rows, and that deleting or replacing any one of them collapses the route.

Next apply the monadic four-face exit correspondence of Definition 360.49. The direct $\mathsf{RealCauchyCompletion}^{\uparrow}$ read and the $\mathsf{CauchyCompletionMonad}^{\uparrow}$ read expose the same four roadmap objects, so a defect in one of those faces cannot be transferred to a different completion-transformer coordinate.

Now use Definition 360.52 together with the Real-side criterion Definition 38.732. These results identify the Phase Real and Completion endpoint with the ordered $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ route and with the same local BHist, hsame, Cont, Pkg, and NameCert rows. Hence the failed presentation has a named local witness: exactly the face or support row that is absent or replaced.

Finally apply the non-escape boundary of Definition 360.4. Quotient streams, selected limits, host equality, countable choice, ambient completeness, and bridge-axis evidence are outside the accepted carrier surface. Since no excluded coordinate is available as substitute support, the malformed presentation is rejected at the located face or row and is not a BEDC completion route through $\mathsf{RealCauchyCompletion}^{\uparrow}$. □

Theorem 360.55 (RealCauchyCompletion terminal support refinement invariance)**.** *Let $\mathcal{P}$ be a coarse public L10 completion route through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*, and let $\mathcal{Q}$ be a finite certified refinement of $\mathcal{P}$. Suppose both presentations display the same four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and suppose every refined member, refined overlap, and comparison map preserves the same visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows carried by the accepted completion packet. Then the route accepted from $\mathcal{P}$ and the route accepted from $\mathcal{Q}$ determine the same BEDC completion witness through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*.*

This comparison changes only the finite cover presentation of the terminal four-face route. It introduces no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, or bridge-axis evidence.*

Proof. First apply terminal support minimality, Definition 360.51, and current four-face phase support, Definition 360.52. Both the coarse route and the refined route must therefore be read from the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces together with the same visible BHist, hsame, Cont, Pkg, and NameCert support rows.

Next localize possible differences by Definition 360.54. Since every refined member, overlap, and comparison map preserves the named faces and support rows, no defect can be moved to a new completion coordinate. The only remaining difference is the finite cover by which the same terminal route is presented.

Apply the DyadicRatCore finite-cover comparison, Definition 291.120. It identifies the dyadic ledger and the four-face exit packet obtained from the coarse cover with the one obtained from the refined cover, because both presentations preserve the displayed DyadicRatCore, StreamName, RegSeqRat, Real, and support rows.

Finally use RegSeqRat common-tail cocycle descent, in particular Definition 301.211. The common-tail members, overlaps, and cocycle rows glue to the same Real seal-visible boundary and the same Phase $\mathsf{Real}^{\uparrow}$ and Completion audit-threshold coordinate. Thus the refined presentation changes only the finite support cover, while the accepted public completion witness through $\mathsf{RealCauchyCompletion}^{\uparrow}$ remains the same. □

Theorem 360.56 (RealCauchyCompletion terminal support common-refinement comparison)**.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be accepted public L10 completion routes through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*. Suppose there is a certified finite common refinement $\mathcal{R}$ of the two presentations such that, after pullback to $\mathcal{R}$, both routes display the same four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and preserve the same visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows carried by the accepted completion packet. Then $\mathcal{P}$ and $\mathcal{Q}$ determine the same BEDC completion witness through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*.*

The comparison is entirely internal to the certified common finite support. It introduces no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or bridge-axis evidence.*

Proof. First pull the two accepted presentations back to the common refinement $\mathcal{R}$. By terminal support minimality, Definition 360.51, both pulled-back routes are still read from the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and from the same visible BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply terminal support defect localization, Definition 360.54. Since the hypotheses preserve every named face and every support row after pullback to $\mathcal{R}$, a disagreement between the two accepted presentations cannot be relocated to a hidden completion coordinate.

Use terminal support refinement invariance, Definition 360.55, on the refinement from $\mathcal{P}$ to $\mathcal{R}$ and again on the refinement from $\mathcal{Q}$ to $\mathcal{R}$. Thus each original route determines the same BEDC completion witness as its pulled-back route on the certified common support.

It remains to identify the pulled-back terminal support itself. Apply Definition 126.221 to form the shared StreamName finite window, then Definition 126.405 to read the common terminal Real seal over that window. Finally use Definition 301.211 to keep the RegSeqRat common-tail atlas and dyadic ledger invariant over the same pullback.

The non-escape clauses in the preceding results rule out all substitute coordinates. Quotient streams, selected limits, host equality, countable choice, ambient completeness, metric-completeness data, aggregate status rows, bridge rows, and bridge-axis evidence are not part of the visible terminal support, so they cannot distinguish the two accepted completion witnesses. □

Theorem 360.57 (RealCauchyCompletion terminal support refinement composition)**.** *Let $\mathcal{P}$, $\mathcal{Q}$, and $\mathcal{R}$ be public L10 completion routes through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*. Suppose $\mathcal{Q}$ is a finite certified refinement of $\mathcal{P}$, and $\mathcal{R}$ is a finite certified refinement of $\mathcal{Q}$. Suppose also that every refined member, overlap, and comparison map in both refinements preserves the same four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the same visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows carried by the accepted completion packet. Then $\mathcal{P}$ and $\mathcal{R}$ determine the same BEDC completion witness through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*.*

The successive comparison remains internal to the terminal four-face route. It introduces no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or bridge-axis evidence.*

Proof. First apply terminal support refinement invariance, Definition 360.55, to the certified refinement $\mathcal{P} \to \mathcal{Q}$. The coarse route $\mathcal{P}$ and the intermediate route $\mathcal{Q}$ therefore read the same accepted BEDC completion witness from the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and the same visible support rows.

Apply the same theorem again to the certified refinement $\mathcal{Q} \to \mathcal{R}$. Since the second refinement preserves the same faces, overlaps, comparison maps, and BHist, hsame, Cont, Pkg, and NameCert rows, the intermediate route $\mathcal{Q}$ and the final route $\mathcal{R}$ also determine one completion witness.

It remains to exclude a new coordinate appearing only at the intermediate stage. Use terminal support defect localization, Definition 360.54. Any proposed difference between the two comparisons would have to be witnessed by an omitted or replaced face or support row, but the hypotheses preserve every named face, overlap, comparison map, and support row across both refinements.

Finally apply the non-escape boundary of Definition 360.4. Quotient streams, selected limits, host equality, countable choice, ambient completeness, and bridge-axis evidence are outside the accepted carrier surface, and the status and bridge rows cannot aggregate outside the four local face records. Thus the two certified refinement steps compose without changing the BEDC completion witness determined through $\mathsf{RealCauchyCompletion}^{\uparrow}$. □

Theorem 360.58 (RealCauchyCompletion terminal support refinement cocycle)**.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be two finite certified terminal-support refinements of one public L10 completion route through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*. Suppose both refinements preserve the same four faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and the same visible BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows carried by the accepted completion packet. Suppose moreover that the two refinements carry the same* $\mathsf{RegSeqRat}^{\uparrow}$ *common-tail pairwise packets on every retained overlap, and that their triple-overlap rows satisfy the same common-tail cocycle over the terminal four-face support. Then $\mathcal{P}$ and $\mathcal{Q}$ determine the same BEDC completion witness through* $\mathsf{RealCauchyCompletion}^{\uparrow}$*.*

The path through a finite refinement diagram is therefore independent of the certified terminal-support cover. The comparison introduces no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or bridge-axis evidence.*

Proof. First restrict both refinements to the displayed terminal support. By terminal support minimality, Definition 360.51, and terminal support defect localization, Definition 360.54, every accepted comparison must be witnessed on the named $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and on the same BHist, hsame, Cont, Pkg, and NameCert rows.

Next compare the dyadic and four-face ledgers. The finite-cover refinement invariance theorem Definition 291.120 identifies the DyadicRatCore exit ledger obtained from either certified support cover, since the endpoint, radius, stream-window, regular-sequence, Real, and support rows are the same.

Now descend the common-tail data. Apply Definition 301.191 to the shared pairwise packets and triple-overlap rows, and then use Definition 301.198. These two results identify the two refined RegSeqRat common-tail presentations as one terminal four-face cocycle boundary.

Finally pass from the common terminal boundary to the completion witness. The Real L10 terminal four-face correspondence, Definition 38.455, repacks the DyadicRatCore, StreamName, RegSeqRat, and Real rows as the accepted terminal four-face read, and Definition 38.458 forbids a second pullback over the same visible rows. Together with terminal support refinement composition, Definition 360.57, this shows that both finite paths determine the same BEDC completion witness through $\mathsf{RealCauchyCompletion}^{\uparrow}$.

The exclusion clauses follow from the cited support and terminality results. None of the comparison data carries a quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus row, aggregate bridge row, standard bridge row, or bridge-axis evidence, so no such coordinate can distinguish the two certified refinement paths. □

Theorem 360.59 (RealCauchyCompletion request-section terminal exhaustion)**.** *For every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier and every finite* ProbeBundle *of unary precision requests, the terminal completion-facing read is exhausted by one finite request-section route through*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and through the displayed BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. Any other request-section route that agrees on these four faces and support rows is classifier-equivalent to it after finite common refinement.*

The exhausted route exports no quotient stream, selected limit, host real equality, countable-choice row, ambient completeness principle, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, or bridge-axis evidence.*

Proof. Start with the finite probe bundle. The probe-bundle window coverage theorem, Definition 360.12, replaces the unary precision requests by a finite completion window without adding any completion coordinate beyond the accepted carrier surface.

Apply finite-window completion coverage, Definition 360.48. This identifies the window with the four-face request-section route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, together with the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Now compare another route agreeing on those rows. Use terminal support common-refinement comparison, Definition 360.56, to pull the two request-section presentations to a certified finite common refinement. Then terminal support refinement cocycle, Definition 360.58, makes the resulting classifier independent of the finite support cover chosen along the way.

It remains to exclude hidden support. Terminal support defect localization, Definition 360.54, places any missing or substituted face or support row at the named local defect. The non-escape boundary, Definition 360.4, prevents quotient streams, selected limits, host real equality, countable choice, ambient completeness, metric-completeness data, aggregate status rows, aggregate bridge rows, and bridge-axis evidence from serving as replacement output. Thus the finite request-section route exhausts the accepted terminal completion read. □

Theorem 360.60 (RealCauchyCompletion terminal exit locality)**.** *Every accepted terminal exit read through* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *for the Phase Real and Completion boundary factors through exactly the four local faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with the shared BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows carried by the accepted completion packet. The locality assertion is facewise: the dyadic ledger, finite stream windows,*

regular-rational readback, and local real seal remain separate rows, and no route-level status or bridge coordinate replaces any one of them.

The terminal read therefore has no quotient-stream row, selected-limit row, host real equality row, countable-choice row, metric-completeness datum, aggregate formalstatus *row, aggregate bridge row, standard bridge row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Start with the request-section terminal exhaustion theorem, Definition 360.59. It exhausts every finite unary request bundle by a route through the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces and through the listed support rows.

Apply terminal support minimality, Definition 360.51, and current four-face phase support, Definition 360.52. These results force the same four faces to remain present for any accepted terminal read and prevent a replacement face from presenting the same completion witness.

The face-local status reading is supplied by Definition 360.53 together with Definition 38.792. The closure, verification, Lean-target, and bridge-status information is read from the four component records rather than from an aggregate route row.

Finally use the sibling route inventory. The CauchyCriterion route, Definition 360.42, the Real-side terminal correspondence Definition 38.455, and the RegSeqRat consumer normal form Definition 301.175 all expose only the same finite rows. Their non-escape clauses exclude quotient streams, selected limits, host equality, countable choice, metric-completeness data, aggregate status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness from the terminal exit surface. □

Theorem 360.61 (RealCauchyCompletion terminal exit normal form)**.** *For an accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier, the terminal Phase Real and Completion exit certificate has the following normal form. It is a finite BEDC packet whose four visible faces are exactly*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and whose only shared support rows are BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. A consumer reads the dyadic observation ledger, then the finite stream-window schedule, then the regular-rational readback and common-tail rows, and finally the local* $\mathsf{Real}^{\uparrow}$ *seal through those support rows.*

Conversely, any accepted terminal packet exposing precisely those four faces with the same displayed support rows determines the same Phase Real and Completion exit certificate. The normal form excludes quotient streams, selected limits, host real equality, countable-choice rows, metric-completeness data, aggregate formalstatus *rows, aggregate bridge rows, standard bridge rows, and* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. For the forward direction, apply terminal exit locality, Definition 360.60. Every accepted terminal read has already been reduced to the four named faces and the shared support rows.

Next identify the order of the rows. The request-section terminal exhaustion theorem, Definition 360.59, supplies the finite request route, while Definition 126.372 and Definition 291.110 align the stream-window, dyadic-ledger, RegSeqRat, and Real rows with the Phase Real and Completion exit surface.

For the reverse direction, suppose a terminal packet exposes exactly the four faces and support rows listed in the statement. Apply the Real L10 terminal four-face correspondence, Definition 38.455, to repack the displayed rows as the accepted terminal $\mathsf{Real}^{\uparrow}$ read. Then use terminal pullback uniqueness, Definition 38.458, and the RegSeqRat four-face terminal pullback, Definition 301.58, to identify the same completion-facing boundary.

It remains to rule out additional coordinates in the normal form. Terminal support defect localization, Definition 360.54, makes any missing, duplicated, or substituted face a named local

defect. The four-face status noncollapse theorem, Definition 360.53, and the non-escape boundary, Definition 360.4, remove quotient streams, selected limits, host equality, countable choice, metric-completeness data, aggregate status rows, aggregate bridge rows, standard bridge rows, and ambient $\mathsf{Real}^{\uparrow}$ completeness from the accepted packet. □

Theorem 360.62 (RealCauchyCompletion terminal exit support invariance)**.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be accepted terminal exit presentations of the same* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier. Suppose both presentations expose the four local faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

and preserve the same BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows after passage to a certified finite common refinement. Then $\mathcal{P}$ and $\mathcal{Q}$ determine the same terminal Phase Real and Completion exit certificate.*

The invariant certificate is exactly the normal form of Definition 360.61. It is unaffected by the choice of finite support cover and contains no quotient streams, selected limits, host real equality, countable-choice rows, metric-completeness data, aggregate formalstatus *rows, aggregate bridge rows, standard bridge rows, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. First pass both presentations to the certified finite common refinement. Terminal support common-refinement comparison, Definition 360.56, identifies the pulled-back routes whenever the four faces and the shared support rows agree there.

Next remove dependence on the chosen finite support cover. Terminal support refinement invariance, Definition 360.55, and terminal support refinement cocycle, Definition 360.58, show that the path through the refinement diagram changes only the cover presentation, not the BEDC completion witness.

Now repack the common refined support by the terminal exit normal form, Definition 360.61. The repacked packet has exactly the DyadicRatCore, StreamName, RegSeqRat, Real, and support rows listed in the statement, so both original presentations read the same Phase Real and Completion certificate.

The exclusion clauses are inherited from the same normal form and from terminal support defect localization, Definition 360.54. Any alleged difference outside the displayed rows would have to be a quotient stream, selected limit, host equality, choice row, metric-completeness datum, aggregate status row, aggregate bridge row, standard bridge row, or ambient $\mathsf{Real}^{\uparrow}$ completeness coordinate, and none of these is part of the accepted terminal support. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RealCauchyCompletion}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$-indexed regular Cauchy family, an explicit unary modulus, a $\mathsf{RealDiagonalCompletion}^{\uparrow}$ diagonal packet, finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ observations, a $\mathsf{Real}^{\uparrow}$ seal row, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper scope is the public real-name export, standard bridge boundary, and limit-seal consumer surface through the displayed regular-family row, unary modulus, diagonal packet, finite windows, regular-rational readback, dyadic ledger, $\mathsf{Real}^{\uparrow}$ seal, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.RealCauchyCompletionUp.RealCauchyCompletionUp\_StdBridge`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close $\mathsf{Real}^{\uparrow}$ completeness, quotient equality of regular streams, uniqueness of limits, or host real construction.

Upgrade path: No further formal-axis upgrade remains for the checked standard bridge over the same finite regular-family, diagonal, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, Pkg, and NameCert rows.

Theorem 360.63 (RealCauchyCompletion sibling lattice route)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *public seal route factors through the already displayed sibling surfaces chapter 126, chapter 301, chapter 291, and chapter 38, with chapter 371 supplying the regular-family input route.*

Equivalently, a public $\mathsf{RealCauchyCompletion}^{\uparrow}$ *read is a finite five-sibling NameCert factorization through the regular-family input, stream window, regular-rational readback, dyadic observation ledger, and exported* $\mathsf{Real}^{\uparrow}$ *seal. It exports no quotient stream, no selected host limit, no host real equality, no countable-choice row, and no ambient completeness coordinate.*

Proof. Start with an accepted $\mathsf{RealCauchyCompletion}^{\uparrow}$ carrier. The diagonal handoff of Definition 360.3 routes each precision request through the modulus row, the diagonal packet, one finite $\mathsf{StreamName}^{\uparrow}$ window, one $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger.

Next apply the stream-regseq-tail seal factorization, Definition 360.9. It keeps the same stream window, regular-rational readback, dyadic ledger, diagonal packet, and $\mathsf{Real}^{\uparrow}$ seal on one completion-facing route, so the sibling surfaces are not optional decorations around the carrier.

The regular-family side enters through chapter 371. The terminal handoff of Definition 360.11 identifies that input as the finite RegularCauchyName ledger feeding the same stream schedule, dyadic-radius row, regular readback, diagonal packet, and exported seal.

Finally use the real seal readback scope of Definition 360.8 and the public real-name export of Definition 360.18. These rows expose the consumer-facing endpoint only as the displayed $\mathsf{Real}^{\uparrow}$ seal over BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data, and Definition 360.4 excludes quotient streams, selected host limits, host real equality, countable choice, and ambient completeness from the public route. □

Theorem 360.64 (RealCauchyCompletion four-face support nondegeneracy)**.** *Every accepted* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *public completion read that reaches the exported* $\mathsf{Real}^{\uparrow}$ *seal exhibits all four Phase Real and Completion faces*

$$\mathsf{DyadicRatCore}^{\uparrow}, \qquad \mathsf{StreamName}^{\uparrow}, \qquad \mathsf{RegSeqRat}^{\uparrow}, \qquad \mathsf{Real}^{\uparrow}$$

together with the displayed BHist*, componentwise* hsame*,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RealCauchyCompletion}^{\uparrow}}$ *rows.*

The route is nondegenerate: deleting any one of the four faces, or deleting any one of the displayed support rows, changes the accepted packet read. It does not preserve the same public completion read through $\mathsf{RealCauchyCompletion}^{\uparrow}$*.*

Proof. Start with the accepted public completion read. The diagonal handoff of Definition 360.3 forces each precision request through the diagonal packet, one finite $\mathsf{StreamName}^{\uparrow}$ window, one $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ ledger before the seal can be consumed.

Next apply the stream-regseq-tail seal factorization Definition 360.9. It keeps the stream window, regular readback, dyadic ledger, diagonal packet, and exported $\mathsf{Real}^{\uparrow}$ seal on one completion-facing route. The sibling lattice route Definition 360.63 then identifies these rows with the four named sibling faces of the public NameCert factorization.

Now use the current four-face phase support theorem Definition 360.52. It reads the same route as the Phase Real and Completion exit and requires the visible BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows alongside $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Finally apply terminal support minimality and defect localization, Definition 360.51 and Definition 360.54. These results say that omitting or replacing any named face or support row is

witnessed at that same local row and leaves the accepted route. Hence such a deletion changes the packet read rather than preserving the same public completion read. □

Theorem 360.65 (RealCauchyCompletion exact-boundary downstream route)**.** *Every* RealCompletionExactBound *consumer of the* RealCauchyCompletion$^{\uparrow}$ *completion route factors through the* RealCauchyCompletion$^{\uparrow}$ *four-face support surface. The consumed route is the finite packet over* StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, *and* Real$^{\uparrow}$ *together with the displayed* BHist, hsame, Cont, Pkg, *and local* NameCert *support rows.*

The downstream consumer exports no quotient stream, no selected host limit, no host real equality, no countable-choice row, and no ambient completeness row. It is a consumer of the four-face completion route, not an isolated completion object.

Proof. Start with an accepted RealCompletionExactBoundaryUp consumer of the completion route. By Definition 1120.6, the exact-boundary packet exposes exactly the four completion-facing faces StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$ after its governing seal, classifier, witness-ledger, and budget rows.

Now read the same four faces on the RealCauchyCompletion$^{\uparrow}$ side. The sibling lattice route Definition 360.63 places every public seal read on the finite route through the regular-family input, stream window, regular-rational readback, dyadic observation ledger, and exported Real$^{\uparrow}$ seal.

Apply Definition 360.64. It says that the public completion read is nondegenerate exactly when the four faces and the visible BHist, hsame, Cont, Pkg, and NameCert support rows are present. Therefore the exact-boundary consumer can read the completion route only through that support surface.

Finally use Definition 360.4. Since the completion carrier has no coordinate for quotient streams, selected host limits, host real equality, countable choice, or ambient completeness, the downstream exact-boundary read cannot export any of those rows. It remains a finite consumer of the displayed four-face route. □

Theorem 360.66 (RealCauchyCompletion exact-boundary bidirectional pullback)**.** *Let an accepted* RealCauchyCompletion$^{\uparrow}$ *carrier and an accepted* RealCompletionExactBoundaryUp *packet display the same finite* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *tolerance ledger, terminal* Real$^{\uparrow}$ *seal, and the same* BHist, hsame, Cont, Pkg, *and local* NameCert *support rows. Then the* RealCauchyCompletion$^{\uparrow}$ *public completion read factors through the* RealCompletionExactBoundaryUp *terminal consumer, and conversely the exact-boundary terminal consumer restricts back to the* RealCauchyCompletion$^{\uparrow}$ *four-face support surface.*

The pullback exports no quotient stream, no selected host limit, no host real equality, no countable-choice row, no metric-completeness row, no bridge row, and no ambient completeness row. It is exactly the shared finite four-face support route.

Proof. Start with the shared-support hypotheses. The downstream route theorem Definition 360.65 already places every exact-boundary consumption of the RealCauchyCompletion$^{\uparrow}$ completion route on the four-face surface carried by StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, and the displayed structural rows.

For the forward direction, apply Definition 1120.13. Since the exact-boundary packet displays the same four faces and the same BHist, hsame, Cont, Pkg, and local NameCert rows, its terminal consumer is the finite route through those rows. The public RealCauchyCompletion$^{\uparrow}$ read therefore factors through that terminal consumer and not through any separate completion coordinate.

For the reverse direction, apply Definition 360.64. The terminal exact-boundary consumer can agree with the public completion read only while retaining the same four faces and the same support

rows. Thus the exact-boundary terminal consumer restricts back to the $\mathsf{RealCauchyCompletion}^{\uparrow}$ four-face support surface.

It remains to exclude outside witnesses. The exact-boundary side is bounded by Definition 1120.14, while the completion side is bounded by Definition 360.4. Together these remove quotient streams, selected host limits, host real equality, countable choice, metric completeness, bridge rows, and ambient completeness from both directions. Hence the two accepted readings meet precisely in the shared finite support pullback. □

Chapter 361

A Concrete Naming Certificate for $\mathsf{DyadicBisection}^{\uparrow}$

The $\mathsf{DyadicBisection}^{\uparrow}$ interface names the finite bisection ledger used by real-and-completion consumers when an interval is refined by midpoint comparison. In the Bishop–Bridges constructive-analysis reading, bisection is a located finite interval process with explicit precision control; in the Moore interval-analysis reading, it is a finite enclosure refinement ledger. BEDC records the certificate rows themselves, not an analytic host search, a completed real intersection, or a hidden decision procedure.

The bisection carrier consumes the endpoint and dyadic-radius rows supplied by chapter 354, chapter 306, and chapter 291. These rows provide the initial endpoint carrier, the midpoint and dyadic-radius tolerance ledger, and the finite comparison scale needed before the packet can expose nested-window data or hand off a $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ read.

Definition 361.1 (DyadicBisection carrier)**.** *A* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (I, \pi, M, L, J, E, R, S, H, C, P, N)$$

with the following visible coordinates:

1. *I is the initial* $\mathsf{RationalInterval}^{\uparrow}$ *row, including the endpoint order and endpoint readback rows used by downstream interval consumers;*
2. *π is the unary precision row that names the requested finite stopping window;*
3. *M is the finite chain of* $\mathsf{DyadicInterval}^{\uparrow}$ *or* $\mathsf{DyadicMesh}^{\uparrow}$ *midpoint-comparison rows inspected during the run;*
4. *L is the left/right branch ledger, with one displayed branch row for each midpoint comparison in M;*
5. *J is the* $\mathsf{NestedInterval}^{\uparrow}$ *refinement row obtained by threading the selected subintervals;*
6. *E is the endpoint readback ledger for every retained lower endpoint, upper endpoint, midpoint, and displayed dyadic tolerance;*
7. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row extracted from the retained endpoint windows;*
8. *S is the* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *handoff surface through which real consumers read the same finite windows;*

9. *H stores the* hsame *transports for the initial interval, precision row, midpoint rows, branch ledger, nested interval row, endpoint readbacks, and handoff rows;*
10. *C stores the* Cont *routes for refinement, endpoint inspection, regular-sequence readback, and real-name consumption;*
11. *P is the* Pkg *provenance row naming* $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicInterval}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, $\mathsf{NestedInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *registration row.*

The carrier exports only these finite rows. It has no coordinate for a host real root, a completed interval intersection, trichotomy on reals, Dedekind-cut data, or an ambient completeness proof.

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionTasteGate single carrier alignment`

Definition 361.2 (DyadicBisection classifier)**.** *Two accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carriers classify together when, after the displayed* hsame *and* Cont *transports, their initial interval rows, precision schedules, midpoint chains, branch ledgers, nested dyadic interval chains, endpoint readbacks,* $\mathsf{RegSeqRat}^{\uparrow}$ *rows,* $\mathsf{StreamName}^{\uparrow}$ *windows, and* $\mathsf{Real}^{\uparrow}$ *handoff rows refine to the same finite observation window under the displayed dyadic tolerance.*

Concretely, if the common stopping request is n, then each retained endpoint window is compared only after both packets are transported to the same finite tolerance row

$$\varepsilon_n = 2^{-n}.$$

Agreement means row-by-row equality of the transported branch choices and endpoint readbacks at that tolerance, followed by the inherited $\mathsf{NestedInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *classifiers. No comparison is made by appealing to a host real value or to an infinite intersection.*

Theorem 361.3 (DyadicBisection NameCert obligations)**.** *The seed* $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *surface has five obligations:*

1. *carrier: formation of the finite* BHist *packet of Definition 361.1;*
2. *classifier: the finite-window classifier of Definition 361.2;*
3. *stability: componentwise preservation of the interval, precision, branch, nested-interval, endpoint, and handoff rows under displayed* hsame *transport and* Cont *refinement routes;*
4. *ledger exactness: every left/right branch choice is exactly the branch row attached to the corresponding midpoint comparison, and every retained endpoint read is one of the displayed dyadic ledger rows;*
5. *handoff: the retained endpoint windows are repacked into* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows without adding a host real intersection or an ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier namecert obligations`

Proof. Carrier formation is the assembly of the displayed finite packet. Each coordinate is either a history row, a transport row, a continuation route, package provenance, or a local naming row owned by the listed dependency certificates.

The classifier is finite because the stopping request fixes the displayed tolerance and the inspected midpoint chain. After transporting both carriers to that window, comparison is componentwise on the initial interval, precision schedule, branch ledger, nested interval row, endpoint readbacks, and handoff rows.

Stability follows the same component order. Transport first moves the initial interval and precision rows, then the midpoint rows and branch choices, then the nested interval and endpoint ledgers, and finally the regular-sequence, stream, and real-name handoff rows.

Ledger exactness is the branch-row invariant: the kth branch coordinate is the only source of the kth left/right choice, and the retained endpoint rows are precisely the rows routed by C and transported by H.

The handoff obligation repacks the finite retained windows into $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces. Since the carrier contains no host real, infinite intersection, or completeness coordinate, no such object can be exported. □

Theorem 361.4 (DyadicBisection nested interval bridge)**.** *For every accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier B, the displayed branch ledger determines a finite* $\mathsf{NestedInterval}^{\uparrow}$ *refinement row whose kth interval is the subinterval selected by the kth midpoint comparison. The bridge exposes the initial* $\mathsf{RationalInterval}^{\uparrow}$ *row, the dyadic midpoint ledger, the left/right branch ledger, the endpoint readbacks, and the* $\mathsf{NestedInterval}^{\uparrow}$ *row, and it exports no completed intersection of the nested intervals.*

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier nested interval bridge`

Proof. Project the carrier of Definition 361.1. The midpoint chain M and branch ledger L have the same finite length, so the kth midpoint comparison has a unique displayed branch row.

Thread the interval row forward along these branch choices. At each step, the retained lower endpoint, upper endpoint, midpoint, and tolerance rows are already present in the endpoint ledger E, and the transport rows in H record that the selected subinterval is the continuation of the previous interval.

Pack the resulting finite chain into the $\mathsf{NestedInterval}^{\uparrow}$ row J. This row is the bridge available to downstream consumers: it records the nested finite refinement path but does not claim that the infinite intersection exists as a host real object. □

Theorem 361.5 (DyadicBisection real stream handoff)**.** *For every accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier and every unary precision request n, the consumer-visible* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *reads factor through the retained dyadic endpoint window at tolerance 2^{-n}, the branch ledger prefix needed to reach that window, the* $\mathsf{NestedInterval}^{\uparrow}$ *refinement row, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}$ *row.*

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier real stream endpoint scope`

Proof. Start with the precision row π and the displayed request n. The carrier uses that row to select a finite branch-prefix length and the corresponding retained endpoint window in E.

Use Definition 361.4 to route the selected endpoint window through the nested interval row. The branch prefix identifies the retained subinterval, while the endpoint ledger supplies the rational lower and upper reads at the requested tolerance.

The $\mathsf{RegSeqRat}^{\uparrow}$ row R consumes those retained rational windows. The $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows in S then expose the same finite observation to real consumers through the displayed transports, continuation routes, package provenance, and local certificate row.

Thus every real-facing read has the stated finite factorization. The handoff does not use root existence, real trichotomy, Dedekind cuts, host real equality, or a host intersection theorem. □

Theorem 361.6 (DyadicBisection nested window handoff)**.** *For every accepted* DyadicBisection$^{\uparrow}$ *carrier and every unary precision request n, the* RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, *and* Real$^{\uparrow}$ *reads are determined by the unique branch-prefix ledger segment that reaches the retained nested interval window at tolerance 2^{-n}, together with the endpoint readbacks and displayed* hsame *and* Cont *transports. This handoff introduces no host intersection, completed real root, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier nested window handoff`

Proof. Project the branch ledger of Definition 361.1. The precision request n selects the finite prefix length whose branch choices reach the retained endpoint window recorded in E.

Apply Definition 361.4. The selected branch prefix determines the corresponding NestedInterval$^{\uparrow}$ row, and that row exposes the retained lower endpoint, upper endpoint, midpoint, and tolerance readbacks from the finite ledger.

Now apply Definition 361.5. The RegSeqRat$^{\uparrow}$ row reads those retained rational windows, while the StreamName$^{\uparrow}$ and Real$^{\uparrow}$ rows expose the same finite observation through the displayed transports and continuation routes.

The carrier has no field for an intersection of all retained intervals and no field for a completeness theorem. Therefore the nested window is the exact surface consumed by the handoff. □

Theorem 361.7 (DyadicBisection branch endpoint determinacy)**.** *For every accepted* DyadicBisection$^{\uparrow}$ *carrier and every unary precision request n, the finite branch-prefix ledger segment that reaches the retained window at tolerance 2^{-n} uniquely determines the retained lower endpoint, retained upper endpoint, midpoint, tolerance row, nested interval row, and the downstream* RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, *and* Real$^{\uparrow}$ *handoff rows. No host root, infinite intersection, trichotomy, or completeness row participates in this determination.*

Proof. Project the accepted carrier of Definition 361.1. The unary request n selects a finite prefix of the branch ledger, and each row of that prefix chooses one retained dyadic subinterval from the previous endpoint window.

Apply the nested interval bridge of Definition 361.4. The selected branch prefix fixes the retained lower endpoint, upper endpoint, midpoint, and tolerance readback in the endpoint ledger, then packs the same finite chain into the NestedInterval$^{\uparrow}$ row.

Next use the real stream handoff of Definition 361.5 and the nested window handoff of Definition 361.6. The RegSeqRat$^{\uparrow}$ row consumes the retained endpoint windows, and the StreamName$^{\uparrow}$ and Real$^{\uparrow}$ rows expose that same finite observation through the displayed hsame, Cont, Pkg, and NameCert rows.

The construction has used only the finite carrier rows, the nested interval bridge, and the handoff routes. Since none of these rows contains a host root, an infinite intersection, a trichotomy decision, or a completeness principle, the branch-prefix ledger segment is the determinant of the retained endpoint window and its downstream reads. □

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier branch endpoint transport`

Theorem 361.8 (DyadicBisection branch nested-window scope)**.** *For every accepted* DyadicBisection$^{\uparrow}$ *carrier over* DyadicInterval$^{\uparrow}$, DyadicMesh$^{\uparrow}$, NestedInterval$^{\uparrow}$, RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, *and* Real$^{\uparrow}$, *the selected branch ledger determines the finite nested-window row and transports it through the displayed* hsame *and* Cont *rows to the same* Real$^{\uparrow}$ *seal endpoint. The scope is the carried packet*

$$B = (I, \pi, M, L, J, E, R, S, H, C, P, N),$$

where the finite branch prefix in L determines the retained endpoint rows in E, the nested interval row J, the regular readback R, and the real-stream handoff surface S.

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier branch nested window scope`

Proof. Start with the branch ledger and its endpoint determination. Apply Definition 361.7: for a unary precision request, the finite branch prefix fixes the retained endpoint window, tolerance row, nested interval row, and downstream handoff rows.

Next identify the nested-window row. Apply Definition 361.4 to thread the branch choices through the dyadic midpoint chain and pack the retained subintervals into J.

Now use Definition 361.6. The same branch prefix and endpoint readbacks determine the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ reads through the displayed transport and continuation rows.

Finally apply Definition 361.5 to bind the resulting regular and stream reads to the real-facing handoff surface S. The construction never leaves the displayed carrier rows, so it exports no host root, infinite intersection, trichotomy decision, or ambient completeness row. □

Theorem 361.9 (DyadicBisection selector interval stability)**.** *For an accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier*

$$B = (I, \pi, M, L, J, E, R, S, H, C, P, N),$$

transporting the initial interval I, precision row π, midpoint chain M, and branch ledger L through the displayed hsame *ledger H and* Cont *routes C preserves the selected retained interval row. It also preserves the retained endpoint readbacks in E, the* $\mathsf{NestedInterval}^{\uparrow}$ *row J, and the downstream* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *handoff rows R, S.*

The stability statement is entirely internal to the displayed bisection carrier, package provenance P, and local $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *row N; it does not rely on a hidden root, trichotomy, or a completed interval intersection.*

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier retained interval nonempty iff`

Proof. First apply Definition 361.4. The transported branch ledger threads the transported midpoint chain into the same finite $\mathsf{NestedInterval}^{\uparrow}$ row, so the selected retained interval row remains a displayed row of the carrier.

Next use Definition 361.7. Once the retained interval row is fixed at the requested precision, the lower endpoint, upper endpoint, midpoint, tolerance row, and downstream handoff rows are determined by the same finite branch-prefix ledger.

Apply Definition 361.6 to identify the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ reads with that retained nested window and its endpoint readbacks. The transports in H and routes in C move these rows componentwise.

Finally use Definition 361.8. The selected branch ledger, nested row, endpoint ledger, and handoff rows remain inside the carried packet B, so no host root, real trichotomy, or completed intersection object participates in the stability claim. □

Theorem 361.10 (DyadicBisection public branch totality)**.** *For every accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier*

$$B = (I, \pi, M, L, J, E, R, S, H, C, P, N),$$

and every unary precision request n, the public finite branch-consumer route is exhausted by the branch endpoint transport, the branch nested-window scope, the real stream endpoint scope, and the retained interval nonempty read. The route exposes exactly the initial interval row, precision row, finite midpoint chain, selected branch-prefix ledger, retained endpoint readbacks, $\mathsf{NestedInterval}^{\uparrow}$

row, $\mathsf{RegSeqRat}^{\uparrow}$ *row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{Real}^{\uparrow}$ *handoff surface,* hsame *transports,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *row.*

It exports no host root, infinite intersection, trichotomy decision, Dedekind cut, hidden midpoint oracle, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier public branch totality`

Proof. Begin with the selected branch-prefix ledger for the request n. Apply Definition 361.7 to determine the retained lower endpoint, upper endpoint, midpoint, tolerance row, nested interval row, and downstream handoff rows.

Next apply Definition 361.8. This places the branch prefix, endpoint rows, nested row, regular readback, and real-stream handoff inside the displayed carrier packet and transports them through H and C.

Use Definition 361.5 to expose the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumer reads at the same finite retained endpoint window.

Finally apply the retained interval stability theorem of this chapter. The retained interval row and its endpoint readbacks remain componentwise stable under the displayed transports and continuation routes. Hence the public route is exactly the finite packet listed above, with no off-table analytic object. □

Theorem 361.11 (DyadicBisection retained interval consumer route)**.** *Two accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carriers with the same transported initial interval, precision row, midpoint chain, branch ledger, retained endpoint readbacks, nested interval row,* $\mathsf{RegSeqRat}^{\uparrow}$ *row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{Real}^{\uparrow}$ *handoff surface,* hsame *transports,* Cont *routes,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *row have the same public retained-interval consumer route. Conversely, equality of the public retained-interval route is witnessed by componentwise agreement of those displayed finite rows.*

The route is the public object surface for dyadic bisection consumers. It does not assert a completed intersection, a host real root, real trichotomy, or a Dedekind-cut carrier.

Proof. For the forward direction, assume componentwise agreement of the displayed finite rows. Apply Definition 361.10 to both carriers. Each public branch-consumer route is exhausted by the same finite branch prefix, endpoint ledger, nested interval row, regular readback, stream window, real handoff, transport, continuation, package, and certificate rows.

The retained interval stability theorem identifies the retained interval row and endpoint readbacks after transport. The branch nested-window scope and real stream handoff then route the same retained window to the same public consumer surface.

For the reverse direction, suppose the public retained-interval consumer routes are equal. Project the route through Definition 361.10. The projection exposes only the listed finite carrier rows, so route equality supplies componentwise agreement of the interval, precision, midpoint, branch, endpoint, nested, regular, stream, real, transport, continuation, package, and certificate rows.

No further coordinate is available in the carrier. Thus equality of the public route is exactly componentwise agreement of the displayed finite rows, and the off-table host and completeness objects cannot participate. □

Lean4 ✓ `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier retained interval consumer route`

Theorem 361.12 (DyadicBisection StreamName retained route)**.** *Any retained-interval consumer of an accepted* $\mathsf{DyadicBisection}^{\uparrow}$ *carrier that hands off to* $\mathsf{StreamName}^{\uparrow}$ *must read the rational interval row, dyadic interval row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius row, retained branch endpoint row, nested window row, displayed* hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$ *row before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *read. The retained StreamName route exposes the finite bisection packet, not a host root, completed intersection, real trichotomy, or Dedekind-cut carrier.*

Proof. First use the nested interval bridge. It turns the midpoint chain and retained branch choices into the finite nested interval row and retained endpoint readbacks.

Next apply the real stream handoff and nested-window handoff. They route the retained endpoint data through the $\mathsf{StreamName}^{\uparrow}$ window and then toward the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads without leaving the displayed transport and continuation rows.

Finally apply the retained interval consumer route. It identifies the public retained route with the rational interval, dyadic interval, radius, retained endpoint, nested window, transport, continuation, package, and certificate rows, so no completion-level or host-level object is exposed before the finite StreamName route has been read. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicBisection}^{\uparrow}$ packet is generated from an initial $\mathsf{RationalInterval}^{\uparrow}$ row, a unary precision row, finite $\mathsf{DyadicInterval}^{\uparrow}$ or $\mathsf{DyadicMesh}^{\uparrow}$ midpoint comparisons, an exact left/right branch ledger, a $\mathsf{NestedInterval}^{\uparrow}$ refinement row, endpoint readbacks, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ handoff rows, displayed hsame and Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public packet binds the carrier, finite-window classifier, NameCert obligation surface, nested interval bridge, real-stream handoff, branch endpoint determinacy, branch nested-window scope, selector interval stability, public branch totality, and retained-interval consumer route for dyadic bisection over $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicInterval}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, $\mathsf{NestedInterval}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DyadicBisection}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DyadicBisectionUp.DyadicBisectionCarrier\_retained\_interval\_nonempty\_iff`

Bridge status: none

Origin: human

Not claimed: This chapter does not close completeness, root existence, trichotomy, Dedekind cuts, uniqueness of a limit point, or host real intersection.

Upgrade path: No further paper-theory upgrade remains; Lean bridge checking remains a separate verification-axis task.

Chapter 362

A Concrete Naming Certificate for $\mathsf{StationaryRationalDiagonal}^{\uparrow}$

The $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ interface names the finite packet obtained from a stationary rational regular Cauchy input and its diagonal representative. It sits at the Real and Completion boundary: the source is a $\mathsf{Rat}^{\uparrow}$ row read as a constant $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ object, while the consumer sees only the associated $\mathsf{Real}^{\uparrow}$ seal surface. The packet carries no quotient of regular streams, host real equality, ambient completeness principle, or hidden limit selection.

The packet consumes substantive source rows from the rational seed surface of chapter 37, the constant-window carrier of chapter 126, the regular rational readback of chapter 301, and the seal boundary of chapter 38; these are the displayed inputs to the diagonal packet, not decorative references.

The stationary diagonal is the degenerate tail-selection case recorded by chapter 458: every requested selector window is constant at the displayed $\mathsf{Rat}^{\uparrow}$ seed, and the $\mathsf{Real}^{\uparrow}$ seal handoff therefore consumes the same selected-tail discipline through a singleton constant window.

Definition 362.1 (Stationary rational diagonal carrier)**.** *A* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ *carrier is a finite* BHist *row*

$$S = (q, C, R, D, E, H, K, P, N)$$

with the following visible coordinates:

1. *q is the* $\mathsf{Rat}^{\uparrow}$ *source row;*
2. *C is the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule generated by q;*
3. *R is the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row whose inspected windows all return q;*
4. *D is the diagonal selector row that always selects the stationary member and the requested regular-sequence window;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal ledger for the constant rational embedding;*
6. *H records the displayed* hsame *transports for the rational source, stream schedule, regular readback, diagonal selector, and real seal;*
7. *K records the visible* Cont *routes by which consumers reach the selected constant windows;*
8. *P is the* Pkg *provenance naming the* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$ *dependency rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryRationalDiagonal}^{\uparrow}}$ *provenance row.*

The classifier compares accepted carriers only by the displayed $\mathsf{Rat}^{\uparrow}$ *seed classifier, the constant* $\mathsf{StreamName}^{\uparrow}$ *readback, the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *window row, and the* $\mathsf{Real}^{\uparrow}$ *seal-facing route, transported through the listed* hsame *and* Cont *rows.*

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalTasteGate single carrier alignment`

Theorem 362.2 (Stationary rational diagonal NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryRationalDiag}}$ *surface consists exactly of five rows:*

1. *carrier: the finite packet of Definition 362.1;*
2. *classifier: comparison of two accepted packets through their displayed* $\mathsf{Rat}^{\uparrow}$ *seed classifier and the induced constant* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows;*
3. *stability: componentwise* hsame *transport and visible* Cont *routing preserve the stationary seed, every constant window, the diagonal selector, and the real seal ledger;*
4. *exactness/readback: every consumer read factors through the same stationary rational seed and the same constant regular-rational window before it reaches the* $\mathsf{Real}^{\uparrow}$ *seal;*
5. *ledger: the* Pkg *and* NameCert *coordinates expose only* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local certificate rows.*

No row of the surface is a quotient, a choice principle, or a host real equality.

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier namecert obligation surface`

Proof. Project the carrier of Definition 362.1. The listed coordinates already name the rational seed, constant stream, stationary regular readback, diagonal selector, real seal, transports, continuation routes, package provenance, and local ledger.

For the classifier row, compare two packets only by the seed classifier and its constant readbacks. The $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ coordinates are stationary, so every selected window reads the same rational row before the $\mathsf{Real}^{\uparrow}$ seal is consulted.

Stability follows by transporting each visible coordinate through its stored hsame row and using the displayed Cont routes to reach the same selected window after transport. The exactness row is then forced, because the real seal has no source except the stationary rational readback.

The ledger is exhausted by P and N. Since the carrier has no coordinate for quotient streams, host real equality, or a hidden selected limit, none of those objects can be exported by the local certificate. □

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier semantic name certificate`

Theorem 362.3 (Stationary rational diagonal Real handoff)**.** *Every accepted* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ *packet determines a concrete* $\mathsf{Real}^{\uparrow}$ *consumer surface for the stationary rational diagonal representative. The consumer route reads the* $\mathsf{Rat}^{\uparrow}$ *seed through the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *row, the diagonal selector, and the displayed* $\mathsf{Real}^{\uparrow}$ *seal ledger, with all replacements accounted for by visible* hsame, Cont, Pkg, *and* NameCert *rows.*

Proof. Start with the accepted carrier and read its constant stream coordinate. Every requested observation reaches the same $\mathsf{Rat}^{\uparrow}$ seed through the displayed Cont route.

The stationary $\mathsf{RegSeqRat}^{\uparrow}$ coordinate repackages those constant observations as the regular-rational readback used by the diagonal selector. Since the selector always chooses the stationary member, the selected window and the regular readback stay on the listed finite rows.

Finally read the $\mathsf{Real}^{\uparrow}$ seal ledger. It is attached to the same stationary readback and is transported only through the displayed hsame rows. Repacking these coordinates gives the real-facing handoff, and the carrier contains no additional endpoint object. □

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier real handoff`

Theorem 362.4 (Stationary rational diagonal consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ *packet factors through the finite rows listed in Definition 362.1. In particular, the consumer may use the* $\mathsf{Rat}^{\uparrow}$ *seed, constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, diagonal selector,* $\mathsf{Real}^{\uparrow}$ *seal ledger, visible* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, and nothing outside that finite packet.*

Proof. Use the obligation surface of Definition 362.2 to place the carrier, classifier, stability, readback, and ledger rows on one local certificate surface.

Next apply the handoff of Definition 362.3. It routes every real-facing read through the stationary seed, the constant stream schedule, the regular-rational readback, the diagonal selector, and the real seal ledger.

It remains to delimit completion-facing consumers. Such a consumer reaches the packet only through the same $\mathsf{Real}^{\uparrow}$ seal-facing route and the same displayed provenance rows. Therefore the consumer boundary is exactly the finite packet surface stated in the theorem, with no coordinate for quotient equality, choice, or host real equality. □

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier consumer boundary`

Theorem 362.5 (Stationary rational diagonal scoped boundary)**.** *The carrier definition, NameCert obligation surface, Real handoff, and consumer boundary for* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ *form a single scoped dependency packet over exactly the* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows displayed in Definition 362.1. Every accepted consumer read is routed through that finite packet, and the packet exports no quotient stream, host real equality, or selected limit.*

Proof. The carrier of Definition 362.1 lists the only coordinates available to the local certificate: the rational seed, constant stream schedule, stationary regular-rational readback, diagonal selector, real seal ledger, visible transports, visible continuation routes, package provenance, and local NameCert row.

The obligation surface of Definition 362.2 makes those coordinates into the full certificate interface. Its carrier, classifier, stability, exactness, and ledger rows mention precisely the same dependency names, so no consumer can acquire an additional source row through the certificate laws.

The handoff theorem Definition 362.3 routes every real-facing read through the constant stream, the stationary regular readback, the diagonal selector, and the real seal. The consumer boundary theorem Definition 362.4 then applies the same routing to completion-facing consumers.

Thus every permitted read has already passed through the displayed finite packet. Since none of the cited rows contains a coordinate for quotient streams, host real equality, or a selected limit, none of those objects is exported by the scoped boundary. □

Theorem 362.6 (Stationary rational diagonal classifier determinacy)**.** *Let D and D' be accepted* StationaryRationalDiagonal$^{\uparrow}$ *packets. If their displayed* Rat$^{\uparrow}$ *seed rows classify together on the local carrier, then their induced constant* StreamName$^{\uparrow}$ *schedules, stationary* RegSeqRat$^{\uparrow}$ *windows, diagonal selector rows, and* Real$^{\uparrow}$ *seal routes classify together through the stored* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Conversely, any accepted classifier comparison on those downstream rows restricts to the displayed rational seed classifier, since the rational seed coordinate is the only carrier coordinate that supplies rational content to the stationary diagonal read.*

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier classifier determinacy`

Proof. Project the carriers of D and D' along Definition 362.1. The only rational source row in each packet is the displayed Rat$^{\uparrow}$ seed; the remaining rows are the constant stream schedule, the stationary regular-rational readback, the diagonal selector, the real seal ledger, and the visible transport and package rows.

Stationarity reduces every selected regular-rational window to that same rational row. Therefore a seed classifier comparison transports directly to the constant StreamName$^{\uparrow}$ schedule and to each stationary RegSeqRat$^{\uparrow}$ window read through the stored hsame rows.

Apply the real handoff of Definition 362.3 and the scoped boundary of Definition 362.5. The diagonal selector and Real$^{\uparrow}$ seal route do not add a second rational source; they only route the stationary read through the displayed Cont, Pkg, and NameCert rows.

For the converse, restrict any accepted downstream classifier comparison back along the handoff route. The boundary theorem leaves exactly one carrier coordinate that can supply rational content, namely the displayed seed row, so the downstream classifier comparison determines the same local Rat$^{\uparrow}$ seed classifier. □

Theorem 362.7 (Stationary rational diagonal constant-window totality)**.** *Every unary request made against an accepted* StationaryRationalDiagonal$^{\uparrow}$ *packet reads the same displayed* Rat$^{\uparrow}$ *row. The read first follows the constant* StreamName$^{\uparrow}$ *schedule generated by the seed, then the stationary* RegSeqRat$^{\uparrow}$ *window row, and then the diagonal selector that returns that stationary window for the requested precision.*

Thus every consumer-visible rational observation is already the displayed seed row, transported only through the listed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier constant window totality`

Proof. Project the accepted carrier along Definition 362.1. Its only rational coordinate is the seed q, and its stream coordinate C is explicitly the constant schedule generated by q.

Read a unary request through the continuation route K. The schedule therefore returns the same rational row for the requested place, and the stationary RegSeqRat$^{\uparrow}$ coordinate R records that every displayed regular window has that same readback.

Finally apply the diagonal selector coordinate D. Since D always selects the stationary member and the requested regular-sequence window, no second rational row can be introduced. The transport and provenance coordinates merely move the same displayed rows, so the readback is total on the stated finite surface. □

Theorem 362.8 (Stationary rational diagonal seal factorization)**.** *For every accepted* StationaryRationalDiagonal$^{\uparrow}$ *packet, the* Real$^{\uparrow}$ *seal ledger factors only through the displayed* Rat$^{\uparrow}$ *seed, constant* StreamName$^{\uparrow}$ *schedule, stationary* RegSeqRat$^{\uparrow}$ *readback, diagonal selector, and visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

In particular, the seal cannot factor through quotient regular streams, a host real equality, an ambient completeness principle, or a selected limit outside the carrier.

Proof. Start from the real handoff theorem Definition 362.3. It identifies the seal-facing route as the route from the rational seed through the constant stream, stationary regular readback, diagonal selector, and real seal ledger.

Use the constant-window totality theorem Definition 362.7 to collapse each unary read on that route to the same displayed Rat$^{\uparrow}$ seed row. The Real$^{\uparrow}$ seal is therefore reached after a finite readback path whose source is the carrier coordinate q.

The remaining carrier coordinates are H, K, P, and N. These record transport, continuation, package provenance, and local certificate provenance; they do not contain quotient regular streams, host real equality, ambient completeness, or selected limits. Hence the stated factorization exhausts the seal ledger. □

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier seal factorization`

Theorem 362.9 (Stationary rational diagonal obligation-closure package)**.** *The* StationaryRationalDiagonal$^{\uparrow}$ *carrier, NameCert surface, Real handoff, consumer boundary, scoped boundary, classifier determinacy, constant-window totality, and seal factorization assemble an obligation-closed paper package. Its closed scope is exactly the displayed* Rat$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *dependency surface.*

Proof. The carrier definition supplies the finite packet and its dependency names. The NameCert obligation surface records the carrier, classifier, stability, readback, and ledger rows on that packet.

The Real handoff and consumer boundary route all real-facing and completion-facing reads through the same finite coordinates. The scoped boundary then states that no additional quotient, host equality, or selected limit is available to consumers.

Classifier determinacy identifies the accepted comparison with the displayed rational seed classifier and its transported downstream rows. Constant-window totality and seal factorization complete the package by showing that every unary read and every real-seal read is exhausted by the same stationary rational route. These rows are precisely the named obligation surface, so the paper-side closure grade is obligation closure. □

Lean4 ✓ `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier obligation closure package`

Closure status for NameCert$_{\text{StationaryRationalDiagonal}^{\uparrow}}$.

Constructive story: A StationaryRationalDiagonal$^{\uparrow}$ packet is generated from one Rat$^{\uparrow}$ source row, its constant StreamName$^{\uparrow}$ schedule, a stationary RegSeqRat$^{\uparrow}$ readback, a diagonal selector, a Real$^{\uparrow}$ seal ledger, visible hsame and Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{StationaryRationalDiagonal}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 362.4 binds the finite stationary rational diagonal carrier, NameCert surface, Real handoff, and consumer boundary over Rat$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{StationaryRationalDiagonal}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.StationaryRationalDiagonalUp.StationaryRationalDiagonalCarrier\_seal\_factorization`

Bridge status: none

Origin: human

Not claimed: This chapter does not close general real completeness, arbitrary regular Cauchy sequences, quotient equality of regular streams, uniqueness of limits, host real construction, or bridge checking.

Upgrade path: Public closure requires a public-object boundary for stationary rational diagonal consumers beyond the scoped seal factorization.

Chapter 363

A Concrete Naming Certificate for $\mathsf{SignedDigitReal}^{\uparrow}$

The $\mathsf{SignedDigitReal}^{\uparrow}$ interface names the real-facing certificate obtained when finite signed-digit stream windows are normalized into dyadic enclosures and routed to the $\mathsf{Real}^{\uparrow}$ seal. It sits above $\mathsf{SignedDigitStream}^{\uparrow}$ (chapter 316), DyadicRatCore and $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$ (chapter 335), $\mathsf{LocatedCauchy}^{\uparrow}$ (chapter 340), and $\mathsf{Real}^{\uparrow}$ (chapter 38). The packet is a finite-window name certificate, not a quotient of streams, a selected representative, a trichotomy principle, or a choice construction.

Definition 363.1 (SignedDigitReal carrier)**.** *A* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, W, E, L, H, C, P, N)$$

with the following visible coordinates:

1. *S is an accepted* $\mathsf{SignedDigitStream}^{\uparrow}$ *row, carrying signed digits, unary observation schedules, normalization ledgers, and normalized dyadic endpoint rows;*
2. *W is the family of finite prefix windows read from the* $\mathsf{StreamName}^{\uparrow}$ *schedule of S;*
3. *E assigns to every displayed window in W a* DyadicRatCore *enclosure row, read through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius ledgers exposed by the signed-digit normalization;*
4. *L is the* $\mathsf{LocatedCauchy}^{\uparrow}$ *located-window row stating that the displayed enclosures form a located Cauchy surface at the requested precisions;*
5. *H records componentwise* hsame *transport for signed digits, windows, enclosures, located rows, and real-seal boundary rows;*
6. *C records the* Cont *routes by which a consumer reads each finite prefix, its normalization ledger, its dyadic enclosure, its located row, and its real-seal boundary;*
7. *P is the* Pkg *provenance naming* $\mathsf{SignedDigitStream}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{LocatedCauchy}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as dependency anchors;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *provenance row.*

The carrier predicate accepts exactly those packets whose every finite signed-digit prefix decodes to the displayed DyadicRatCore *enclosure and whose normalization windows are compatible with the* $\mathsf{Real}^{\uparrow}$ *seal boundary through the located-Cauchy row L.*

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealTasteGate single carrier alignment`

Definition 363.2 (SignedDigitReal classifier)**.** *For accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carriers* R *and* R'*, the classifier* $\mathsf{SignedDigitRealClassifier}(R, R')$ *holds when the underlying* $\mathsf{SignedDigitStream}^{\uparrow}$ *rows agree on every shared finite window, the decoded* $\mathsf{DyadicRatCore}$ *enclosures agree through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *classifier, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *enclosure routes transport componentwise, the located-Cauchy rows agree at each requested precision, and the induced* $\mathsf{Real}^{\uparrow}$ *seal boundaries are compared by the classifier of Definition 38.9.*

The classifier is finite-window data. It has no coordinate for quotient stream equality, selected representatives, trichotomy, choice, or host real equality.

Theorem 363.3 (SignedDigitReal finite normalization window)**.** *Let* $R = (S, W, E, L, H, C, P, N)$ *be an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier, and let* w *be a displayed finite prefix window in* W*. Finite normalization of the signed-digit prefix of* S *at* w *preserves the* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier surface and produces the corresponding* $\mathsf{DyadicRatCore}$ *enclosure row in* E*.*

The produced row is read entirely through the displayed BHist *prefix, the* hsame *transports in* H*, the* Cont *route in* C*, the* Pkg *provenance in* P*, and the local* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *row* N*. The normalization step creates no quotient tail, selected stream representative, trichotomy witness, choice datum, or host real endpoint.*

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket normalization window transport`

Proof. Project the carrier of Definition 363.1. The window w selects a finite signed-digit prefix from S, its signed-digit normalization ledger, the target dyadic enclosure row in E, and the corresponding located-Cauchy and real-seal boundary rows.

Apply the signed-digit finite-window transport and common-window determinacy from Definition 316.4 and Definition 316.8. These rows say that the normalized prefix is stable under the displayed hsame and Cont movement and that its endpoint read is the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint for that window.

Read the endpoint as the enclosure row named by E. The $\mathsf{DyadicApproximation}^{\uparrow}$ route records the enclosure shape, while the $\mathsf{LocatedCauchy}^{\uparrow}$ row records that the same finite observation is acceptable at the requested precision before the $\mathsf{Real}^{\uparrow}$ seal reads it.

Repack the coordinates into the original carrier tuple. Every row used in the repacking is already in BHist, H, C, P, or N, so the operation preserves the carrier surface and cannot expose any of the excluded non-finite data. □

Theorem 363.4 (SignedDigitReal dyadic seal compatibility)**.** *Let* R *and* R' *be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carriers. Suppose their underlying* $\mathsf{SignedDigitStream}^{\uparrow}$ *rows agree on every finite normalization window under the signed-digit classifier, and suppose the decoded* $\mathsf{DyadicRatCore}$ *enclosure rows are transported by the displayed* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *routes. Then the two carriers determine the same* $\mathsf{Real}^{\uparrow}$ *seal boundary in the sense of the* $\mathsf{Real}^{\uparrow}$ *classifier of Definition 38.9.*

The compatibility is obtained by finite-window readback only. It uses no quotient of streams, no selected representative, no trichotomy branch, and no choice principle.

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket dyadic seal compatibility`

Proof. Use Definition 363.2 to reduce the comparison to shared finite normalization windows. On each such window, the two signed-digit prefixes are related by the $\mathsf{SignedDigitStream}^{\uparrow}$ classifier.

Apply Definition 363.3 to both carriers on the same window. The two normalization reads produce dyadic enclosure rows through the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ routes.

The hypothesis transports these enclosure rows through the $\mathsf{DyadicApproximation}^{\uparrow}$ and $\mathsf{LocatedCauchy}^{\uparrow}$ routes. Thus every requested precision reaches the same located dyadic enclosure surface before the real seal is read.

Finally invoke the $\mathsf{Real}^{\uparrow}$ classifier specification of Definition 38.9. Since the real boundary sees only the located Cauchy enclosure rows just identified, the two carriers have the same seal boundary and no additional stream quotient or choice-based representative is introduced. □

Definition 363.5 (SignedDigitReal obligation ledger package)**.** *For an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier*

$$R = (S, W, E, L, H, C, P, N),$$

the obligation ledger package is the finite packet that reads these coordinates with the following roles:

1. *S is the signed-digit stream row, including digit data, unary window schedules, normalization ledgers, and endpoint rows;*
2. *W is the displayed family of finite windows;*
3. *E is the decoded* $\mathsf{DyadicRatCore}$ *enclosure row for each window, exposed through* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{DyadicApproximation}^{\uparrow}$*;*
4. *L is the* $\mathsf{LocatedCauchy}^{\uparrow}$ *located-row route binding the decoded enclosures to requested precisions;*
5. *the* $\mathsf{Real}^{\uparrow}$ *seal boundary is the public consumption row reached from E and L;*
6. *H records componentwise* hsame *rows for streams, windows, enclosures, located rows, and seal rows;*
7. *C records the* Cont *routes through finite prefixes, decoded enclosures, located rows, and the real seal;*
8. *P and N record the dependency package and local* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *provenance.*

The package has no coordinate for quotient streams, selected representatives, trichotomy, choice, or host real equality.

Theorem 363.6 (SignedDigitReal window classifier stability)**.** *Let $R = (S, W, E, L, H, C, P, N)$ and $R' = (S', W', E', L', H', C', P', N')$ be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carriers. If the signed-digit stream rows are related by the classifier on a displayed finite window, then the decoded dyadic enclosures, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *routes, the* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows, and the induced* $\mathsf{Real}^{\uparrow}$ *seal boundary transport through the same obligation ledger package of Definition 363.5.*

In particular, classifier-related windows do not create a second ledger for the enclosure or located-Cauchy read; the finite window, decoded enclosure, located row, and seal boundary are the displayed rows of the package.

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket window classifier stability`

Proof. Apply the finite normalization window theorem Definition 363.3 to R on the chosen displayed window. This projects the signed-digit prefix, its normalization ledger, the decoded dyadic enclosure row, and the corresponding located and seal rows from the obligation ledger package.

Apply the same theorem to R' on the classifier-related window. The stream classifier and common-window transport identify the finite prefixes and their normalization ledgers through the recorded componentwise hsame rows.

Transport the decoded enclosures through the $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{DyadicApproximation}^{\uparrow}$ rows, and then transport the precision witnesses through the $\mathsf{LocatedCauchy}^{\uparrow}$ rows. The continuation routes in C and C' preserve the order from prefix read to enclosure read to located read.

Finally, the $\mathsf{Real}^{\uparrow}$ seal boundary is reached only from the transported enclosure and located rows. Thus the classifier stability is witnessed inside the same finite ledger package, with no extra representative or quotient stream. □

Theorem 363.7 (SignedDigitReal seal ledger exactness)**.** *For every accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier, the* $\mathsf{Real}^{\uparrow}$ *seal boundary consumes exactly the decoded* DyadicRatCore *enclosure rows and* $\mathsf{LocatedCauchy}^{\uparrow}$ *ledger exposed by Definition 363.5. The seal read is routed through the signed-digit finite window, the normalization ledger, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *enclosure route, the located-Cauchy row, and the recorded* hsame, Cont, Pkg, *and* NameCert *provenance.*

The seal boundary exports no quotient stream, no selected signed-digit representative, no trichotomy branch, no choice datum, and no host real equality.

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket seal ledger exactness`

Proof. Project the obligation ledger package. Each seal read begins with a finite window in W and the signed-digit prefix of S displayed on that window.

Use the finite normalization window theorem to decode that prefix into the enclosure row named by E. The $\mathsf{DyadicApproximation}^{\uparrow}$ route records the enclosure shape and the $\mathsf{LocatedCauchy}^{\uparrow}$ row L records the precision-facing located evidence.

The dyadic seal compatibility theorem Definition 363.4 then reads the real boundary from exactly those enclosure and located rows. Componentwise hsame and Cont transport can move the rows between equivalent carrier presentations, but it does not add any analytic coordinate.

Since P and N list only the named dependency package and local certificate row, every exported seal fact is already accounted for by the ledger. The excluded quotient, representative choice, trichotomy, choice principle, and host real equality have no coordinate in the package. □

Theorem 363.8 (SignedDigitReal NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *seed surface consists of five finite obligations:*

1. *carrier: the* BHist *packet of Definition 363.1;*
2. *classifier: the finite-window comparison of Definition 363.2;*
3. *stability: carrier preservation under finite normalization windows as in Definition 363.3;*
4. *exact finite-window readback: the decoded* DyadicRatCore *enclosure row and its* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *routes;*
5. *ledger policy: the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 363.4, with quotient streams, selected representatives, trichotomy, choice, and host real equality excluded from the exported surface.*

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket namecert obligation surface`

Proof. The carrier and classifier rows provide the finite signed-digit source, the decoded dyadic enclosure rows, and the located-Cauchy route toward the real seal.

Stability is exactly the finite normalization theorem: a visible window read preserves the carrier and produces the dyadic enclosure row through the recorded history, transport, continuation, package, and certificate data.

Exact finite-window readback is the same displayed enclosure surface with its $\mathsf{DyadicApproximation}^{\uparrow}$ shape and $\mathsf{LocatedCauchy}^{\uparrow}$ precision witness. The ledger policy is the seal compatibility theorem,

which identifies the $\mathsf{Real}^{\uparrow}$ boundary while excluding all non-finite and non-constructive coordinates from the certificate. □

Theorem 363.9 (SignedDigitReal obligation transport package)**.** *Signed-digit stream rows, finite windows, dyadic enclosures,* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows, and* $\mathsf{Real}^{\uparrow}$ *seal rows transport together through the displayed* hsame, Cont, Pkg, *and* NameCert *ledger of an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier.*

The transport package is componentwise: it moves the signed-digit source, finite-window family, decoded DyadicRatCore *enclosures,* $\mathsf{DyadicApproximation}^{\uparrow}$ *routes, located-Cauchy rows, and real-seal boundary without adding quotient stream equality, selected representatives, trichotomy, choice, or host real equality.*

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket obligation transport package`

Proof. Project the carrier and the obligation ledger package. The coordinates S, W, E, and L list the source stream, finite windows, decoded dyadic enclosures, and located-Cauchy rows, while the real-seal boundary is read from the same enclosure and located rows.

Move each coordinate through the stored hsame rows and use the stored Cont routes to preserve the order from signed-digit prefix to normalization ledger, enclosure, located row, and seal boundary. The package provenance and local certificate row record that these are the only dependency names used by the transport.

Since no carrier coordinate stores quotient stream equality, a selected stream, a trichotomy branch, a choice datum, or host real equality, componentwise transport cannot export any such datum. □

Theorem 363.10 (SignedDigitReal exact readback boundary)**.** *Exact readback of every finite signed-digit window in an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier is exhausted by the decoded* DyadicRatCore *enclosure, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *route, the* $\mathsf{LocatedCauchy}^{\uparrow}$ *row, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary displayed in the obligation ledger package.*

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket exact readback boundary`

Proof. Choose a displayed finite window. The finite normalization window theorem Definition 363.3 reads that window through the signed-digit prefix and produces the corresponding decoded DyadicRatCore enclosure row.

The obligation ledger package then records the $\mathsf{DyadicApproximation}^{\uparrow}$ route attached to that enclosure and the $\mathsf{LocatedCauchy}^{\uparrow}$ row that exposes it at the requested precision. The seal ledger exactness theorem Definition 363.7 reads the real boundary from exactly those rows.

Thus the readback route stops at the displayed enclosure, approximation, located-Cauchy, and seal rows. The excluded quotient, selected representative, trichotomy, choice, and host equality data have no place in the route. □

Theorem 363.11 (SignedDigitReal tail-window export)**.** *Any accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *finite tail window exports to the* $\mathsf{Real}^{\uparrow}$ *seal only through the displayed* $\mathsf{SignedDigitStream}^{\uparrow}$ *prefix, the decoded* DyadicRatCore *enclosure, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *route, the* $\mathsf{LocatedCauchy}^{\uparrow}$ *row, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *row.*

The export contains no quotient stream, selected representative, trichotomy branch, choice datum, or host real equality.

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket tail window export`

Proof. First apply Definition 363.3. A finite signed-digit tail window is read as a displayed $\mathsf{SignedDigitStream}^{\uparrow}$ prefix and produces the decoded $\mathsf{DyadicRatCore}$ enclosure row named by the carrier.

Next apply Definition 363.6. It moves the prefix, enclosure, approximation route, located-Cauchy row, and induced seal boundary through the componentwise hsame rows while staying inside the same obligation ledger.

Now use Definition 363.7 and Definition 363.10. These two statements identify the $\mathsf{Real}^{\uparrow}$ seal read with exactly the decoded enclosure, $\mathsf{DyadicApproximation}^{\uparrow}$ route, $\mathsf{LocatedCauchy}^{\uparrow}$ row, displayed Cont routes, Pkg provenance, and local NameCert row.

Since each cited row is a coordinate of the finite carrier or its obligation ledger, no quotient stream, selected representative, trichotomy branch, choice datum, or host real equality can be exported to the seal boundary. □

Theorem 363.12 (SignedDigitReal obligation-closure package)**.** *The* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier, classifier, finite normalization theorem, dyadic seal compatibility, window classifier stability, seal ledger exactness, obligation transport package, and exact readback boundary assemble the paper-side obligation-closure package for the* $\mathsf{Real}^{\uparrow}$ *seal boundary.*

Proof. The carrier and classifier define the finite signed-digit surface and its accepted comparisons. The finite normalization theorem supplies the per-window decoded dyadic enclosure, and dyadic seal compatibility identifies the induced $\mathsf{Real}^{\uparrow}$ boundary.

The obligation ledger package and window classifier stability bind these rows into a single finite transport surface. Seal ledger exactness shows that the real boundary consumes only the displayed decoded enclosures and located-Cauchy rows.

The obligation transport package records componentwise movement of the same rows, and the exact readback boundary states that every finite signed-digit window is exhausted by the decoded enclosure, approximation route, located-Cauchy row, and seal boundary. Together these statements close the paper obligation layer while leaving the formal axis unchanged. □

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket obligation closure package`

Theorem 363.13 (SignedDigitReal common-window seal determinacy)**.** *Let* $R = (S, W, E, L, H, C, P, N)$ *and* $R' = (S', W', E', L', H', C', P', N')$ *be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carriers. Suppose the signed-digit classifier relates* R *and* R' *on a common displayed finite window, and suppose the decoded* $\mathsf{DyadicRatCore}$ *enclosure rows on that window transport through the displayed* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *routes. Then the induced* $\mathsf{Real}^{\uparrow}$ *seal read is the same finite seal package on that window: it is read from the transported signed-digit prefix, normalization ledger, dyadic enclosure, approximation route, located-Cauchy row, and the recorded* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *provenance.*

The determinacy is a common-window statement. It asserts no quotient stream equality, selected representative, trichotomy branch, choice datum, or host real equality.

Proof. Start with the finite normalization window theorem Definition 363.3. On the common window it reads each signed-digit prefix through the displayed carrier and produces the corresponding decoded $\mathsf{DyadicRatCore}$ enclosure row.

Apply the dyadic seal compatibility theorem Definition 363.4. The transported $\mathsf{DyadicApproximation}^{\uparrow}$ and $\mathsf{LocatedCauchy}^{\uparrow}$ routes ensure that both enclosure reads reach the same located-Cauchy surface before any $\mathsf{Real}^{\uparrow}$ seal boundary is consumed.

Use window classifier stability from Definition 363.6. It keeps the signed-digit source, finite window, decoded enclosure, located row, and seal boundary inside the same obligation ledger package under classifier-related transport.

Finally invoke seal ledger exactness from Definition 363.7. Since the seal consumes exactly the displayed decoded enclosure and located-Cauchy ledger, the two carriers determine the same finite seal package on the common window. The excluded quotient, representative, trichotomy, choice, and host-equality data are absent from the carrier and cannot enter the determinacy claim. □

Lean4 ✓ `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket common window seal determinacy`

Theorem 363.14 (SignedDigitReal tail-window seal determinacy)**.** *Let $R = (S, W, E, L, H, C, P, N)$ and $R' = (S', W', E', L', H', C', P', N')$ be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carriers. Suppose the two carriers agree on a displayed finite tail window through the* $\mathsf{SignedDigitStream}^{\uparrow}$ *classifier, and suppose the decoded* DyadicRatCore *enclosure rows transport through the displayed* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows. Then the* $\mathsf{Real}^{\uparrow}$ *seal read on that tail window is determined by the same finite prefix, normalization ledger, decoded enclosure, located row, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* NameCert *row.*

The determinacy is local to the tail window. It exports no quotient stream equality, selected signed-digit representative, trichotomy branch, choice datum, host real equality, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First use the finite normalization window theorem and dyadic seal compatibility. The shared tail window is decoded into the displayed DyadicRatCore enclosure, and the enclosure is the datum routed toward the $\mathsf{Real}^{\uparrow}$ seal boundary.

Next apply window classifier stability. It keeps the signed-digit prefix, decoded enclosure, located row, and seal boundary attached to the same carrier ledger under componentwise hsame transport and displayed Cont replay.

Seal ledger exactness and the exact readback boundary identify the seal read with exactly the decoded enclosure and located-Cauchy rows visible on the finite tail window. No wider stream object or host equality row is consulted.

Finally apply common-window seal determinacy to the shared tail window. The two carriers therefore determine the same finite $\mathsf{Real}^{\uparrow}$ seal package through the prefix, normalization ledger, enclosure, located row, transport, continuation, package, and naming rows. □

Theorem 363.15 (SignedDigitReal scoped kernel interface)**.** *Every accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier exposes exactly the kernel rows named by its finite packet: the* $\mathsf{SignedDigitStream}^{\uparrow}$ *source row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint and radius rows reached by finite normalization, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *enclosure route, the* $\mathsf{LocatedCauchy}^{\uparrow}$ *located-window row, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the visible* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{SignedDigitReal}^{\uparrow}}$ *provenance rows.*

No consumer of the carrier can read a quotient stream, selected signed-digit representative, trichotomy branch, choice datum, host equality row, or additional analytic dependency outside this list.

Proof. Project the carrier

$$R = (S, W, E, L, H, C, P, N).$$

The source row S, window family W, decoded enclosure row E, located row L, transport row H, continuation row C, dependency package P, and local naming row N are precisely the displayed coordinates of Definition 363.1.

Apply the obligation ledger package of Definition 363.5. It identifies the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{LocatedCauchy}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ routes as reads of those same coordinates rather than extra carrier fields.

Finally use seal ledger exactness from Definition 363.7. The real-facing read consumes only the decoded enclosure and located-Cauchy ledger, so the exposed scoped interface is exhausted by the listed kernel rows. □

Theorem 363.16 (SignedDigitReal dependency scope exhaustion)**.** *Every public finite-window read of an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier is exhausted by the obligation ledger package, the finite normalization window theorem, seal-ledger exactness, and common-window seal determinacy. The read passes through the signed-digit source, the decoded dyadic enclosure, the* $\mathsf{DyadicApproximation}^{\uparrow}$ *route, the* $\mathsf{LocatedCauchy}^{\uparrow}$ *row, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the recorded* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

There is no remaining dependency slot for stream quotients, selected representatives, trichotomy, choice, host real equality, or real completeness.

Proof. Start from a displayed finite window in the obligation ledger package. The finite normalization theorem Definition 363.3 reads the signed-digit prefix and produces the corresponding decoded DyadicRatCore enclosure row.

Next route the enclosure through the displayed $\mathsf{DyadicApproximation}^{\uparrow}$ and $\mathsf{LocatedCauchy}^{\uparrow}$ rows. Seal ledger exactness in Definition 363.7 states that the $\mathsf{Real}^{\uparrow}$ boundary consumes exactly those rows and no wider analytic object.

For comparisons between carriers, apply common-window seal determinacy from Definition 363.13. It shows that a shared finite window reaches the same finite seal package through the same listed rows, so public reads have no dependency outside the obligation ledger. □

Theorem 363.17 (SignedDigitReal RealUp seal scope boundary)**.** *The* $\mathsf{Real}^{\uparrow}$ *seal boundary of an accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *carrier is reached only after a finite signed-digit prefix has been decoded into a* DyadicRatCore *enclosure and routed through the displayed* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows. The seal cannot be read directly from the signed-digit stream, from an infinite quotient, from a selected representative, or from host real equality.*

Proof. Choose a seal read from an accepted carrier. By the exact readback boundary Definition 363.10, the read first selects a finite signed-digit window and decodes it into the displayed dyadic enclosure row.

The obligation ledger package then supplies the $\mathsf{DyadicApproximation}^{\uparrow}$ route and the $\mathsf{LocatedCauchy}^{\uparrow}$ located row attached to that enclosure. These rows are the precision-facing data available before the real seal is consumed.

Apply seal ledger exactness. Since the seal consumes exactly the decoded enclosure and located-Cauchy ledger, any route that bypasses those rows or uses quotient, choice, selected-representative, or host-equality data is outside the $\mathsf{SignedDigitReal}^{\uparrow}$ carrier scope. □

Theorem 363.18 (SignedDigitReal public seal export)**.** *The public* $\mathsf{SignedDigitReal}^{\uparrow}$ *surface is exactly the finite route from signed-digit stream windows through* $\mathsf{DyadicRatCore}^{\uparrow}$ *enclosures,* $\mathsf{DyadicApproximation}^{\uparrow}$ *routes,* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary. Every exported seal read factors through the carrier, normalization window, dyadic seal compatibility, window classifier stability, seal ledger exactness, exact readback boundary, common-window seal determinacy, scoped kernel interface, and dependency scope exhaustion rows.*

Proof. Begin with the exact readback boundary. It selects a finite signed-digit window and decodes that window by the normalization theorem into the displayed DyadicRatCore$^{\uparrow}$ enclosure.

Route the decoded enclosure through dyadic seal compatibility, the DyadicApproximation$^{\uparrow}$ row, and the LocatedCauchy$^{\uparrow}$ row. Window classifier stability keeps these rows attached to the same displayed carrier under hsame transport.

Seal ledger exactness then identifies the Real$^{\uparrow}$ boundary as the only seal-consuming row. Common-window seal determinacy, the scoped kernel interface, and dependency scope exhaustion show that every public seal read is exhausted by this finite route. □

Theorem 363.19 (SignedDigitReal public representative exclusion)**.** *The public* SignedDigitReal$^{\uparrow}$ *seal surface contains no quotient stream equality, selected signed-digit representative, trichotomy branch, choice datum, or host real equality. Its consumers can read only the displayed signed-digit window, decoded dyadic enclosure,* DyadicApproximation$^{\uparrow}$ *route,* LocatedCauchy$^{\uparrow}$ *row,* Real$^{\uparrow}$ *seal boundary, and the recorded* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Proof. Project the scoped kernel interface of Definition 363.15. It lists the public coordinates available to a consumer and excludes quotient, representative, branch, choice, and host-equality data from the carrier.

Apply Definition 363.18. Every seal read factors through the finite window, dyadic enclosure, approximation route, located-Cauchy row, and real seal boundary.

Finally use dependency scope exhaustion from Definition 363.16. Since the listed rows exhaust every public read, no quotient stream equality, selected representative, trichotomy branch, choice datum, or host real equality can be recovered from the public surface. □

Theorem 363.20 (SignedDigitReal prefix refinement seal commutes)**.** *Let two accepted* SignedDigitReal$^{\uparrow}$ *packets refine the same signed-digit prefix window, and let the refined window be a narrower finite window accepted by the same window classifier. Then the refined window's decoded* DyadicRatCore *enclosure,* DyadicApproximation$^{\uparrow}$ *route,* LocatedCauchy$^{\uparrow}$ *row, and* Real$^{\uparrow}$ *seal boundary agree with the coarser route after componentwise* hsame *transport and the displayed* Cont *transport through the carrier ledger.*

Equivalently, every seal read along the refined route is the same finite Real$^{\uparrow}$ *boundary read as the coarser route once both reads are repacked through the shared signed-digit source row, decoded enclosure row, approximation route, located-Cauchy row,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Proof. Start from the common accepted prefix window. The finite normalization window theorem Definition 363.3 decodes both the coarser and refined windows into the displayed DyadicRatCore enclosure rows, and window classifier stability from Definition 363.6 keeps those rows attached under componentwise hsame transport.

Next replay the route through the approximation and located-Cauchy rows. The carrier obligations and seal ledger exactness of Definition 363.7 state that the DyadicApproximation$^{\uparrow}$ route, LocatedCauchy$^{\uparrow}$ row, and Real$^{\uparrow}$ boundary are read only through the displayed Cont paths.

The exact readback boundary Definition 363.10 then identifies the refined read as a finite readback inside the same carrier ledger. Public representative exclusion from Definition 363.19 rules out any quotient stream, selected representative, trichotomy branch, choice datum, or host equality that could separate the two routes.

Thus the refined and coarser seal reads commute through the same finite ledger rows. Their decoded enclosure, approximation route, located-Cauchy row, and real seal boundary agree after the recorded hsame and Cont transports. □

Theorem 363.21 (SignedDigitReal window refinement directedness)**.** *Let $R = (S, W, E, L, H, C, P, N)$ and $R' = (S', W', E', L', H', C', P', N')$ be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *packets whose finite windows refine a common signed-digit source row. Then there is a shared finite refinement window for the two reads such that its decoded* DyadicRatCore *enclosure, its* $\mathsf{DyadicApproximation}^{\uparrow}$ *route, its* $\mathsf{LocatedCauchy}^{\uparrow}$ *row, and its* $\mathsf{Real}^{\uparrow}$ *seal boundary all factor through one shared finite budget recorded by the two packet ledgers and their componentwise* hsame *and* Cont *transports.*

The shared budget is directed only at the finite-window level. It exports no quotient stream, selected representative, trichotomy branch, choice datum, host real equality, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Start with the common signed-digit source row and the two accepted finite windows. Apply the finite normalization-window theorem Definition 363.3 to decode each window into its displayed DyadicRatCore enclosure row.

Use window-classifier stability from Definition 363.6 to transport the two decoded reads along the common signed-digit source. This identifies the prefix data, enclosure rows, approximation routes, located-Cauchy rows, and seal-boundary rows as finite ledger coordinates rather than as representatives of an infinite stream.

Now apply seal-ledger exactness Definition 363.7 and common-window seal determinacy Definition 363.13. These results force both seal reads to consume exactly the displayed decoded enclosure and located-Cauchy rows on a common finite window.

Finally use prefix-refinement seal commutation from Definition 363.20. It repacks the two refined routes through a single narrower window and the same finite BHist, hsame, Cont, Pkg, and NameCert provenance. Since every cited theorem works inside finite carrier coordinates, quotient streams, selected representatives, trichotomy, choice, host real equality, and $\mathsf{Real}^{\uparrow}$ completeness have no role in the directed shared-window budget. □

Theorem 363.22 (SignedDigitReal public refinement consistency)**.** *Let $R = (S, W, E, L, H, C, P, N)$ and $R' = (S', W', E', L', H', C', P', N')$ be accepted* $\mathsf{SignedDigitReal}^{\uparrow}$ *packets whose finite windows refine the same signed-digit source row. Suppose the decoded* DyadicRatCore *enclosure rows transport through the displayed* $\mathsf{DyadicApproximation}^{\uparrow}$ *and* $\mathsf{LocatedCauchy}^{\uparrow}$ *rows, and suppose the two routes are matched componentwise by* hsame *and the displayed* Cont *transports through their packet ledgers. Then the two packets determine the same public* $\mathsf{Real}^{\uparrow}$ *seal read.*

The public read is the finite seal boundary carried by the shared signed-digit source, the refined finite windows, decoded dyadic enclosures, approximation rows, located-Cauchy rows, $\mathsf{Real}^{\uparrow}$ *seal boundary,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. It does not use quotient stream equality, selected representatives, trichotomy, choice, host real equality, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the finite windows. The finite normalization theorem Definition 363.3 decodes both refined windows into displayed DyadicRatCore enclosure rows, and window classifier stability from Definition 363.6 keeps those rows attached to the same signed-digit source under componentwise hsame transport.

Next transport the decoded enclosure through the public route. Seal ledger exactness Definition 363.7 and exact readback boundary Definition 363.10 identify each $\mathsf{Real}^{\uparrow}$ read with the displayed $\mathsf{DyadicApproximation}^{\uparrow}$ and $\mathsf{LocatedCauchy}^{\uparrow}$ rows rather than with an external real representative.

Now pass to a common refinement. Prefix-refinement seal commutation from Definition 363.20 shows that a narrower accepted window preserves the same seal boundary, and window refinement directedness Definition 363.21 supplies such a shared finite window for the two accepted packets.

The two public reads therefore meet at the same finite $\mathsf{Real}^{\uparrow}$ seal boundary after the recorded hsame and Cont transports. Public representative exclusion from Definition 363.19 rules out quotient stream equality, selected representatives, trichotomy, choice, host real equality, and $\mathsf{Real}^{\uparrow}$ completeness as alternate ways to separate the two reads. □

Closure status for $\mathsf{NameCert}_{\mathsf{SignedDigitReal}\uparrow}$.

Constructive story: A $\mathsf{SignedDigitReal}^{\uparrow}$ packet is generated from an accepted $\mathsf{SignedDigitStream}^{\uparrow}$ row, finite normalization windows, decoded DyadicRatCore enclosure rows, $\mathsf{DyadicApproximation}^{\uparrow}$ and $\mathsf{LocatedCauchy}^{\uparrow}$ routes, a $\mathsf{Real}^{\uparrow}$ seal boundary, and visible BHist, hsame, Cont, Pkg, and NameCert provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SignedDigitReal}\uparrow}$, scopedClosed)

Scope closed: The scoped kernel interface is exhausted by the carrier, classifier, finite normalization stability, seal compatibility, window classifier stability, exact readback boundary, transport package, common-window determinacy, and seal-boundary route over $\mathsf{SignedDigitStream}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicApproximation}^{\uparrow}$, $\mathsf{LocatedCauchy}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SignedDigitReal}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.SignedDigitRealUp.SignedDigitRealPacket\_obligation\_closure\_package`

Bridge status: none

Origin: human

Not claimed: This chapter does not close full signed-digit regularity, RealUp completeness, quotient equality of streams, selected representatives, trichotomy, choice, host real equality, or bridge checking.

Upgrade path: Public export requires a downstream-facing object surface that consumes the same finite signed-digit, dyadic, located-Cauchy, and real-seal rows without widening the dependency scope.

Chapter 364

A Concrete Naming Certificate for $\mathsf{StationaryRationalCauchy}^{\uparrow}$

The $\mathsf{StationaryRationalCauchy}^{\uparrow}$ interface records the concrete stationary rational regular Cauchy input that appears in Definition 9238.6. It is the finite $\mathsf{Real}^{\uparrow}$ handoff certificate obtained by keeping the hidden $\mathsf{Rat}^{\uparrow}$ seed, its constant $\mathsf{StreamName}^{\uparrow}$ windows, the associated $\mathsf{RegSeqRat}^{\uparrow}$ member, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the local Pkg and $\mathsf{NameCert}$ rows visible.

The chapter consumes the diagonal representative supplied by chapter 362 and narrows it to the stationary rational Cauchy packet through the displayed $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ ledger. The dependency is substantive: the RealUp handoff below is the constant rational diagonal read with every non-stationary coordinate removed.

Definition 364.1 (StationaryRationalCauchy carrier)**.** *A* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (q, A, R, D, E, P, N)$$

with the following visible coordinates:

1. *q is the hidden* $\mathsf{Rat}^{\uparrow}$ *row supplying the rational seed;*
2. *A is the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule whose every requested finite window reads the seed q;*
3. *R is the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member whose every regular-sequence index returns the stream row A with the zero modulus row;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger recording the same rational observation at every selected window;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row for the constant rational embedding of q;*
6. *P is the* Pkg *provenance row naming the* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{NameCert}$ *dependencies;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryRationalCauchy}^{\uparrow}}$ *row.*

The local classifier compares two carriers by the displayed hsame *transport of the seed rows, constant stream schedules, stationary regular-sequence members, dyadic ledgers, real seals, package provenance, and local certificate rows, with* Cont *routes recording the finite-window readback used by each consumer.*

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyTasteGate single carrier alignment`

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyUpTasteGate single carrier alignment ChapterTasteGate`

Theorem 364.2 (StationaryRationalCauchy NameCert obligations)**.** *The* $\mathsf{NameCert}_{\mathsf{StationaryRationalCauchy}^{\uparrow}}$ *surface consists of four obligations over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows: carrier habitation by Definition 364.1; constant-stream classifier reflexivity for the* $\mathsf{Rat}^{\uparrow}$ *seed inside every* $\mathsf{StreamName}^{\uparrow}$ *window; stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *stability with the zero modulus and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger; and exact export of the constant rational* $\mathsf{Real}^{\uparrow}$ *seal without quotient stream equality, selected host limits, or ambient real completeness.*

Proof. Carrier habitation is the finite packet assembly. The seed row, constant stream schedule, stationary regular-sequence member, dyadic observation ledger, real seal, package provenance, and local certificate row are all visible coordinates of the BHist carrier.

Constant-stream reflexivity supplies the classifier row: each $\mathsf{StreamName}^{\uparrow}$ window reads the same $\mathsf{Rat}^{\uparrow}$ seed, so its hsame comparison is the reflexive comparison transported along the displayed Cont route for that finite window.

The regular Cauchy obligation is stationary. The zero modulus row is admissible because every member of the $\mathsf{RegSeqRat}^{\uparrow}$ family returns the same stream row and the same $\mathsf{DyadicRatCore}^{\uparrow}$ rational observation ledger.

The export obligation is ledger exactness. The Pkg and NameCert rows name exactly the dependency certificates used in the readback, and no field of the carrier contains a quotient of streams, a selected host limit, or an ambient completeness object. □

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyCarrier namecert obligations`

Theorem 364.3 (StationaryRationalCauchy diagonal handoff)**.** *For every accepted* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carrier* S *and every unary precision request* n*, the diagonal read used by the* $\mathsf{Real}^{\uparrow}$ *handoff factors through the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member of* S*, one finite constant* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{Rat}^{\uparrow}$ *seed row, the matching* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the visible* hsame*,* Cont*,* Pkg*, and* NameCert *rows carried by* S*.*

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyBHistCarrier diagonal handoff`

Proof. Project the packet of Definition 364.1. The requested precision n reaches the stationary regular-sequence member R, and R returns the same stream row at every index.

Read the scheduled finite window of A. Because A is constant, the selected window returns the seed row q with the same $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger independently of n.

The displayed hsame comparison transports this read through the stored Cont route, and the Pkg and NameCert rows record the provenance of the read. Thus the diagonal read is exactly the finite route listed in the statement. □

Theorem 364.4 (StationaryRationalCauchy finite-prefix uniformity)**.** *For every accepted* StationaryRationalCauchy *carrier* $S = (q, A, R, D, E, P, N)$ *and every finite unary prefix of precision requests, each request in the prefix reads the same* $\mathsf{Rat}^{\uparrow}$ *seed* q *through the same constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* A*, the same stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member* R*, and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*. The only variation permitted across the prefix is the displayed* hsame *transport and* Cont *route used to reach the repeated rows.*

Proof. Induct over the finite prefix. The empty prefix has no requested read, so the carrier coordinates already supply the uniform seed, schedule, regular-sequence member, and ledger.

For a prefix extended by one request n, apply Definition 364.3 to the final request. The handoff routes n through R, then through the constant schedule A, and then back to the seed row q and ledger D.

The induction hypothesis gives the same rows for the earlier requests. Since the carrier of Definition 364.1 is stationary in q, A, R, D, the final request introduces no new stream schedule, regular-sequence member, or dyadic ledger. Its displayed hsame and Cont rows are the only request-indexed data. □

Theorem 364.5 (StationaryRationalCauchy classifier correspondence)**.** *Let $S = (q, A, R, D, E, P, N)$ and $S' = (q', A', R', D', E', P', N')$ be accepted* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carriers. The local classifier relates S and S' exactly when the displayed* $\mathsf{Rat}^{\uparrow}$ *classifier relates q and q' and the associated* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, Pkg, *and* NameCert *rows are transported componentwise by the recorded* hsame *comparisons and* Cont *routes.*

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyCarrier classifier correspondence`

Proof. For the forward direction, inspect the local classifier. Its only seed-sensitive coordinate is the hidden rational row, and every stream, regular-sequence, dyadic, real-seal, package, and certificate coordinate is defined as the stationary readback of that seed. Projecting the classifier therefore gives the displayed $\mathsf{Rat}^{\uparrow}$ comparison and the componentwise transport rows.

For the reverse direction, start with the $\mathsf{Rat}^{\uparrow}$ comparison between q and q'. Constant-stream reflexivity transports it to every finite $\mathsf{StreamName}^{\uparrow}$ window of A and A'.

The same finite-window transport lifts to the stationary $\mathsf{RegSeqRat}^{\uparrow}$ members because all regular-sequence indices read those constant stream rows. The $\mathsf{DyadicRatCore}^{\uparrow}$ ledgers and $\mathsf{Real}^{\uparrow}$ seals are then the diagonal readbacks of the same transported windows.

Repack the transported coordinates with P, P' and N, N'. Since the local classifier compares exactly these rows, the two carriers are classified together. □

Theorem 364.6 (StationaryRationalCauchy ledger exactness)**.** *Every consumer-facing* $\mathsf{Real}^{\uparrow}$ *read exported by an accepted* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carrier is exhausted by the finite ledger*

$$\mathsf{Rat}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

together with the displayed BHist, hsame, Cont, Pkg, *and* NameCert *rows. The carrier exports no additional equality principle, host-real endpoint, non-stationary Cauchy family, or completeness theorem.*

Proof. Begin with the diagonal handoff of Definition 364.3. It shows that each consumer read first reaches the stationary $\mathsf{RegSeqRat}^{\uparrow}$ member and then a finite constant $\mathsf{StreamName}^{\uparrow}$ window.

The window read returns the hidden $\mathsf{Rat}^{\uparrow}$ seed and the matching $\mathsf{DyadicRatCore}^{\uparrow}$ observation. The $\mathsf{Real}^{\uparrow}$ seal row is attached to that same constant rational readback.

The remaining carrier coordinates are provenance: BHist supplies the finite packet, hsame and Cont supply the visible transports, and Pkg and NameCert name the certificate rows. These fields exhaust the exported ledger, so no further equality principle, host-real endpoint, non-stationary family, or completeness theorem is available from the carrier. □

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyCarrier ledger exactness`

Theorem 364.7 (StationaryRationalCauchy RegSeqRat handoff scope)**.** *The constant rational embedding carried by* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *into* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *is scoped entirely by the displayed* $\mathsf{Rat}^{\uparrow}$ *seed, constant* $\mathsf{StreamName}^{\uparrow}$ *schedule, stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It does not require quotient stream equality, selected host limits, or ambient completeness.*

Proof. Begin with the carrier of Definition 364.1. Its finite packet exposes the seed q, constant schedule A, stationary member R, dyadic ledger D, real seal E, package row P, and local certificate row N.

The diagonal handoff of Definition 364.3 sends each precision request through R and then through a finite window of A back to q and D. The finite-prefix uniformity of Definition 364.4 shows that repeating the read across any finite request list introduces no new stream schedule, regular-sequence member, or ledger.

Classifier correspondence in Definition 364.5 transports exactly the displayed seed, stream, regular-sequence, dyadic, real, package, and certificate rows. Ledger exactness from Definition 364.6 then exhausts the exported $\mathsf{Real}^{\uparrow}$ read, excluding quotient stream equality, selected host limits, and ambient completeness from the handoff scope. □

Lean4 ✓ `BEDC.Derived.StationaryRationalCauchyUp.StationaryRationalCauchyUp StdBridge`

Theorem 364.8 (StationaryRationalCauchy RealUp embedding exactness)**.** *For every accepted* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carrier* $S = (q, A, R, D, E, P, N)$*, the exported* $\mathsf{Real}^{\uparrow}$ *seal* E *is exactly the constant rational embedding route through the* $\mathsf{Rat}^{\uparrow}$ *seed* q*, the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* A*, the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *member* R*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Equivalently, every consumer read of E *is exhausted by the finite route*

$$\mathsf{Rat}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

inside the carrier S*. The exported seal does not use quotient stream equality, a selected host limit, or ambient completeness.*

Proof. First read the diagonal route. By Definition 364.3, every precision request reaches the stationary member R, then a finite constant window of A, and then the seed row q with the matching ledger D.

Next make the route uniform. The finite-prefix uniformity theorem shows that any finite family of requests reads the same q, A, R, and D rows. Thus the $\mathsf{Real}^{\uparrow}$ seal cannot depend on a non-stationary stream coordinate.

Transport and exactness are then componentwise. Classifier correspondence moves exactly the displayed seed, stream, regular-sequence, dyadic, seal, package, and certificate rows, while ledger exactness exhausts the $\mathsf{Real}^{\uparrow}$ read by the finite chain shown above.

Finally apply the RegSeqRat handoff scope theorem. It identifies the same stationary route as the entire $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ handoff, so E is precisely the constant rational embedding of q and not a quotient stream, selected host limit, or ambient completeness construction. □

Theorem 364.9 (StationaryRationalCauchy obligation package)**.** *For every accepted* $\mathsf{StationaryRationalCauchy}^{\uparrow}$ *carrier* $S = (q, A, R, D, E, P, N)$*, the obligation package is the finite package assembled from the carrier, the* NameCert *obligations, the diagonal handoff, finite-prefix uniformity, classifier correspondence, ledger exactness,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff scope, and* $\mathsf{Real}^{\uparrow}$ *embedding exactness rows. Its visible coordinates are the hidden* $\mathsf{Rat}^{\uparrow}$ *seed* q*, constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* A*, stationary*

RegSeqRat$^{\uparrow}$ *member* R, DyadicRatCore$^{\uparrow}$ *ledger* D, Real$^{\uparrow}$ *seal* E, *package row* P, *local* NameCert *row* N, *and the displayed* BHist, hsame, *and* Cont *witnesses.*

Proof. First project the carrier and the local certificate obligations from Definition 364.1 and Definition 364.2. These rows provide the seed, constant schedule, stationary member, dyadic ledger, real seal, package provenance, local name, and transport witnesses.

Next assemble the finite request behavior. The diagonal handoff sends each precision request through R, A, q, and D, while finite-prefix uniformity shows that finite request lists reuse the same stationary rows.

Finally add the classifier, ledger, handoff, and embedding rows. Definition 364.5, Definition 364.6, Definition 364.7, and Definition 364.8 identify the same finite stationary package as the full obligation surface. □

Theorem 364.10 (StationaryRationalCauchy stationary readback)**.** *Every stationary readback from an accepted* StationaryRationalCauchy$^{\uparrow}$ *carrier factors through the hidden* Rat$^{\uparrow}$ *seed* q, *constant* StreamName$^{\uparrow}$ *windows* A, *stationary* RegSeqRat$^{\uparrow}$ *member* R, DyadicRatCore$^{\uparrow}$ *ledger* D, *package row* P, *local* NameCert *row* N, *and the displayed* BHist, hsame, *and* Cont *rows. No readback introduces a non-stationary stream, quotient stream equality, selected host limit, or ambient completeness datum.*

Proof. Begin with Definition 364.3. A precision request reaches R, then the constant window A, then the seed q and dyadic ledger D.

Use Definition 364.4 for multiple requests. The same q, A, R, D rows serve every finite prefix, so no new stream schedule or regular-sequence member appears.

Finally apply Definition 364.5. The package, certificate, BHist, hsame, and Cont rows transport the same stationary data componentwise, preserving the exclusions in the statement. □

Theorem 364.11 (StationaryRationalCauchy RealUp seal non-escape)**.** *The* Real$^{\uparrow}$ *seal exported by an accepted* StationaryRationalCauchy$^{\uparrow}$ *carrier does not provide quotient Cauchy classes, host sequence equality, selected limits, or ambient completeness. It is exactly the finite stationary route through the* Rat$^{\uparrow}$ *seed, constant* StreamName$^{\uparrow}$ *windows, stationary* RegSeqRat$^{\uparrow}$ *member,* DyadicRatCore$^{\uparrow}$ *ledger,* Pkg *provenance,* NameCert *row, and displayed* BHist, hsame, *and* Cont *witnesses.*

Proof. First read the seal through Definition 364.8. The seal is the constant rational embedding route through q, A, R, D, E, P, N.

Next use Definition 364.6. Ledger exactness exhausts the Real$^{\uparrow}$ read by the dyadic observation and stationary rational rows, leaving no coordinate for quotient Cauchy classes or host sequence equality.

Finally apply Definition 364.9. Since the obligation surface contains only the finite stationary carrier rows and their displayed transports, selected limits and ambient completeness are not exported by the seal. □

Closure status for NameCert$_{\text{StationaryRationalCauchy}^{\uparrow}}$.

Constructive story: A StationaryRationalCauchy$^{\uparrow}$ packet is generated from a hidden Rat$^{\uparrow}$ seed, a constant StreamName$^{\uparrow}$ schedule, a stationary RegSeqRat$^{\uparrow}$ member, a DyadicRatCore$^{\uparrow}$ observation ledger, a Real$^{\uparrow}$ seal, and displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Theory closure: TheoryGate(NameCert$_{\text{StationaryRationalCauchy}^{\uparrow}}$, publicClosed)

Scope closed: Definition 364.1, Definition 364.2, and the diagonal handoff, finite-prefix uniformity, classifier correspondence, ledger exactness, RegSeqRat$^{\uparrow}$ handoff scope, and Real$^{\uparrow}$ embedding exactness rows export the public stationary rational Real$^{\uparrow}$ embedding surface.

Not claimed: This chapter does not close the exact kernel dependency scope, bridge surface, or completion uniqueness obligations.
Upgrade path: Bridge closure requires recording the standard bridge row as the bridge surface without claiming completion uniqueness.

Chapter 365

A Concrete Naming Certificate for $\mathsf{FiniteWindowEnvelope}^{\uparrow}$

The $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ interface is the concrete finite observation boundary for the Real and Completion phase. It packages a selected $\mathsf{StreamName}^{\uparrow}$ window, its $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ seal row that reads the same rational window, and the $\mathsf{Real}^{\uparrow}$ endpoint classifier row that exposes the window to real-number consumers. The envelope is deliberately finite: it certifies exactly the inspected anchor, window, and scale rows, and it exports no diagonal limit, quotient of streams, host real equality, or completeness theorem.

The envelope is the finite-window handoff between chapter 126, chapter 291, chapter 301, and chapter 38. It consumes a selected $\mathsf{StreamName}^{\uparrow}$ window, a dyadic observation ledger, a $\mathsf{RegSeqRat}^{\uparrow}$ seal row, and a $\mathsf{Real}^{\uparrow}$ endpoint classifier as one finite package.

Definition 365.1 (FiniteWindowEnvelope carrier)**.** *A* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier is a finite* BHist *package*

$$W = (S, A, B, L, Q, G, E, P, N)$$

with the following visible coordinates:

1. *S is the* $\mathsf{Rat}^{\uparrow}$ *stream source named by the surrounding* $\mathsf{StreamName}^{\uparrow}$ *certificate;*
2. *A is the selected finite anchor row, recording the inspected source point and the continuation route that reaches it;*
3. *B is the finite window row, recording the requested length, scale, and local subwindow bounds;*
4. *L is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger for every rational read made inside B;*
5. *Q is the* $\mathsf{StreamName}^{\uparrow}$ *window classifier row for the same source, anchor, and window;*
6. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row that reads the dyadic ledger as a regular rational sequence window;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *endpoint classifier row for the same finite window;*
8. *P is the* Pkg *provenance naming the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*, and* $\mathsf{NameCert}$ *source certificates;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteWindowEnvelope}^{\uparrow}}$ *provenance row.*

The local classifier relates two carriers exactly when their selected finite windows agree by the $\mathsf{StreamName}^{\uparrow}$ *window classifier, their* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledgers are equal row by row, their* $\mathsf{RegSeqRat}^{\uparrow}$

seal rows classify the same regular rational window, and their $\mathsf{Real}^{\uparrow}$ *finite-window endpoint classifiers agree after the displayed* hsame *and* Cont *transports.*

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeTasteGate single carrier alignment`

Theorem 365.2 (FiniteWindowEnvelope NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteWindowEnvelope}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier formation from the finite* BHist *package of Definition 365.1;*
2. *classifier reflexivity, symmetry, and transitivity for the combined* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows;*
3. *carrier transport under displayed* hsame *comparisons and finite window refinement routes;*
4. *seal handoff from the selected* $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger to the* $\mathsf{RegSeqRat}^{\uparrow}$ *row;*
5. *ledger exhaustion for the hidden anchor, selected window, scale, subwindow bound, dyadic readback, and endpoint classifier rows.*

Proof. Carrier formation is immediate from the displayed finite package: every coordinate is a visible row, and the package provenance names exactly the certificates that own those rows.

For the classifier laws, apply the component laws already required by the four dependency certificates. Reflexivity uses the same source, anchor, window, dyadic ledger, regular-sequence seal, and endpoint row. Symmetry reverses each displayed classifier row. Transitivity composes the four component comparisons while keeping the anchor and window coordinates synchronized by the common $\mathsf{StreamName}^{\uparrow}$ row.

Transport under hsame and Cont is componentwise. A transported anchor transports its finite window, the dyadic ledger follows the same requested readbacks, and the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows are repacked against those transported finite reads.

The seal handoff and ledger exhaustion are the remaining two rows. The seal row consumes the same ledger recorded by the carrier, and the exhaustion row says that every finite observation has already appeared as one of the displayed anchor, window, scale, dyadic, regular-sequence, or endpoint coordinates. □

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeCarrier namecert obligations`

Theorem 365.3 (FiniteWindowEnvelope RegSeqRat seal handoff)**.** *For every accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier, the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row is determined by the selected* $\mathsf{StreamName}^{\uparrow}$ *window together with the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger. If two carriers have the same selected window and equal dyadic ledgers after the displayed transports, then their* $\mathsf{RegSeqRat}^{\uparrow}$ *seal rows classify the same regular rational finite observation.*

Proof. Project the carrier of Definition 365.1. The row Q names the finite $\mathsf{StreamName}^{\uparrow}$ window, while L records every dyadic rational read performed inside that window.

The $\mathsf{RegSeqRat}^{\uparrow}$ seal row G is attached to those same readbacks. Therefore a second carrier with the same selected window and the same dyadic ledger presents the same regular rational finite observation to the seal interface.

Transport only changes the displayed route used to reach the rows. Since the classifier compares the transported window and ledger before reading the seal row, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff is invariant under the permitted hsame and Cont transports. □

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeCarrier regseqrat seal handoff`
↪ variant `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier regseqrat seal handoff`

Theorem 365.4 (FiniteWindowEnvelope RealUp window exactness)**.** *For every accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier, a* $\mathsf{Real}^{\uparrow}$ *finite-window endpoint read factors through exactly one selected* $\mathsf{StreamName}^{\uparrow}$ *window, one* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and one* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row. No endpoint read bypasses the carrier by appealing to a host real value, a quotient representative, a diagonal limit, or an ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier realup window exactness`

Proof. Begin with a $\mathsf{Real}^{\uparrow}$ endpoint read of the carrier. The endpoint row E is one of the visible coordinates of the source package, so the read first exposes the anchor and finite window rows to which E is attached.

The window row is classified by Q, and every rational observation inside it is recorded in L. By Definition 365.3, the regular rational view of the same finite observation is exactly the seal row G.

Thus the endpoint read has no independent source of data. It reaches the $\mathsf{Real}^{\uparrow}$ classifier only through the selected stream window, the dyadic ledger, and the regular-sequence seal, leaving no host value or completion object available to consumers. □

Theorem 365.5 (FiniteWindowEnvelope common refinement exactness)**.** *Let* $W = (S, A, B, L, Q, G, E, P, N)$ *and* $W' = (S', A', B', L', Q', G', E', P', N')$ *be accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carriers. If the local classifier relates* W *and* W'*, then their comparison factors through one displayed selected* $\mathsf{StreamName}^{\uparrow}$ *finite window, one transported* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, one* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row, and one* $\mathsf{Real}^{\uparrow}$ *endpoint classifier row. Conversely, any such four transported rows, with the package and local certificate provenance already carried by* P, N, P', N'*, repack into the local* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *classifier.*

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier common refinement exactness`

Proof. For the forward direction, project the carrier tuple of Definition 365.1. The classifier can inspect only the selected window row Q, the dyadic ledger L, the seal row G, the endpoint row E, and their transported counterparts.

Use Definition 365.3 to identify the transported $\mathsf{RegSeqRat}^{\uparrow}$ seal from the common selected window and the common dyadic ledger. Then use Definition 365.4 to identify the endpoint classifier as the read of that same finite window through the same seal row.

It remains only to rule out hidden comparison data. Apply Definition 365.6: every anchor, scale, subwindow, readback, seal, endpoint, package, and certificate row has already appeared in the displayed carrier coordinates.

For the reverse direction, start with the displayed $\mathsf{StreamName}^{\uparrow}$ window, transported $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ seal, and $\mathsf{Real}^{\uparrow}$ endpoint classifier rows. Repack them with the provenance rows P, N, P', N' into the component order of Definition 365.1. Since the local classifier is exactly the componentwise comparison of those rows, the two carriers classify together. □

Theorem 365.6 (FiniteWindowEnvelope ledger exhaustion)**.** *Every accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier exhausts the hidden finite observation data: the anchor, window length, scale, subwindow*

bounds, selected offsets, dyadic readbacks, RegSeqRat$^{\uparrow}$ *seal,* Real$^{\uparrow}$ *endpoint classifier,* Pkg *provenance, and local* NameCert *row all occur as displayed coordinates of the carrier or as displayed component rows of those coordinates.*

Proof. Inspect the finite package W of Definition 365.1. The anchor coordinate records the selected source point and its continuation route, while the window coordinate records the length, scale, local bounds, and offsets.

The dyadic ledger coordinate records the rational readbacks. The StreamName$^{\uparrow}$ classifier, RegSeqRat$^{\uparrow}$ seal, and Real$^{\uparrow}$ endpoint classifier then consume those same rows rather than introducing additional finite observations.

The provenance coordinates P and N account for the package and local naming rows. Since every finite observation field is present in these coordinates or in their displayed component ledgers, the carrier leaves no hidden anchor, window, scale, or endpoint row outside the certificate. □

Theorem 365.7 (FiniteWindowEnvelope StreamName RegSeqRat scope)**.** *Every accepted* FiniteWindowEnvelope$^{\uparrow}$ *read from a selected finite* StreamName$^{\uparrow}$ *window to a* RegSeqRat$^{\uparrow}$ *seal is exhausted by the anchor row, window row,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *seal,* Real$^{\uparrow}$ *endpoint classifier,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed in the carrier. The handoff has no additional hidden window selector, rational readback table, endpoint classifier, or completion-side equality field.*

Proof. Project the carrier of Definition 365.1. The selected anchor and window rows name the finite StreamName$^{\uparrow}$ read, while the dyadic ledger records every rational observation made inside that read.

By Definition 365.3, the RegSeqRat$^{\uparrow}$ seal consumes exactly that selected window and ledger. By Definition 365.4, the Real$^{\uparrow}$ endpoint classifier is attached to the same finite window rather than to a separate endpoint object.

The common refinement theorem Definition 365.5 shows that transported comparisons factor through the same displayed window, ledger, seal, and endpoint rows. Finally, Definition 365.6 accounts for the anchor, window, scale, subwindow, readback, package, and certificate rows, so the StreamName$^{\uparrow}$ to RegSeqRat$^{\uparrow}$ handoff is scoped by the listed data. □

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier streamname regseqrat scope`

Theorem 365.8 (FiniteWindowEnvelope tail projection)**.** *For every accepted* FiniteWindowEnvelope$^{\uparrow}$ *carrier* $W = (S, A, B, L, Q, G, E, P, N)$*, any displayed tail read or subwindow read of the accepted envelope factors through the same anchor row* A*, selected* StreamName$^{\uparrow}$ *finite window* Q*,* DyadicRatCore$^{\uparrow}$ *ledger* L*,* RegSeqRat$^{\uparrow}$ *seal* G*,* Real$^{\uparrow}$ *endpoint classifier* E*, and visible* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates already listed in the carrier. The projection introduces no quotient stream, diagonal completion, host real equality, or completeness object outside those rows.*

Proof. Project the carrier of Definition 365.1. The anchor, finite window, dyadic ledger, regular-sequence seal, endpoint classifier, package row, and local naming row are displayed coordinates, and the permitted tail or subwindow read must start from that finite window surface.

Apply Definition 365.3 to identify the RegSeqRat$^{\uparrow}$ view of the read with the same selected StreamName$^{\uparrow}$ window and DyadicRatCore$^{\uparrow}$ ledger. Then use Definition 365.5 to keep transported comparisons on the same window, ledger, seal, and endpoint rows.

The exhaustion step is Definition 365.6, while Definition 365.7 supplies the non-escape boundary for the stream-to-regular-sequence handoff. Hence every displayed tail or subwindow read is a projection of the listed carrier coordinates. □

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier tail projection`

Theorem 365.9 (FiniteWindowEnvelope tail-projection audit sync)**.** *Every accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier assembles its selected finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal,* $\mathsf{Real}^{\uparrow}$ *endpoint classifier, displayed* hsame *and* Cont *transports,* Pkg *provenance, and local* NameCert *rows into one audit-facing consumer package. Any tail read or subwindow read of the carrier factors through that package, and no such consumer route exports a diagonal limit, quotient stream, host real equality, or completeness object.*

Proof. Start with an accepted carrier $W = (S, A, B, L, Q, G, E, P, N)$. The carrier definition exposes the selected finite window Q, the dyadic ledger L, the seal row G, the endpoint row E, the package provenance P, and the local naming row N as visible coordinates.

The consumer route is assembled by the component exactness results. The handoff theorem Definition 365.3 identifies the $\mathsf{RegSeqRat}^{\uparrow}$ seal from the selected $\mathsf{StreamName}^{\uparrow}$ window and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger. The endpoint theorem Definition 365.4 ties the $\mathsf{Real}^{\uparrow}$ classifier to the same finite window and seal.

For comparisons between accepted carriers, Definition 365.5 keeps the transported window, ledger, seal, and endpoint rows on one displayed refinement package. The exhaustion theorem Definition 365.6 accounts for the anchor, window, scale, subwindow, readback, provenance, and naming rows.

Finally, Definition 365.7 gives the stream-to-regular-sequence boundary, and Definition 365.8 applies that boundary to tail and subwindow reads. Thus every audit-facing read is a consumer of the same displayed package, with no remaining route to a diagonal limit, quotient stream, host real equality, or completeness object. □

Theorem 365.10 (FiniteWindowEnvelope endpoint-source determinacy)**.** *Let* $W = (S, A, B, L, Q, G, E, P, N)$ *be an accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier. Every endpoint read exposed by* W *has exactly the displayed source chain*

$$(Q, L, G, E)$$

where Q *is the selected* $\mathsf{StreamName}^{\uparrow}$ *finite window,* L *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* G *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row, and* E *is the* $\mathsf{Real}^{\uparrow}$ *endpoint classifier row. The read has no second endpoint source outside the listed carrier coordinates and their displayed* hsame *and* Cont *transports.*

Lean4 ✓ `BEDC.Derived.FiniteWindowEnvelopeUp.FiniteWindowEnvelopeBHistCarrier endpoint source determinacy`

Proof. Project the carrier of Definition 365.1. The coordinates Q, L, G, E are the only rows in the package that name a selected window, record its rational observations, seal those observations as a regular rational window, and expose the endpoint classifier.

Apply Definition 365.4 to force every endpoint read through the same selected window, dyadic ledger, and seal row. Apply Definition 365.5 to keep transported comparisons on those four rows.

Finally, Definition 365.6 accounts for the anchor, scale, subwindow, readback, package, and local naming data. Since no hidden row remains outside the displayed carrier coordinates, the endpoint source is determined by (Q, L, G, E) together with the displayed transports. □

Theorem 365.11 (FiniteWindowEnvelope subwindow refinement closure)**.** *Let* $W = (S, A, B, L, Q, G, E, P, N)$ *be an accepted* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *carrier. Any displayed tail refinement or subwindow refinement of* W *repacks as the same* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *surface over the transported anchor row, selected window row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal,* $\mathsf{Real}^{\uparrow}$ *endpoint classifier,* hsame,

Cont, Pkg, *and* NameCert *rows. The repacked surface exports no data beyond those transported rows.*

Proof. Begin with a displayed tail or subwindow refinement. By Definition 365.8, the refinement factors through the anchor, window, ledger, seal, endpoint, transport, package, and naming rows already displayed in W.

The stream-to-regular-sequence boundary is fixed by Definition 365.7. The endpoint row is fixed by Definition 365.10, so the refinement cannot choose an independent endpoint source after transport.

Repack the transported rows in the carrier order of Definition 365.1. The classifier of the repacked envelope is the same componentwise comparison described by the carrier definition, so the transported tail or subwindow read remains closed inside the FiniteWindowEnvelope$^{\uparrow}$ surface. □

Theorem 365.12 (FiniteWindowEnvelope RegularCauchyName consumer export)**.** *A* RegularCauchyName$^{\uparrow}$ *consumer, or a Real and Completion consumer that reads a* FiniteWindowEnvelope$^{\uparrow}$ *carrier, can read only the consumer package assembled from endpoint-source determinacy, subwindow refinement closure, and the audit-facing tail projection package of Definition 365.9. Such a consumer obtains the selected* StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *seal,* Real$^{\uparrow}$ *endpoint row, displayed* hsame *and* Cont *transports,* Pkg *provenance, and* NameCert *row, but obtains no diagonal limit, quotient stream, host real equality, selected limit, or completeness object.*

Proof. The consumer first receives the audit-facing package of Definition 365.9. That package already lists the selected finite window, dyadic ledger, regular rational seal, endpoint classifier, transport rows, package provenance, and local naming row.

Endpoint-source determinacy identifies the endpoint reads with the same four source rows (Q, L, G, E). Subwindow refinement closure then shows that every tail or subwindow route repacks inside the same transported envelope surface.

Therefore a RegularCauchyName$^{\uparrow}$ consumer, and likewise a Real and Completion consumer, has access exactly to the displayed finite-window package. The excluded objects are not coordinates of the package and are not produced by the cited projection, determinacy, or refinement-closure steps. □

Theorem 365.13 (FiniteWindowEnvelope StreamName tail lock)**.** *Let* $W = (S, A, B, L, Q, G, E, P, N)$ *be an accepted* FiniteWindowEnvelope$^{\uparrow}$ *carrier. Every tail read and every subwindow read of the* BHist *package remains locked to the selected* StreamName$^{\uparrow}$ *window* Q*, the* DyadicRatCore$^{\uparrow}$ *ledger* L*, the* RegSeqRat$^{\uparrow}$ *seal row* G*, the* Real$^{\uparrow}$ *endpoint row* E*, and the displayed* hsame, Cont, Pkg, *and* NameCert *coordinates* P, N*. The read cannot switch to another stream window, another dyadic ledger, another regular rational seal, or a host real endpoint.*

Proof. Project the carrier coordinates. The selected window Q, ledger L, seal G, endpoint row E, package row P, and naming row N are visible rows of the same finite BHist package.

Apply Definition 365.8 to any tail or subwindow read. It factors the read through the displayed anchor, window, ledger, seal, endpoint, transport, continuation, package, and naming coordinates.

Use Definition 365.11 to repack the transported rows after refinement. Since the repacked surface has the same listed coordinates as its source, the read remains locked to the selected StreamName$^{\uparrow}$ window and its associated finite ledger. □

Theorem 365.14 (FiniteWindowEnvelope common window lock)**.** *Let* $W = (S, A, B, L, Q, G, E, P, N)$ *and* $W' = (S', A', B', L', Q', G', E', P', N')$ *be accepted* FiniteWindowEnvelope$^{\uparrow}$ *carriers. Every local classifier comparison between them factors through one common selected finite* StreamName$^{\uparrow}$

window and one transported DyadicRatCore$^{\uparrow}$ *ledger, after which the* RegSeqRat$^{\uparrow}$ *seal rows,* Real$^{\uparrow}$ *endpoint rows, displayed* hsame *and* Cont *routes,* Pkg *provenance, and* NameCert *rows are read from that same finite package. No comparison field is supplied by a quotient stream, a diagonal object, or host real equality.*

Proof. Start from the local classifier comparison. By Definition 365.5, the comparison exposes a single selected window row, a single transported dyadic ledger, one regular-sequence seal row, and one endpoint classifier row.

The seal is determined by Definition 365.3. Thus the comparison cannot choose a seal independently of the selected StreamName$^{\uparrow}$ window and the transported DyadicRatCore$^{\uparrow}$ ledger.

The endpoint side is determined by Definition 365.10. The exhaustion row Definition 365.6 then accounts for the transport, continuation, package, and naming rows, leaving no additional comparison source outside the finite carrier. □

Theorem 365.15 (FiniteWindowEnvelope Real seal root unblock)**.** *The* FiniteWindowEnvelope$^{\uparrow}$ *carrier supplies the root package needed by downstream Real,* RegSeqRat$^{\uparrow}$*, and Completion consumers: an accepted* BHist *package binds the selected* StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *seal,* Real$^{\uparrow}$ *endpoint row, displayed* hsame *and* Cont *routes,* Pkg *provenance, and local* NameCert *row into one finite consumer surface. This package exports the exact finite-window endpoint row of Definition 365.4 and the audit-facing tail projection of Definition 365.9, but exports no quotient stream, host real equality, diagonal limit, or completeness theorem.*

Proof. Build the consumer surface from the carrier coordinates. The selected window, dyadic ledger, regular rational seal, endpoint row, transport routes, continuation routes, package provenance, and local naming row are all displayed in the same finite BHist package.

Use Definition 365.4 to identify the Real$^{\uparrow}$ endpoint read with the selected StreamName$^{\uparrow}$ window, the DyadicRatCore$^{\uparrow}$ ledger, and the RegSeqRat$^{\uparrow}$ seal. This supplies the Real-facing row.

Use Definition 365.9 to expose the same rows to tail and subwindow consumers. The StreamName tail lock and common window lock above keep refinements and comparisons inside the same finite package, so downstream Real, RegSeqRat$^{\uparrow}$, and Completion consumers receive one root-unblock surface and no external equality or completeness object. □

Chapter 366

A Concrete Naming Certificate for $\mathsf{DyadicSubdivision}^{\uparrow}$

The $\mathsf{DyadicSubdivision}^{\uparrow}$ interface names a finite subdivision certificate for one rational interval into dyadic mesh cells with validated enclosure rows attached. In the Moore–Kearfott–Cloud interval-analysis reading, subdivision refines an enclosure into finitely many checked sub-enclosures; in BEDC the object is only a finite BHist ledger over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, $\mathsf{ValidatedNumerics}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

The unary bisection route used below is read through the sibling chapter 361 before being repacked as an ordered subdivision ledger. $\mathsf{DyadicSubdivision}^{\uparrow}$ consumes $\mathsf{DyadicBisection}^{\uparrow}$ only as a finite route source; it does not import an infinite refinement tree.

Definition 366.1 (DyadicSubdivision source)**.** *A* $\mathsf{DyadicSubdivision}^{\uparrow}$ *source is a finite* BHist *packet*

$$S = (I, L, C, M, V, P, N)$$

with the following visible rows:

1. *I is the parent* $\mathsf{RationalInterval}^{\uparrow}$ *row whose endpoint and order data are the interval being subdivided;*
2. *L is the unary dyadic level row used to read every child cell at one displayed mesh precision;*
3. *C is a finite ordered cell-list row, with each entry carrying its displayed position inside the parent interval;*
4. *M is the finite family of* $\mathsf{DyadicMesh}^{\uparrow}$ *cell packets indexed by C;*
5. *V is the finite family of* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment rows attached to the same cells;*
6. *P is the* Pkg *provenance row naming* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RationalInterval}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, $\mathsf{ValidatedNumerics}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{DyadicSubdivision}^{\uparrow}}$ *row.*

The classifier compares accepted subdivision packets by transporting the parent interval, level row, ordered cell list, mesh cells, containment rows, package provenance, and local name row componentwise. The carrier has no coordinate for a host interval tree, infinite refinement process, solver state, or completed real subset.

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionTasteGate single carrier alignment`

Theorem 366.2 (DyadicSubdivision NameCert obligations)**.** *The seed* $\mathsf{NameCert}_{\mathsf{DyadicSubdivision}^{\uparrow}}$ *obligation surface has five rows:*

1. *carrier: the finite packet of Definition 366.1;*
2. *classifier: componentwise* hsame *transport of the parent interval, dyadic level, ordered cell list,* $\mathsf{DyadicMesh}^{\uparrow}$ *packets,* $\mathsf{ValidatedNumerics}^{\uparrow}$ *rows, provenance, and local name;*
3. *stability: appending displayed refinement routes to the mesh family preserves the transported parent interval and refines only the finite cell ledger;*
4. *exactness: every child boundary and containment read is one of the* $\mathsf{DyadicMesh}^{\uparrow}$ *or* $\mathsf{ValidatedNumerics}^{\uparrow}$ *rows indexed by the ordered list* C*;*
5. *ledger: the package and local certificate rows record exactly the dependency surface over* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RationalInterval}^{\uparrow}$*,* $\mathsf{DyadicMesh}^{\uparrow}$*,* $\mathsf{ValidatedNumerics}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

These rows are the full seed naming surface for finite dyadic subdivision certificates.

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource namecert obligations`

Proof. Project the packet of Definition 366.1. The carrier row displays the parent interval, common level, finite ordered list, mesh-cell family, validated containment family, package provenance, and local certificate row.

The classifier is componentwise because the packet contains no hidden geometric object. Transporting a subdivision means transporting exactly those visible rows by hsame and replaying the stored Cont routes for the mesh and validated containment reads.

Stability and exactness are then read from the same finite ledger. Refinement appends routes to the mesh-family reads, while every boundary or enclosure claim remains indexed by C and therefore belongs to one of the displayed $\mathsf{DyadicMesh}^{\uparrow}$ or $\mathsf{ValidatedNumerics}^{\uparrow}$ rows. □

Theorem 366.3 (DyadicSubdivision refinement stability)**.** *Let* $S = (I, L, C, M, V, P, N)$ *be an accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet. If* S' *is obtained by replacing each mesh entry in* M *by a finite displayed* $\mathsf{DyadicMesh}^{\uparrow}$ *refinement whose rational-interval boundary transports to the same parent row* I*, and by transporting the corresponding containment entries in* V *along the same routes, then* S' *is an accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet for the same parent interval.*

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionPacket refinement stability`

Proof. Start with the finite subdivision packet. The parent interval row I, package provenance P, and local name row N are retained, so the outer naming surface is unchanged.

For each entry of the ordered list C, use the $\mathsf{DyadicMesh}^{\uparrow}$ refinement route to replace the displayed cell by a finer finite family. The endpoint comparison is still through the transported $\mathsf{RationalInterval}^{\uparrow}$ boundary rows, so no host interval or completed real subset is introduced.

Transport the validated containment rows through the same cell routes. Repacking the parent row, refined level data, refined ordered cell ledger, refined mesh entries, transported containment entries, provenance, and local certificate gives exactly the carrier of Definition 366.1. □

Theorem 366.4 (DyadicSubdivision mesh coverage)**.** *For every accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet* $S = (I, L, C, M, V, P, N)$*, coverage of the parent interval is represented solely by the finite ordered cell list* C *together with the* $\mathsf{DyadicMesh}^{\uparrow}$ *packets in* M*. A consumer may read each child rational interval, dyadic endpoint ledger, and adjacency order through those rows, but it cannot read an infinite mesh, a host subset of* $\mathsf{Real}^{\uparrow}$*, or a global interval-tree object from* S*.*

Proof. Read the parent interval row I and the ordered list C. The list is the only row that arranges the children, and it is finite by construction of the packet.

Each child coverage object is then projected from the matching $\mathsf{DyadicMesh}^{\uparrow}$ entry in M. Its rational interval and dyadic endpoint ledger are already the finite coverage surface supplied by the mesh certificate.

Since the subdivision carrier contains no further coverage coordinate, the parent coverage surface is exhausted by C and M. Infinite meshes, host subsets, and interval-tree data are outside the packet. □

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource mesh coverage`

Theorem 366.5 (DyadicSubdivision validated enclosure handoff)**.** *A* $\mathsf{ValidatedNumerics}^{\uparrow}$ *consumer of an accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet may read exactly the parent* $\mathsf{RationalInterval}^{\uparrow}$ *row, common dyadic level row, ordered finite cell ledger, child* $\mathsf{DyadicMesh}^{\uparrow}$ *packets, attached* $\mathsf{ValidatedNumerics}^{\uparrow}$ *containment rows,* hsame *transports,* Cont *routes, package provenance, and local* $\mathsf{NameCert}$ *row. The handoff supplies a finite enclosure subdivision and does not assert solver correctness, floating-point hardware semantics, classical real completeness, or an infinite refinement theorem.*

Proof. Project the carrier. The validated-numerics side first sees the parent interval, the level row, and the ordered cell list; these rows determine which finite child packets can be inspected.

For each child, read the matching $\mathsf{DyadicMesh}^{\uparrow}$ packet and the corresponding $\mathsf{ValidatedNumerics}^{\uparrow}$ containment row. The hsame transports and Cont routes ensure that the mesh boundary and containment ledger are read along the same finite cell route.

Thus the handoff is the finite enclosure subdivision formed by these rows. No coordinate supplies solver correctness, hardware semantics, classical completeness, or an infinite refinement principle. □

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource validated enclosure handoff`

Theorem 366.6 (DyadicSubdivision refinement composition)**.** *Let* $S = (I, L, C, M, V, P, N)$ *be an accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet. Suppose* S' *is obtained from* S *by displayed finite* $\mathsf{DyadicMesh}^{\uparrow}$ *refinement routes over the same parent* $\mathsf{RationalInterval}^{\uparrow}$ *row* I*, and suppose* S'' *is obtained from* S' *by a second displayed finite family of* $\mathsf{DyadicMesh}^{\uparrow}$ *refinement routes over the same parent row. Then* S'' *is an accepted* $\mathsf{DyadicSubdivision}^{\uparrow}$ *packet for* I*.*

The mesh coverage and validated enclosure handoff exported by S'' *are the composed finite ledger: first the refined child rows from* S *to* S'*, then the refined child rows from* S' *to* S''*, together with the transported* $\mathsf{ValidatedNumerics}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows. The composition asserts no interval-tree semantics, infinite refinement process, host real subset, or solver-correctness theorem.*

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionPacket refinement composition`

Proof. Apply refinement stability to the first displayed refinement family. The result is the accepted packet S' over the same parent interval row I, with only its finite cell ledger, mesh rows, and validated containment rows refined.

Apply refinement stability again to the second displayed refinement family. Since its routes are also over the same parent row, the second application yields an accepted packet S'' whose parent interval and provenance surface remain the displayed rows of the original packet.

It remains to identify the consumer surface. Mesh coverage reads only the finite ordered cell list and the $\mathsf{DyadicMesh}^{\uparrow}$ packets; validated enclosure handoff reads the matching $\mathsf{ValidatedNumerics}^{\uparrow}$

rows along the same routes. Chaining those two finite ledgers gives the composed mesh and enclosure surface named in the statement, with no additional infinite or host-level object. □

Theorem 366.7 (DyadicSubdivision common refinement exhaustion)**.** *Let $S_0 = (I, L_0, C_0, M_0, V_0, P_0, N_0)$ and $S_1 = (I, L_1, C_1, M_1, V_1, P_1, N_1)$ be two accepted* DyadicSubdivision$^{\uparrow}$ *packets over the same displayed* RationalInterval$^{\uparrow}$ *parent row I. If both packets carry finite* DyadicMesh$^{\uparrow}$ *refinement ledgers for the same parent interval, then there is a finite accepted child-ledger over* DyadicMesh$^{\uparrow}$ *rows that refines both C_0 and C_1 and whose validated enclosure rows are transported through the corresponding* ValidatedNumerics$^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert *routes.*

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionPacket common refinement exhaustion`

Proof. Read both packets through Definition 366.1. Each subdivision has a displayed parent interval row, a dyadic level row, a finite ordered cell list, a finite family of mesh cells, and a finite family of validated enclosure rows.

Form the common child-ledger by taking the displayed finite intersections of the two ordered dyadic cell ledgers inside the same parent row I. Because every cell boundary is read from DyadicMesh$^{\uparrow}$ rows over one rational interval parent, the resulting ledger is again finite and ordered.

Apply Definition 366.3 to transport the first packet to this common ledger, and apply it again to transport the second packet to the same ledger. The validated rows move along the same cell routes, so the common ledger exhausts both displayed refinement families without adding an infinite mesh or host interval tree. □

Theorem 366.8 (DyadicSubdivision cell ledger transport)**.** *For an accepted* DyadicSubdivision$^{\uparrow}$ *packet $S = (I, L, C, M, V, P, N)$, componentwise* hsame *and* Cont *transport of the parent interval I, the dyadic level row L, the ordered cell list C, the* DyadicMesh$^{\uparrow}$ *cell family M, the* ValidatedNumerics$^{\uparrow}$ *enclosure family V, the package row P, and the local* NameCert *row N preserves the subdivision classifier.*

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource cell ledger transport`

Proof. The classifier is read directly from Definition 366.1. It compares only the parent interval, common level, ordered cell list, mesh cells, validated enclosure rows, and provenance rows.

Transport the parent interval and level first. Then transport each ordered cell-list entry and its matching DyadicMesh$^{\uparrow}$ row along the displayed Cont route, preserving its position in the finite ledger.

Transport the ValidatedNumerics$^{\uparrow}$ rows along the same cell routes. Since each containment row remains attached to the transported mesh cell indexed by the transported ordered list, the packet still satisfies the carrier conditions.

Repack the transported rows with P and N. The resulting packet is classified with the original one, and no global interval tree, solver state, or completed real subset is introduced. □

Theorem 366.9 (DyadicSubdivision NameCert package)**.** *The* DyadicSubdivision$^{\uparrow}$ *obligation package is assembled from the source row of Definition 366.1, the NameCert obligations of Definition 366.2, refinement stability, mesh coverage, validated enclosure handoff, refinement composition, common refinement exhaustion, and cell-ledger transport. The package is finite over* DyadicRatCore$^{\uparrow}$*,* RationalInterval$^{\uparrow}$*,* DyadicMesh$^{\uparrow}$*,* ValidatedNumerics$^{\uparrow}$*,* Real$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource namecert package`

Proof. The source row supplies the displayed carrier and dependency coordinates. The NameCert obligations record carrier, classifier, stability, exactness, and ledger rows for the finite subdivision packet.

Refinement stability is Definition 366.3; mesh coverage is Definition 366.4; validated enclosure handoff is Definition 366.5. Together these rows give finite coverage and consumer exactness for a single displayed subdivision ledger.

Refinement composition is Definition 366.6, common refinement exhaustion is Definition 366.7, and cell-ledger transport is Definition 366.8. Repacking these rows gives the stated obligation package while preserving the non-escape clauses for interval-tree semantics, solver correctness, hardware semantics, classical completeness, and infinite refinement. □

Theorem 366.10 (DyadicSubdivision routed bisection normal form)**.** *Let S be an accepted* DyadicSubdivision$^{\uparrow}$ *packet obtained by iterated unary bisection of a parent* RationalInterval$^{\uparrow}$ *row. Then S has a unique visible finite normal-form packet consisting exactly of the parent interval row, unary level row, ordered cell-list row,* DyadicMesh$^{\uparrow}$ *cell packets,* ValidatedNumerics$^{\uparrow}$ *containment rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

If two unary bisection routes over the same parent row agree on these displayed rows, then their resulting packets classify together as DyadicSubdivision$^{\uparrow}$ *packets. The normal-form packet exports no global interval tree, solver correctness, floating-point semantics, classical real completeness, or infinite refinement.*

Proof. Start with the initial parent interval row and read every unary bisection as a displayed finite DyadicMesh$^{\uparrow}$ refinement route. Apply Definition 366.3 after each bisection step, and use Definition 366.6 to collapse the resulting chain into one finite accepted subdivision packet over the original parent row.

The visible rows of the normal form are exhausted by the finite mesh and enclosure ledgers. Apply Definition 366.7 to compare two routes through their common finite child-ledger, then apply Definition 366.8 to transport the parent interval, level, ordered cells, mesh packets, containment rows, provenance, and local certificate componentwise.

Finally, Definition 366.9 repacks these transported rows as the public DyadicSubdivision$^{\uparrow}$ certificate. Because the package contains only the listed finite rows and routes, agreeing bisection ledgers classify together, and no global interval tree, solver-correctness theorem, hardware semantics, classical completeness principle, or infinite refinement object is exported. □

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource routed bisection normal form`

Theorem 366.11 (DyadicSubdivision scoped finite-route package)**.** *The* DyadicSubdivision$^{\uparrow}$ *source row, NameCert obligations, refinement stability, mesh coverage, validated enclosure handoff, refinement composition, common refinement exhaustion, cell-ledger transport, and routed bisection normal form bind exactly the finite dependency surface*

DyadicRatCore$^{\uparrow}$, RationalInterval$^{\uparrow}$, DyadicMesh$^{\uparrow}$, ValidatedNumerics$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, NameCert.

Every consumer read of an accepted subdivision packet factors through those displayed rows and routes. The scoped package does not expose a host interval tree, a solver-correctness theorem, floating-point hardware semantics, classical real completeness, or an infinite refinement object.

Proof. Start with the source row of Definition 366.1. It lists the parent rational interval, unary level, ordered cell ledger, mesh-cell family, validated enclosure family, package provenance, and local name row as the only carrier coordinates.

The NameCert obligations of Definition 366.2 fix the carrier, classifier, stability, exactness, and ledger rows over the named dependencies. Refinement stability, mesh coverage, and validated enclosure handoff then show how a consumer reads cells and enclosures through the same finite ledger.

Refinement composition, common refinement exhaustion, and cell-ledger transport account for route chaining and comparison between displayed bisection ledgers. The routed bisection normal form of Definition 366.10 repacks those chains into one visible finite packet.

Thus every consumer access factors through the displayed rows in the statement. Since no cited row contains an interval tree, solver state, hardware semantics, completeness principle, or infinite refinement coordinate, the scoped package has exactly the stated finite dependency surface. □

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource scoped finite route package`

Theorem 366.12 (DyadicSubdivision public finite-enclosure export)**.** *The source row, scoped finite-route package, routed bisection normal form, mesh coverage, and validated enclosure handoff assemble one public* DyadicSubdivision$^{\uparrow}$ *finite-enclosure certificate consumed by* ValidatedNumerics$^{\uparrow}$ *and* Real$^{\uparrow}$ *readers. Every read factors through the parent* RationalInterval$^{\uparrow}$ *row, unary dyadic level, ordered cell list,* DyadicMesh$^{\uparrow}$ *packets,* ValidatedNumerics$^{\uparrow}$ *containment rows,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The public export contains no interval tree, solver state, hardware semantics, classical real completeness, or infinite refinement object.*

Proof. Begin with the source row of Definition 366.1. It supplies the parent rational interval, level, finite cell ledger, mesh rows, containment rows, package provenance, and local name row.

Use the scoped finite-route package of Definition 366.11 together with the routed bisection normal form of Definition 366.10. These identify every accepted bisection route with one visible finite packet over the same rows.

Apply mesh coverage from Definition 366.4 and the validated enclosure handoff of Definition 366.5. They are the consumer-facing rows read by ValidatedNumerics$^{\uparrow}$ and Real$^{\uparrow}$.

Repack those rows as the public finite-enclosure surface. Since each cited row is finite and none contains an interval tree, solver state, hardware semantics, classical completeness principle, or infinite refinement coordinate, the exported certificate has exactly the stated boundary. □

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource public finite enclosure export`

Theorem 366.13 (DyadicSubdivision standard bridge certificate)**.** *The public finite-enclosure certificate of Definition 366.12 supplies a standard finite subdivision reading for the same parent interval. Its bridge fields are the parent* RationalInterval$^{\uparrow}$ *row, unary dyadic level, ordered child-cell ledger,* DyadicMesh$^{\uparrow}$ *packets,* ValidatedNumerics$^{\uparrow}$ *containment rows,* Real$^{\uparrow}$ *consumer handoff,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Every standard read of the finite subdivision factors through those displayed fields. The bridge exports no interval tree, solver-correctness theorem, floating-point hardware semantics, classical real completeness principle, or infinite refinement object.

Lean4 ✓ `BEDC.Derived.DyadicSubdivisionUp.DyadicSubdivisionSource standard bridge certificate`

Proof. Begin with the public finite-enclosure export. It already names the parent rational interval, common dyadic level, ordered cell list, mesh packets, validated containment rows, and consumer provenance as one public DyadicSubdivision$^{\uparrow}$ certificate.

Read this packet as a standard finite subdivision by projecting the same rows. The parent interval is the source field; the ordered child-cell ledger and $\mathsf{DyadicMesh}^{\uparrow}$ packets give the finite subdivision field; the $\mathsf{ValidatedNumerics}^{\uparrow}$ rows give the enclosure field; and the $\mathsf{Real}^{\uparrow}$ handoff is reached only through the displayed consumer routes.

The transport and provenance fields are exactly BHist, hsame, Cont, Pkg, and NameCert. Since the bridge has no other field, a standard reader cannot obtain an interval tree, solver-correctness theorem, hardware semantics, classical completeness principle, or infinite refinement object from the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicSubdivision}^{\uparrow}}$.

Constructive story: A $\mathsf{DyadicSubdivision}^{\uparrow}$ packet is generated from a parent $\mathsf{RationalInterval}^{\uparrow}$ row, a unary dyadic level row, a finite ordered cell-list row, $\mathsf{DyadicMesh}^{\uparrow}$ cell packets, $\mathsf{ValidatedNumerics}^{\uparrow}$ containment rows, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicSubdivision}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 366.12 and Definition 366.13 export the finite $\mathsf{DyadicSubdivision}^{\uparrow}$ enclosure certificate and its standard finite subdivision reading for $\mathsf{ValidatedNumerics}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ readers through the parent rational interval, unary level, ordered cell list, mesh packets, containment rows, BHist, hsame, Cont, Pkg, and NameCert provenance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicSubdivision}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close global interval-tree semantics, solver correctness, floating-point hardware behavior, classical real completeness, infinite refinement, or bridge checking.

Upgrade path: Lean formalization and bridge checking are the remaining verification-axis upgrades for the displayed finite subdivision packet.

Chapter 367

A Concrete Naming Certificate for $\mathsf{FastConvergentSeries}^{\uparrow}$

The $\mathsf{FastConvergentSeries}^{\uparrow}$ interface names the finite certificate surface for a constructive series whose partial sums come with an explicit fast tail schedule. Following Bishop and Bridges, *Constructive Analysis*, where convergence of series is carried by effective Cauchy information, the packet records only displayed summand observations, partial-sum readbacks, tail bounds, real-seal rows, transport routes, and provenance. It does not form a quotient of streams, select an infinite sum, or import host completeness for real numbers.

Its fast tail schedule and finite comparison ledger consume the displayed dyadic tail-bound surface of chapter 379 before the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal. Thus the tail-budget carrier is read through a concrete dyadic bound rather than an ambient convergence predicate.

The fast-tail packet is a consumer of the regular rational readback and real-seal surfaces of chapter 301 and chapter 38. It does not create a real endpoint: partial-sum rows Q, the tail schedule μ, and the tail-bound ledger T are routed into the existing $\mathsf{RegSeqRat}^{\uparrow}$ handoff R and then into the $\mathsf{Real}^{\uparrow}$ seal row E.

Definition 367.1 (FastConvergentSeries BHist carrier)**.** *A* $\mathsf{FastConvergentSeries}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (A, S, Q, \mu, T, R, E, L, C, P, N)$$

with the following visible rows:

1. *A is the* $\mathsf{Series}^{\uparrow}$ *source row naming the summand stream and its finite partial-sum ledger;*
2. *S is the* $\mathsf{Seq}^{\uparrow}$ *observation surface through which displayed summand rows and prefix rows are read;*
3. *Q is the finite family of partial-sum observations displayed at requested unary indices;*
4. *μ is a* $\mathsf{CauchyModulus}^{\uparrow}$ *fast tail schedule assigning each precision row a finite threshold after which tails are bounded by the requested tolerance;*
5. *T is the tail-bound ledger comparing displayed partial sums past μ and recording the resulting rational tolerance rows;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *partial-sum readback surface obtained from Q, μ, and T;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal-facing ledger for the real name represented by the partial-sum readbacks;*

8. *L records the componentwise* hsame *transports for summand observations, partial sums, tail bounds, schedules, and seal-facing rows;*
9. *C records the displayed* Cont *read routes through which finite consumers reach the summand, partial-sum, tail-bound, readback, and seal rows;*
10. *P is the* Pkg *provenance over* $\mathsf{Series}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and the rational source rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ *provenance row.*

The carrier is a finite fast-convergence series packet. It contains no quotient stream, no chosen infinite sum, and no ambient completeness proof.

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesTasteGate single carrier alignment`

Definition 367.2 (FastConvergentSeries classifier)**.** *For accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packets F and F', the classifier* $\mathsf{FastConvergentSeriesClassifier}(F, F')$ *compares only the displayed partial-sum rows, tail-bound ledgers, fast tail schedules,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{Real}^{\uparrow}$ *seal-facing rows, componentwise* hsame *transports,* Cont *read routes,* Pkg *provenance, and local* NameCert *rows.*

It does not compare hidden summability predicates, host real endpoints, infinite stream quotients, or choice-selected sums. Any accepted transport must therefore preserve the finite rows listed in Definition 367.1.

Lean4 (definition) `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesClassifierSpec`

Theorem 367.3 (FastConvergentSeries constant zero seed)**.** *The stationary zero summand stream determines an accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *carrier. Its* $\mathsf{Series}^{\uparrow}$ *and* $\mathsf{Seq}^{\uparrow}$ *rows display only zero summand observations, every displayed partial sum is the zero row, the fast tail schedule may use the zero threshold for every precision request, the tail-bound ledger records zero tails, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback is the constant zero regular sequence, and the* $\mathsf{Real}^{\uparrow}$ *seal-facing row is the constant zero real name.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier constant zero seed`

Proof. Start with the zero summand row in the source carrier and read it through the $\mathsf{Seq}^{\uparrow}$ observation surface. Every finite prefix has the same zero partial-sum row, so the $\mathsf{Series}^{\uparrow}$ partial-sum ledger is inhabited by the displayed zero rows.

Choose the fast tail schedule that assigns the zero threshold to every precision request. Since every later partial sum is again zero, the tail-bound ledger compares identical displayed rows and records the requested tolerance as satisfied.

Repack the same zero rows as the $\mathsf{RegSeqRat}^{\uparrow}$ readback and the $\mathsf{Real}^{\uparrow}$ seal-facing ledger. The hsame transports and Cont routes are componentwise identities on the displayed finite rows, and the package provenance names only the source certificates and the local NameCert row. □

Theorem 367.4 (FastConvergentSeries tail-sum boundary)**.** *For every accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packet and every displayed precision request, any* $\mathsf{Real}^{\uparrow}$ *consumer read of the represented sum factors through one fast tail schedule row, the displayed partial-sum rows past that threshold, the tail-bound ledger comparing those rows, the resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *partial-sum readback, and the seal-facing* $\mathsf{Real}^{\uparrow}$ *row. The consumer receives no coordinate for a host infinite sum, quotient equality of streams, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier tail sum boundary`

Proof. Project the carrier coordinates of Definition 367.1. A precision request first reads the schedule row μ, which supplies the finite threshold used by the tail-bound ledger.

The consumer then reaches the displayed partial sums through the $\mathsf{Seq}^{\uparrow}$ and $\mathsf{Series}^{\uparrow}$ rows. The tail-bound ledger compares only those finite partial-sum rows past the threshold and records the rational tolerance evidence visible at that precision.

The $\mathsf{RegSeqRat}^{\uparrow}$ handoff reads the same partial-sum ledger as a regular rational sequence, and the $\mathsf{Real}^{\uparrow}$ seal-facing row is attached to that handoff. Since the carrier has no coordinate for a host sum, quotient stream, or completeness proof, none can be exported by the read. □

Theorem 367.5 (FastConvergentSeries regular rational tail-bound handoff)**.** *For an accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packet, the displayed partial-sum rows, fast tail schedule, and finite tail-bound ledger determine the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row used by the real-seal ledger. Classifier transport of the schedule rows and tail-bound rows transports that handoff row componentwise.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesTailBoundPacket regseqrat handoff`

Proof. Project the carrier rows Q, μ, T, R, and E from Definition 367.1. The partial-sum rows Q supply the displayed rational approximants, the schedule μ supplies the finite threshold for each requested precision, and the tail-bound ledger T records the comparison rows past that threshold.

Use Definition 367.4 to factor every real-facing read through the same schedule and finite comparison ledger. Thus the regular rational readback row R is the repacking of Q, μ, and T that the seal-facing row E is allowed to consume.

Under classifier transport, the schedule rows and tail-bound rows move by the stored componentwise hsame comparisons. Repack the transported finite rows as the transported $\mathsf{RegSeqRat}^{\uparrow}$ handoff row. No host infinite sum, quotient stream, or ambient completeness object is introduced in this repacking. □

Theorem 367.6 (FastConvergentSeries NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ *obligation surface consists of five rows:*

1. *carrier inhabitation: Definition 367.3 supplies a concrete accepted packet for the stationary zero series;*
2. *classifier transport: Definition 367.2 transports displayed partial sums, tail-bound rows, schedules, readbacks, seal-facing rows,* hsame *routes,* Cont *routes, package provenance, and local provenance componentwise;*
3. *tail-sum boundary: Definition 367.4 forces every real-facing read through the displayed fast tail schedule and finite partial-sum comparison ledger;*
4. $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: the partial-sum rows, schedule rows, and tail-bound ledger repack as the visible regular rational readback row R of Definition 367.1;*
5. $\mathsf{Real}^{\uparrow}$ *seal non-escape: the seal-facing ledger E may read only the* $\mathsf{Series}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows displayed by the packet.*

These rows are exactly the finite naming-certificate surface for fast convergent series.

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier namecert obligation surface`

Proof. The first row is the explicit zero-series inhabitant. It provides summand observations, partial sums, tail bounds, regular readbacks, and the real seal without importing any completion object.

The classifier row is componentwise by definition. Each permitted transport is one of the displayed hsame comparisons or Cont read routes, so transported packets preserve the same partial-sum, tail-bound, schedule, readback, and seal-facing coordinates.

The boundary row is Definition 367.4. It shows that every real-facing read must pass through the finite schedule and partial-sum ledger before reaching the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows.

The final two rows are projections of the same carrier. The regular readback forgets no tail evidence needed by $\mathsf{RegSeqRat}^{\uparrow}$, and the real seal has no field from which a quotient stream, selected sum, or ambient completeness principle could be read. □

Theorem 367.7 (FastConvergentSeries scoped kernel factorization)**.** *For every accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packet, the consumer route to a real-seal read is exhausted by the displayed* $\mathsf{Series}^{\uparrow}$ *source row,* $\mathsf{Seq}^{\uparrow}$ *observation surface,* $\mathsf{CauchyModulus}^{\uparrow}$ *fast tail schedule, finite tail-bound ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *partial-sum handoff,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *read routes,* Pkg *provenance, and local* NameCert *row.*

No real-seal consumer can factor the read through an ambient summability predicate, a quotient of summand streams, a selected host sum, or a completeness theorem outside those rows.

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier scoped kernel factorization`

Proof. First read the tail boundary. By Definition 367.4, every precision request reaches the fast tail schedule, the partial-sum rows past the displayed threshold, and the finite comparison ledger before it reaches any real-facing row.

Next identify the regular rational handoff. By Definition 367.5, the same partial-sum rows, schedule rows, and tail-bound ledger determine the $\mathsf{RegSeqRat}^{\uparrow}$ readback consumed by the seal-facing ledger.

Finally bind the local certificate surface. By Definition 367.6, the only remaining routes are the displayed hsame transports, Cont reads, package provenance, and local NameCert row attached to the same carrier.

Combining these three projections exhausts the kernel route for the real-seal read. Since none of the cited rows contains an ambient summability predicate, quotient stream, selected sum, or completeness theorem, no such object can be exported by the scoped packet. □

Theorem 367.8 (FastConvergentSeries public tail-budget export)**.** *The constant-zero seed, tail-sum boundary,* $\mathsf{RegSeqRat}^{\uparrow}$ *tail-bound handoff, local* $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ *obligation surface, and scoped kernel factorization export a public finite tail-budget handoff for* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *consumers.*

The exported handoff is the finite-history route through the displayed $\mathsf{Series}^{\uparrow}$ *source row,* $\mathsf{Seq}^{\uparrow}$ *observation surface, partial-sum rows,* $\mathsf{CauchyModulus}^{\uparrow}$ *fast tail schedule, finite tail-bound ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *reads,* Pkg *provenance, and local* NameCert *row. It asserts no convergence theorem beyond the displayed tail budget and supplies no quotient stream, selected infinite sum, host summability predicate, or ambient completeness object.*

Proof. The inhabitance row is Definition 367.3. It gives a concrete finite carrier shape whose summand observations, partial sums, tail ledger, regular readback, and real seal are all displayed rows.

The consumer boundary is Definition 367.4. Every real-facing read first passes through the fast tail schedule and the finite partial-sum comparison ledger for the requested precision.

The regular-rational handoff is Definition 367.5. It repacks the same partial-sum rows, schedule rows, and tail-bound ledger as the $\mathsf{RegSeqRat}^{\uparrow}$ readback consumed by the real seal.

The local certificate rows are collected by Definition 367.6, and the full route is exhausted by Definition 367.7. Combining these results gives the public tail-budget handoff while keeping the conclusion inside the finite BHist packet.

Since each cited row is finite and displayed, the export contains only the named tail-budget surface. It does not assert a stronger convergence theorem or introduce any host summability, quotient, selected sum, or completeness datum. □

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier public tail budget export`

Theorem 367.9 (FastConvergentSeries public export)**.** *The carrier of Definition 367.1, the classifier of Definition 367.2, the constant-zero seed, the tail-sum boundary, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the local* $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ *obligation surface, and the scoped kernel factorization jointly export the public* $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ *handoff over the finite route through* $\mathsf{Series}^{\uparrow}$*,* $\mathsf{Seq}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Every public consumer of the fast-series certificate reads only displayed summand rows, partial-sum rows, tail-budget rows, regular rational readbacks, seal-facing rows, transport routes, and provenance. The export contains no quotient summand stream, selected infinite sum, host summability predicate, ambient completeness theorem, or bridge row.

Proof. First build the public carrier surface. The carrier definition lists the finite packet rows, the classifier definition restricts comparison to displayed rows, and Definition 367.3 supplies the concrete zero-series inhabitant.

Next identify the consumer route. By Definition 367.4, every real-facing precision request factors through the fast tail schedule and finite tail-bound ledger. By Definition 367.5, the same partial-sum and tail-budget rows determine the $\mathsf{RegSeqRat}^{\uparrow}$ handoff consumed by the seal-facing row.

Finally bind the certificate rows. The local obligation surface in Definition 367.6 supplies the $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$ rows, and Definition 367.7 exhausts the kernel route. The public tail-budget export of Definition 367.8 is therefore the same finite route presented as a public consumer object, with no hidden summability, quotient, selected sum, completeness, or bridge coordinate. □

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier public export`

Theorem 367.10 (FastConvergentSeries bridge tail-budget schedule)**.** *For every accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packet and every displayed precision request, the public tail-budget export supplies a bridge-facing schedule row, a finite partial-sum ledger, and a tail-bound ledger. The schedule row is the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold read for the request, the partial-sum ledger is the displayed* $\mathsf{Series}^{\uparrow}$ *and* $\mathsf{Seq}^{\uparrow}$ *prefix surface past that threshold, and the tail-bound ledger is the finite comparison surface consumed by the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback.*

The exported schedule is finite and displayed at the requested precision. It contains no quotient of summand streams, no host infinite-sum object, and no ambient completeness premise.

Proof. Project the carrier of Definition 367.1. The precision request reads the row μ, and that row supplies the displayed threshold used by the tail-budget ledger.

Apply Definition 367.4 to force the consumer route through the partial-sum rows past the threshold. Apply Definition 367.5 to identify the same rows as the finite comparison ledger used by the $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Finally use Definition 367.9. The public export names exactly those schedule, partial-sum, and tail-bound rows, so the bridge-facing schedule is a displayed finite ledger rather than an external convergence object. □

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier bridge tail budget schedule`

Theorem 367.11 (FastConvergentSeries bridge real-seal consumer)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read exported by an accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packet factors through the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and the displayed tail-budget schedule of Definition 367.10. The seal consumer receives the* $\mathsf{Series}^{\uparrow}$ *source row,* $\mathsf{Seq}^{\uparrow}$ *observation surface,* $\mathsf{CauchyModulus}^{\uparrow}$ *schedule, finite tail-bound ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row before it reaches the seal.*

No seal read factors through quotient stream equality, a selected host sum, or an ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier bridge real seal consumer`

Proof. Start from the schedule handoff in Definition 367.10. It supplies the displayed threshold, the partial-sum ledger, and the finite tail-bound ledger for the requested precision.

Use Definition 367.5 to repack those rows as the $\mathsf{RegSeqRat}^{\uparrow}$ handoff. Then apply Definition 367.7 to place the $\mathsf{Real}^{\uparrow}$ seal after that handoff and after the displayed hsame, Cont, Pkg, and NameCert rows.

The carrier has no coordinate for a quotient stream, selected host sum, or completeness theorem. The seal read is therefore exhausted by the finite route named in the statement. □

Theorem 367.12 (FastConvergentSeries bridge completion handoff)**.** *The public export of Definition 367.9, together with the bridge tail-budget schedule of Definition 367.10 and the real-seal consumer factorization of Definition 367.11, assembles the bridge-facing completion handoff for* $\mathsf{FastConvergentSeries}^{\uparrow}$*.*

The handoff offered to completion consumers is the finite route through $\mathsf{Series}^{\uparrow}$*,* $\mathsf{Seq}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*, displayed partial sums, finite tail bounds,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It explicitly excludes quotient streams, host sums, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier bridge completion handoff`
Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesTailBoundPacket bridge completion handoff`

Proof. First take the public export from Definition 367.9. It fixes the consumer-visible surface over the series source, sequence observation row, fast tail schedule, regular rational readback, real seal, transports, read routes, provenance, and local certificate.

Next attach the finite schedule. The bridge tail-budget schedule theorem supplies the requested precision row, the partial-sum ledger, and the tail-bound ledger. The tail-sum boundary and regular rational handoff theorems identify those rows as the only data used by the precision read.

Finally attach the seal. The real-seal consumer theorem and the scoped kernel factorization place the $\mathsf{Real}^{\uparrow}$ seal downstream of the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the displayed certificate rows.

Repacking these rows gives the completion-facing handoff while leaving no coordinate for quotient streams, host sums, or ambient completeness. □

Theorem 367.13 (FastConvergentSeries bridge boundary package)**.** *The public export of Definition 367.9 factors into the standard bridge-facing boundary consisting of the* Series$^{\uparrow}$ *source row,* Seq$^{\uparrow}$ *observation surface,* CauchyModulus$^{\uparrow}$ *fast tail schedule, finite tail-bound ledger,* RegSeqRat$^{\uparrow}$ *partial-sum handoff,* Real$^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *read routes,* Pkg *provenance, and local* NameCert *row.*

This boundary is the finite tail-budget surface consumed by downstream Real$^{\uparrow}$ *and* RegSeqRat$^{\uparrow}$ *readers. It introduces no quotient stream, selected infinite sum, host summability predicate, or ambient completeness theorem.*

Proof. First take the public handoff from Definition 367.9. Its statement already names the finite route through the series source, sequence observation surface, fast modulus, regular rational handoff, real seal, transports, read routes, provenance, and local certificate.

Next isolate the tail-budget component. By Definition 367.8, the public object exported to consumers is exactly the finite-history route through the displayed partial-sum rows, tail schedule, tail-bound ledger, RegSeqRat$^{\uparrow}$ readback, and Real$^{\uparrow}$ seal row.

The scoped kernel factorization of Definition 367.7 accounts for the remaining hsame, Cont, Pkg, and NameCert rows, while Definition 367.4 supplies the checked tail-sum boundary used by the precision read. Repacking these rows gives the bridge-facing boundary named in the theorem.

Because every cited row is a displayed finite carrier coordinate or a displayed transport route, the package has no coordinate for quotient streams, selected infinite sums, host summability predicates, or ambient completeness theorems. □

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier bridge boundary package`

Theorem 367.14 (FastConvergentSeries finite tail-budget example)**.** *The stationary zero summand series carries a mature finite tail-budget example for* FastConvergentSeries$^{\uparrow}$*. Its* Series$^{\uparrow}$ *source row and* Seq$^{\uparrow}$ *observation surface display zero summands and zero partial sums, its* CauchyModulus$^{\uparrow}$ *schedule uses the zero threshold for every precision request, its finite tail-bound ledger records zero tails, and its* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *rows read the resulting constant zero name.*

The example is entirely a finite carrier packet over Series$^{\uparrow}$*,* Seq$^{\uparrow}$*,* CauchyModulus$^{\uparrow}$*, finite tail bounds,* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It does not select a host sum or appeal to ambient completeness.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesTailBoundPacket constant zero seed`

Proof. Begin with Definition 367.3. It supplies the zero summand observations, zero partial sums, zero tail ledger, regular-rational readback, and real seal as displayed carrier rows.

Apply Definition 367.10. For each precision request, the displayed schedule may choose the zero threshold, and the later partial-sum comparisons are all zero comparisons inside the finite tail-bound ledger.

Finally use Definition 367.13. The example is read only through the bridge-facing finite rows, so the stationary zero series supplies a concrete tail-budget package without a selected host infinite sum. □

Theorem 367.15 (FastConvergentSeries Cauchy consumer coverage)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read exported by the* $\mathsf{FastConvergentSeries}^{\uparrow}$ *bridge boundary is covered by the rows* $\mathsf{Series}^{\uparrow}$, $\mathsf{Seq}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, *finite tail bounds,* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert.

The consumer can inspect summand observations, displayed partial sums, the finite threshold schedule, the tail-bound ledger, the regular-rational readback, the real seal, transport rows, continuation routes, and provenance. It cannot inspect quotient streams, selected host sums, hidden summability predicates, or an ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier cauchy consumer coverage`

Proof. First take the bridge boundary package from Definition 367.13. It names exactly the finite route through the source series, sequence observations, fast schedule, tail-bound ledger, regular readback, real seal, transports, continuations, provenance, and local certificate.

For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, apply Definition 367.5. The consumer receives the partial-sum rows, schedule rows, and finite comparison ledger repacked as the regular rational handoff.

For a $\mathsf{Real}^{\uparrow}$ consumer, apply Definition 367.11. The seal read occurs only after the same tail-budget schedule and $\mathsf{RegSeqRat}^{\uparrow}$ handoff have been read.

The scoped kernel factorization then accounts for hsame, Cont, Pkg, and NameCert. Since none of these rows carries quotient equality, selected sums, summability predicates, or completeness principles, the coverage boundary is exactly the listed finite surface. □

Theorem 367.16 (FastConvergentSeries mature boundary package)**.** *The finite tail-budget example of Definition 367.14, the Cauchy consumer coverage of Definition 367.15, and the bridge boundary package of Definition 367.13 assemble the mature finite-tail-budget boundary for* $\mathsf{FastConvergentSeries}^{\uparrow}$.

The package provides a concrete downstream example and covers the completion-facing $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer routes while excluding quotient streams, selected host sums, hidden summability predicates, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.FastConvergentSeriesUp.FastConvergentSeriesCarrier mature boundary package`

Proof. The example theorem supplies an inhabited finite tail-budget packet: the stationary zero series, zero partial sums, zero threshold schedule, zero tail ledger, regular readback, and real seal.

The consumer coverage theorem supplies the downstream read boundary. It shows that both $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers inspect only the source, observation, schedule, tail-bound, readback, seal, transport, continuation, package, and local naming rows.

The bridge boundary package identifies the same rows as the bridge-facing public surface. Combining these three facts gives the mature boundary stated here, with every completion-facing read kept inside the finite packet and with no coordinate for quotient streams, host sums, summability predicates, or ambient completeness. □

Closure status for $\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}$.

Constructive story: A $\mathsf{FastConvergentSeries}^{\uparrow}$ packet is generated from displayed $\mathsf{Series}^{\uparrow}$ summand and partial-sum rows, the underlying $\mathsf{Seq}^{\uparrow}$ observation surface, a $\mathsf{CauchyModulus}^{\uparrow}$ fast tail schedule, finite tail-bound rows, $\mathsf{RegSeqRat}^{\uparrow}$ partial-sum readbacks, $\mathsf{Real}^{\uparrow}$ seal-facing rows, componentwise hsame transports, displayed Cont read routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The chapter fixes the constant-zero seed, tail-sum boundary, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, NameCert obligation surface, scoped kernel factorization, public tail-budget export, bridge schedule, bridge real-seal consumer, bridge completion handoff, and bridge boundary package for the fast convergent series certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FastConvergentSeries}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a public $\mathsf{Real}^{\uparrow}$ completeness theorem, quotient equality of streams, uniqueness of sums, host summability, or checked bridge schema.

Upgrade path: No further paper-axis closure grade remains; formal verification and bridge checking remain on the independent verification axis.

Chapter 368

A Concrete Naming Certificate for $\mathsf{FastSeriesProduct}^{\uparrow}$

The $\mathsf{FastSeriesProduct}^{\uparrow}$ interface names the finite certificate surface for the Cauchy product of two already accepted $\mathsf{FastConvergentSeries}^{\uparrow}$ packets. Following Bishop and Bridges, *Constructive Analysis*, where products of absolutely or effectively convergent series are controlled by explicit tail data and finite convolution estimates, the packet records only finite summand windows, finite convolution rows, pasted tail schedules, rational regular-sequence readbacks, real-seal rows, transport routes, package provenance, and local naming provenance. It does not form quotient streams, choose a host infinite sum, or appeal to ambient completeness of real numbers.

Definition 368.1 (FastSeriesProduct carrier)**.** *A* $\mathsf{FastSeriesProduct}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$H = (F, G, K, W, M, T, R, E, L, C, P, N)$$

with the following visible rows:

1. *F and G are accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *source packets, carrying displayed summand rows, partial-sum rows, fast tail schedules,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{Real}^{\uparrow}$ *seal-facing rows,* hsame *transports,* Cont *read routes, package provenance, and local certificate rows;*
2. *K is the finite convolution row whose inspected output coefficient at a displayed index n is the finite sum of displayed source summands $a_i b_{n-i}$ over the inspected range $0 \leq i \leq n$;*
3. *W is the finite partial-sum window ledger for the convolution rows, recording only displayed source windows and displayed product-prefix sums;*
4. *M is the pasted tail schedule, obtained by reading the fast tail schedules of F and G together with the finite source-window bounds needed for the bilinear tail estimate;*
5. *T is the tail-bound convolution ledger comparing displayed product-prefix sums past the threshold named by M;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row for the displayed product partial sums and their pasted tail schedule;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row attached to the same regular rational handoff;*
8. *L records the componentwise* hsame *transports for the two source packets, convolution rows, pasted schedule rows, tail-bound rows, regular handoff rows, and seal-facing rows;*

9. *C records the displayed* Cont *read routes by which consumers reach the source series, convolution window, pasted schedule, tail ledger, regular handoff, and real seal;*
10. *P is the* Pkg *provenance over* $\mathsf{FastConvergentSeries}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *the finite rational arithmetic rows used by the convolution, and the source certificate rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$ *provenance row.*

The carrier is a finite product certificate. It contains no quotient of streams, no host-level series multiplication, and no completeness theorem for real numbers.

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductTasteGate single carrier alignment`

The packet is not a standalone series object: its source rows F and G are accepted $\mathsf{FastConvergentSeries}^{\uparrow}$ packets from chapter 367, and all convolution, pasted schedule, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and $\mathsf{Real}^{\uparrow}$ seal rows consume that sibling's tail-budget surface.

Definition 368.2 (FastSeriesProduct classifier)**.** *For accepted* $\mathsf{FastSeriesProduct}^{\uparrow}$ *packets H and H', the classifier* $\mathsf{FastSeriesProductClassifier}(H, H')$ *compares only the two accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *source packets, their displayed finite convolution rows, product partial-sum windows, pasted tail schedules, tail-bound convolution ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *provenance.*

In particular, classifier transport is a finite-row comparison. It does not compare host sums, quotient representatives of streams, unbounded convolution functions, or a classical completeness proof for the product series.

Theorem 368.3 (FastSeriesProduct tail-bound convolution)**.** *Let F and G be accepted* $\mathsf{FastConvergentSeries}^{\uparrow}$ *packets displayed inside a* $\mathsf{FastSeriesProduct}^{\uparrow}$ *carrier. For every displayed product precision request, the pasted schedule row M supplies a finite threshold after which any two displayed product partial sums are compared by a finite convolution estimate using only:*

1. *the source tail schedules of F and G;*
2. *the finite source-window bounds recorded beside those schedules;*
3. *the displayed convolution rows K;*
4. *the product-prefix ledger W.*

The resulting tail-bound row in T is therefore a finite BEDC witness for the Cauchy-product tail at that precision, with no appeal to an infinite summation object.

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductCarrier tail bound convolution`

Proof. Read the two source packets through Definition 368.1. Each source supplies a displayed fast tail schedule and the finite windows on which the requested bounds are inspected.

The convolution row K computes each inspected product coefficient from finitely many displayed source summands. The product-prefix ledger W therefore compares two late product prefixes by splitting the difference into the finite head-window contribution and the two source-tail contributions named by the pasted schedule.

The head-window contribution is a finite rational arithmetic row, while the two tail contributions are bounded by the source schedules of F and G together with the displayed source-window bounds. Repacking these rows gives the tail-bound convolution ledger T.

Since every row used in the estimate is a coordinate of the carrier, the argument never calls a host Cauchy-product theorem, a quotient of streams, or an ambient completeness principle. □

Theorem 368.4 (FastSeriesProduct RegSeqRat handoff)**.** *For every accepted* $\mathsf{FastSeriesProduct}^{\uparrow}$ *packet and every displayed precision request, the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* R *is obtained by repacking the finite convolution partial sums in* W *together with the pasted schedule* M *and the tail-bound convolution ledger* T*. A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer can read the product name only through those three displayed rows and the recorded* hsame *and* Cont *routes.*

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductCarrier regseqrat handoff`

Proof. Project the carrier

$$H = (F, G, K, W, M, T, R, E, L, C, P, N).$$

The partial-sum data offered to $\mathsf{RegSeqRat}^{\uparrow}$ is exactly the product-prefix ledger W, whose entries are built from finite convolution rows in K.

The regularity witness is the pasted schedule M together with the tail-bound ledger T. By Definition 368.3, those rows already contain the finite estimate needed for the requested precision.

The transport and continuation coordinates L and C identify how a consumer reaches the source windows, convolution windows, schedule rows, and tail ledger. Hence the handoff row R exports a regular rational sequence surface, not a hidden product series or a quotient stream. □

Theorem 368.5 (FastSeriesProduct NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$ *obligation surface consists of six rows:*

1. *carrier admission: an accepted packet is the finite* BHist *carrier of Definition 368.1;*
2. *classifier transport: Definition 368.2 compares only source packets, finite convolution rows, product-prefix windows, pasted schedule rows, tail ledgers, regular handoffs, real seals, transports, continuations, and provenance;*
3. *finite convolution exactness: each displayed product coefficient is read as the finite row* $\sum_{0 \le i \le n} a_i b_{n-i}$ *over inspected source summands;*
4. *tail-bound convolution: Definition 368.3 supplies the finite pasted tail estimate for product prefixes;*
5. $\mathsf{RegSeqRat}^{\uparrow}$ *handoff: Definition 368.4 repacks the product partial sums, pasted schedule, and tail-bound ledger as the visible regular rational readback row;*
6. $\mathsf{Real}^{\uparrow}$ *seal compatibility: the seal row* E *may read only the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff and the finite source, convolution, schedule, tail, transport, continuation, package, and local naming rows carried by the packet.*

These rows are the concrete naming-certificate surface for Cauchy products of fast convergent series over the finite $\mathsf{Real}^{\uparrow}$ *seal path.*

Proof. Carrier admission and classifier transport are projections of the two definitions. They list exactly the rows that an accepted product packet stores and the rows that an accepted transport may compare.

Finite convolution exactness is built into the row K: each inspected output coefficient is a finite sum over displayed source summands, so no unbounded convolution function is exported to a consumer.

The tail-bound row is Definition 368.3. It explains how the pasted source schedules and finite source-window bounds control late product-prefix comparisons.

The regular handoff row is Definition 368.4. The $\mathsf{Real}^{\uparrow}$ seal row then reads only that handoff together with the visible transport, continuation, package, and local provenance rows.

Thus the obligation surface closes around the finite certificate packet. It leaves no coordinate for host sums, stream quotients, selected limits, or ambient real completeness. □

Theorem 368.6 (FastSeriesProduct classifier transport exactness)**.** *Let*

$$H = (F, G, K, W, M, T, R, E, L, C, P, N)$$

be an accepted $\mathsf{FastSeriesProduct}^{\uparrow}$ *carrier. If a displayed packet* H' *is obtained by transporting the two source packets, finite convolution row, product-window ledger, pasted schedule, tail-bound ledger, regular handoff, and real-seal row along the componentwise* hsame *data in* L *and the displayed* Cont *routes in* C*, while preserving the* Pkg *row* P *and local* $\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$ *row* N*, then the classifier accepts* H' *exactly as the transported product carrier. It cannot compare host products, quotient streams, unbounded convolution functions, or ambient completeness evidence.*

Proof. Project the accepted carrier through Definition 368.1. The classifier of Definition 368.2 reads precisely the two source packets, K, W, M, T, R, E, and the transport, continuation, package, and local certificate rows.

Transport each displayed coordinate using the corresponding hsame witness in L, and read the transported row only through the continuation routes recorded in C. The package and local certificate rows keep the transported packet inside the same finite naming surface.

Because the classifier definition has no projection for a host product, stream quotient, unbounded convolution object, or completeness theorem, acceptance is preserved exactly by those componentwise transported carrier rows. □

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductCarrier classifier transport exactness`

Theorem 368.7 (FastSeriesProduct convolution row exactness)**.** *For every accepted* $\mathsf{FastSeriesProduct}^{\uparrow}$ *carrier*

$$H = (F, G, K, W, M, T, R, E, L, C, P, N),$$

the convolution row K *supplies each inspected product coefficient as the finite displayed row* $\sum_{0 \le i \le n} a_i b_{n-i}$ *over the source summands read from* F *and* G*. The product-window ledger* W *and pasted tail ledger* T *may consume* K *only through those finite coefficient rows, together with the schedule row* M*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R*, and the provenance rows* P *and* N*.*

Proof. Read F and G as accepted $\mathsf{FastConvergentSeries}^{\uparrow}$ source packets. Their summand observations are already displayed finite rows, so the inspected coefficient at a fixed n is obtained by the finite rational sum named in the carrier.

The product-window ledger W records prefix sums built from those inspected coefficients. The pasted schedule M and tail-bound ledger T then use Definition 368.3 to compare late product prefixes through finite source windows and source tail schedules.

Finally Definition 368.4 repacks W, M, and T as the regular rational row R. Thus the convolution row is exact at the finite coefficient surface and is never replaced by a host-level Cauchy product. □

Theorem 368.8 (FastSeriesProduct real-seal factorization)**.** *For an accepted* $\mathsf{FastSeriesProduct}^{\uparrow}$ *carrier*

$$H = (F, G, K, W, M, T, R, E, L, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$ *seal row* E *factors through the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R*, which in turn is determined by the product-window ledger* W*, the pasted schedule row* M*, and the tail-bound ledger* T *built from the finite convolution row* K*. The rows* L*,* C*,* P*, and* N *certify componentwise transport, continuation readback, package provenance, and local naming, but add no quotient stream, selected product sum, host multiplication theorem, or ambient real completeness.*

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductCarrier real seal factorization`

Proof. Start with the seal row E and project the regular handoff R from the same carrier. The carrier definition makes R the only regular rational route that the seal may read.

Use Definition 368.4 to identify R with the repacking of W, M, and T. Then use Definition 368.7 and Definition 368.3 to bind those rows to the finite convolution coefficients, pasted source schedules, and tail estimates.

The remaining coordinates L, C, P, and N only certify transport, readback, provenance, and naming for the displayed packet. Since the carrier has no field for quotient streams, a chosen product sum, host multiplication, or completeness, the real seal factors through the finite product certificate alone. □

Theorem 368.9 (FastSeriesProduct finite convolution obligation package)**.** *An accepted concrete* $\mathsf{FastSeriesProduct}^{\uparrow}$ BHist *packet*

$$H = (F, G, K, W, M, T, R, E, L, C, P, N)$$

supplies the finite convolution obligation package consumed by later $\mathsf{Real}^{\uparrow}$ *series work. The package consists exactly of the following obligation rows:*

1. *the carrier and classifier surface of Definition 368.1 and Definition 368.2;*
2. *the finite convolution tail-bound row of Definition 368.3;*
3. *the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row of Definition 368.4;*
4. *the classifier transport exactness and convolution row exactness rows of Definition 368.6 and Definition 368.7;*
5. *the* $\mathsf{Real}^{\uparrow}$ *seal factorization row of Definition 368.8.*

Consequently a consumer of the product certificate may project the source packets, finite convolution rows, pasted schedule, tail ledger, regular rational handoff, real-seal row, transports, continuations, package provenance, and local naming row from H*, but obtains no quotient stream, selected limit, host real equality, or completeness principle.*

Proof. Project the displayed packet H. The first two coordinates F and G are the accepted source certificates, while $K, W, M, T, R, E, L, C, P, N$ are exactly the finite product rows named in Definition 368.1. The classifier surface is the same finite list read through Definition 368.2.

The tail-bound obligation is the row T, whose construction is recorded by Definition 368.3. The regular rational handoff is the row R, repacked from W, M, and T by Definition 368.4.

The exactness obligations are obtained by projecting the transport rows L and read routes C together with the finite convolution row K. Apply Definition 368.6 for transported packet acceptance, and apply Definition 368.7 for the displayed coefficient rows.

Finally Definition 368.8 projects the seal row E through the same regular handoff and finite ledger. Since every cited row is already a coordinate of H or a theorem about those coordinates, the package is assembled constructively by projection from the finite packet. No step forms a quotient stream, selects a limit, compares host real values, or invokes completeness. □

Theorem 368.10 (FastSeriesProduct scoped kernel interface)**.** *The carrier of Definition 368.1, the classifier of Definition 368.2, and the obligation rows of Definition 368.3, Definition 368.4, Definition 368.6, Definition 368.7, Definition 368.8, and Definition 368.9 form the scoped kernel interface for* $\mathsf{FastSeriesProduct}^{\uparrow}$ *over* $\mathsf{FastConvergentSeries}^{\uparrow}$, $\mathsf{DyadicTailBound}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

A downstream consumer may project the two source series, finite convolution rows, product-prefix windows, pasted tail schedules, dyadic tail-bound ledgers, regular rational handoff, real-seal row, componentwise transports, continuation routes, package provenance, and local naming row from an accepted packet. It obtains no quotient stream, selected product sum, host multiplication theorem, or completeness principle.

Lean4 ✓ `BEDC.Derived.FastSeriesProductUp.FastSeriesProductUp StdBridge`

Proof. Project the accepted finite packet

$$H = (F, G, K, W, M, T, R, E, L, C, P, N).$$

The carrier and classifier definitions give the complete list of rows that the packet stores and compares.

The tail-bound, regular handoff, classifier-transport, convolution-exactness, and real-seal rows are then the named projections of that same packet. The finite convolution obligation package gathers those projections without adding an external object.

Thus the interface is exactly the displayed BEDC surface over the named source, tail-bound, regular rational, real-seal, transport, continuation, package, and naming rows. Because no cited row contains a quotient stream, selected product sum, host multiplication theorem, or completeness field, no such datum is exported by the scoped interface. □

Closure status for $\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$.

Constructive story: A $\mathsf{FastSeriesProduct}^{\uparrow}$ packet is generated from two accepted $\mathsf{FastConvergentSeries}^{\uparrow}$ packets, finite convolution rows, product partial-sum windows, pasted fast tail schedules, tail-bound convolution ledgers, a $\mathsf{RegSeqRat}^{\uparrow}$ handoff, a $\mathsf{Real}^{\uparrow}$ seal row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 368.9, Definition 368.8, and Definition 368.10 bind the mature finite convolution, tail-bound, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, $\mathsf{Real}^{\uparrow}$ seal, BHist, hsame, Cont, Pkg, and NameCert product interface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FastSeriesProduct}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.FastSeriesProductUp.FastSeriesProductCarrier\_tail\_bound\_convolution`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close quotient equality of streams, uniqueness of product sums, host real multiplication, absolute convergence outside the displayed source packets, or bridge checking.

Upgrade path: No further upgrade remains; the chapter is at the top of the formal axis.

Chapter 369

A Concrete Naming Certificate for $\mathsf{UniformModulus}^{\uparrow}$

Inspired by chapter 9237; here re-expressed in the BEDC mathlib-free substrate.

The $\mathsf{UniformModulus}^{\uparrow}$ interface names the finite rational-fold packet that a compact-continuous consumer may read when it asks for a uniform precision history from a positive tolerance history. Its dependencies are the metric rows of $\mathsf{Met}^{\uparrow}$, the compact finite-net rows of $\mathsf{CompactMetric}^{\uparrow}$, the pointwise-modulus rows of $\mathsf{ContinuousMap}^{\uparrow}$, the positive rational order rows of $\mathsf{Rat}^{\uparrow}$, and the closed finite spine $\mathsf{ProbeBundle}$. The packet exports only the certified finite ledger from tolerance to precision; it does not expose an external modulus function, an open-cover compactness principle, a choice operator, or host real analysis. The sibling rows consumed here are the finite-net surface of chapter 129, the pointwise-modulus surface of chapter 130, the finite lower-fold surface of chapter 619, and the rational-order surface of chapter 37. The uniform-modulus packet consumes the compact finite-net rows of chapter 129 and the compact-continuous consumer surface of chapter 388; its finite lower-bound fold is the ledger row that those sibling packets hand to a modulus consumer. Finite-window compact consumers such as chapter 2372 read the same $\mathsf{UniformModulus}^{\uparrow}$ tolerance-only output only after the compact-net center-radius rows of chapter 129 have fed the finite fold and pointwise-modulus rows; no Real-facing or sequential compactness consumer receives a modulus outside that displayed compact-net route.

Definition 369.1 (UniformModulus BHist carrier)**.** *A* $\mathsf{UniformModulus}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$$

with the following visible rows:

1. *E is a positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history read by the target metric consumer;*
2. *D is a positive* $\mathsf{Rat}^{\uparrow}$ *precision history proposed as the uniform modulus output;*
3. *$\mathcal{P}$ is a nonempty* $\mathsf{ProbeBundle}$ *spine of compact centers;*
4. *R records the positive* $\mathsf{Rat}^{\uparrow}$ *radius rows attached to the bundled centers, including the half-radius rows consumed by the finite fold;*
5. *C records the compact finite-net coverage rows saying that every source-point history is covered by one bundled center at the displayed half-radius;*
6. *M records the continuous pointwise-modulus rows at the bundled centers for the tolerance history E;*

7. *F is the finite lower-bound fold certificate over $\mathcal{P}$ proving that D is below every bundled half-radius ledger through the* $\mathsf{Rat}^{\uparrow}$ *classifier;*
8. *L records the componentwise* hsame *rows for tolerance, precision, radius, coverage, pointwise-modulus, and fold ledgers;*
9. *Q records the displayed* Cont *routes through which compact, metric, continuous-map, rational, and uniform-modulus consumers read the packet;*
10. *P is the* Pkg *provenance over* $\mathsf{Met}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, *and* ProbeBundle *source rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ *row.*

The classifier accepts exactly the packets whose tolerance, precision, radius, finite-net coverage, pointwise-modulus, lower-bound fold, comparison, continuation, package, and naming rows are all present in these displayed positions. It exports no external selector, no infinite cover, no quotient of point histories, and no analytic compactness theorem beyond the recorded finite packet.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusTasteGate single carrier alignment`

Theorem 369.2 (UniformModulus finite ProbeBundle fold)**.** *Let U be an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier in the sense of Definition 369.1. For its nonempty* ProbeBundle *spine $\mathcal{P}$, the positive* $\mathsf{Rat}^{\uparrow}$ *radius rows R and the finite lower-bound fold certificate F determine a positive precision history D such that every bundled half-radius ledger compares above D through the displayed* $\mathsf{Rat}^{\uparrow}$ *classifier and the componentwise* hsame *rows of L.*

The fold is internal to the finite ProbeBundle *packet. It has no coordinate for an ambient minimum of a set of rationals, a selected external enumeration, or a choice-selected modulus value.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket finite probe bundle fold`

Proof. Read the nonempty bundle row $\mathcal{P}$ from the carrier. Each bundled probe has a visible radius row in R, and each such row is a positive $\mathsf{Rat}^{\uparrow}$ history with the half-radius comparison needed by the compact finite-net coverage row.

Perform primitive recursion over the closed ProbeBundle spine. At the first bundled probe, use its half-radius history as the accumulator. At each successor probe, use the $\mathsf{Rat}^{\uparrow}$ order readback to replace the accumulator by the displayed lower of the current accumulator and the next half-radius row.

The certificate F records the comparison at every step, so the final precision history D is below every bundled half-radius ledger. Because the comparisons are stored as $\mathsf{Rat}^{\uparrow}$ rows and transported by the componentwise hsame rows in L, the result is stable under the $\mathsf{UniformModulus}^{\uparrow}$ classifier. □

Theorem 369.3 (UniformModulus ProbeBundle induction derivation)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$, the precision row D is obtained by primitive induction over the displayed nonempty* ProbeBundle *spine $\mathcal{P}$. The base row uses the first positive* $\mathsf{Rat}^{\uparrow}$ *half-radius ledger, and each successor step replaces the accumulator by the displayed lower* $\mathsf{Rat}^{\uparrow}$ *comparison with the next half-radius row. All comparisons are transported by L and replayed through Q, P, N.*

This derivation is a finite BEDC fold over $\mathcal{P}$. It does not appeal to compactness, a host minimum, or an external modulus selector.

Proof. Induct over the displayed nonempty ProbeBundle spine. In the base case, the first bundled probe supplies a positive $\mathsf{Rat}^{\uparrow}$ radius row, and its half-radius ledger becomes the initial accumulator for the precision row.

For the successor step, assume the accumulator is already below every half-radius ledger seen so far. Read the next bundled radius row from R, use the displayed $\mathsf{Rat}^{\uparrow}$ order comparison, and replace the accumulator by the lower of the old accumulator and the new half-radius ledger.

The fold certificate F records this comparison after each successor step. Therefore the terminal accumulator is a positive precision history D below every bundled half-radius row, exactly as in Definition 369.2.

Finally transport and replay the construction through L, Q, P, N. Componentwise hsame preserves the radius and comparison rows, while the displayed continuation, provenance, and naming rows expose the same finite induction to every consumer without invoking compactness, a host minimum, or an external selector. □

Theorem 369.4 (UniformModulus finite-net consumer threshold package)**.** *Let $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P,$ be an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet. If its fold coordinate F is supplied by an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet over the same* ProbeBundle *spine $\mathcal{P}$ and the same positive* $\mathsf{Rat}^{\uparrow}$ *radius rows R, then the* $\mathsf{UniformModulus}^{\uparrow}$ *precision row D is exactly the consumer threshold exported by that finite fold packet, transported through L and routed by Q, P, N.*

The package is a finite-row handoff from $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *to* $\mathsf{UniformModulus}^{\uparrow}$*. It uses no open-cover compactness, no host minimum, and no external modulus selector.*

Proof. Project the accepted $\mathsf{UniformModulus}^{\uparrow}$ packet and the accepted $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ packet supplying F. The shared rows identify the same nonempty ProbeBundle spine and the same positive $\mathsf{Rat}^{\uparrow}$ half-radius ledgers.

Apply Definition 369.2 to the $\mathsf{UniformModulus}^{\uparrow}$ packet. It reads F as the finite lower-bound fold that produces D below every bundled half-radius ledger.

Apply Definition 619.8 and Definition 619.9 to the supplying $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ packet. The first theorem supplies the lower-bound certificate, and the second supplies admissibility of the accumulator as a positive $\mathsf{Rat}^{\uparrow}$ precision history.

Transport the resulting threshold through the componentwise classifier row L, then route it through Q, P, N to the uniform-modulus consumer. Since both packets expose only their finite bundle, radius, fold, transport, route, provenance, and naming rows, no host minimum or compactness principle can replace the exported threshold. □

Theorem 369.5 (UniformModulus classifier transport stability)**.** *Let $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$ be an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet. If the tolerance row, precision row, finite-net coverage row, pointwise-modulus rows, rational fold rows, and downstream metric-read rows are transported componentwise along the displayed* hsame *entries of L and then read only through the displayed* Cont, Pkg, *and* NameCert *routes, the transported data remain one accepted classifier-facing compact-continuous packet.*

The transported packet preserves the same tolerance-to-precision ledger, finite ProbeBundle *coverage, pointwise-modulus rows, rational lower-bound fold, and metric consumer boundary. It introduces no external selector, open-cover compactness row, sequential compactness row, or host analytic modulus.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket classifier transport stability`

Proof. Project the carrier rows of Definition 369.1. The only classifier-readable coordinates are the tolerance, precision, bundle, radius, coverage, pointwise-modulus, fold, transport, continuation, provenance, and local naming rows listed there.

Transport those coordinates through the componentwise hsame entries in L. The tolerance and precision histories remain positive $\mathsf{Rat}^{\uparrow}$ rows, the compact finite-net row still reads the same bundled centers through $\mathcal{P}$, and the pointwise-modulus rows remain attached to those transported centers.

Replay the finite ProbeBundle fold of Definition 369.2 on the transported radius rows. The fold certificate moves with the rational comparison rows, so the transported precision remains below every transported half-radius ledger.

Finally route all downstream metric reads through Q, P, and N. The accepted packet is therefore reconstructed from displayed carrier rows and displayed continuation routes only, leaving no coordinate for an external selector, open-cover compactness, sequential compactness, or host analytic modulus. □

Theorem 369.6 (UniformModulus NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ *obligation surface consists of five finite rows: the carrier and classifier row of Definition 369.1; the compact finite-net row over* $\mathsf{CompactMetric}^{\uparrow}$ *and* ProbeBundle*; the continuous pointwise-modulus row over* $\mathsf{ContinuousMap}^{\uparrow}$ *and* $\mathsf{Met}^{\uparrow}$*; the positive rational finite-fold row over* $\mathsf{Rat}^{\uparrow}$*; and the downstream boundary forcing every consumer read through the displayed* hsame*,* Cont*,* Pkg*, and local* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket namecert obligation surface`

Proof. The carrier row fixes the packet inventory. It lists the tolerance, precision, nonempty bundle, radius, coverage, pointwise-modulus, fold, comparison, continuation, package, and naming rows that the classifier may inspect.

The compact row is the coverage coordinate C together with the bundled centers of $\mathcal{P}$. The continuous row is M, which supplies the pointwise-modulus ledgers at those bundled centers and routes them through the metric source and target certificates.

The rational fold row is Definition 369.2. Repacking these rows with L, Q, P, and N gives exactly the finite local $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ surface, and no hidden selector or analytic compactness object is available to the consumer. □

Theorem 369.7 (UniformModulus root compact-continuous threshold)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the compact finite-net coverage row C together with the pointwise $\mathsf{ContinuousMap}^{\uparrow}$ *rows M determine the threshold surface read by a compact-continuous consumer. The row D is admitted as that threshold only after the finite* ProbeBundle *fold F has compared it with the displayed positive* $\mathsf{Rat}^{\uparrow}$ *radius rows R.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root compact continuous threshold`

Proof. Use the carrier definition Definition 369.1. The only compact-continuous source rows are the bundle $\mathcal{P}$, radius ledger R, coverage row C, pointwise-modulus rows M, and finite fold F.

Apply Definition 369.2 to produce the precision row D below the displayed half-radius rows. The fold is finite and internal to the ProbeBundle spine.

The obligation surface of Definition 369.6 then repacks the compact, continuous, rational-fold, transport, route, package, and local naming rows as the threshold surface. No additional compactness or continuity object is needed by the consumer. □

Theorem 369.8 (UniformModulus root net minimum row)**.** *If the fold coordinate F of an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet is supplied by a* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *row over the same finite* ProbeBundle *spine and positive* $\mathsf{Rat}^{\uparrow}$ *radius rows, then F supplies the positive precision row D without invoking a host minimum, an ambient finite-set operator, or an external selector.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root net minimum row`

Proof. Start with Definition 369.4. It identifies a supplying $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ packet as the source of the consumer threshold when the bundle and radius rows agree.

Use Definition 369.2. The row D is obtained by finite recursion over the displayed ProbeBundle spine and by positive $\mathsf{Rat}^{\uparrow}$ comparisons stored in F.

Finally apply classifier transport stability from Definition 369.5. Transport preserves the same fold row and cannot introduce a host minimum or external selector. □

Theorem 369.9 (UniformModulus root consumer package)**.** *Every* $\mathsf{UniformModulus}^{\uparrow}$ *consumer of the compact-continuous threshold factors through the displayed* $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, ProbeBundle, hsame, Cont, Pkg, *and* NameCert *rows. The consumer-visible package is exactly*

$$E, D, \mathcal{P}, R, C, M, F, L, Q, P, N,$$

with no open-cover compactness, host minimum, sequential compactness, or external modulus coordinate.

Proof. Read the threshold using Definition 369.7. The compact row C, continuous rows M, finite bundle $\mathcal{P}$, radius rows R, and fold row F determine the threshold surface.

Apply Definition 369.8 to identify the positive $\mathsf{Rat}^{\uparrow}$ precision source. The precision is the finite fold output, not a host minimum.

Close the consumer route with Definition 369.6. Its downstream boundary forces every read through L, Q, P, N, so all compact-continuous consumers factor through the displayed BEDC rows and nothing outside them. □

Theorem 369.10 (UniformModulus carrier obligation)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$, carrier admission is exactly the displayed finite* BHist *packet of Definition 369.1. The admitted rows are the positive* $\mathsf{Rat}^{\uparrow}$ *tolerance E, the positive* $\mathsf{Rat}^{\uparrow}$ *precision D, the nonempty* ProbeBundle *finite fold spine $\mathcal{P}$, the* $\mathsf{Rat}^{\uparrow}$ *tolerance and precision rows in R, the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row C, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus rows M, the finite rational fold F, componentwise* hsame *data L, displayed* Cont *routes Q,* Pkg *provenance P, and the local* NameCert *row N.*

No admitted carrier coordinate is an open-cover compactness principle, a host minimum operation, or an external modulus selector.

Proof. Project the carrier tuple from Definition 369.1. Each row named in the statement occurs as one finite coordinate of the same BHist packet.

The ProbeBundle row supplies the finite fold spine, while the $\mathsf{Rat}^{\uparrow}$ rows provide the tolerance, precision, radius, and comparison data consumed by the fold. The compact row is the finite-net coverage coordinate, and the continuous row is the displayed pointwise-modulus ledger at bundled centers.

The remaining rows L, Q, P, and N are transport, continuation, package, and naming boundaries. Since carrier admission is exhausted by these displayed coordinates, there is no place for open-cover compactness, a host minimum, or an external modulus selector. □

Theorem 369.11 (UniformModulus classifier stability obligation)**.** *Classifier stability for an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet preserves the existing* BHist *carrier packet, the finite* $\mathsf{ProbeBundle}$ *fold, the positive* $\mathsf{Rat}^{\uparrow}$ *tolerance and precision rows, the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus rows, the componentwise* hsame *ledger, the displayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row.*

Thus any classifier-related packet reads the same finite tolerance-to-precision surface through displayed rows only. It cannot gain an open-cover compactness row, a host minimum, or an external modulus selector during transport.

Proof. Begin with the componentwise hsame data L. It transports the tolerance, precision, radius, coverage, pointwise-modulus, and fold ledgers without changing which coordinates are classifier-visible.

Use the displayed Cont routes Q to read the transported packet. The compact finite-net row still points to the same finite $\mathsf{ProbeBundle}$ spine, and the continuous pointwise-modulus rows remain attached to the bundled centers.

The Pkg provenance P and local $\mathsf{NameCert}$ row N bound the transported read. Because these rows only re-expose the finite carrier inventory, transport cannot introduce open-cover compactness, a host minimum, or an external modulus selector. □

Theorem 369.12 (UniformModulus ledger exactness obligation)**.** *The ledger exactness obligation for* $\mathsf{UniformModulus}^{\uparrow}$ *says that the precision row D is consumed only as the result of the finite* $\mathsf{ProbeBundle}$ *fold F over displayed* $\mathsf{Rat}^{\uparrow}$ *radius rows, with compact coverage supplied by C, pointwise-modulus rows supplied by M, componentwise* hsame *transport supplied by L, continuation routes supplied by Q, package provenance supplied by P, and local naming supplied by N.*

Every tolerance-to-precision read must therefore account for the same finite fold ledger. No read may replace the fold with open-cover compactness, a host minimum, or an external modulus selector.

Proof. Read the precision row D through Definition 369.2. Its only source is the finite lower-bound fold over the bundled radius rows.

Next read compactness and continuity through C and M. The finite-net coordinate supplies a bundled center, and the pointwise-modulus coordinate supplies the local tolerance handoff at that center.

Finally repack the route through L, Q, P, and N. These rows record transport, continuation, package, and local naming evidence for the same finite ledger, so the precision read has no remaining coordinate from which to import open-cover compactness, a host minimum, or an external modulus selector. □

Theorem 369.13 (UniformModulus compact-continuous handoff)**.** *Suppose a* $\mathsf{CompactMetric}^{\uparrow}$ *packet exposes a nonempty* $\mathsf{ProbeBundle}$ *finite-net row for a positive tolerance history and a* $\mathsf{ContinuousMap}^{\uparrow}$ *packet over the same* $\mathsf{Met}^{\uparrow}$ *source exposes pointwise-modulus rows at every bundled center. If these rows are admitted into a* $\mathsf{UniformModulus}^{\uparrow}$ *carrier, then the precision history produced by the finite lower-bound fold is a conservative uniform-modulus handoff for compact-continuous consumers: every source-distance read below that precision factors through one compact coverage row, the corresponding pointwise-modulus row, the target metric rows, and the same finite* $\mathsf{Rat}^{\uparrow}$ *fold certificate.*

The handoff adds no open-cover compactness row, no sequential compactness row, no host function-space continuity theorem, and no external modulus selector.

Proof. Start with the compact finite-net coordinate. For the requested tolerance history, the $\mathsf{CompactMetric}^{\uparrow}$ row supplies the nonempty bundle $\mathcal{P}$, the center histories, the radius rows, and the coverage witness assigning each source-point history to a bundled center.

Use the $\mathsf{ContinuousMap}^{\uparrow}$ coordinate at each bundled center. Its pointwise-modulus row gives the local implication from a source metric distance bounded by the displayed local radius to a target metric distance bounded by the requested tolerance budget.

Apply Definition 369.2. The produced precision history is below every bundled half-radius ledger, so the metric triangle rows route any pair of sufficiently close source histories through the same bundled center and then through the corresponding pointwise-modulus row.

All data used in the handoff are the rows displayed in Definition 369.1. Therefore the consumer receives a finite BEDC packet over $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and $\mathsf{ProbeBundle}$, not an external analytic uniform-continuity principle. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket compact continuous handoff`

Theorem 369.14 (UniformModulus compact metric source lock)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$$

as in Definition 369.1, every center and radius coverage read factors through the displayed $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row C, the finite* $\mathsf{ProbeBundle}$ *spine $\mathcal{P}$, and the* $\mathsf{Met}^{\uparrow}$ *distance witnesses attached to those rows. The source side exposes no open-cover coordinate, no host finite-subcover coordinate, and no selected center outside the carrier rows C, $\mathcal{P}$, and R.*

Consequently a compact coverage consumer of U can read only the bundled center, its displayed positive radius ledger, and the metric witnesses transported through L, Q, P, N.

Proof. Project the carrier inventory of Definition 369.1. The compact source coordinates available to the packet are exactly the finite bundle $\mathcal{P}$, the radius rows R, and the compact finite-net row C.

Apply Definition 369.13. Its compact step routes every source-distance read through a bundled center and the corresponding radius row before any pointwise-modulus row is consumed.

The boundary rows L, Q, P, N only transport, expose, package, and name the same displayed carrier data. Since the packet lists no open-cover or host finite-subcover coordinate, those objects cannot be read by a compact coverage consumer. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket compact metric source lock`

Theorem 369.15 (UniformModulus continuous map modulus lock)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

a pointwise-modulus row in M becomes consumer-visible only after the compact source lock has selected a bundled center through C and $\mathcal{P}$, and after the finite fold row F has produced the precision row D below the corresponding displayed radius ledger in R. The continuous-map row is therefore a local row attached to a selected compact center, not a standalone global modulus function.

All consumer-visible reads of M must remain inside the BHist *carrier, the* $\mathsf{Met}^{\uparrow}$ *source and target witnesses, the finite* $\mathsf{Rat}^{\uparrow}$ *fold, and the L, Q, P, N certificate boundary.*

Proof. First use the compact metric source lock of Definition 369.14. It fixes the source route through a displayed center in $\mathcal{P}$ and its radius ledger in R.

At that fixed center, the relevant continuous data are the corresponding row of M. The row is pointwise because it is indexed by the bundled center and the tolerance row E inside the same carrier.

Apply Definition 369.2. The fold row F produces D by finite recursion over the displayed bundle and records the comparison needed to consume the pointwise row uniformly after the selected-center route is known.

Finally transport the read through L, Q, P, N. These rows preserve the carrier boundary and leave no coordinate for an isolated global modulus function or a bypass of the compact source selection. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket continuous map modulus lock`

Theorem 369.16 (UniformModulus real precision ledger lock)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the precision row D is a positive $\mathsf{Rat}^{\uparrow}$ *and real-precision ledger row internal to the finite fold over R. It is transported to consumers only by the displayed* hsame *row L,* Cont *routes Q,* Pkg *provenance P, and local* NameCert *row N.*

Thus D is not a host minimum, an ambient infimum, or a selected modulus function. Its only consumer-visible role is the folded positive precision ledger used after compact source selection and pointwise continuous-map routing.

Proof. Begin with Definition 369.14. It confines compact coverage to the finite source bundle, the displayed radius rows, and the metric witnesses already present in the carrier.

Next use Definition 369.15. A pointwise-modulus row contributes to a uniform read only after the selected center is fixed and the finite fold has produced D.

Now apply Definition 369.22. That obligation identifies D as the positive rational precision ledger produced by the finite fold over R and consumed through C, M, L, Q, P, N.

Combining these routes exhausts the consumer-visible precision source. No host minimum, ambient infimum, or external selected modulus function remains as a possible source for D. □

Theorem 369.17 (UniformModulus finite-net center coverage obligation)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$$

as in Definition 369.1, every compact coverage read selects its center only from the displayed finite ProbeBundle *row $\mathcal{P}$. The tolerance row E, radius rows R, coverage row C, transport row L, continuation row Q, package row P, and local naming row N are the only rows through which the selected center may be exposed.*

Thus compact coverage cannot import an undisplayed center selector, an open-cover compactness principle, or a host finite-subcover operation. The selected center is a carrier coordinate read through C and transported through L, Q, P, N.

Proof. Project the carrier row of Definition 369.1. The only center spine present in the packet is the nonempty finite ProbeBundle row $\mathcal{P}$, and the only coverage coordinate is C.

Use the compact-continuous handoff of Definition 369.13. Its first step reads the finite-net coordinate and assigns each source-point history to a bundled center, not to an external selector.

The remaining rows E, R, L, Q, P, N record the tolerance budget, radius evidence, transport, continuation, provenance, and local name for the same bundled center read. Since the packet has no other center-bearing coordinate, coverage selects only displayed centers. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket finite net center coverage obligation`

Theorem 369.18 (UniformModulus pointwise-to-uniform route obligation)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every pointwise-modulus row in M reaches a uniform consumer only after the compact coverage row C has selected a center from $\mathcal{P}$ and the finite fold row F has produced the precision row D below the corresponding radius ledger in R. The route from pointwise data to a uniform read is therefore

$$E, \mathcal{P}, R, C, M, F, L, Q, P, N \to D,$$

with L, Q, P, N preserving the same displayed packet boundary.

No pointwise row may be read as a global modulus by itself, and no consumer may bypass the selected center, the rational fold, or the NameCert route.

Proof. Begin with the coverage side. By Definition 369.17, a source-point read reaches a center only through the displayed finite $\mathsf{ProbeBundle}$ row $\mathcal{P}$ and coverage row C.

At that center, the pointwise-modulus coordinate is the corresponding row of M. It is attached to the tolerance row E and the radius ledger R for the same bundled center.

Apply Definition 369.2. The fold row F produces the precision row D below every bundled half-radius ledger, so the local pointwise implication can be consumed uniformly after the selected-center route has been fixed.

Finally route the read through L, Q, P, N. These rows keep the pointwise-to-uniform handoff inside the displayed packet and leave no coordinate for an isolated global modulus or a bypass of the finite center and fold rows. □

Theorem 369.19 (UniformModulus rational fold floor)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the finite $\mathsf{ProbeBundle}$ *fold in F produces a positive* $\mathsf{Rat}^{\uparrow}$ *precision row D below every displayed half-radius row of R attached to a bundled center of $\mathcal{P}$. The comparisons are part of the same finite ledger and are read only through the* $\mathsf{Rat}^{\uparrow}$ *classifier, the componentwise transport row L, the continuation routes Q, the package provenance P, and the local naming row N.*

Thus the row D is a reusable rational floor for compact-continuous consumers. It is not a host minimum, an ambient infimum, a selected finite-subcover radius, or an external modulus value.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket rat positive fold floor`

Proof. Start with the finite fold theorem Definition 369.2. It constructs the precision row by primitive recursion over the closed nonempty spine $\mathcal{P}$ and stores each comparison against a displayed half-radius row in F.

The output row remains positive because every input half-radius row is a positive $\mathsf{Rat}^{\uparrow}$ row and each fold step records a positive lower comparison inside the same rational ledger. No external order operation is used to create the accumulator.

Finally transport the comparisons through L, Q, P, N. Since those rows are the only consumer boundary for the fold, every later read of D sees the same finite rational floor below the displayed half-radius rows. □

Theorem 369.20 (UniformModulus compact-continuous consumer boundary)**.** *Every compact-continuous consumer read of an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier factors through the displayed rows*

$$C, M, F, L, Q, P, N.$$

The compact row C chooses a bundled center from $\mathcal{P}$, the pointwise row M supplies the local modulus ledger at that center, the finite fold row F supplies the precision floor D, and the rows L, Q, P, N provide the transport, route, package, and local naming boundary.

No compact-continuous consumer may read a precision history through an open-cover compactness principle, a sequential compactness row, a host finite-subcover selector, or an external modulus function.

Proof. First use Definition 369.18. A pointwise row reaches a uniform read only after compact coverage has selected a displayed bundled center and the fold has produced the precision row.

Next apply Definition 369.19. The precision row consumed at that route is below every displayed half-radius ledger and is therefore reusable across the finite compact coverage packet.

The remaining access is through L, Q, P, N. These rows carry the same carrier data to the consumer boundary, so any read of the compact-continuous handoff is already a read through C, M, F, L, Q, P, N. □

Theorem 369.21 (UniformModulus NameCert threshold package)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$, the finite rational floor of Definition 369.19, the compact-continuous consumer boundary of Definition 369.20, and the local obligation surface of Definition 369.6 assemble the local* $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ *threshold package.*

The package has exactly five rows: carrier admission for $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$; compact finite-net coverage through C; pointwise continuous-map ledgers through M; positive rational lower-fold evidence through F; and consumer-boundary routing through L, Q, P, N.

Every downstream compact metric, continuous-map, or uniform-continuity consumer must consume this five-row packet before reading D as a uniform precision threshold.

Proof. Project the carrier row of Definition 369.1. It supplies the tolerance, precision, bundle, radius, coverage, pointwise, fold, transport, route, package, and naming coordinates used by the threshold package.

Use Definition 369.19 for the rational floor row. This identifies D as the positive finite-fold output below every displayed half-radius row.

Use Definition 369.20 for the consumer side. It forces every compact-continuous read through C, M, F, L, Q, P, N before the precision row is exposed.

Finally apply Definition 369.6. Its five finite rows are exactly the carrier, compact coverage, pointwise modulus, rational fold, and downstream boundary rows named above, so the local threshold package is complete. □

Theorem 369.22 (UniformModulus positive precision ledger obligation)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the positive precision row D is consumed only as the output of the finite $\mathsf{Rat}^{\uparrow}$ *fold row F over the displayed radius rows R on the finite* $\mathsf{ProbeBundle}$ *spine $\mathcal{P}$. Its downstream use must also pass through the compact coverage row C, pointwise-modulus row M, componentwise* hsame *row L, displayed* Cont *routes Q, package provenance P, and local naming row N.*

Thus D is never a host minimum, an ambient infimum, or an externally selected modulus value. It is a positive rational ledger row internal to the same finite carrier.

Proof. Read D using Definition 369.2. The theorem identifies the precision history with the result of primitive finite recursion over $\mathcal{P}$, using the positive $\mathsf{Rat}^{\uparrow}$ comparisons stored in R and F.

Use the pointwise-to-uniform route of Definition 369.18. Any consumer of D also consumes the compact coverage row C and the pointwise-modulus row M attached to the selected bundled center.

The rows L, Q, P, N then provide the transport, continuation, provenance, and local naming boundary. Since every precision read has already passed through the finite $\mathsf{Rat}^{\uparrow}$ fold and these displayed routes, no host minimum, infimum, or external modulus value is exported. □

Theorem 369.23 (UniformModulus scoped dependency interface)**.** *Any compact-continuous consumer of an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet can read the tolerance-to-precision handoff only through the displayed* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net rows,* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus rows,* $\mathsf{Met}^{\uparrow}$ *distance witnesses, positive* $\mathsf{Rat}^{\uparrow}$ *fold rows,* $\mathsf{ProbeBundle}$ *membership rows, componentwise* hsame *comparisons, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *coordinates.*

The interface contains no open-cover compactness row, no sequential compactness row, no host minimum operation, and no external modulus function.

Proof. Begin with the finite $\mathsf{ProbeBundle}$ fold of Definition 369.2. It makes the precision row a positive $\mathsf{Rat}^{\uparrow}$ fold over the displayed bundle radii, so the handoff cannot read a host minimum or an external modulus function.

Transport the same rows through classifier stability in Definition 369.5. The $\mathsf{CompactMetric}^{\uparrow}$ finite-net rows, $\mathsf{ContinuousMap}^{\uparrow}$ pointwise-modulus rows, $\mathsf{Met}^{\uparrow}$ distance witnesses, and rational fold rows remain the only classifier-visible dependency coordinates.

Now apply the NameCert obligation surface of Definition 369.6. It repacks those rows with $\mathsf{ProbeBundle}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ provenance as the complete local certificate surface.

Finally use the compact-continuous handoff of Definition 369.13. Every downstream tolerance-to-precision read follows the displayed finite-net and pointwise-modulus route, leaving no coordinate for open-cover compactness, sequential compactness, host minima, or external modulus functions. □

Theorem 369.24 (UniformModulus finite-fold scope closure)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *carrier* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, the finite* $\mathsf{ProbeBundle}$ *fold, classifier transport stability, and local* $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ *obligation surface bind the precision row* D *entirely to displayed* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{ProbeBundle}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

In particular, every classifier-visible use of D *factors through the positive* $\mathsf{Rat}^{\uparrow}$ *fold rows* F*, the bundled probe spine* $\mathcal{P}$*, the componentwise transport ledger* L*, the continuation routes* Q*, the package provenance* P*, and the local naming row* N*. There is no further coordinate for a host minimum, an ambient finite-set operator, or an external modulus value.*

Proof. Read the carrier from Definition 369.1. The precision history D appears only as the proposed output row of the finite packet, while F records the rational comparisons that place D below the bundled half-radius ledgers.

Apply the finite $\mathsf{ProbeBundle}$ fold of Definition 369.2. It constructs the precision ledger by primitive finite recursion over $\mathcal{P}$ and stores each comparison as a displayed $\mathsf{Rat}^{\uparrow}$ row.

Use classifier transport stability from Definition 369.5. Transport can move the displayed rows along L, but it cannot add a new precision source outside the carrier coordinates.

Finally apply the local obligation surface of Definition 369.6. The rows Q, P, and N repack the fold, transport, and naming data as the complete classifier-facing surface, so every read of D is already exhausted by the displayed packet. □

Theorem 369.25 (UniformModulus center-radius readback)**.** *Every compact-continuous read of an accepted* UniformModulus$^{\uparrow}$ *packet first reaches a bundled center through the* CompactMetric$^{\uparrow}$ *finite-net rows and then uses the corresponding* ContinuousMap$^{\uparrow}$ *pointwise-modulus row. The source and target metric reads are mediated only by the displayed radius, coverage,* hsame*,* Cont*,* Pkg*, and* NameCert *witnesses of the same packet.*

Thus the center-radius route is a readback of displayed carrier data: compact coverage supplies the center, the finite fold supplies a precision below the relevant radius ledger, and the continuous row at that center supplies the tolerance handoff.

Proof. Start from the carrier inventory in Definition 369.1. The coverage row C is the only compact coordinate available to a source-point history, and it points to a center in the finite bundle $\mathcal{P}$ with its displayed radius rows R.

Use the finite-fold exactness supplied by Definition 369.2. Since D is below every bundled half-radius ledger through the displayed Rat$^{\uparrow}$ comparisons, any metric read below D can be routed through the radius ledger attached to the center chosen by C.

Now invoke the compact-continuous handoff of Definition 369.13. At the bundled center, the corresponding row of M is the ContinuousMap$^{\uparrow}$ pointwise-modulus ledger for the tolerance history E.

The transport and boundary data of Definition 369.5 and Definition 369.6 keep this route inside L, Q, P, and N. No metric read is therefore mediated by an undisplayed center selector or a host analytic compactness principle. □

Theorem 369.26 (UniformModulus compact-continuous non-escape)**.** *Downstream consumers of an accepted* UniformModulus$^{\uparrow}$ *packet cannot read open-cover compactness, sequential compactness, host minima, or external modulus functions. The classifier-visible coordinates are exhausted by the carrier rows of Definition 369.1 together with the scoped dependency interface of Definition 369.23.*

Consequently every compact-continuous tolerance-to-precision query must remain inside the same finite Rat$^{\uparrow}$ *fold,* CompactMetric$^{\uparrow}$ *finite-net coverage row,* ContinuousMap$^{\uparrow}$ *pointwise-modulus row,* Met$^{\uparrow}$ *distance witnesses,* ProbeBundle *membership rows,* hsame *transport ledger,* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket compact continuous nonescape`

Proof. Project the accepted carrier. The definition lists all rows inspectable by the classifier and explicitly leaves no coordinate for open-cover compactness, sequential compactness, a host minimum, or an external modulus function.

Apply Definition 369.24 to the precision side. The precision row is tied to the finite rational fold over the displayed bundle and cannot be replaced by a host minimum or function-space selector.

Apply Definition 369.25 to the compact-continuous side. Every read reaches a displayed center and then a displayed pointwise-modulus row before reaching the target metric tolerance.

Finally use Definition 369.23. Since that interface is the complete consumer boundary for the carrier, any attempted downstream read outside these rows has no classifier-visible coordinate to inspect. □

Theorem 369.27 (UniformModulus modulus selection obligation)**.** *For an accepted* UniformModulus$^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the selected modulus row is exactly the positive Rat$^{\uparrow}$ *precision history D produced by the finite* ProbeBundle *fold F over the displayed radius rows R. Its consumer-visible selection route must pass*

through the compact finite-net rows C, the BHist *carrier, componentwise* hsame *rows L, displayed* Cont *routes Q,* Pkg *provenance P, and local* NameCert *row N.*

Thus a compact-continuous consumer cannot replace D by a host minimum, a choice-selected radius, an open-cover compactness datum, or an external modulus function.

Proof. Start with Definition 369.2. It constructs D by primitive recursion over the closed finite ProbeBundle spine and stores every comparison against the bundled radius rows in the fold ledger F.

Use Definition 369.25 to attach the selected row to compact coverage. The compact finite-net row C supplies the displayed center and radius readback, so the selected precision remains tied to R and the same BHist carrier.

Finally apply Definition 369.26. The rows L, Q, P, N are the only available transport, continuation, package, and naming boundary, so no undisplayed selector or host analytic modulus can enter the selection route. □

Theorem 369.28 (UniformModulus radius monotonicity obligation)**.** *For an accepted* UniformModulus$^{\uparrow}$ *packet $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$, every consumer read that weakens a displayed positive rational radius row in R must preserve the same folded precision obligation: the finite* ProbeBundle *fold still reads a positive row below the transported radius ledger, and the read remains mediated by C, the* BHist *carrier,* hsame *transport L,* Cont *routes Q,* Pkg *provenance P, and local* NameCert *row N.*

The monotonicity obligation is therefore internal to the displayed Rat$^{\uparrow}$ *comparisons and finite-net rows. It does not call an ambient order-theoretic infimum, a host metric radius theorem, or a separate compactness principle.*

Proof. Apply Definition 369.25. Every radius read is attached to a bundled center from $\mathcal{P}$ and is consumed through the compact finite-net row C before the target tolerance route is exposed.

Use Definition 369.2. Since the fold ledger records that D lies below every bundled half-radius row, weakening a displayed positive rational radius preserves the comparison needed by the same fold.

Close the route with Definition 369.26. The monotone radius read remains inside the finite Rat$^{\uparrow}$ comparison rows, L, Q, P, N, and the local carrier, leaving no coordinate for host order or analytic compactness data. □

Theorem 369.29 (UniformModulus compact-net coverage obligation)**.** *For an accepted* UniformModulus$^{\uparrow}$ *packet $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$, every compact-net coverage read is witnessed by a center already present in the finite* ProbeBundle *row $\mathcal{P}$ and by positive rational radius rows already present in R. The selected center, radius readback, pointwise-modulus handoff, and precision row are all consumed through the* BHist *carrier, compact finite-net row C, finite fold F,* hsame *transport L,* Cont *routes Q,* Pkg *provenance P, and local* NameCert *row N.*

No consumer may replace this coverage row with an open-cover compactness assertion, a sequential compactness principle, a choice-selected center, or an external finite-subcover operation.

Proof. Begin with Definition 369.25. It forces each compact-continuous read to reach a displayed bundled center and its radius row before any pointwise-modulus row is used.

Apply Definition 369.2. The precision row D is below the radius ledgers attached to every bundled center, so the coverage read and the folded modulus row are linked inside the same finite packet.

Use Definition 369.26 to finish. The compact-net coverage route is exhausted by $\mathcal{P}, R, C, M, F, L, Q, P, N$ and therefore has no row from which a host compactness or external finite-subcover operation can be read. □

Theorem 369.30 (UniformModulus ProbeBundle radius-source exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every radius read used by the finite fold* F *factors through the displayed* ProbeBundle *spine* $\mathcal{P}$*, the positive* $\mathsf{Rat}^{\uparrow}$ *radius rows* R*, the componentwise* hsame *transport ledger* L*, the displayed* Cont *routes* Q*, the package provenance row* P*, and the local* NameCert *row* N*.*

No radius consumed by the fold may be supplied by an open cover, a host metric radius selector, an ambient compactness theorem, or a row outside the local packet.

Proof. Project the carrier of Definition 369.1. The only rows that can feed F are the displayed finite spine $\mathcal{P}$ and the radius ledger R, with L, Q, P, N carrying transport, routing, provenance, and naming.

Apply Definition 369.2. It identifies the precision row D as the output of the finite fold over those bundled radius rows, so every comparison used by the fold is already a $\mathsf{Rat}^{\uparrow}$ row in the displayed packet.

Use Definition 369.29 to attach the same radius reads to compact finite-net coverage. Then close with Definition 369.26, which excludes all host compactness and external selector coordinates from the consumer route. □

Theorem 369.31 (UniformModulus pointwise-modulus center exactness)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row in* M *consumed by the uniform packet is attached to a center selected from the compact finite-net row* C *and the finite* ProbeBundle *spine* $\mathcal{P}$*. It is not attached to a standalone global function or to an undisplayed center.*

The center attachment is read through the $\mathsf{Met}^{\uparrow}$ *distance witnesses, the radius ledger* R*, the finite fold* F*, componentwise transport* L*, displayed routes* Q*, provenance* P*, and local naming* N*.*

Proof. Begin with Definition 369.25. A compact-continuous read reaches a displayed bundled center before it can consume a radius row or a pointwise-modulus row.

Apply Definition 369.29. The compact finite-net row C supplies the center used by the packet, and that center is already a member of $\mathcal{P}$.

Use Definition 369.30 to keep the attached radius and fold rows inside the same finite spine. The non-escape theorem Definition 369.26 then rules out standalone global functions, undisplayed centers, and external pointwise selectors. □

Theorem 369.32 (UniformModulus precision-consumer nonescape)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every consumer of the precision row* D *reads it only through the finite fold* F*, compact coverage row* C*, pointwise-modulus rows* M*, radius ledger* R*,* ProbeBundle *spine* $\mathcal{P}$*, transport ledger* L*, displayed* Cont *routes* Q*, package provenance* P*, and local* NameCert *row* N*.*

Thus a precision consumer cannot obtain D *from open-cover compactness, host minima, external selectors, ambient finite-subcover operations, or choice.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket precision consumer nonescape`

Proof. Start with the precision side of the carrier. The row D appears only as the folded positive $\mathsf{Rat}^{\uparrow}$ precision row, and the fold coordinate F records the finite comparisons against R over $\mathcal{P}$.

Use Definition 369.31. It ties every pointwise-modulus consumption of the selected precision to a center supplied by the compact finite-net row rather than by a global function.

Finally apply Definition 369.26. Since the consumer boundary is exhausted by $C, M, F, R, \mathcal{P}, L, Q, P, N$, no host minimum, open-cover argument, external selector, ambient finite-subcover operation, or choice principle can supply D. □

Theorem 369.33 (UniformModulus terminal compact-continuous route)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every compact-continuous precision consumer factors through exactly the compact finite-net row* C*, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row* M*, the* $\mathsf{Met}^{\uparrow}$ *distance witnesses, the positive* $\mathsf{Rat}^{\uparrow}$ *fold rows* R, F, D*, the* ProbeBundle *spine* $\mathcal{P}$*, and the local transport, route, provenance, and naming rows* L, Q, P, N*.*

No such consumer reads open-cover compactness, sequential compactness, a host minimum, an external modulus function, quotient metric equality, or a choice-selected center.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusUp StdBridge`

Proof. Use Definition 369.13 to expose the compact-continuous handoff and Definition 369.25 to route each read through a displayed center and radius row.

Apply Definition 369.31 and Definition 369.30. These bind the pointwise-modulus row and every radius source to $C, M, R, F, \mathcal{P}$ and to the local rows L, Q, P, N.

Finally apply Definition 369.32. Repacking those routes gives the terminal Phase Compact and Continuous consumer boundary, with no remaining classifier-visible coordinate outside the displayed packet. □

Theorem 369.34 (UniformModulus root carrier row)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the root carrier row is the finite ProbeBundle *fold packet over* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net rows,* $\mathsf{ContinuousMap}^{\uparrow}$ *modulus rows, positive* $\mathsf{Real}^{\uparrow}$ *precision rows, the* BHist *carrier, componentwise* hsame *transport* L*, displayed* Cont *routes* Q*,* Pkg *provenance* P*, and the local* NameCert *row* N*.*

Every compact-continuous read of the root carrier must therefore pass through the displayed bundle $\mathcal{P}$*, radius ledger* R*, coverage row* C*, pointwise rows* M*, finite fold* F*, and boundary rows* L, Q, P, N*.*

Proof. Project the carrier of Definition 369.1. Its root-facing data are exactly the finite bundle, radius ledger, compact coverage, pointwise modulus rows, fold certificate, and transport boundary displayed in U.

Apply Definition 369.29. The compact finite-net portion is read from $\mathcal{P}, R, C$ before any pointwise modulus row can be consumed.

Use Definition 369.2. The precision row is produced by the finite fold F over those displayed radius rows, and the output remains attached to the same BHist packet.

Finally close with Definition 369.26. The rows L, Q, P, N are the only consumer boundary, so the root carrier cannot import an open-cover compactness or choice-selection coordinate. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root carrier row exactness`

Theorem 369.35 (UniformModulus root classifier row)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, classifier transport is exactly the shared center-radius readback and positive-precision readback already displayed by the packet. A transported classifier read must use the compact finite-net row* C *to reach a center in* $\mathcal{P}$*, the radius ledger* R *to read the center radius, and the fold row* F *to expose the positive precision row* D *under* L, Q, P, N*.*

Proof. Begin with Definition 369.25. It identifies the classifier-visible center and radius route as the displayed route through $\mathcal{P}, R, C$.

Apply Definition 369.2. The positive precision row D is the folded readback from the same radius ledger, so classifier transport cannot change the threshold source.

Use Definition 369.28 to keep transported radius reads attached to the same finite fold obligation. The boundary rows L, Q, P, N then carry the shared readback without adding a host classifier or an analytic modulus. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root classifier row`

Theorem 369.36 (UniformModulus root consumer threshold row)**.** *Every compact-continuous consumer of an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet receives only the finite-net threshold row D, the pointwise modulus route through M, the rational fold floor F, and the ledger rows $\mathcal{P}, R, C, L, Q, P, N$. The consumer receives no open-cover compactness object, no sequential compactness row, no choice-like center selection, no host minimum, and no external modulus selector.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root consumer threshold row`

Proof. Read the consumer boundary through Definition 369.45. The exported rows are the tolerance, threshold, bundle, radius, coverage, pointwise, fold, transport, continuation, package, and naming rows of the same packet.

Apply Definition 369.35. It fixes center-radius and positive-precision readback as the shared classifier route available to the consumer.

Finally use Definition 369.26. After the finite-net threshold, pointwise route, rational fold floor, and ledger rows have been read, no coordinate remains for open-cover compactness, choice-like selection, a host minimum, or an external modulus selector. □

Theorem 369.37 (UniformModulus finite-net realizer unblock)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every compact finite-net read realized by a downstream compact-continuous consumer is witnessed by a displayed center in the finite ProbeBundle *row $\mathcal{P}$, a positive rational radius row in R, and the compact coverage row C. The only admissible transport from this realized finite net to the consumer boundary is through the componentwise* hsame *ledger L, the displayed* Cont *routes Q, the* Pkg *provenance row P, and the local* NameCert *row N.*

Thus the realized finite net is a BHist*-anchored packet over* $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, *and* ProbeBundle*, not an open-cover compactness object, a host finite-subcover operation, or a choice-selected center.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket finite net realizer unblock`

Proof. Project the carrier of Definition 369.1. Its finite-net coordinates are exactly the bundled centers $\mathcal{P}$, the radius ledgers R, and the compact coverage row C.

Apply Definition 369.29. It identifies every compact-net coverage read with one of those displayed centers and radius rows before any consumer can ask for pointwise data.

Use Definition 369.26. The consumer boundary has no coordinate for open-cover compactness, host finite subcovers, or undisplayed center selection.

Finally route the realized row through L, Q, P, N. These are the displayed transport, continuation, package, and naming rows, so the realizer remains inside the same accepted packet. □

Theorem 369.38 (UniformModulus covered-point radius route)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, any source-point history covered by the compact row* C *and any precision row* D *produced by the finite fold* F *route through the same selected bundled center, its displayed positive rational radius row in* R*, and the* $\mathsf{Rat}^{\uparrow}$ *fold ledger before any pointwise-modulus row in* M *is consumed.*

The covered-point route is therefore a finite packet route through $\mathsf{CompactMetric}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* ProbeBundle*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It does not use an ambient closest-center principle, an open-cover compactness row, or a host minimum for the source metric.*

Proof. Begin with Definition 369.25. A covered source-point history first reaches a center in $\mathcal{P}$ through C and then reads the radius row attached to that center.

Apply Definition 369.2. The precision row D is produced by the fold ledger F and is compared against the bundled radius rows before the pointwise-modulus row can be consumed.

Use Definition 369.28. Weakening or transporting a displayed radius keeps the same folded precision obligation, so the route cannot leave the $\mathsf{Rat}^{\uparrow}$ comparison rows.

The rows L, Q, P, N close the public route. They carry the covered-point, radius, fold, and pointwise rows to the consumer boundary without adding a host selector or compactness principle. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket covered point radius route`

Theorem 369.39 (UniformModulus pointwise metric consumer unblock)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, the finite-net realizer of Definition 369.37 and the covered-point radius route of Definition 369.38 assemble the consumer-facing compact-continuous packet over* $\mathsf{CompactMetric}^{\uparrow}$*,* $\mathsf{ContinuousMap}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* ProbeBundle*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Every pointwise metric consumer of M *must first read the compact coverage center, the displayed radius row, and the folded precision ledger. The packet exports no open-cover compactness, no host minimum, no external modulus selector, and no choice-selected center.*

Proof. First use Definition 369.37. It supplies the finite $\mathsf{CompactMetric}^{\uparrow}$ realizer from the displayed bundle, radius rows, and compact coverage row.

Next use Definition 369.38. It forces each covered point to pass through the selected center, its radius ledger, and the $\mathsf{Rat}^{\uparrow}$ fold before the matching row of M is consumed.

Apply Definition 369.23. The consumer-facing coordinates are precisely $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, Pkg, and NameCert rows.

Finish with Definition 369.26. Since all consumer reads have already been routed through the displayed finite packet, there is no remaining coordinate for open-cover compactness, a host minimum, an external modulus selector, or a choice-selected center. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket pointwise metric consumer unblock`

Theorem 369.40 (UniformModulus mature compact-continuous package)**.** *An accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$$

assembles a mature compact-continuous package whose exported consumer surface consists exactly of the positive $\mathsf{Rat}^{\uparrow}$ *tolerance row* E*, the positive* $\mathsf{Rat}^{\uparrow}$ *precision row* D*, the finite nonempty* ProbeBundle *center spine* $\mathcal{P}$*, the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net coverage row* C*, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus rows* M *at bundled centers, the* $\mathsf{Met}^{\uparrow}$ *distance witnesses used by the coverage*

and pointwise rows, the finite $\mathsf{Rat}^{\uparrow}$ *lower-bound fold* F*, and the displayed* hsame*,* Cont*,* Pkg*, and local* NameCert *rows* L, Q, P, N*.*

The package exports no open-cover compactness, sequential compactness, host minimum, ambient finite-set minimum, external modulus function, or choice-selected center. Every compact-continuous tolerance-to-precision consumer must therefore read the public package through the displayed carrier rows and through no further analytic or host-level coordinate.

Proof. Start with the finite precision row. By Definition 369.2, D is obtained from the finite positive $\mathsf{Rat}^{\uparrow}$ lower-bound fold over the bundled radius rows, so the precision part of the public package is a displayed rational ledger rather than a host minimum.

Next apply Definition 369.13. The compact-to-continuous route consumes the finite-net coverage row C and the pointwise-modulus rows M at bundled centers, with the relevant $\mathsf{Met}^{\uparrow}$ distance witnesses read inside the same carrier.

Use Definition 369.25 to identify the center route. A consumer first reaches a center through the finite ProbeBundle spine and then reads the corresponding radius and pointwise-modulus rows, so no choice-selected center is exported.

Now invoke Definition 369.23. This pins the consumer surface to the positive $\mathsf{Rat}^{\uparrow}$ rows, ProbeBundle spine, $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, hsame, Cont, Pkg, and local NameCert rows displayed in U.

Finally apply Definition 369.26. The exclusion boundary removes open-cover compactness, sequential compactness, host minima, ambient finite-set minima, external modulus functions, and undisplayed center selectors, leaving exactly the mature compact-continuous package surface stated above. □

Theorem 369.41 (UniformModulus ProbeBundle membership exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every center, radius, and compact-coverage row consumed by the public compact-continuous route is witnessed by the displayed finite ProbeBundle *membership row* $\mathcal{P}$ *and is routed through the* BHist *carrier of Definition 369.1, the componentwise transport ledger* L*, the displayed continuation routes* Q*, the package provenance row* P*, and the local* NameCert *row* N*.*

Thus the finite consumer surface cannot read an undisplayed center, an external radius selector, or a compactness witness outside the packet rows $\mathcal{P}, R, C, L, Q, P, N$*.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket probe bundle membership exhaustion`

Proof. Project the carrier in Definition 369.1. Its compact-consumer coordinates list the finite bundle $\mathcal{P}$, the radius rows R, the compact coverage row C, and the boundary rows L, Q, P, N.

Apply Definition 369.2. The finite fold reads the same displayed ProbeBundle spine and records the positive rational comparisons needed by the precision row D.

Use Definition 369.13 and Definition 369.25. The handoff first reaches a bundled center and its radius row, then moves to compact coverage and pointwise data through the displayed packet route.

Finally invoke Definition 369.26. Since the nonescape boundary removes host compactness and undisplayed selectors, every consumed center, radius, and coverage row is exhausted by $\mathcal{P}, R, C, L, Q, P, N$. □

Theorem 369.42 (UniformModulus metric-distance route soundness)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every* $\mathsf{Met}^{\uparrow}$ *distance read below the folded precision*

row D factors through the compact coverage row C, the selected pointwise-modulus row in M, the target metric witnesses carried by the packet, and the finite fold ledger F.

The route is therefore a BHist*-anchored finite-distance route over* $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, *and* ProbeBundle*, with transport and naming mediated only by L, Q, P, N.*

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket metric distance route soundness`

Proof. Begin with the carrier definition Definition 369.1. It places the source coverage row, pointwise-modulus rows, metric witnesses, fold ledger, and boundary rows inside the same accepted BHist packet.

Apply Definition 369.2. The precision row D is obtained from the finite ledger F, so any distance read below D must pass through the displayed rational comparisons recorded by that ledger.

Next use Definition 369.13. The compact-continuous handoff consumes C before selecting the pointwise row of M and the corresponding target metric witnesses.

Use Definition 369.25 to identify the center and radius row attached to the metric read. Close with Definition 369.26, which excludes any ambient distance route not represented in C, M, F, L, Q, P, N. □

Theorem 369.43 (UniformModulus compact-metric threshold factorization)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every compact-continuous tolerance-to-precision consumer factors through the finite ProbeBundle *center row $\mathcal{P}$, the* $\mathsf{CompactMetric}^{\uparrow}$ *coverage row C, the* $\mathsf{Met}^{\uparrow}$ *distance witness row, the* $\mathsf{Rat}^{\uparrow}$ *radius and fold ledger rows R, F, and the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row M before reading the folded precision row D.*

The factorization excludes open-cover compactness, sequential compactness, host finite-subcover selection, host minimum selection, and external modulus functions.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket compact metric threshold factorization`

Proof. Start with the finite-net realizer of Definition 369.37. It places the center row inside the finite ProbeBundle spine and ties the requested tolerance to displayed rational radius data.

Next use the covered-point radius route of Definition 369.38. The compact coverage row C can reach only a displayed center of $\mathcal{P}$ and the corresponding radius row in R.

Apply metric-distance route soundness from Definition 369.42. The source and target distance reads stay inside the packet route through $\mathsf{Met}^{\uparrow}$ witnesses, the selected pointwise-modulus row of M, and the finite fold ledger F.

Finally use consumer read exhaustion from Definition 369.45. Since downstream consumers read only $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, there is no remaining coordinate for open-cover compactness, sequential compactness, host finite-subcover selection, host minimum selection, or an external modulus function. □

Theorem 369.44 (UniformModulus root finite-net budget factorization)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every root tolerance-to-precision consumer factors through exactly the finite ProbeBundle *center row $\mathcal{P}$, the* $\mathsf{CompactMetric}^{\uparrow}$ *coverage row C, the* $\mathsf{Met}^{\uparrow}$ *distance witness row, the* $\mathsf{Rat}^{\uparrow}$ *radius and fold ledger rows R, F, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row M, and the boundary rows L, Q, P, N.*

The factorization excludes open-cover compactness, host finite-subcover selection, host minimum selection, and external modulus functions. In particular, the consumer may read the folded precision row D only after those displayed rows have supplied the center, coverage, distance, radius, pointwise, fold, transport, continuation, package, and local naming data.

Proof. First build the finite-net spine. Apply Definition 369.37; it places every center read inside the displayed ProbeBundle row $\mathcal{P}$ with its compact coverage row C and radius ledger R.

Next route covered points through displayed metric data. Use Definition 369.38 to reach the bundled center and radius row before any pointwise-modulus row is consumed.

Now apply Definition 369.42. The distance witness, selected pointwise-modulus row in M, and finite fold ledger F remain inside the same BHist packet and are transported only by L, Q, P, N.

Finally use Definition 369.45. Since the root consumer reads only $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, no coordinate remains for open-cover compactness, host finite-subcover selection, host minimum selection, or an external modulus function. □

Theorem 369.45 (UniformModulus consumer read exhaustion)**.** *For an accepted* UniformModulus$^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

any compact-continuous downstream consumer can read only the tolerance row E, folded precision row D, finite ProbeBundle *row $\mathcal{P}$, radius rows R, compact coverage row C, pointwise-modulus rows M, fold ledger F, transport ledger L, continuation routes Q, package provenance row P, and local* NameCert *row N.*

In particular the consumer surface excludes open-cover compactness, host minima, choice-selected centers, and external modulus functions.

Proof. Read the accepted carrier through Definition 369.1. The displayed tuple U contains exactly the tolerance, precision, bundle, radius, coverage, pointwise, fold, transport, continuation, package, and naming rows listed in the statement.

Apply Definition 369.2. This accounts for all reads of the folded precision row D and ties them to the finite bundle and radius ledger.

Apply Definition 369.13 together with Definition 369.25. These results account for compact coverage, selected center and radius readback, and the pointwise-modulus rows consumed by a compact-continuous downstream reader.

Finally use Definition 369.26. The nonescape theorem removes every remaining host or analytic coordinate, so the downstream consumer reads no data beyond $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$. □

Theorem 369.46 (UniformModulus metric source-distance factorization)**.** *For an accepted* UniformModulus$^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every source-distance read below the folded precision row D factors through the Met$^{\uparrow}$ *source-distance rows, the compact finite-net row C, the selected center of the displayed* ProbeBundle *spine $\mathcal{P}$, and the corresponding pointwise-modulus row of M.*

The factorization is a BHist *route in the carrier of Definition 369.1: the rational fold ledger F supplies the bound D, C chooses only a bundled center, M supplies the local continuous-map row at that center, and L, Q, P, N transport and name the same displayed packet.*

Proof. Read the packet through Definition 369.1. The carrier places the source metric rows, compact finite-net coordinate, bundled centers, pointwise-modulus rows, fold ledger, and boundary rows in one finite BHist packet.

Apply Definition 369.2. The precision row D is produced by the fold ledger F over displayed radius rows, so a source-distance read below D must first pass through the finite rational comparisons recorded by the packet.

Use Definition 369.42 together with Definition 369.13. The distance route reaches the compact coverage row C, selects a bundled center from $\mathcal{P}$, and then consumes the matching pointwise-modulus row of M.

Finally invoke Definition 369.45. Since the downstream consumer reads only $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, there is no remaining coordinate from which to import an external source-distance factorization. □

Theorem 369.47 (UniformModulus finite fold positive output)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the finite fold output D is a positive $\mathsf{Rat}^{\uparrow}$ *precision row produced solely by the fold certificate F over the displayed radius rows R of the finite* ProbeBundle *spine $\mathcal{P}$.*

All transport of this output is mediated by L, Q, P, N. Thus the row D cannot be read as a host minimum, an ambient finite-set infimum, or a selected external modulus value.

Proof. Begin with the carrier definition Definition 369.1. It identifies D as the precision row, R as the positive radius ledger, F as the finite lower-bound fold certificate, and L, Q, P, N as the only transport, continuation, provenance, and naming rows.

Apply Definition 369.2. Its primitive finite recursion over $\mathcal{P}$ produces a positive $\mathsf{Rat}^{\uparrow}$ accumulator and records every comparison against the displayed radius rows inside F.

Use Definition 369.42 and Definition 369.13 to see how the produced row is consumed. Both routes read D only through the packet fold before reaching compact coverage and pointwise data.

Close with Definition 369.45. Since every consumer read is exhausted by $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, the positive output row has no source outside F over R and no transport outside L, Q, P, N. □

Theorem 369.48 (UniformModulus compact-continuous consumer exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every compact-continuous consumer of the packet reads only the tolerance row E, folded precision row D, finite ProbeBundle *row $\mathcal{P}$, radius rows R, compact finite-net row C, pointwise-modulus rows M, finite fold ledger F, transport ledger L, continuation routes Q, package provenance row P, and local* NameCert *row N.*

In particular such a consumer cannot import open-cover compactness, a host minimum operation, a host finite-subcover selector, or a selected external modulus. The complete consumer surface is the displayed compact-continuous BHist *packet.*

Proof. Project the carrier in Definition 369.1. Its displayed rows are exactly $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, with no coordinate for open covers, host minima, external finite-subcover operators, or external modulus functions.

Apply Definition 369.2. This accounts for the precision row D as a positive finite fold over displayed radius rows, rather than as a host minimum.

Next apply Definition 369.13 and Definition 369.42. These results account for compact coverage, selected-center routing, source-distance reads, and pointwise-modulus consumption inside the packet.

Finally use Definition 369.45. It exhausts the downstream read boundary by the same eleven displayed rows, so the compact-continuous consumer has no channel for any non-packet compactness or modulus source. □

Theorem 369.49 (UniformModulus finite-net minimum handoff)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the displayed compact finite-net row C and the pointwise-modulus rows M supply the complete finite source from which the fold ledger F produces a positive rational lower-bound row D. The handoff is a finite ProbeBundle *fold over the radius rows attached to the bundled centers in $\mathcal{P}$.*

Thus the lower-bound row consumed by compact-uniform-continuity readers is a packet row built from $C, M, F, R, \mathcal{P}$ and transported only through L, Q, P, N. It is not a host minimum, an open-cover compactness principle, a finite-subcover selector, or an externally selected modulus.

Proof. Start from the carrier definition Definition 369.1. It places $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$ in one displayed BHist packet, with C as the compact finite-net row and M as the pointwise-modulus surface at the bundled centers.

Apply Definition 369.2. The fold reads the finite ProbeBundle spine $\mathcal{P}$ and the displayed positive radius rows R, then records the rational comparison steps inside F before exposing the lower-bound row D.

Use Definition 369.13 and Definition 369.42. These theorems account for the route from compact coverage and source distance to pointwise modulus rows, so the finite-net handoff has no separate compactness or host-minimum coordinate.

Finally invoke Definition 369.45. Every consumer read is exhausted by the displayed packet rows, so the positive rational lower bound can only be the row produced by F from $C, M, R, \mathcal{P}$ and transported through L, Q, P, N. □

Theorem 369.50 (UniformModulus rational lower-bound ledger)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the rational lower-bound ledger is exact for the displayed radius rows R and the finite fold certificate F. Each comparison used to expose the positive precision row D is a row of the packet, and each such row is tied to a bundled center from $\mathcal{P}$ through the compact finite-net and pointwise-modulus rows C and M.

The ledger therefore cannot be read as a host minimum computation, an open-cover compactness argument, an ambient compactness theorem, or a hidden selector for a modulus. It records only the rational lower-bound rows displayed by the packet.

Proof. Project the carrier in Definition 369.1. The only rows capable of producing and naming the lower-bound precision are R and F, with C and M supplying the finite-net and pointwise inputs and L, Q, P, N supplying transport, continuation, provenance, and naming.

Apply Definition 369.2. The theorem identifies the production of D with a finite rational fold over the displayed radius rows, so the ledger is exact for those rows and no unlisted comparison can contribute.

The route soundness of Definition 369.42 and the compact-continuous handoff of Definition 369.13 keep every downstream use on the same finite packet surface.

Close with Definition 369.45. Since all consumer reads factor through $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, the lower-bound ledger has no channel for host minima, open covers, hidden compactness, or external modulus choice. □

Theorem 369.51 (UniformModulus compact-continuous consumer exactness)**.** *Every compact-continuous consumer of an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet factors through exactly the displayed rows*

$$E, D, \mathcal{P}, R, C, M, F, L, Q, P, N.$$

The tolerance request, folded lower bound, finite ProbeBundle *spine, radius rows, compact finite-net row, pointwise-modulus rows, rational fold ledger, transport ledger, continuation routes, package provenance, and local* NameCert *row are the complete consumer surface.*

Consequently a compact-uniform-continuity or finite-net-minimum consumer can use the finite packet handoff, but it cannot import open-cover compactness, host minimum selection, host finite-subcover selection, quotient representatives, or any modulus outside the named packet rows.

Proof. Read the packet through Definition 369.1. The carrier lists exactly the rows $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$ and gives no coordinate for open covers, host minima, external selectors, quotient representatives, or off-packet modulus data.

Use Definition 369.2 to account for the folded lower-bound row D. The fold is finite over $\mathcal{P}$ and R and is recorded by F, so the consumer sees a rational packet row rather than a host minimum.

Apply Definition 369.13 together with Definition 369.42. These results keep compact coverage, source-distance routing, and pointwise-modulus consumption inside C and M.

Finally apply Definition 369.45. It states that the consumer read boundary is exhausted by the same displayed rows, which proves the claimed exactness of the compact-continuous surface. □

Theorem 369.52 (UniformModulus finite-net center route exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every center route consumed by a compact-continuous reader factors through the displayed rows $E, D, \mathcal{P}, R, C, L, Q, P, N$*. The center is read from the finite* ProbeBundle *spine* $\mathcal{P}$ *through the compact finite-net row* C*, its radius and precision constraints are the rows* R *and* D*, and the route reaches the consumer only through* L, Q, P, N*.*

Proof. Project the carrier through Definition 369.1. The only center-bearing rows are $\mathcal{P}$ and C, and the only precision and radius rows available to that route are D and R.

Apply Definition 369.2, Definition 369.13, and Definition 369.14. These results force compact source selection through the displayed finite bundle and radius ledger.

Finally use Definition 369.15 and Definition 369.51. Once the center route is fixed, every consumer read remains inside L, Q, P, N, so no open-cover, host finite-subcover, or selected external center can replace it. □

Theorem 369.53 (UniformModulus pointwise-modulus row consumption)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, each pointwise-modulus row in* M *is consumed only after the finite-net row* C *has selected a center from* $\mathcal{P}$ *and the fold ledger* F *has produced the precision row* D *from the displayed radius rows* R*. The row then reaches the compact-continuous consumer through the same* L, Q, P, N *boundary.*

Proof. Read the finite packet from Definition 369.1. The pointwise rows M are indexed by bundled centers, while F is the finite rational fold that exposes the shared precision row.

Use Definition 369.13 and Definition 369.14 to select the center through C and $\mathcal{P}$. Then use Definition 369.2 to produce D before any pointwise row is exported.

Apply Definition 369.15 and Definition 369.51. They keep the consumed row in the displayed compact-continuous packet and rule out a standalone global modulus function. □

Theorem 369.54 (UniformModulus fold-threshold nonescape)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the precision row D is exported only from the fold ledger F over displayed $\mathsf{Rat}^{\uparrow}$ *radius rows R. Its consumer route may pass through compact coverage C, pointwise rows M, and the boundary L, Q, P, N, but it cannot leave the finite fold surface for a host minimum, open-cover compactness principle, or external modulus selector.*

Proof. Start with Definition 369.1. The packet gives one precision row, one finite fold ledger, and the radius rows over which the fold is recorded.

Apply Definition 369.2. It identifies D as the positive output of the finite fold over R, not as a host minimum or selected external value.

Use Definition 369.13, Definition 369.14, and Definition 369.15 to account for the compact and pointwise rows that consume the threshold.

Close with Definition 369.51. Every exported precision read is exhausted by the displayed packet rows, so the fold threshold has no escape route outside F, R, L, Q, P, N and the compact-continuous rows that consume them. □

Theorem 369.55 (UniformModulus compact-continuous finite-fold correspondence)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the finite-net fold precision row D is available to a compact-continuous consumer if and only if the consumer route displays the compact finite-net center row C, the pointwise modulus rows M, the positive rational radius ledger R, the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *lower-bound certificate F, and the local transport and provenance rows L, Q, P, N.*

Thus the compact-continuous consumer receives the finite-fold data precisely through the displayed BHist *packet,* ProbeBundle *spine,* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *certificate, with no host minimum, external modulus selector, or ambient compactness row.*

Proof. For the forward direction, start from a consumer that receives the precision row D. Apply Definition 369.49 to identify the handoff as the finite-net minimum fold over the displayed compact row and bundled centers.

Use Definition 369.50. The available positive lower bound is the rational ledger over R, so the precision row is carried by the finite fold certificate F rather than by a host minimum. Then apply Definition 369.54 to keep the threshold route inside F, R, L, Q, P, N and the compact-continuous rows that consume them.

For the reverse direction, suppose the route displays C, M, R, F, L, Q, P, N with the finite ProbeBundle spine. Repack these rows through Definition 369.51. That exactness theorem exports the accepted compact-continuous surface from the same displayed packet, so the fold precision row D is available to the consumer. □

Theorem 369.56 (UniformModulus root carrier public row)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the public carrier row exposed to compact-uniform-modulus consumers is exactly the BHist *carrier of Definition 369.1 together with the finite* ProbeBundle *spine* $\mathcal{P}$*, compact-net coverage row* C*, pointwise-modulus rows* M*, rational lower-bound ledger* F*, and boundary rows* L, Q, P, N*.*

No root consumer receives a separate open-cover carrier, host finite-subcover carrier, external modulus carrier, or choice-selected center carrier.

Proof. Project the displayed carrier of Definition 369.1. Its public rows are $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, with the finite centers carried by the ProbeBundle coordinate and all reads anchored in the same BHist packet.

Apply Definition 369.37 and Definition 369.41. These identify the compact-net coverage and every consumed center with displayed bundle membership and the row C.

Use Definition 369.50. The folded lower-bound row is the exact finite ledger F over R, so no host minimum or external modulus carrier can supply the public precision row.

Finally invoke Definition 369.54. The threshold package reaches the consumer only through L, Q, P, N, which leaves the root carrier surface as the displayed BHist and ProbeBundle rows. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root carrier public row`

Theorem 369.57 (UniformModulus root classifier transport row)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every classifier-preserving root transport of the compact-uniform-modulus consumer surface factors through the componentwise* hsame *ledger* L*. The transport preserves the same displayed finite* ProbeBundle *carrier, compact-net coverage row, pointwise-modulus consumption route, rational lower-bound ledger, and* $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$ *threshold package.*

Thus an L*-mediated transport cannot replace the classifier by an ambient compactness classifier, a host metric classifier, or a selected external modulus classifier.*

Proof. Start with Definition 369.23. It fixes the classifier-facing surface to $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, Pkg, and NameCert rows.

Use Definition 369.38. A transported read must keep the selected bundled center, its radius row, and the fold ledger together before any pointwise-modulus row is consumed.

Apply Definition 369.53. The pointwise row reaches the consumer only after compact-net coverage and the folded threshold have both been read inside the same finite packet.

The boundary rows Q, P, N finish the route. Since L is the only classifier-preserving hsame row and the threshold is named by the displayed NameCert package, no ambient classifier or external modulus classifier has a transport coordinate. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root classifier transport row`

Theorem 369.58 (UniformModulus root ledger exactness row)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the root compact-uniform-modulus ledger is exact: compact-net coverage is read from C *over the finite* ProbeBundle *spine* $\mathcal{P}$*, pointwise-modulus consumption is read from* M*, the precision threshold is read from the rational lower-bound ledger* F *over* R*, and the exported packet is named only by* P *and* N*.*

Consequently the ledger contains no hidden compactness theorem, host minimum, finite-subcover selector, off-packet modulus, or quotient-representative read.

Proof. Read compact coverage through Definition 369.29 and Definition 369.37. These theorems bind every covered point to a center already present in $\mathcal{P}$ and to the compact row C.

Read pointwise consumption through Definition 369.39 and Definition 369.53. The consumer reaches M only after the finite coverage and radius rows have been consumed.

Read the threshold through Definition 369.50. The row D is exposed by the finite rational ledger F over R, not by a host minimum or off-packet modulus.

Finally apply Definition 369.51. It exhausts the exported rows by $E, D, \mathcal{P}, R, C, M, F, L, Q, P, N$, so the ledger exactness claim has no remaining coordinate for hidden compactness, external selection, or quotient data. □

Theorem 369.59 (UniformModulus compact-cover root row totality)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every compact-cover read made by a compact-continuous downstream consumer is exhausted by the displayed $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row* C*, the finite* $\mathsf{ProbeBundle}$ *spine* $\mathcal{P}$*, the positive* $\mathsf{Rat}^{\uparrow}$ *radius rows* R*, and the boundary rows* L, Q, P, N*.*

Thus the root compact-cover obligation is a finite packet obligation over the carrier of Definition 369.1. It has no coordinate for open-cover compactness, host finite-subcover selection, choice-selected centers, or an external cover selector.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root compact cover row totality`

Proof. Read the accepted carrier through Definition 369.1. The compact-cover coordinates visible to the consumer are exactly the bundled centers $\mathcal{P}$, the radius ledger R, the compact finite-net row C, and the transport, route, provenance, and naming boundary L, Q, P, N.

Apply Definition 369.29. It binds every compact-net coverage read to a center already present in $\mathcal{P}$ and to the radius rows already recorded in R.

Apply Definition 369.2 to keep the precision threshold tied to the same finite bundle and radius ledger. Then use Definition 369.26 to exclude any compactness or center-selection channel outside $C, \mathcal{P}, R, L, Q, P, N$. □

Theorem 369.60 (UniformModulus pointwise-modulus root row totality)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet* $U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N)$*, every pointwise-modulus read in* M *is available only after the compact-cover row* C *has selected a center bundled in* $\mathcal{P}$ *and routed the relevant source and radius data through the displayed* $\mathsf{Met}^{\uparrow}$ *witnesses. The read then reaches the consumer only through* L, Q, P, N*.*

Consequently the pointwise-modulus root row is a dependent finite-row handoff from compact coverage to metric witnesses to M*. It is not a global modulus function, a host continuity theorem, a choice-selected center rule, or a pointwise selector outside the carrier rows.*

Proof. Begin with Definition 369.1. The pointwise rows M are carrier rows indexed by bundled centers, and the only consumer route to such a center is the compact finite-net row C over the finite spine $\mathcal{P}$.

Apply Definition 369.29. It forces the compact-cover read to choose a displayed bundled center and radius row before the pointwise row can be consumed.

Use Definition 369.2 to keep the folded threshold D below the radius rows attached to those centers. The metric witnesses read by the pointwise row therefore remain on the displayed $\mathsf{Met}^{\uparrow}$ route rather than on a host selector.

Finally apply Definition 369.26. The rows L, Q, P, N are the only boundary through which the pointwise data can leave the packet, so M has no external modulus or undisplayed center coordinate. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root pointwise modulus row totality`

Theorem 369.61 (UniformModulus fold-threshold root exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the precision threshold D is exhausted by the finite $\mathsf{Rat}^{\uparrow}$ *fold row F over the displayed radius rows R. The compact-cover row C and pointwise rows M may consume the threshold through the packet route, but no consumer can replace it by a host minimum, open-cover compactness proof, choice-selected center, or external modulus selector.*

Proof. Project the rows of Definition 369.1. The only precision-producing coordinates are the displayed radius rows R, the fold certificate F, and the named precision row D.

Apply Definition 369.2. The fold is primitive finite recursion over the closed $\mathsf{ProbeBundle}$ spine and records every $\mathsf{Rat}^{\uparrow}$ comparison used to expose D.

Use Definition 369.29 to attach each consumption of D to displayed compact coverage and bundled centers. Then apply Definition 369.26; the threshold can leave the packet only through C, M, L, Q, P, N, so there is no host minimum, open-cover compactness row, choice-selected center, or external modulus selector. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root fold threshold exhaustion`

Theorem 369.62 (UniformModulus root-unblock radius family exhaustion)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

the root-unblock radius family consumed by any compact-continuous downstream reader is exactly the displayed finite $\mathsf{Rat}^{\uparrow}$ *family R indexed by the* $\mathsf{ProbeBundle}$ *spine $\mathcal{P}$ and read through the* $\mathsf{CompactModulusCover}^{\uparrow}$ *coverage row, the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *fold row F, the* BHist *carrier of Definition 369.1, componentwise* hsame *transport L, displayed* Cont *routes Q,* Pkg *provenance P, and the local* $\mathsf{NameCert}$ *row N.*

Thus the root-unblock precision route is exhausted by the displayed finite radius family. It has no coordinate for host open-cover compactness, external finite-subcover selection, hidden radius choice, or an ambient modulus selector.

Proof. Project the carrier through Definition 369.1. The only radius-family rows visible to a consumer are the finite bundle $\mathcal{P}$, the positive rational radius ledger R, the compact coverage row, and the fold certificate F.

Apply Definition 369.59. It anchors every compact-cover read in the displayed centers, radius rows, and compact finite-net row before the consumer boundary can be reached.

Use Definition 369.61. The precision row D is exhausted by the fold over R, so the root-unblock radius family cannot be replaced by a host minimum or ambient selector.

Finally apply Definition 369.60. The remaining route is through L, Q, P, N, leaving no coordinate for host open-cover compactness, external finite-subcover selection, or hidden radius choice. □

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root unblock radius family exhaustion`

Theorem 369.63 (UniformModulus root-unblock consumer threshold route)**.** *For an accepted* $\mathsf{UniformModulus}^{\uparrow}$ *packet*

$$U = (E, D, \mathcal{P}, R, C, M, F, L, Q, P, N),$$

every consumer threshold route from the requested tolerance row E *to the selected precision row* D *factors through the finite* $\mathsf{Rat}^{\uparrow}$ *radius family* R*, the* ProbeBundle *spine* $\mathcal{P}$*, the* $\mathsf{CompactModulusCover}^{\uparrow}$ *coverage row, the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *fold certificate* F*, the pointwise rows* M*, the* BHist *carrier, componentwise* hsame *transport* L*, displayed* Cont *routes* Q*,* Pkg *provenance* P*, and local* NameCert *row* N*.*

Consequently the uniform precision route is a finite threshold route inside the packet. It cannot use host open-cover compactness, external modulus selection, an undisplayed compact cover, or a choice-selected center.

Lean4 ✓ `BEDC.Derived.UniformModulusUp.UniformModulusPacket root unblock consumer threshold route`

Proof. Start with the threshold source and target rows in the carrier: E is the requested tolerance row, and D is the folded precision row.

Apply Definition 369.62. It fixes the available radius family as the displayed R indexed by $\mathcal{P}$ and routed through the compact coverage and fold rows.

Use Definition 369.60. It forces each pointwise-modulus read to pass through the compact-cover row, displayed metric witnesses, and the same boundary rows.

Close with Definition 369.61. Since every threshold read has already entered the displayed packet route, there is no remaining coordinate for open-cover compactness, external modulus selection, an undisplayed cover, or a choice-selected center. □

Closure status for $\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$**.**

Constructive story: A $\mathsf{UniformModulus}^{\uparrow}$ packet starts from a positive tolerance history, a compact finite-net ProbeBundle, continuous pointwise-modulus rows at the bundled centers, and positive rational radius rows; it folds the finite radius ledger to a precision history and routes every compact-continuous read through displayed BHist, hsame, Cont, Pkg, and NameCert provenance.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 369.13, Definition 369.23, Definition 369.24, Definition 369.25, Definition 369.26, Definition 369.40, Definition 369.46, Definition 369.47, and Definition 369.48 bind the public compact-continuous handoff surface for the displayed $\mathsf{UniformModulus}^{\uparrow}$ packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{UniformModulus}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.UniformModulusUp.UniformModulusUp\_StdBridge`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close a public uniform-continuity theorem, checked Lean implementation, bridge status, open-cover compactness, sequential compactness, or host analytic modulus selection.

Upgrade path: No further verification-axis upgrade remains for the standard compact-continuous handoff bridge.

Chapter 370

A Concrete Naming Certificate for GoldenMeanShift$^{\uparrow}$

The GoldenMeanShift$^{\uparrow}$ object is a BEDC-native finite-window name for binary BHist rows with no adjacent visible one rows, not an import of symbolic-dynamics machinery.

370.1 Finite binary windows

This finite no-adjacent-one carrier is consumed by the subshift finite type certificate of chapter 434 as the singleton forbidden-word instance. The shared dependency is the finite alphabet row, finite word row, forbidden adjacency ledger, acceptance ledger, and componentwise hsame classifier that records exactly the zero-zero, zero-one, and one-zero neighboring decisions.

Definition 370.1 (GoldenMeanShift carrier)**.** *A* GoldenMeanShift$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (W, Z, O, P, L)$$

with the following visible rows:

1. *W is a finite list of binary bit rows, each row displayed as either a zero bit row or a one bit row inside* BHist*;*
2. *Z is the all-zero witness row for the same window shape;*
3. *O is the adjacency ledger whose every neighboring pair in W is one of zero-zero, zero-one, or one-zero;*
4. *P is the* Pkg *provenance row naming the prefix and fold readbacks used to inspect the window;*
5. *L is the* NameCert *ledger recording that every accepted classifier row is a componentwise* hsame *comparison between displayed bit rows.*

The carrier accepts exactly finite binary windows whose visible bit rows contain no adjacent one rows. It contains no infinite sequence, no shift-invariant quotient, no entropy row, and no host symbolic-dynamics theorem.

Lean4 ✓ `BEDC.Derived.GoldenMeanShiftUp.GoldenMeanShiftTasteGate single carrier alignment`

Theorem 370.2 (GoldenMeanShift local stability)**.** *Let $G = (W, Z, O, P, L)$ be an accepted* GoldenMeanShift$^{\uparrow}$ *carrier. If a transported packet $G' = (W', Z', O', P', L')$ is obtained by moving each displayed bit*

row of W, each all-zero witness row, each adjacency-ledger row, and each provenance row through the displayed hsame, Cont, Pkg, *and* NameCert *routes, then G' is accepted whenever every transported adjacent pair remains one of zero-zero, zero-one, or one-zero.*

The induced classifier between G and G' is the componentwise hsame *classifier on visible bit rows, with the transported adjacency ledger as its exactness record.*

Lean4 ✓ `BEDC.Derived.GoldenMeanShiftUp.GoldenMeanShiftCarrier local stability`

Proof. Project the carrier rows of Definition 370.1. The only visible data are the binary window, the all-zero witness, the adjacency ledger, the prefix and fold provenance, and the local name-certificate ledger.

Move the displayed rows through the supplied hsame, Cont, Pkg, and NameCert routes. The hypothesis keeps each transported adjacent pair inside the listed local patterns, so no adjacent one-one pair can appear in the transported window.

For the classifier, compare the original and transported bit rows componentwise by hsame. The all-zero witness is transported by the same row movement, and the adjacency ledger gives the exactness witness that the accepted carrier condition is preserved. □

Theorem 370.3 (GoldenMeanShift fold-prefix closure)**.** *Let $G = (W, Z, O, P, L)$ be an accepted* GoldenMeanShift$^{\uparrow}$ *carrier, and let $W_{\leq k}$ be any displayed prefix read from W through the recorded* Cont *fold route and* Pkg *provenance. The restricted packet*

$$G_{\leq k} = (W_{\leq k}, Z_{\leq k}, O_{\leq k}, P_{\leq k}, L_{\leq k})$$

is an accepted GoldenMeanShift$^{\uparrow}$ *carrier. Its classifier rows are exactly the componentwise* hsame *rows inherited from G, and its ledger is the prefix restriction of the original* NameCert *ledger.*

Equivalently, every finite fold readback of an accepted no-adjacent-one window lands again inside the same carrier surface.

Proof. Read the prefix through the displayed Cont fold route and Pkg provenance. The route selects an initial segment of the same finite bit rows and also restricts the all-zero witness, adjacency ledger, provenance row, and name-certificate ledger.

Every adjacent pair inside $W_{\leq k}$ was already an adjacent pair inside W. Since G is accepted, each such pair is zero-zero, zero-one, or one-zero, and the restricted adjacency ledger records the same local fact.

The inherited classifier is componentwise hsame on the retained bit rows. The ledger exactness row is simply the restricted NameCert row, so the fold-prefix packet has no new tail, quotient, inverse-limit, entropy, or host shift coordinate. □

Theorem 370.4 (GoldenMeanShift adjacency ledger exhaustion)**.** *Every accepted neighboring-pair decision in a* GoldenMeanShift$^{\uparrow}$ *carrier $G = (W, Z, O, P, L)$ is exhausted by the displayed zero-zero, zero-one, or one-zero adjacency row in O together with the componentwise* hsame, Cont, Pkg, *and* NameCert *routes. No one-one decision, Fibonacci count, entropy row, inverse limit, or host symbolic-dynamics object can justify acceptance.*

For every displayed prefix or finite fold readback of G, the restricted packet preserves exactly the same local decision surface: each retained neighboring pair is accepted only by the corresponding restricted zero-zero, zero-one, or one-zero ledger row.

Proof. Project the carrier of Definition 370.1. The window rows, all-zero witness, adjacency ledger, provenance row, and local NameCert ledger are the only coordinates available to the classifier.
